In ASC Z-365 surveillance is the main aspect from which stem two branches: on one hand evaluation and management of CTD, on the other hand working tasks analysis. A suspected CTD implies the intervention of a Health Care Provider (HCP) for therapy and follow-up. The aim is an effective secondary prevention. Early diagnosis permits the immediate start of therapy, therapeutic efficacy increases and prognosis improves. At the same time, days missed for sickness decrease and health costs consequently decrease.

Whenever surveillance identifies risk factors for CTD o HCP assesses CTD work-related, work analysis is carried out. The aim is to detect risk factors for CTD. It is not necessary if the ergonomic solution of the problem detected is obvious and simple. Once work analysis is performed, the ergonomic intervention program follows to eliminate risk factors and possible cases of CTD. Subsequently the health periodic surveillance will verify whether the problem is under control.

3.5. USA: Draft Ergonomics Program Standard (OSHA)

In 1999 the Occupational Safety and Health Administration (OSHA) developed a Draft Ergonomics Program Standard. This standard is intentionally simplified to be easily understood. It has been developed from the answers to the questions most often asked by the employer when he faces an ergonomic standard. It clarifies if, how and when it needs to be applied; what the duties are; how and when detection, analysis and control of risk for WRMD need to be performed; how to have training, health surveillance, evaluation of the ergonomic program.

It is a simple and clear draft: it consists also of tables

illustrating different steps of the ergonomic program, duties and people who have them, and periodicity of the health surveillance.

Work-related Musculoskeletal Disorders: General Issues

B. Silverstein

Safety & Health Assessment and Research for Prevention (SHARP),
Washington State Department of Labor and Industries, Olympia, WN
98504-4330, USA

1. INTRODUCTION

Musculoskeletal disorders (MSD) are injuries and illnesses of the muscles, tendons, ligaments, joints, nerves, vessels and supporting structures that are involved in locomotion. They are usually manifested by pain, numbness, tingling, swelling or loss of function, and are primarily located in the upper limb, back and, to a lesser extent, the lower limbs. The term "MSD" is not a diagnosis but a category of specific and non-specific diagnoses related to the above tissues that have some common features. MSD related to work occur when there is an imbalance in the work system that overwhelms the individual either suddenly (acute onset) or over weeks, months or years (gradual onset). Examples of these disorders most often found related to workplace activities and conditions are shown in table 1. There are at least three major areas of confusion regarding MSD and work.

First, workplace factors are not the *sole causes* of MSD. There can be a number of personal factors that can contribute to MSD either with or without a contribution of work factors, including systemic diseases, recreational activities, age and gender. It is only when workplace factors are significant contributors to the cause or exacerbation of these MSD that they become "work-related" or WMSD. Although the diagnosis of a specific order (e.g. rotator cuff tendinitis) may be made in the same way irrespective of what "caused" it, the importance of distinguishing that factors are primary has more to do with prevention possibilities in the workplace. Personal factors such as age and gender are not as easily modifiable as changing the location or type of tool used in a workplace.

The second area of confusion has to do with *onset* of MSD. These disorders can have either a seemingly sudden onset or gradual onset over weeks, months or years. For example, while

Table 1. Examples of work-related musculoskeletal disorders.

Muscle	trapezius myalgia
Tendon-related	tenosynovitis, tendinitis, peritendinitis epicondylitis, deQuervains disease rotator cuff tendinitis, bicipital tensosynovitis
Nerve	carpal tunnel syndrome, pronator teres syndrome Guyon canal syndrome, cubital tunnel syndrome radial tunnel syndrome sciatica
Vessel/nerve	hand–arm vibration syndrome
Ligament	ulnar collateral ligament laxity of the thumb (gamekeeper's thumb)
Joint	cox arthrosis of the hip

cox arthrosis of the hip can take years of heavy physical load to manifest itself in farmers, low back problems can occur suddenly from a fall or gradually with over exertion due to repeated lifting with an awkward trunk posture over weeks, months or years depending on the exposure and individual capacity. To add to the confusion, how the "onset" of the back trouble is reported often depends on medical payment systems in different locations. For example, low back problems identified as being caused by a sudden or unusual event are more likely to be accepted by many workers compensation systems whereas the more gradual onset disorders are not.

The third area of confusion has to do with "how much is too much" exposure in the workplace. This confusion is largely focused on the "gradual onset" MSD, although the lines of demarcation are not always clear. Designers and engineers want specific "safe" limit values or at least ranges depending on the population for whom they are designing jobs, equipment and processes. The answer "well, it depends" is an area of enormous frustration for practitioners, employers and workers.

The multifactorial nature of gradual onset work-related MSD is not dissimilar from other areas of occupational health such as occupational hearing loss or occupational asthma in which there is an interplay between individual and workplace factors occurring over time that eventually manifest in loss of function or frank disease or injury. There is much that remains to be learned about causation and prevention of WMSD but as Hill aptly wrote: "All scientific work is incomplete. … All scientific work is liable to be upset or modified by advancing knowledge. That does not confer upon us a freedom to ignore the knowledge we already have, or to postpone the action that it appears to demand at a given time."

While other chapters present different ways to evaluate system imbalance, the focus here is to provide an overview of the scope and magnitude of the problem, what is known about the workplace risk factors for MSD and to recommend general prevention strategies based on what can be modified. The discussion concentrates on gradual onset WMSD although much of this discussion is also applicable to sudden onset disorders.

2. CONCEPTUAL MODEL OF GRADUAL ONSET WORK–RELATED MUSCULOSKELETAL DISORDER

Armstrong *et al.* (1993) proposed a cascading conceptual model for gradual onset WMSD where the external environment included exposure (work requirements) that lead to an internal dose (e.g. tissue loads) which sets off a series of internal cascading responses which are in turn modified by individual capacity (figure 1).

This cascading process can lead to training effects or, if overwhelmed without sufficient recovery, to MSD. This model allowed researchers to assess where their own research fits into the process. The model was expanded in 1998 at a US National Academy of Sciences workshop to look at the interplay of a variety of "external" factors that contributed to the development and consequences of prolonged overloading of the internal system (figure 2). This extended model looks at the basic interplay between load on and tissue tolerance in the individual. The social context in which it takes place, organizational and physical work conditions, as well as individual physical and psychological factors

Figure 1. Cascade model of gradual onset work-related musculoskeletal disorders.

Figure 2. National Academy of Sciences Steering Committee model of work-related musculoskeletal injuries.

all have impacts on this relationship. This load-tolerance interplay alone and in the context of the external factors results in physiological responses and perhaps symptoms, which in turn may be reported and eventually result in disability. The many feedback loops in this system illustrate the complexity of causation and suggest multifactorial solutions.

3. MAGNITUDE OF GRADUAL ONSET WORK–RELATED MUSCULOSKELETAL DISORDER

Figure 3 illustrates the difficulty in estimating the true magnitude of the problem of MSD. Case definitions, populations surveyed and the severity of the reported "cases" differ between studies and workers compensation laws differ. Usually studies of workers

Figure 3. Estimation of magnitude depends on how musculoskeletal disorders are identified.

with symptoms report two-to-three times the prevalence as those based on symptoms and clinical findings. While there is some indication of under-reporting of these disorders through official registers, this data usually covers large populations. Focus on disability has a large impact on direct monetary costs but limits prevention opportunities in at risk work groups.

Workers compensation data from Washington State (table 2) can be used to estimate the magnitude of the problem in most industrialized countries for gradual onset upper limb and back disorders over all and for some specific diagnostic categories (Silverstein and Kalat 1998). The more specific the diagnosis, the longer the lost workdays and the higher the cost. Women tend to be disproportionately represented in hand/wrist/carpal tunnel syndrome, whereas males are in the back/sciatica categories. Compared with all industry, those industries with at least a 5-fold increased rate of upper limb claims included temporary help in assembly and machine operations, shake mills, seafood canneries, meat products manufacturing, wallboard installation and roofing. For gradual onset back disorders, the industries with at least a 5-fold increased rate included shake mills, wallboard installation, roofing, pipe manufacturing, temporary help in assembly and moving companies.

4. WORKPLACE RISK FACTORS

Workplace risk factors have been identified in a number of epidemiological studies, population surveys, clinical studies, human and animal experimental studies. Bernard et al. (1997) conducted an exhaustive review of the epidemiological literature.

Table 2. Washington State workers compensation average claims incidence rate (CIR) and cost for gradual onset upper limb and back musculoskeletal disorders.

	CI per 10 000/year	% 4+ lost workdays	No. of lost workdays	Cost ($)	% female	Median age (years)
Upper extremity	90.6	35.4	171	5986	43.2	34
Shoulder	30.6	38.5	202	7692	35.6	34
Rotator cuff sydrome	20.9	64.3	250	15 370	33.2	38
Elbow	12.3	36.2	229	7428	36.5	38
Epicondylitis	12.1	46.0	201	6536	40.0	39
Hand/wrist	44.2	41.3	201	7401	51.0	33
Carpal tunnel syndrome	28.2	68.6	219	12 821	55.9	36
Back	161.9	35.4	171	5986	28.4	32
Sciatica	5.0	80.9	442	39 797	31.7	37

Table 3. Epidemiological evidence for causal relationship between physical work factors and gradual onset musculoskeletal disorders (Bernard *et al.*).

	Repetition	Force	Posture	Vibration	Combination	Other
Neck	**	**	***	+/-		
Shoulder	**	+/-	**	+/-		
Elbow	+/-	**	+/-		***	
Carpal tunnel syndrome	**	**	+/-	**	***	
Hand/wrist tendinitis	**	**	**		***	
Hand–arm vibration syndrome				***		
Back		lifting ***	**	whole body ***		heavy work**
						static postures +/-

+/- Insufficient evidence; **evidence; ***strong evidence.

Based only on epidemiological studies of working populations, they concluded that there was sufficient evidence for causal relationships between a number of risk factors including high repetitiveness, high force, awkward postures, and vibration and disorders of different body areas (table 3). The evidence was strong particularly when risk factors were combined. The NRC Report (1998) came to similar conclusions based on a wider array of evidence. Psychosocial aspects of work, such as low autonomy and high demand with little supervisory support have also been identified as at least exacerbaters of physical load and WMSD. The problem with many of the epidemiological studies is the lack of specificity in exposure assessment that makes quantitative dose–response relationships difficult to determine. On the other hand, laboratory studies can quantify exposure but the outcome measure is not illness or injury but rather some measure of localized fatigue, discomfort, capacity or acceptability. The relationship between fatigue and illness/injury requires further research. Nonetheless, the quantitative estimates are more useful for designers and practitioners who are responsible for ensuring a safe work design. The mere existence of a "hazard," such as a 50 kg box, does not put a worker "at risk" until there is some interaction between the worker and the hazard that can be described in terms of the temporal variation, duration and intensity of the contact. Although a similar critical review of the laboratory data has not been published, different combinations of risk factors have provided quantitative estimates based on reduced capacity or acceptability ratings. The psychophysical

tables for material handling "acceptable limits" of Snook and Cirello (1991) and 1991 Revised NIOSH Lifting Equation (Waters *et al.* 1993) have provided valuable guidance for designers, despite some of their limitations. Similar work is taking place for the upper extremity, particularly in looking at "repetitive work."

There are basically three methods for conducting exposure assessment: ask (interviews, questionnaires, diaries), look (checklists, videotapes) and direct measurement (surface electromyography, electrogoniometry, force transducers, accelerometers). There are tradeoffs in simplicity, precision, interpretation and utility between these methods. An important goal for ergonomists is developing a common taxonomy for describing the duration, intensity and temporal patterns of exposure to different risk factors, irrespective of method. This would allow for better comparisons of findings between studies. The University of Michigan's effort to provide written descriptions of different upper limb risk factors intensity levels and a catalog of videotapes of jobs that match those level descriptions, may provide the basis for being able to combine the "ask" and "look" domains of exposure assessment.

The Swedish regulation's guidance on an approach to assessing risk in repetitive work (1998) (table 4) can assist employers in evaluating a number of workplace factors that contribute to upper limb disorders. This guide looks at short work cycle, lack of opportunity to change postures and movements, lack of freedom of action, single-task job content and lack of learning possibilities as putting an individual at

Table 4. Assessing physically monotonous, repetitive work (adapted from Swedish National Board of Occupational Health 1998).

	Red	Yellow	Green
Work cycle	Repeated several times/minute for at least half a shift	Repeated several times/min for at least 1 h or many times an hour for at least half a shift	Repeated a few times every hour
Working postures and movements	Constrained or uncomfortable	Limited scope for changing work postures and movements	Good possibilities of varying working postures and movements
Job decision latitude	Work is completely controlled external to the worker	Work partly controlled external to worker. Limited possibility to influence way task is performed	Good possibilities to adapt work to one's ability. Influence on planning, work arrangement
Job content Training/competence	Does isolated task in production process. Short training phase	Does several tasks in production process. Training for several tasks	Does several tasks or whole process including planning, instruction. Continuous competence development

extreme risk. This allows the employer and workers to identify why these factors are present and what to improve to provide a healthier work environment. All four of these dimensions of work could be obtained by asking or looking, while more precision could be obtained through direct measurement of work cycle time, and postures and movements. These dimensions could also be used to design new jobs. Similarly, Kilbom (1994) provided quantitative guidance to practitioners on when jobs with repetitive motions of different upper limb areas should be evaluated more closely when combined with > 1 h duration and high physical loads or "force." While all of these guidelines are provided with various caveats about not necessarily being safe for all individuals, they try to provide sufficient specificity for designers and practitioners to use in assessing jobs. Recognizing that these quantitative estimates provide no guarantes, they should be used, tested and the results reported in the literature for future refinement.

A recent employer survey of ~5000 employers from different sizes and industry sectors indicated that ~10% of employers had no employees exposed to musculoskeletal risk factors associated with manual handling or repetitive work (Foley and Silverstein 1999). In multivariate modeling of employer reported numbers of employees exposed to different durations of 14 risk factors, there were significant increases in workers compensation claims rates with increases in total available employee work hours exposed to most manual handling risk factors (lifting heavy loads, frequent lifting, lifting with awkward postures) and upper limb risk factors (working with hands above shoulder height, repetitive arm movements and vibrating tool use). This suggests that employers have the capacity to identify, at least crudely, significant risk factors. The same survey indicated that for those employers taking prevention steps, they not only had reductions in injury frequency and severity (> 50%) but also in collateral benefits of reduced absenteeism and turnover and increases in productivity, quality and employee morale (25–35%).

5. PREVENTION STRATEGIES

The critical next step after performing risk assessment is in identifying why unacceptable risk may be present in any particular job or process. A systems approach provides the best opportunities for process changes that can both improve health and performance. The opportunities vary depending on the job life cycle. The greatest opportunity for engineering controls is in the product design and then the process development phases. Engineering controls are still possible in the production implementation and personnel use phases but administrative improvements also play a role at this point and tend to be less effective.

Basic principals of risk reduction efforts in individual job design at the process, production and personnel phases include:
- Provide workstations where workers can reach, see and fit (avoid extremes in range of motion).
- Provide variability in tasks that can lead to variability in postures and motions (reduce risk from fixed postures and highly repetitive movements).
- Keep loads close to reduce biomechanical disadvantage.
- Provide opportunities for adjustment in tools, equipment and workstations especially where there are multiple users.

- Provide preventive maintenance for tools and equipment to reduce exertion requirements.
- Provide opportunities for workers to control the way they perform the job and to learn new things.
- Use a collaborative problem-solving process to identify the solutions that solve the most problems simultaneously without introducing new ones.

6. CONCLUSIONS

Most practitioners would suggest incorporating ergonomics into a regular part of doing business. Implementing ergonomics related processes and practices requires ongoing top management commitment, supervisor and employee knowledge and involvement and ongoing evaluation of the effectiveness of the process in reducing MSD. In most countries, voluntary efforts in this direction are necessary but have rarely been demonstrated to be sufficient to prevent WMSD in all workplaces. While there is much to learn about quantifying relevant exposures and their interactions, enough is known to use general principles to reduce hazardous exposures now.

Work-related Musculoskeletal Disorders: Overview

L. Forcier† and I. Kuorinka‡

†Institut de recherche en santé et sécurité du travail, 505 Blvd Maisonneuve O., Montréal Québec Canada H3A 3C2

‡F-46 160 Gréalou, France

1. INTRODUCTION AND DEFINITIONS: SORTING THROUGH THE CONFUSION

Work-related musculoskeletal disorders (WMSD) are known by a variety of terms across the world. In the USA, "cumulative trauma disorders" (CTD) is sometimes used to refer to this group of disorders. In Japan, they have been known as "occupational cervicobrachial disorders" (OCD), in Canada and Australia as "repetitive strain injuries" (RSI), and more recently in Australia as "occupational overuse syndrome" (OOS). Lately, WMSD has gained popularity, worldwide, as the preferred designation for this group of disorders.

Although the exact description of what constitute WMSD may vary among countries, states or provinces, and indeed among researchers, generally speaking they are chronic disorders (as opposed to due to an accident) of the upper and lower limbs and are, by definition, related to work. These work-related chronic disorders of the limbs may involve tendons, muscles, bones and cartilage, bursa, or peripheral nerves and also include some selected vascular disorders (Table 1) (Kuorinka and Forcier 1995). Of course, these same disorders may occur in non-working populations or their development may be associated with factors not related to work; when such is the case, these disorders are not considered *work-related musculoskeletal disorders*.

Theoretically speaking, musculoskeletal back disorders can also be work-related and may share quite a few similarities with WMSD of the limbs; however, historically, research on back disorders has been separate and often the term WMSD excludes the back (in this chapter the back is *excluded*). There is far more information on WMSD of the upper limbs than of the lower limbs; however, evidence is mounting which shows that lower limbs, their tendons, bursa, etc., are also at risk of developing WMSD.

It is important to make here another small a part on the terminology involved in WMSD. Dorland's *Illustrated Medical Dictionary* (1974: 465) defines *disorder* as: "A derangement or abnormality of function; a morbid physical or mental state." Disorders as in WMSD, therefore, encompasses some clinically well defined *diseases* ("a definite morbid process having a characteristic train of symptoms … its etiology, pathology, and prognosis may be known or unknown"; Dorland's 1974: 453), for example, de Quervain's disease, and some well defined *syndromes* ("a set of symptoms which occur together; the sum of signs of any morbid state"; Dorland's 1974: 1575), for example the carpal tunnel syndrome. WMSD also include some clinically less defined conditions, for example tension neck syndrome, and some non-specific groupings of musculoskeletal symptoms (Table 1).

Finally the term "work-related musculoskeletal *problems*" may also be used, especially in research projects. This term may only refers to symptoms (subjective evidence, e.g. pain, ache, fatigue, discomfort) and/or signs (objective evidence, e.g. limited movements) of musculoskeletal dysfunction without a full pledge diagnosis, although sometimes the term "problems" may be used to embrace both the disorders *and* various non specific groupings of symptoms and/or signs. When the latter occurs, of course, work-related musculoskeletal *problems* and work-related musculoskeletal disorders mean the same thing.

Definition of the WMSD is partly problematic because the underlying phenomenon is a medical issue, described in medical

Table 1. Examples of work related musculoskeletal disorders (based on Kuorinka and Forcier 1995).

Anatomical structures involved	Examples of possible WMSD[1]
Tendons	•Tendinitis/peritendinitis/tenosynovitis/ insertion tendinitis (enthesopathy)/synovitis of most joints, in particular shoulder, elbow and hand-wrist •Epicondylitis •de Quervain's disease (stenosing tenosynovitis) •Trigger finger
Nerves	•Median nerve entrapment: Carpal tunnel syndrome (CTS) (entrapment at the wrist) and Pronator teres syndrome (entrapment at the elbow) •Ulnar nerve entrapment: Cubital tunnel syndrome (entrapment at the elbow) anf Guyon canal syndrome (entrapment at the Guyon canal) •Radial tunnel syndrome (radial nerve entrapment at the elbow) •Thoracic outlet syndrome (TOS) (neurogenic TOS = entrapment of the brachial plexus at different locations) •Cervical syndrome (radiculopathy) (compression of nerve roots)
Circulatory/Vascular structures	•Hand-arm vibration syndrome (involves vascular and nerve damage) •Hypothennar hammer syndrome •Raynaud's syndrome
Joints (cartillage and bone)	•Osteoarthritis of most joints/degenerative joint disease
Muscles	•Tension neck syndrome
Bursa	•Bursitis of most joints
	•NON SPECIFIC GROUPINGS OF SYMPTOMS[1]

[1] It should be noted that sometimes the terms WMSD, CTD, RSI, etc have been used as umbrella terms to group everything shown in this table and at other times they have been used to soley refer to the non-specific groupings of symptoms.

terms and organized using a medical taxonomy. A problem arises when the medical issue is associated with determining "work relatedness," which makes the whole concept fuzzy and imprecise rather than clarifying it. For an ergonomist, it might be most useful to adopt a pragmatic approach and to accept the WMSD concept in its largest sense. Such attitude is the basis for preventive actions, actions in which the ergonomist has a far more useful role than in arguing the work relatedness of WMSD cases.

2. SCOPE OF WMSD: WHICH COUNTRY, INDUSTRY, AND JOB? A LOOK AT STATISTICS

In the USA, the incidence of disorders due to repeated trauma, as they are known by the Bureau of Labour Statistics (BLS), has risen. In private industry, from 1984 to 1997 it increased from 5.1 to 32 cases per 10 000 full time worker (Hales and Bernard 1996, BLS 1999). Some of the explanations *postulated* for this increase include (1) increased awareness that these disorders may be work-related leading to improved recording, improved detection and increased reporting, and expanded workers compensation law, and (2) increased number of cases due to (a) increased productivity (b) increased number of women on the work force (c) shift to service industry jobs and (d) increased VDT use (Brogmus *et al.* 1996, Hales and Bernard 1996).

WMSD have been observed worldwide, in developed, developing and underdeveloped countries. They are also found in many industries and jobs; indeed they can be found wherever there is the presence at work of certain risk factors thought to be associated with the development or aggravation of these disorders. They have been noted in agriculture, forestry, fishing, mining, construction, manufacturing, transport, wholesale trade, retail trade, and service industries and public administration, in blue and white collar workers, trades and professional jobs. However they can be more prevalent in some industries and jobs (Table 2). Among the occupations or industries more at risk, many are

good-producing related. Indeed, in an analysis of the 1993 CTD of the upper extremities claims from the Liberty Mutual Group (largest writer of worker's compensation insurance in the USA since 1936), 30 of the 39 highest risk jobs for CTD claims were manufacturing (although manufacturing jobs account for only 21% of US employment), and 11% of claims were associated with jobs with heavy VDT use (Brogmus *et al.* 1996).

There is no perfect agreement on the rate of WMSD between geographical areas, or on which industries or jobs are more at risk (Table 2). This is not surprising since compensation statistics represent only what is legally acceptable as a compensation claim at one point in time, in any given country, state or province.

In fact, workers compensation statistics are likely to show only part of the scope of WMSD, not only because their "case definition" (i.e. acceptable claim) is restricted, but because other mechanisms may also be operational and have an impact on the number of disorders reported. Known since 1885 (Fox and Collier 1976), the *healthy worker effect* may be one such mechanism. Although this effect is comprised of many element (Choi 1993, Last 1995), one element is particularly pertinent to compensation statistics (and OHS research). It is known that workers who have developed health problems in their work have a tendency to quit their work, which may result in fewer WMSD being reported and claimed. Also noteworthy, in terms of reducing the number of claims for WMSD, workers may not report a WMSD but may use days of absence from work to deal with a WMSD.

When researchers study a workplace with known risk factors they do tend to find that the *size* of the problem *is greater than that shown by compensation rates*. Of course, the case definition (i.e. what will be considered as a WMSD) used by researchers is very different than that used in the compensation system and in fact varies from one research project to the next. The results of a study by Chiang *et al.* (1993) for 207 workers in the fish processing industry will be briefly mentioned here to illustrate

Table 2. Examples of workers compensation statistics for WMSD (top five industries).

USA (Private industry–disorders associated with repeated trauma in 1997 (Incidence rate per 1,000 full–time workers[1])	CANADA (Manitoba Workers Compensation Board, 1991 RSI data for the upper limbs) (Rate per 1,000 full–time workers[2])	AUSTRALIA (RSI for the upper limits for 1985–1986 for South Australia) Industry incidence (cases per 1,000 person–years[3])	
		Men	Women
•Meat packing plants (119.2)	•Manufacturing: Packing houses, manufacturing meat products, poultry processing, stockyards (23.5)	•Textiles, clothing footwear manufacturing (4.7)	•Basic metal manufacturing (16.7)
•Motor vehicles and car bodies manufacture (74.1)	•Manufacturing of aeroplanes (9.1)	•Food and beverage manufacturing (4.5)	•Transport equipment manufacturing (16.2)
•Poultry slaughtering and processing (52.3)	•Manufacturing: Bakeries, food, and dairy products (3.4)		•Electricity, gas, water (13.4)
•Knit underwear mills (49.4)		•Miscellaneous manufacturing (4.4)	•Miscellaneous manufacturing (13.4)
•Men and boys' trousers and slacks	•Manufacturing: Planing mills, tanneries, sash and door factories, monument dealers, manufacture of furniture and concrete blocks (3.3)	•Public administration (3.9)	•Fabricated metal manufacturing (9.0)
	Manufacturing: Foundries, rolling mills, machine shops, scrap metal dealers, agricultural machinery, manufacturing of vehicles (3.0)	•Agriculture (3.1)	

[1] In 1997 the incidence rate for all US private industry combined was 3.2 per 1,000.
[2] Manitoba overall RSI claim rate was 1.0 per 1,000.
[3] South Australia overall RSI claim rate was 1.9 per 1,000.

the type of rates that can be found in a research study. Besides having been conducted in a high risk industry, this study was selected here because it met the 4 quality criteria mentioned in the a National Institute of Occupational Safety and Health (NIOSH) review of the literature (1997) (70% participation rate or more; used a physical exam to assess WMSD; used observation or measurements for risk factor analysis; and investigators were blinded to cases and exposure status). For physician observed disorders of shoulder girdle pain, Chiang *et al.* found that 10% of workers were a case in their *low* risk factor exposure group, 37% in the *mid*-exposure group and 50% in the *high* exposure group (for 1000 workers this means a rate of 100 in the low, 370 in the mid-, and 500 in the high). For the carpal tunnel syndrome the case rates per 1000 workers were, respectively for each group: 80 for low, 150 for mid-, and 290 for high.

Statistics based on different case definitions will, therefore, define a greater or lesser population of workers with the WMSD. The road between the beginning of a work-related musculoskeletal problem to the declared and compensated claim is long and not understood; consequently to correctly establish OHS priorities, ergonomic interventions and prevention programs, it would be preferable to have the broadest picture possible, using WMSD data collected in the workplace itself and not just the company's WMSD compensation data.

3. RISK FACTORS AND EVIDENCE OF THE WORK RELATEDNESS OF VARIOUS DISORDERS

Factors which are known, on the basis of epidemiological evidence, to be associated with the development or aggravation of a health outcome (musculoskeletal disorders for our purposes here) are considered risk factors (Last 1995). These may be factors to do with inborn or inherited characteristics (grouped here under the term "personal factors") or lifestyle and environmental exposures (divided here into "*work* risk factors" and "outside work risk factors"). Although presented as separate categories of risk factors, there are links between factors (a certain personality or physical stature may be predisposed to choose or be given a certain type of job), and interactions between factors (cumulative exposure to repetitive use of a limb at work and in sports), irrespective of category. This section of the article will concentrate on work risk factors, with only a mention of the other risk factors. Table 3 shows a list of possible work risk factors; usually workers"

exposure is not limited to one work risk factor but combinations of risk factors are present.

It should be noted that the terms risk factors and work factors are often used loosely and interchangeably to describe any factor at work which could possibly be associated with WMSD even in the absence of statistical/epidemiological evidence or even if far remove in the chain of events (e.g. poor lighting is called a risk factor when the underlying risk factor is the poor posture that may result).

Research investigating the possibility of a link between *physical* work factors and these musculoskeletal disorders has been reviewed (Kuorinka and Forcier 1995, Hales and Bernard 1996, NIOSH 1997, Viikari-Juntura 1995, 1998). These reviews *included all studies with a determined level of quality, irrespective* of whether the results *did not support* a link with work or *did indicate* the possibility of an association. Generally speaking, there is agreement between these *independent* reviews: there are, indeed, links between various risk factors at work and musculoskeletal disorders. Table 4 represents a fusion the NIOSH (1997) and Viikari-Juntura (1998) findings after examination of the association between some selected disorders and some physical work exposures. There is no systematic examination of the work-relatedness of lower limbs in either of these reviews, however Kuorinka and Forcier (1995) did review knee bursitis and found that there was evidence for a relationship between posture (kneeling) and the disorder. Finally, among physical risk factors at work, exposure to cold or working in a cold environment has been postulated as associated with musculoskeletal disorders. Although none of these reviews systematically assessed the relationship with cold, there is a section in the Kuorinka and Forcier (1995) which discusses briefly some existing studies.

Currently there is more information available on physical risk factors than on psychosocial risk factors. Generally speaking, studies have shown associations between WMSD and psychosocial factors related to job and task demands (especially heavy workload, time and work pressure, limited job control, and monotonous work) (Hales and Bernard 1996, NIOSH 1997). There are also studies that have found links between lack of job clarity and WMSD (Hales and Bernard 1996, NIOSH 1997). Finally, poor social support at work (from supervisor and/or co-workers) has also been linked with WMSD. Mechanisms postulated to explain such associations are based on the possibility

Table 3. Possible risk factors for WMSD at work (inspired from Huorinka and Forcier 1995, Hales and Bernard 1996, and NIOSH 1997).

Physical risk factors at work	
•Force	Forceful exertions, and/or shock, impact and impulsive loading, and/or local mechanical stresses
•Repetition	Cyclical work activities, repeated tasks or work that involve frequent and/or prolonged cyclical movement or repetitive movement of selected body segments/joints
•Posture	Awkward, adverse or extreme postures and static postures leading to loading of anatomical structures
•Cold	Working in a cold environment, drafts and other local/segmental exposure to cold (e.g. gripping cold objects)

Psychosocial risk factors at work[1]	
Factors related to job or task demands	e.g. heavy workload, monotonous tasks, poor work content, time pressure, increasing work pressure, lack of autonomy, limited job control . . .
Factors related to the organisation as a whole	e.g. job insecurity and lack of job clarity, employee–supervisor relationship and poor social support, shiftwork . . .

[1] Factors between and within categories overlap.

Table 4. Epidemiological evidence for association between physical risk factors at work and selected WMSDs (adapted from the NIOSH review, 1987, with notes from the Viikari-Juntura, 1998, review where there are differences).

Physical risk factor at work	Neck (including neck/shoulder studies which were likely to be specific to neck)[1]	Shoulder tendinitis[2]	Lateral Epicondylitis[3]	Carpal Tunnel Syndrome[4]	Hand/wrist tendinitis[5]	Hand–Arm vibration
Force	Evidence	Insufficient evidence	Evidence	Evidence	Evidence	
Repetition	Evidence	Evidence	Insufficient evidence	Evidence	Evidence	
Posture	Strong evidence	Evidence	Insufficient evidence	Insufficient evidence[6]	Evidence	
Vibration	Insufficient evidence	Insufficient evidence		Evidence[7]		Strong evidence
Combination of the above factors	Insufficient evidence	See table note[8]	Strong evidence[9]	Strong evidence	Strong evidence	

[1] Includes some studies on tension neck syndrome and some studies of neck and/or neck and shoulder problems based on symptoms alone or based on symptoms and physical examination.

[2] Some studies included a diagnosis of shoulder tendinitis while others used a combination of symptoms and physical examination findings or symptoms alone but do not necessarily diagnose them as tendinitis.

[3] Includes some studies with physical examination for epicondylitis and some studies using symptoms only as case definition.

[4] Includes a few studies where CTS was assessed by symptoms alone, and studies where CTS was assessed by symptoms and physical findings and/or electrophysiological tests of nerve function.

[5] Includes studies on de Quervain's disease, trigger finger, tenosynovitis, peritendinitis, tendinitis. All studies used at least a physical examination to determine cases.

[6] Viikari-Juntura denotes the results of research as showing "Evidence".

[7] Viikari-Juntura denotes the results of research as showing "Strong evidence".

[8] NIOSH, in its summary table, does not comment on the possibility of a link between combination of these risk factors and neck disorders, however, Viikari-Juntura, in her summary table, indicates that there is "Evidence" for an association between combination of these factors and Rotator cuff tendinitis.

[9] Viikari-Juntura denotes the results of research as showing "Evidence".

of a direct relationship (i.e. these factors increase stress which in turn increases muscle strain and subsequently the response to physical risk factors) and/or indirect relationship (i.e. these factors mediate the employees" perception and response to the physical risk factors). Job dissatisfaction has also received much attention and has shown some links with WMSD (NIOSH 1997); however here we did not consider it as a work risk factor since it is likely to made up of very many components and appears to lie more at the junction of work/personal/outside work risk factors.

Some personal factors (e.g. gender, age, weight, some anatomical differences, etc.) and outside work risk factors (e.g. tasks at home) have also been linked with the development of musculoskeletal disorders. Many studies have reported that women have a higher WMSD rate than men (for example, see South Australian incidence rates in Table 2). Depending on culture, some women may report and seek treatment more readily than men; as well, they may have added personal or outside work exposure. However, generally speaking, women also occupy very different jobs than men, usually jobs of a more repetitive nature. Further, workplace design may have traditionally been thought of in terms of men. In some studies where occupational exposure factors are controlled there is no longer an association with gender (e.g. Stevens 1988). Beside gender, Kuorinka and Forcier (1995) and Hales and Bernard (1996) have examined some other personal factors such as age, weight and a few others.

Obviously, if only personal factors and/or outside work factors contributed to the development of a particular disorder, for that particular case in that particular individual, we are no longer dealing with a *work-related* musculoskeletal disorder. However, in cases declared at work, some could be associated with work risk factors alone, while others may involve a mixture of work and personal/outside work factors. Currently, unless in the presence of very compelling evidence concerning one type of factor versus another, it is difficult to apportion the various contributions. Rather than deal with a case by case scenario, it is by far preferable to look at the work environment of employees with problems and their close co-workers, and do population statistics and risk factor detection to see if risk does exist at work, irrespective of each individual's personal and out of work exposure profile. After all, in work environments where there are extensive WMSD risk factors identified, the role of personal and outside work risk factors is likely to be far less important (Kuorinka and Forcier 1995). In the Chiang study (1993) cited in the previous section, the low exposure group showed low prevalence of WMSD. In a recent article, Battevi *et al*. (1998) observed workers *not exposed to* tasks considered at risk of WMSD and found low prevalence of WMSD (1.9% for males and 5.2% for females for a total of 3.9%) as well as low prevalence of pain, irrespective or duration and frequency (13.5 % for men and 9.6% for women for a total of 11.2%). The authors conclude that "the prevalence were on average quite low . . . hence the authors recommend that even minimal prevalence detected in particular work environment should not be underestimated" (see the Waldermar surveillance article in this volume).

4. A NOTE ON THE LINK WITH WORK, WMSD ETIOLOGY AND PATHOPHYSIOLOGY OF THE DISORDERS

Partly, what renders understanding the mechanisms behind the links between work risk factor and the development or aggravation of the disorders difficult is that, in many cases, the pathophysiology processes involved in the varied disorders are not understood. Each type of disorder is likely to have its own process, although some may share similarities. It is also hard to know if the development or the aggravation of WMSD occurs suddenly (sudden onset) or over days, weeks, months or years of exposure (gradual onset) and in a cumulative fashion even in the presence of small exposures and/or in one or a series of overdose. The safe "value" for exposure to each risk factor is unknown. The resulting exposure "value" of the interaction between various work risk factors (additive impact?, synergism?, some cancellation?) is also unknown. Further, the role of remedial factors (e.g. time of recuperation allowed between each exposure) or possible protective factors (e.g. individual physical and mental fitness) is not fully understood. And, again, all of this is likely to vary according to the actual disorder.

5. EXPLANATORY MODELS

WMSD are a heterogeneous group of pathological conditions. Many efforts have been made to explain the natural history and the chain of events leading to WMSD, however, no generally accepted model is available (e.g. Johansson and Sojka 1991, Armstrong *et al.* 1993). The reason may be that it can be hypothesized that each WMSD condition may have different causes and the same cause may produce different outcomes. However, a relative consensus seems to exist that the final link in the chain of events leading to a WMSD pathology is the mechanical stress on the musculoskeletal system.

6. IDENTIFICATION OF FACTORS AT WORK

Whether talking of physical work risk factors (mechanical exposures) or psychosocial work risk factor, there is no perfect method for identifying and measuring risk factors. Each method has its advantages and its drawback; the choice of which method to use will depend on the context, the level of depth required of the results, the costs and resources available, and the factor(s) to be measured. This section will briefly discuss detection of physical risk factors at work with a passing mention of psychosocial factors.

Table 5 provides a brief overview of various types of methods available to identify and measure physical risk factors in order to be able to estimate the mechanical exposure which result from being exposed to these risk factors. As one travels across this table from exploratory "measures" to direct measurements, the precision/quality of the results increases, however so are the costs and efforts involved in collecting and analyzing the data.

Some of the same types of methods which are used to measure physical risk factors (Table 5) can also be used to measure other work factors. We define here "other work factors" as work variables (e.g. workstation design, design of work areas and other

Table 5. Overview of various types of methods available for identifying and measuring physical risk factors at work (inspired from Kuorinka and Forcier 1995 and van der Beek and Frangs-Dresen 1998).

	Exploratory	Subjective measurements	Systematic observations	Direct measurements	Interpretation of results
Types of methods	•Informal interviews •Self-reports	•Self-reports •Questionnaire techniques •Expert judgement	•Observations at workplace •Video observations	•Direct measurement at workplace •Measurements during simulation in laboratory	•Experts opinion •Panels •Reference groups
Examples	•Interviews •Discussions •Collecting opinions	•Questionnaires •Diaries •Quick checklists	•Systematic samples of tasks and work of individual workers	•Physiological (e.g. EMG) •Biomechanical (e.g. tendon buckle transducers to measure achilles tendon forces) •Activity analysis	•Group discussions •Expert groups •Autoconfrontation

architectural features, tools available, objects lifted, their weight, shape, etc.) which are part of the chain leading to the presence (or absence) of risk factors. In the prevention of WMSD, actions taken are often aimed at these work factors thought to be associated with the risk factors (e.g. re-designing a tool so that the force exerted is lessened).

Where to start? If a company has an active risk factor surveillance program, some basic data on risk factors is already available. If not, it is best to start with the less costly methods (e.g. a quick checklist) to first examine if there is the presence of risk factors and what seems to be the problem. Then, depending on what was found, one can move on to more precise methods (and more expensive) to measure risk factors and work determinants, as required. Van der Beek and Frings-Dresen (1998) have compared the usefulness of the types of methods for measuring physical risk factors and some other work factors. Irrespective of the method(s) chosen, once having measured and analyzed the work factors (risk factors or otherwise), there will be a need for some form of discussion and consultation with appropriate individuals to interpret the results and decide on the best approach possible to deal with the findings.

For most psychosocial factors there are few direct measuring methods. Although with variables such as workload there is the possibility to measure objectively, for many psychosocial factors the measurements are of the subjective type.

It should be noted that it is usually very difficult to collect in depth information on all risk factors at once (all physical factors or all psychosocial factors or both); choices usually need to be made. These choices will inevitably direct the possibilities for intervention and prevention; one can only deal with issues one sees. Further, even if it were possible to collect at once information on all factors, it could be difficult to later establish which are likely to be the more important factors, that is to establish those factors on which to intervene in an attempt to reduce exposure. Besides all that is unknown about safe values and interactions between factors, there is also the problem that not all factors were measured with the same degree of accuracy (the same type of measures). If a factor seems more important it could be that its measure was more precise. Still, even with our current limits, much can be done to detect and exert control over risk factors at work and thus prevent WMSD.

7. POSSIBLE ERGONOMIC APPROACH TOWARDS PREVENTION OF WMSD

In this context prevention of the WMSD is presented mainly from the point of view of primary prevention (prevention at the source). The authors are convinced that ergonomics is an important, maybe the most important, mean of realizing prevention of the WMSD in the working environment.

7.1. Prevention Strategies

From an operational point of view it is necessary to analyze different levels of preventive actions. Depending on the social context where the prevention is practiced, different actors are engaged and different means may be employed – in more generic terms different strategies may be adopted.

The *most general level is societal* which operates through legislation, norms and indirectly through social insurance schemes. Most industrialized countries have legislated at least some aspects (recognition, surveillance, compensation, etc.) of WMSD. In the international scene, the International Labour Organisation (ILO) is the authoritative agent in that respect. Recently important initiatives for creating new legislation and to establish new norms concerning the WMSD have been undertaken for example in Europe, Canada and in the United States. Viikari-Juntura (1997) provides an overview of some recent standards and specific research based guidelines.

One step down, but still at a wide level, various programs and campaigns, often combining awareness raising and some forms of activation, have been run by diverse organizations (e.g. the state or province's compensation body, unions, etc.) and by various public funded voluntary/lobby groups. These programs generally aim to motivate the target population into action to deal with WMSD. Programs may also contain an educational aspect, for example to help the targeted individuals analyze their own work places with respect to WMSD risk. The results of campaigns and programs are rarely followed up, thus we do not know much of their efficacy.

From an ergonomics point of view, *strategies employed in industry* are of special importance. Ergonomists may have on this level direct influence on the content and on the accomplishment of such strategies.

The industrial strategies are as varied as the industries

themselves. The comparative analysis of the efficiency of individual strategies is usually not possible due to lack of published data. Examples of possible strategies follow.

Strategies using normal existing OHS channels. In cases where occupational safety and health (OSH) is firmly rooted in to the practices and customs of an organization, it is only natural to channel prevention through it. A definite advantage of such situation is the already acquired high competence of OHS officers (and ergonomists) on the subject matter. However, in such a strategy, depending on how existing OHS is structured (e.g. separated from the operational side of the company and falling under the resource/personnel management aspect), prevention may be understood as a specialist isolated function. This could reduce the interest and involvement of the production folks, that are, really, in a central position to realize the prevention.

Strategies using existing safety audits. Some North-American industries have adopted systematic safety audit practices. Incorporating the necessary elements for the control of WMSD in the safety audit has shown to be useful in prevention of the WMSD at least in some cases known to authors. Lack of data prevents a more detailed analysis.

Strategies using existing company standards. Major industries may have their own standards on widely varied issues. This makes it at least theoretically possible to incorporate preventive elements for WMSD to such a standard base. The internal standards (which may in some cases be huge bases of knowledge) may concern principles of technical design, including work places, tools, production, and working methods, etc. They may also be guidelines for acquisition of production means, tools, furniture and others. Such issues, if they may be influenced, are most useful in prevention of the WMSD.

Strategies using the creation of special programs. Prevention strategy may take the form of special programs. For example, some companies support physical activity programs which may concern WMSD either as part of general schemes for improving physical fitness or sometimes specifically oriented towards WMSD (most often these programs have been geared towards the prevention of low back pain). The usefulness of such programs remains to be demonstrated.

Finally, irrespective of the chosen strategy, *it should be noted that commitment is the first building block*. Raising awareness about the WMSD is proposed as means to uncover the supposedly hidden problems and permit the organization to take adequate decisions to prevent it. "Let the sleeping dogs lie" has been often preferred to this approach and it seems that the organizational culture must be strongly committed to prevent WMSD to be able to take the risk of waking up the dogs.

7.2. Preventive Actions

Whatever strategy is adopted, it has to converge towards a certain number of actions. Theoretically, the number of preventive actions is large but the feasibility and economic factors limit the number to a fairly small collection of identifiable issues.

The preventive action may be aimed at a collectivity of workers, a company as a whole, a professional group or other, or it may have the individual considered at risk (or already experiencing symptoms) as a target. The preventive action may be aimed at generic risk factors themselves or it may be directed towards specific work factors which are thought to be in the chain of events leading to WMSD.

The following is not exhaustive list but shows the types of actions reported in the literature:

- Preparing or acquiring informative material on WMSD.
- Exploring and employing strategies to convince management of the usefulness of preventing WMSD.
- Mounting awareness raising programs aimed at individual workers. Such a program should be completed with means that permit individuals to react and act adequately to improve his/her situation.
- Designing and implementing tools with technical designers, supervisors and work-study engineers.
- Finding ways to incorporate the prevention into the company culture.
- Working with production engineers, architects, etc. to design work environments with reduced WMSD risk.

7.3. Ergonomics as Means of Preventing WMSD

Ergonomics is by definition an important tool and mean of preventing WMSD in an industrial and other occupational context. Ergonomists are usually capable of analyzing risk factors in a specific context and of understanding how to correct the situation. The following list describes elements often found in an ergonomic intervention.

- Identification of risk factors.
- Analysis of relevant aspects of the production process and organization which may result in these risk factors existing. This phase is necessary to be able to proceed to the next step, identification of risk situations.
- Identification of risky situations

An ergonomist's competence should be – and usually is – sufficient to be able to identify in a given operational situation the generic risk factors of WMSD. An ergonomist must be able to find out when, where and how these risk factors occur, how they are linked to other relevant factors and to the production process in general. One of the problems is that WSMD research has described poorly the interrelations between risk factors themselves and with other relevant factors. Further knowing an epidemiological correlation between factors is not sufficient.

- Identification of potential solutions and preventive approaches.

In a given situation, many different solutions and preventive approaches may be present. Each of them may have specific merits and seem to promise results in the preventive sense. A closer look may show, however, that certain approaches may not be realizable for some theoretical, practical, economic or other reason. This leads to an iterative priority setting process, involving not just the ergonomist but employees and management at various levels of the company, where proposed approaches are scrutinized over and over again until a balanced approach is identified which seems to be most feasible.

- Choosing feasible preventive approaches.

After identifying the most appropriate approach a *formal* decision should be taken which should enable all concerned parties to agree upon and to commit themselves to work towards a common goal.

- Implementing of prevention.
- Securing the follow up and evaluating the impact of the chosen approach(es).

8. CONCLUSIONS

WMSD are a heterogeneous group of conditions. Many aspects of WMSD are not clearly defined and understood. Still, statistics report that these are an important problem in industry and cannot be ignored. Literature reviews also show that there are, indeed, links between work and these musculoskeletal disorders, and there is information available on risk factors at work. Although the knowledge base is incomplete, ergonomics has an important role to play towards prevention of WMSD.

Work-related Musculoskeletal Disorders in Dental Care Workers

D. C. Murphy

Occupational Health Specialist, New York University College of Dentistry, USA

1. OBJECTIVES

After reading this article, the reader will be able to:

- describe historical developments in both the practice of dentistry and federal regulations which impact on the current situation
- list three or more risk factors associated with the development of WMSDs in dentistry
- identify three strategies for preventing/reducing WMSDs in DCWs

2. INTRODUCTION

This article offers a comprehensive overview of the current state of ergonomics, specifically, work-related musculoskeletal disorders (WMSDs), as they relate to dentistry and dental care workers (DCWs). Apart from some historical background information and statistics which assist the reader in appreciating the scope of the problem, the focus is on identified risk factors and effective preventive strategies.

An abbreviated summary of the most relevant literature offers multiple examples of research findings which demonstrate a positive association between dental tasks/procedures and adverse effects on various parts of the DCWs' musculoskeletal system — namely, cervical spine/neck area, shoulder, elbow, wrist, hand, fingers, and lower back. Methodologies employed by the researchers include, but are not limited to, worker surveys, videotapes, electromyography, visual analog scale, and records review. Preventive strategies are also enumerated from two different viewpoints: (a) recommendations from independent researchers and (b) interventions based upon a "hierarchy of controls" developed by OSHA (Occupational Safety & Health Administration); however, there are many noticeable similarities. Application of the various preventive interventions to dentistry are given with examples. There are statements made that refer to the forthcoming legislation and its supporters and opponents, and a plea for the integration of official policies with people, practice, and product development.

3. HISTORICAL OVERVIEW TO THE PRESENT

Ergonomics is defined in many ways according to the discipline providing the definition; however, a simple straightforward description is "the science of fitting the job to the worker and when there is a 'mismatch' between the physical requirements of the job and the physical capacity of the worker, work-related musculoskeletal disorders — WMDSs — can result" (OSHA 1999). Historically, in dentistry, fitting the job to the dental care worker, was not a common practice, and in fact some of the same attitudes continue to this day.

3.1. Working Position

Historically, the dental chair was designed to treat the patient in the upright position — hence the need for the dentist to stand, resulting in the following problems: (1) muscle fatigue (2) need to lean awkwardly over the chair in a twisted position, and (3) need for one foot to always be seeking the foot lever to operate the chair and equipment, thereby putting most of the weight on one leg rather than evenly distributing it. As years in dental practice increased (i.e. "duration of exposure" increased), these fixed contorted positions resulted in a high incidence of circulatory and musculoskeletal conditions among dentists: scoliosis, kyphosis, lordosis, varicosities, and other leg and foot problems were common.

In an effort to reduce the physical fatigue of standing and the resultant adverse effects on health, dental stools began to be used in the 1950s and thus the term "*sit down*" dentistry was coined. However, the initial stools were single pedestaled, and often tilted and rotated, presenting a safety problem. While the design of the stool has been greatly improved since that time, current researchers have identified potential ergonomic conditions related to sitting. In a sample of 3316 dental care providers, lower back pain was associated with sitting for four or more hours per day.

3.2. Tools and Equipment

Traditionally the old "drills" used in dentistry were run by stepping on a pedal that rotated a belt. This slower, labor-intensive method has been replaced by compressed air-driven high-speed handpieces. While the increased speed of the new instruments improves the quality of care and reduces the time required to complete the dental procedure, it has also resulted in vibration-related hand and wrist conditions.

3.3. Personnel

A third significant development in dentistry involves the move from a single practitioner, i.e. the dentist, to "four-handed dentistry". This switch now incorporates a professionally trained "helper", usually a dental hygienist, into the daily practice. Like most changes there have been benefits such as a reduction in the length of the patient visit due to increased efficiency — and there have been liabilities — such as the development of WMSDs in a whole new cadre of workers.

3.4. Current Situation

As early as the 1950s, researchers recognized the fact that the practice of dentistry is associated with several musculoskeletal disorders that may be attributable to risk factors found in the typical dental work environment. Since that time, we have seen the passage of the Williams-Steiger Act (Occupational Safety and Health Act of 1970), which led to the creation of the Occupational Safety and Health Administration (OSHA) as well as the National Institute for Occupational Safety and Health (NIOSH), whose respective missions, while somewhat different, converge in a shared concern and responsibility for the health of American workers.

During the past decade, both federal agencies (NIOSH and OSHA) have recognized a disturbing increase in the incidence of musculoskeletal disorders among various worker populations, including (but not limited to) office workers, telephone operators, post office employees and supermarket baggers. Despite national

and international studies documenting the existence of this type of condition in dental care workers, limited attention has been paid to this worker population by federal agencies. Additionally, private organizations including the American Industrial Hygiene Association (AIHA) and the American National Standards Institute (ANSI) have supported the position associating workplace risk factors in the dental care environment with the development of musculoskeletal injuries. In fact, a comprehensive report recently issued by the National Academy of Science (NAS) concluded that "ergonomic hazards at work cause musculoskeletal disorders, and intervention measures to prevent these disorders currently exist" (Work-related MSDs: a Review of the Evidence, National Academy of Science, 1998).

4. SCOPE OF THE PROBLEM

Since the early 1980s, NIOSH has been waving a red flag alerting the nation to the ever-increasing number of cases of WMSDs reported in a variety of workplaces.

Although death is not a likely outcome due to the presence of the more common deficiencies that would be addressed by an OSHA Ergonomics Standard, disability is common. In 1997, there were 276 600 cumulative trauma disorders (CTDs) in the United States, representing 64 percent of all workplace illnesses, according to the Bureau of Labor Statistics (BLS) in their BLS Annual Survey of Workplace Injuries and Illnesses for 1997. There were more than 1.25 million work-related back injuries, with an average cost of $24 000 for each claim filed. According to the National Council on Compensation Insurance Inc (NCCI) in its Annual Statistical Bulletin 1998, it is estimated that these disorders cost American industry more than $20 billion annually and the cost is escalating. Unfortunately BLS statistics on dental care workers are questionable due to limited or underreporting of conditions as well as a "clumping together" of all illnesses and injuries among this worker population in the Bureau's current system.

In March 1995, OSHA issued a Draft Proposed Ergonomic Protection Standard. It was a comprehensive, prescriptive document several hundred pages in length including non-mandatory appendices. There were two criteria for assessing ergonomic risk: signal risk factors, and the presence of work-related musculoskeletal disorders.

Comment was solicited and a firestorm of response was received. In June 1995, Congress prohibited the use of OSHA funds to issue a proposed or final Ergonomics Standard or guidelines. With this prohibition no longer in effect, the agency director is determined to have an approved standard in place by the year 2000.

Although the American Dental Association (ADA) directed interest toward this emerging health issue as early as 1963, when it published a lengthy article in its national journal entitled "Body Mechanics Applied to the Practice of Dentistry" (ADA 1963), its current stance is guarded at best. Some of the concerns voiced by the ADA and its members include the financial costs to the dentist (for example, to purchase new instruments or retrofit equipment) as well as lack of conviction regarding "a scientific documented linkage between cause and effect".

5. REVIEW OF THE LITERATURE

The inclusion of dental care workers in the forthcoming OSHA

Ergonomic Standard as a worker population at risk of developing MSDS is still unresolved, but a review of the relevant literature helps answer this question. To summarize: (1) much of the literature discussing musculoskeletal disorders and dental care workers is found in non-dental journals — primarily those whose audience consists of physical therapists, industrial hygienists, occupational therapists, orthopedic surgeons, and ergonomists; (2) the earliest international article found was the publication in 1955 of a research study of dentists done in the United Kingdom, while the first American article was a 1963 entry in the Journal of the American Dental Association; (3) there are multiple studies of various design — using different research methodologies — that demonstrate an association between dental tasks and musculoskeletal disorders; (4) the prevalence of WMSDs is an international occurrence, not just national; and (5) more than one anatomical site is commonly affected.

- *Data collection* has been on-going by independent researchers as well as various organizations including, but not limited to, the Occupational Safety and Health Administration, the National Institute for Occupational Safety and Health, the American Industrial Hygiene Association, the American National Standards Institute, the National Academy of Science and the American Dental Association.
- *Study design* varied, and included case-control, cohort, cross-sectional, and retrospective approaches while the populations studied were dental hygienists, dentists, dental assistants, and control groups such as pharmacists who were matched for significant variables with the study (DCW) population.
- *Tools and methods* included worker questionnaires, surveys, videotaping, motion analysis, biological monitoring (heart rate, nerve conduction, x-rays) and review of pertinent records, i.e. worker compensation data, medical charts, etc.

6. RISK FACTORS

The question is: How do we assess the risk of developing a work-related musculoskeletal disorder in a particular worker population (i.e. dental care workers)?

The suggested answer is to survey the workplace of concern for the presence of specified risk factors. Independent researchers have identified six risk factors for the development of WMSDs and they are: repetition, awkward postures, force, vibration, direct pressure, and insufficient rest. In addition, they state that a

Figure 1. Deviated upper-body positions during a dental task.

Table 1. Risk factors: comparison

General risk factor	Signal risk factor
Repetition	Performance of same motion/motion pattern every few seconds for 2–4 hours at a time
Awkward postures	fixed or awkward postures for more than 2–4 hours
Vibration	use of vibrating or impact tools/equipment more than a total of 3–4 hours per work shift
Force	using forceful hand exertions for more than a total of 2–4 hours at a time

combination — i.e. the presence of more than one risk factor — markedly increases the potential for the development of CTDs.

An observation of dental care providers in their workplace clearly demonstrates the presence of more than one of these risk factors during the performance of most dental procedures (see figure 1).

The Occupational Safety and Health Administration has cited two criteria for assessing risks, including the presence of "signal risk factors" and the presence of work-related musculoskeletal disorders. The "signal risk factors"— similar to the previously stated list of six risk factors — are more specific (see table 1).

7. ANATOMICAL SITES INVOLVED

While work-related musculoskeletal disorders have been known to affect most parts of the body, disorders of the back and upper extremities are the most frequent in the general population. Conditions that have been associated with dentistry specifically include disorders of virtually every sector of the musculoskeletal system, including (but not limited to) upper and lower back, wrist and hand, arms, lower extremities, neck, shoulders (including osteoarthritis), and shoulders and neck.

7.1. Neck and Shoulder

Various study methodologies have been used including videotaping, questionnaires, time studies, Electromagnetic Graphs (EMG), and direct observations made on DCW groups since the 1960s. There was sufficient evidence to identify prolonged static neck flexion, repetitive neck movements, shoulder abduction or flexion, lack of upper extremity support and insufficient work breaks, as risk factors for developing WMSDs in the neck and shoulder regions (see figure 2).

7.2. Wrist and Hand

Various study methodologies have been used including vibrometry. Reported and observed signs and symptoms such as

Figure 3 Awkward posture of elbow and wrist with fingers in pincer grip.

numbness, pain, and degenerative changes in distal interphalangeal joints were significantly greater in the study group than those in selected control groups. Demonstrated risk factors which result in wrist and hand WMSDs include highly repetitive work, forceful work, wrist/hand vibrations, extended work periods, repetitive wrist flexion and extension, and high precision grip (see figure 3).

7.3. Low Back Disorders (LBD)

Various study methodologies were used including electromyography, X-rays, and self-reported lumber pain and neuralgia among practicing dentists. Evidence was found supporting an association between LBDs and the following risk factors: heavy physical work, forceful movement, work-related awkward postures, whole body vibration, prolonged sitting and static work in the sitting position requiring spinal flexion and rotation (see figure 4).

8. MANAGEMENT AND CONTROL STRATEGIES

The development of an effective management and control program requires the inclusion of several components, including:

   (a) prevention — the most important component
   (b) diagnosis — early and accurate
   (c) treatment — to relieve signs and symptoms and to minimize disabilities
   (d) possibly a change of careers if all else fails

While the focus of this section is on prevention, a few words about early diagnosis and treatment are warranted. It is imperative that any DCW experiencing signs and symptoms of WMSDs be evaluated as early as possible and by a qualified clinician. There are many board-certified occupational physicians who are oriented to an inclusion of workplace conditions as a potential

Figure 2 Awkward posture involving neck and shoulders.

Figure 4 Twisting of lower back during dental procedure.

cause and/or contributor to any illness or injury reported by the patient. This physician, after assessing the role of the workplace on the patient's condition, will usually recommend a conservative treatment approach which may include but is not limited to: exercise, physical therapy, a work-hardening or work-conditioning program, medication, modification of work process, work layout, work schedule or equipment/tools, or alternative therapies such as herbs, massage or acupuncture. Surgical intervention is usually only considered after the aforementioned conservative modalities are tried unsuccessfully. As a last resort, the worker may be advised to consider a change of careers.

9. PREVENTION: AN OVERALL APPROACH AND SPECIFIC STRATEGIES

The area of "prevention" also comprises multiple components. First, one must make an accurate assessment of one's workplace and this can be done by the use of various tools such as employee survey, videotaping of actual tasks and postures, or reviewing relevant records — for example, workers' compensation claims or medical records. Using these investigative techniques will then allow the identification of high(er)-risk tasks and procedures as well as higher-risk personnel. (There is some documentation in the literature associating non-work-related personal characteristics such as arthritis, diabetes, pregnancy, and some activities (knitting) with the development of musculoskeletal disorders.) These findings can then be utilized to identify and apply effective intervention measures. As with all diseases, the emphasis needs to be on prevention or limitation of the adverse event (i.e. work-related musculoskeletal disorders); similarly, as with other disease (illnesses and injuries), there are proven strategies for effectively preventing or reducing the incidence of WMSDs. There are two sources of information for preventing WMSDs in dental care workers: (a) the reported results of various independent researchers, and (b) recommendations made in the most recent draft of the Ergonomic Standard proposed by the Occupational Safety and Health Administration. While varying in subject categories, their recommendations are similar.

9.1. Prevention Based on Independent Research Findings

As mentioned previously, there have been a relatively large number of domestic and international studies conducted on both the predictors of risk and prevalence of musculoskeletal disorders in the dental care worker population, and as a result, researchers have been able to identify, implement, and recommend effective interventions. Specific preventive strategies as categorized by anatomical site are outlined below.

9.1.1 Neck and Shoulders
Support for upper extremities
Elimination of static neck flexion
Elimination of shoulder abduction or flexion
Adequate work breaks
Avoiding work with elbows higher than shoulder
Exercise to strengthen musculature and improve flexibility

9.1.2 Wrist/Hand

Avoid forceful exertions
Reduce repetition of task
Reduce length of time doing a repetitive task
Reduce/eliminate repetitive wrist flexion and extension
Exercises to strengthen musculature and improve flexibility

9.1.3 Low Back
Alternate between standing and sitting
Avoid prolonged sitting
Use back support
Avoid awkward postures
Avoid spine flexion and rotation/twisting while sitting or standing
Exercises to strengthen musculature and improve flexibility

9.1.4 Elbow
Avoid repetitive rotation of wrist
Avoid repetition
Avoid reaching beyond 15 degrees
Exercises to strengthen musculature and improve flexibility

The following case example, which applies these preventive strategies, demonstrates the feasibility of using a safe approach in dentistry.

9.1.5 Case example
There is currently an American dentist (Dr Daryl Beach) who has been living and practicing dentistry in Japan for the past 35 years. In the early 1970s, he developed a unique approach to practice for the dental care worker. The original intention of this system was to intuitively — or "proprioceptively" — derive the most natural, non-stressful body position for performing dental procedures (see table 2). This would provide the operator with the optimal hand and finger control needed for fine motor tasks, which, in turn, would result in the operator's acquisition of superior technical skill and accuracy in the performance of dental practice.

There have been many articles published pertaining to this unique practice system (the Beach System). However, there is only one research article (Kaneko 1994) which focuses on the ergonomic aspects of the system rather than the measurement of skill, accuracy, and productivity. While there are limitations to Kaneko's study design and methodology, his findings — based on interview and videotaping of Japanese dentists — were as follows: (a) a head shift of >15 cm from the neutral centralized position results in high stress in that area; in dentists using conventional practices, for 60% of their workday their head shift was > 15 cm compared to the Beach group which employed a head shift of > 15 cm in only 1.3 % of their work day; (b) reported

Table 2. Sensory receptors.

Exteroceptor	receptor for external stimuli, for example, heat
Interoceptor	receptor: internal organs, for example, thirst
Proprioceptor	internal receptor that: allows one to sense body positions, relationships, movements and forces; is located in the joints and muscles; in the most important type of receptor for fine and precise finger control; 'pd'

Table 3. Reported musculoskeletal pain (Kaneko 1994).

Site of pain	Group A (conventional)	Group B (beach)
Back	51%	8%
Shoulder	44%	0%
Neck	36%	0%
Arms	40%	0%

Group A = 121 participants
Group B = 12 participants

musculoskeletal pain in several body sites was significantly greater in the group using conventional practice methods (see table 3)

Beach introduced and implemented a system of practice that incidentally resulted in eliminating many of the researcher-identified risk factors for WMSDs, including flexed or bent cervical neck positions, abducted elbows and shoulders, twisting and turning of the lower back, and wrist and hand deviation from the neutral plane (see figures 5 and 6).

9.2. Preventive Strategies Based on OSHA's Hierarchy of Controls:

The Occupational Safety and Health Administration has devised its own systematic approach to work-related health and safety issues, namely its 'Hierarchy of Controls' which in order of importance are as follows: engineering, administrative, work practice and personal protective equipment. Prior to deciding which type of control is needed, it is imperative that an analysis of the workplace is conducted (see table 4) to determine both the risks and, eventually, appropriate control measures.

As mentioned earlier in this article, determination of risk is made by the presence of signs and symptoms of WMSDs (see table 5) and the presence of "signal risk factors" (see table 1). If it is determined that both signs and symptoms and signal risk factors exist, application of one of the control strategies is warranted.

10. ENGINEERING CONTROLS:

Engineering controls are physical changes to jobs that control exposure to WMSD hazards; they act on the source of the hazard. Examples applied to dentistry include:

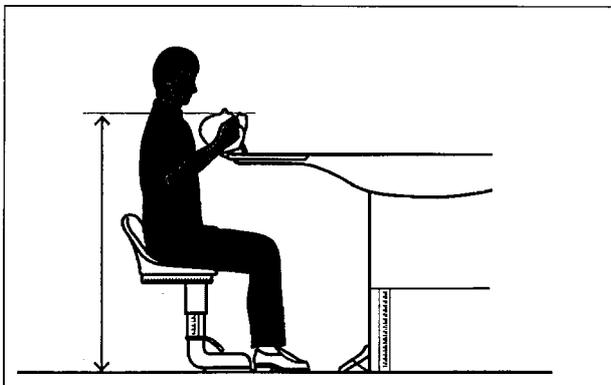
- *Processes*: use safe work practices
- *Equipment*: for example, the stool or seat for the dental


Figure 5a The balanced operator with patient in horizontal position.
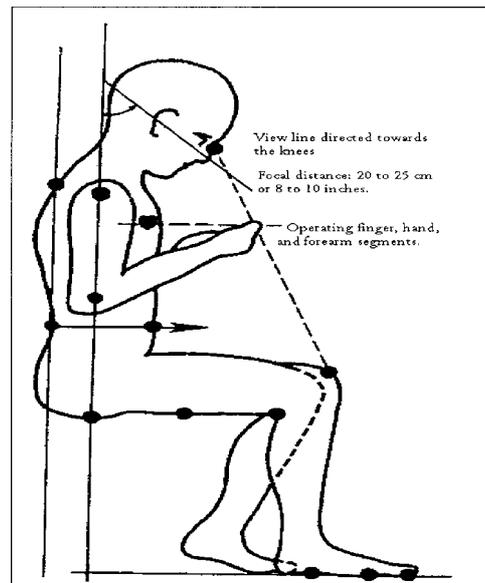

Figure 5b The balanced operator.

operator should be adjustable in height, have a lumbar support, and possibly a frontal support
- *Tools*: for example, dental instruments should be located within 15 inches reach, should be of high quality and sharp, should be lightweight to reduce fatigue, have increased surface holding area to minimize the force needed and should be angled so that the wrist may be maintained in a neutral position, i.e. the instrument bends rather than the wrist.

11. ADMINISTRATIVE CONTROLS

Administrative controls are procedures and methods instituted by the employer that significantly reduce daily exposure to WMSD hazards by altering the way in which work is performed. Examples in dentistry include rotation of employees for tasks such as scaling, adjusting the work pace (slowing it down), alternation of tasks done by individual workers to reduce repetitions, provision of adequate rest breaks in between procedures, reduction in patient load, and shortened recall periods when possible to reduce the amount of work needed on patients per visit.

12. WORK PRACTICE CONTROLS

Work practice controls are controls that decrease the likelihood of exposure to WMSD hazards through alteration of the manner in which a job/work activity is performed; it acts on the source of

Figure 6 Correct alignment of operator's shoulders, elbows and wrists.

Table 4. Job hazard analysis.

Job factors	Components
Physical demands	Force, repetition, work postures, duration
Workstation layout and space	Work reaches, work heights, seating and floor surfaces
Equipment used/objects handled	Size and shape, weight, vibration, handles and grasps
Enviromental conditions	Cold, heat, glare (as related to awkward postures)
Work organization	Work rate, work recovery cycles, task variability

the hazard and examples include: safe work practices such as the use of automation rather than hand-scaling, use of proper body positioning, i.e. avoid bending neck and/or twisting lower back, and maintenance of neutral positions — wrist, neck, torso, etc. — whenever possible. Conditioning for newly hired or newly returned employees is also recommended and may involve simple brief exercises that can be done at the work site or extensive work-hardening/work-conditioning programs of longer duration conducted under the guidance of a trained professional such as a physical therapist, ergonomist or occupational physician.

Randolph conducted a research study on a group of workers in a meat processing plant whose risk factors were comparable to those of dental care workers — namely, low force with high repetitions. She taught the workers a series of exercises for flexors and extensors of the upper extremities to be done daily over a period of six weeks. At the end of the study period, using employee surveys and a visual analog scale (VAS), Randolph reported 78% of the participants said their upper extremities felt better, 69% said the exercises made their job easier, 69% reported less fatigue at the end of the work shift and 65% said they had increased strength (Randoph 1999).

13. PERSONAL PROTECTIVE EQUIPMENT (PPE)

Personal protective equipment or PPE are interim control devices worn/used while working to protect the employee from exposure to WMSD hazards. An example of PPE used in dentistry are gloves. From an ergonomic perspective, recommendations pertaining to gloves include the use of those designed specifically for the left and right hands rather than ambidextrous gloves, and selection of the correct size for the individual since gloves that are too small can increase pressure to the hand and wrist, while gloves that are too large increase the grip force needed.

14. SUMMARY

The documented cases of WMSDs in the USA by the Bureau of Labor Statistics, coupled with strong evidence in the research

Table 5. Signs and symptoms of WMSDs.

Signs of WMSDs	objective, physical findings examples are decreased range of motion, decreased grip strength, loss of function, swelling, redness
Symptoms of WMSDs	subjective, physical indications of a developing WMSD vary in severity and can appear gradually examples are numbness, tingling, burning, aching, pain, stiffness

literature, support the need for official intervention — namely, in the form of the proposed Ergonomic Standard from OSHA. There has been a great deal of opposition to the standard and some of the reasons stated are: economic costs to the employer (purchase of new equipment, etc.), the complexity of identifying hazards, and the sometimes debatable linkage between cause and effect (for example, hobbies such as knitting have frequently been cited as non-workplace activities that contribute to some wrist and hand disorders). Despite the resistance, it seems quite certain that a standard will be in place by the year 2000. This author would like to recommend an integration of various related segments in order to achieve optimum ergonomic working conditions for all dental care workers; these segments — referred to as "4 Ps"— are Policy (the OSHA Standard as well as formal supportive policies from bodies such as the American Dental Association), People (DCWs themselves need to become involved and take responsibility for their musculoskeletal well-being through awareness, education, and continued research), Products (manufacturers must continue to improve upon instruments and equipment used in dentistry), and Practice (utilize rest breaks, task rotation, and exercise programs).

15. RELEVANT TERMINOLOGY AND ABBREVIATIONS

WMSDs:work-related musculoskeletal disorders
CTDs:cumulative trauma disorders
RMIs:repetitive motion injuries
OSHA:Occupational Safety and Health Administration
NIOSH:National Institute for Occupational Safety and Health
ADA:American Dental Association
DCWs:dental care workers (includes dentists, dental hygienists and dental assistants)

Analysis of Worker's Compensation Data

F. T. Conway

State of Wisconsin Department of Workforce Development, Worker's
Compensation Division, Madison, WI 53703, USA

1. INTRODUCTION

Worker's compensation data are a rich source of information that
can be used to identify and subsequently to control occupational
injuries. Worker's compensation law exists at the state, federal
and national levels of jurisdiction. The purpose of these laws is
to provide some financial support for injuries and diseases that
arise out of the and in the course of employment. This legal
requirement involves various parties including employers, the
employee, insurance companies, medical providers and the state,
federal or national entity that serves to distribute such compen-
sation and adjudicate the disagreements resulting from such
claims. This chapter will identify critical information that is
currently collected through current claim forms and associated
documentation related to claims, using a form filed for compen-
sable injuries in the State of Wisconsin as a template. It will pro-
pose some opportunities for utilizing the claim information to
study and control occupational injuries. It will identify some of
the shortcomings of such information and discuss the implications
of such research to control occupational injuries.

2. CLAIM INFORMATION RELEVANT TO OCCUPATIONAL INJURIES

The information collected on a compensable claim from the
Employer's First Report of Injury or Disease (Wisconsin WKC-
12 [Revised 2/98]) includes salient aspects of the occupational
injury. The injury description field in the form is interpreted
through a coding structure into categories of the nature of the
injury, part(s) of body affected, type of accident and source of
the injury. The nature of the injury categorizes the injury
description noted on the form into groupings describing the injury
in medical terms like amputation, contusion or strain. The part
of body field categorizes the area(s) impacted by the injury like
the head, finger or wrist. The type of the accident is a categoriza-
tion of how the accident occurred, such as caught between, struck
by or fall. The source of the injury is a categorization of what
caused the injury like equipment, hand tools or co-worker.
Temporal aspects of the injury are collected on the form in the
date of injury, time of day and the time the injury occurred in the
shift being worked fields. Employer and insurer information is
included on the form in the name, mailing address and Fein
number fields. Employee information is collected regarding the
name, age, gender and employee length of tenure with the cur-
rent employer. The days of healing period for the injury is calcu-
lated by subtracting the date of return to work following the
injury from the last day worked. This computation provides an
indication of the extent of the injury. Additionally, the perma-
nency of the injury is noted in the medical evaluation of the
injury as well as the disabling nature of the injury as total or
partial. As a claim is paid, information regarding the indemnity
cost of that claim is associated with the claim and tracked to
ensure that claims agreed to be compensable or deemed by liti-
gation to be compensable are paid appropriately. Litigated claims
collect information regarding the hearing scheduling and settle-
ment time periods associated with the legal administration of
each claim as well the legal outcome.

3. OPPORTUNITIES FOR THE ANALYSIS OF CLAIMS FOR OCCUPATIONAL INJURY CONTROL

3.1. Macro-analysis of Compensable Claims

One area of opportunity for the analysis of claims is the surveil-
lance of injury trends at a macro-level that collects aggregates of
compensable claims and looks at injuries of significant volume
across all types of business. This information is often examined
yearly and provides totals of the different classifications men-
tioned above. The analysis can identify in broad terms the types
of injuries occurring frequently and some of the associated costs
for the injuries (for example, Berkowitz and Burton Jr 1987, Leigh
et al. 1997, Feuerstein *et al.* 1998). The most dangerous indus-
tries can be identified. Specific factors that led to injuries can be
determined. Injury control can benefit from this analysis by draw-
ing attention to the types of injuries occurring most often as well
as the frequency of occupationally related diseases like asbes-
tosis and silicosis. Such a frequency can be compared across time
to get a perspective on the changing nature of that injury or ill-
ness. A comparison of occupational injuries across industries can
provide some context for additional research into reducing injuries
and illnesses in target industries as is often done by the US
Occupational Safety and Health Administration.

3.2. Micro-analysis of Compensable Claims

A different focus on occupational injury control can be addressed
by examining the lost-time experience of a specific employer or
a group of employers within the same industry. This can provide
a comparison of the nature, frequency and severity of injuries in
a particular industry that can be used to identify employers with
excellent safety records regarding compensable claims as well as
those that may benefit from safety education or training. One
such comparison by the State of Wisconsin was part of an educa-
tional program titled "Safety Works." This program targeted
employers with no lost-time injuries over a time frame and
recognized their success. Additionally, educational materials were
sent to those employers with an incident rate of claims many
times higher than similar industries. It is expected that this pro-
gram will lead to collaboration opportunities for employers with
labor to work to reduce hazards in the workplace. Another
analysis of compensable claims has been undertaken as part of a
study of the medical care provider practices of some State of
Wisconsin employers. Five industry groups have been compared
in terms of their incident claims rate, indemnity cost per claim,
percentage of claims litigated and median healing period for
the time away from work. These were compared with others
with compensable claims that are in the same industry. This

comparison will shed some light on how the medical care provider practices can result in an improved safety climate and a reduction in compensable injuries and associated costs.

At the individual worker level, worker compensation data provides an excellent opportunity to track an individual employee's health over time. An individual with a repetitive strain or cumulative trauma injury can be tracked over time to examine resulting health effects of the work assignments. This would evaluate the appropriateness of the specific work tasks assigned to an individual with such a disorder. Aggregating this analysis for employees with such injuries would provide an employer the opportunity to establish low-risk tasks for employees with injuries, and to maintain productivity and reduce lost work time. The analysis of compensable claims for a particular company could combine the lost-time injuries information for a period with specific safety practices and equipment in a work setting to determine the injury costs and highlight areas of improvement for injury reduction. This would provide the detail of the cost-saving benefits of job re-design strategies like rest breaks or safety precautions like machine guarding. The continual collection of compensable claims also provides the opportunity for the longitudinal analysis of injuries for a workforce. Compensable claims also provide information regarding the permanency of an injury as well as fatal injuries. Analysis of this type of information can provide context regarding the most hazardous industries and accidents for a particular business.

At the company financial level, analysis of worker compensation data provides critical information regarding lost time and indemnity payments to injured employees to help manage the business. The direct demonstration of a financial relationship between work injuries and financial expenditures can provide additional incentive for increased efforts for occupational safety and health at work. Additionally, the lost time for the employee is recorded on a worker compensation system and indicates a measure of the amount of lost work time for that employee, and in aggregate, for the company. Such lost time has to be compensated for with additional hiring and training of temporary staff to make up for the absent employee. The importance of return to work for injured employees has prompted studies examining the factors related to successful return to work. One such study examines which factors were related to return to work when the employee had a low back pain claim (Gallagher *et al.* 1995).

At the company safety and health level, there is additional value in the evaluation of compensated injuries as they are coded in terms of part of body, nature of injury, description of injury and cause of injury. All of these fields can provide insight into the details regarding how the nature of the work or the environment in which the work is performed may cause injuries and illnesses. This detail can point out areas of work that may be hazardous or may be associated with a disproportionate number of injuries, which can provide a focal point for efforts to control occupational injuries. Worker compensation data can also provide a valuable comparison of an employer to other similar employers, like those in similar industries. This comparison can provide a competitive advantage for that company relative to other companies performing similar work. Shift work can also be studied in compensable claims. A direct comparison of night- and dayshift injury rates and severities within a given company will indicate the influence of shiftwork schedules on employee health and the associated loss of work time from injuries.

Another strength of worker compensation data are that it can be linked to the adjudication process for the compensable claims to provide an indication of the potential for legal action for certain injuries, as well as the settlement rates for such litigated claims. A comparison of employers in a similar industry in terms of the percentage of claims litigated can provide an interesting insight into which injuries are contested often. One study suggested some evidence of an increased likelihood for a poor health outcome when a worker's compensation claim was litigated (Vaccaro *et al.* 1997).

4. LIMITATIONS AND IMPLICATIONS OF THE ANALYSIS OF COMPENSABLE CLAIMS

A shortcoming of the information available regarding compensable claim data is that some claims lack some necessary information to make the comparisons suggested above. The number of compensable injuries needs to be associated with an employment base to have a reasonable ratio of compensable injuries for that workforce. A total number of employees for that company is not collected on claim forms and must be attained elsewhere to compare rates of compensable injuries across employers. A field that omitted on some compensable claim forms is the field of job title. This omission weakens the ability to identify hazardous occupations and link exposures to hazardous substances or working conditions directly to specific occupations. Further, an indication of how often the individual performs that task is also rarely included in the claim. This weakens the potential to infer the worker knowledge or expertise in the job and the familiarity of the employee with the risks associated with that job. A weakness of the system of sending in compensable claims is that there is no presumption of safety knowledge for the individual filing the claim, which can result in a loss of information relevant to the claim that may be important in determining the causal nature of the injury. Similarly, accidents often result from a complex series of events that cannot be adequately described with a single classification system (Sanders and McCormick 1993). As with any reporting system, there is the potential for a bias in the reporting of injuries, and some research has indicated that accidents may be underreported by as much as 15-20% (Beaumont 1980). A serious limitation to the analysis of compensable claims is that a compensable claim carries with it a minimum number of days of lost work time necessary for the claim to be filed. Thus, there are a lot of injuries and accidents that do not appear in the data as they fail to rise to that level of lost work time. This results in a bias of compensable claim data in the direction of more serious injuries and only represents a portion of the occupational injuries and illnesses experienced at work.

5. CONCLUSIONS

Worker's compensation data provides many opportunities to perform analysis that results in occupational injury control. The data can identify hazardous conditions and exposures and the associated health consequences. Combining the data with specific company safety measures can evaluate the effectiveness of interventions like machine guarding. Comparison of compensation data between employers in a similar industry can identify the competitive advantage of a safety and health program. Analysis

of worker compensation data are more powerful when combined with other sources of information to provide an accurate context of all of the factors related and a work-related injury or illness.

Collaborative Learning Environment in Higher Education: Implementing Job and Organizational Learning Theories in Academia

K. Sanders and C. Carlson-Dakes
University of Wisconsin-Madison, Madison, WI 53706, USA

1. INTRODUCTION

As Human Factors Engineers specializing in Sociotechnical Systems, we have found it intriguing and greatly rewarding to apply our understandings of job and organizational design to the world around us: higher education. Specifically, we have spent the last five years working to help faculties redesign their jobs, beginning with teaching, so that they find the experience more rewarding, satisfying, stimulating, and less isolated. We have done this by designing faculty development programs that are completely voluntary, intense, and centered on collaboration, helping faculty learn how to collaborate effectively in order to change the institutional policies and procedures so that they and their students learn and grow.

To those around us, specifically those from educational theory and/or faculty development backgrounds, we have been surprisingly successful. Our program grew from an Industrial Engineering dissertation (Sanders 1993) to a college-wide pilot program, then to a three-year, federally funded campus research program, and most recently to be integrated into the institution as a center, "Creating a Collaborative Academic Environment," which is now part of the Provost's Office at UW-Madison.

It was clear from the start of the dissertation study in 1993 that many people doubted that faculties from a large, decentralized research institution would volunteer to spend 1.5 hours each week learning about learning in small groups of diverse colleagues. We were told that faculties would not be interested in teaching or collaboration, and certainly would not have time to devote to professional development in teaching. In fact, we were told that unless we did paid them, there would be no hope of participation.

We are glad to report that those concerns did not turn out to be our reality. We have found that it is possible to translate the classic theories from Herzberg, House and Kahn, Lawler, and Trist into a meaningful and motivating learning experience for faculties. In fact, our particular interpretations share much in common with research findings from adult education. The effects of CCLE have been shown to be lasting in over 135 faculties, and the resultant changes in their attitudes and behaviors have resulted in changes in organizational policy and procedure at the department, college, and divisional levels. Additionally, with our integration into the central administration, we now have an opportunity to bring together groups that previously have not communicated or collaborated. We feel that we are at the very beginning of wider scale organizational change, all resulting from a small, grassroots program designed from classic literature in the meaningfulness of work and the reduction of stress.

In this article, we offer to you the principles on which we base our work. We have used these principles to design our original faculty development program for learning and teaching, Creating a Collaborative Learning Environment (CCLE), as well as the foundation for our newer projects, the Peer Review of Teaching Project, the Teaching/Learning Colloquium Series, and our parts of collaborative projects in the NSF Foundation Coalition and the Leadership Institute. Our future projects will include sister programs for faculty development in research and service, the design of which will also be grounded in these few principles. The specific program structure and effects of CCLE are reported elsewhere (Sanders *et al.* 1993), and will not be included here.

2. KEY PRINCIPLES

2.1. Program Structure: Collaboration, Connectedness, Diversity, Safety, Responsiveness

Our faculty development approach centers on our core beliefs about how learning happens, and the atmosphere necessary for personal and professional growth. Essentially, we create structures where people can work together in a safe, respectful manner, so that they all feel their contributions are not only heard, but valued and an integral part of the group's progress.

2.1.1. Collaboration

We view learning as a complex, social process of making meaning. As we know from classic job enrichment literature, learning which is meaningful to an individual, can be motivational. That is, people will want to apply their new understandings to their work environment if they view their new learning as relevant, and have the social support and resources to experiment. Given our assumptions about the social nature of learning, collaborative learning is a logical choice. Additionally, collaboration skills are required for organizational movement on a larger scale. We suggest that program structures and activities be designed to teach collaboration explicitly, in addition to any specific program content.

2.1.2. Connectedness

We also consider learning to be an ongoing process of making connections and interpreting relationships between previous experiences and new information and experiences. This is key in designing faculty development experiences, because many workshops and short-term interactions do not take into account that continuity and time engaged in meaning-making are key to deep learning. We ask that participants continue to engage in deep discussions every week over the course of eight months. This intense approach works because we all know that people are more likely to remember what they have experienced, lived, or discussed at length. When you seek deep change, in our opinion, you must create a learning experience that creates strong connections between individual learners and their peers, their teachers, and the content matter. We create a community of learners by structuring the program so that all participants recognize that a group of colleagues knows them, their concerns, and their contributions.

Diversity is also a central focus in terms of team construction. We place people in deep conversation with colleagues they might never meet in another setting. We have found that the groups with the most diversity (for example, a team might consist of faculties from African Languages and Literature, Genetics, Mechanical Engineering, Physiology, Children's Literature, Rural Sociology, Human Ecology).

2.1.3. Safety

In addition to enhanced creativity, the diverse teams also help to ensure that people are not placed in groups with colleagues they might know from other settings. For example, we do not recommend placing people from the same department in the same team because they carry with them certain expectations of each other and personal histories, perhaps not positive, that inhibit fresh insights and inquiries. In order to be safe and respectful, groups must be formed in such a way that individuals do not feel as if they can predict the perspectives and positions of others. Instead, we wish people to feel that they are exploring new territories, new ideas and vantage points, that they would not be able to create as individuals, through the social construction of knowledge.

We structure working groups by scheduling weekly meetings around participants' availability, so that in as much as possible, the programs accommodate their schedules. Faculties meet each week for 1.5 hours over an entire academic year, in small groups of seven to eight with a program facilitator. It is important this facilitator is not a colleague, but instead someone with no vested outcome in the conclusions reached by the group.

2.1.4. Responsiveness

Formative program assessment must be built into the program structure from the very beginning. That means that there must be a way for the developers to gather and assess information about what the teams are learning, and what actions they are taking with that new knowledge. In CCLE we interview faculty participants at the end of each semester of participation to hear what they have learned, and how the program is or is not meeting their needs. The interviews are then transcribed and reviewed for patterns across groups and over time with individuals. We are an action research program, however, even when we run purely applied programs we always have the groups discuss their progress with each other in structured discussions, and we ask them to write down as individuals, what they are learning, what is working well for them, and what is not working so well. We actively solicit their input to help us redesign and refine the program structure and activities as needed.

2.2. Program Activities: Challenge, Complexity, Creativity, Interpretation, Reflection

The exact program activities necessary for any particular professional development program are highly dependent on the topic area under exploration. However, we do have a number of underlying principles that we consistently use when designing new programs, which are also interwoven with our assumptions about the nature of learning described in the previous section.

2.2.1. Challenge

Challenge people to reconsider their underlying, unconscious beliefs about their work and their colleagues. We find that many

people assume that they are alone, isolated in their desires and concerns. They assume no one understands, that they are the only people who feel something is missing in their work, that things are the way they are because someone put thought into creating them that way. Bringing people together and structuring conversations in a safe and nurturing environment brings to light the fact that indeed, we are in this together, no one of us is alone. The current system is just that — the current system. We do not have to continue in the same pattern. To do this, we have participants explicitly reconsider their core ideas and assumptions about what they are trying to accomplish as individuals and as members of the university, at work and in their lives as a whole. We ask them to read literature that is likely to be outside their areas of expertise, not for the purpose of believing everything, but instead for the purpose of awakening to new possibilities, new disciplines, new avenues of thought that might take them to different destinations. We consciously attempt to avoid feeding the idea that there is 'one answer' somewhere in the world, and that they need only find that answer. Instead, we challenge them to create their own answers, their own questions, their own action plans. Our role is to stimulate their questioning, open doors of opportunity for exploration, and to provide social support and feedback for their journeys.

2.2.2. Complexity

Do not simplify what is not simple. We believe that one of the reasons we have been successful in engaging faculty at a pre-imminent research university in extended discussions about learning and teaching is because we do not reduce the complexity of the topic or the system it exists in. That is, we hold the complexity central by drawing it into the activities explicitly. We have faculty describe and map out how institutional policies and procedures affect the outcomes they are interested in — in this case, student learning. They make connections between the tenure system, grading, mass education, and teaching approaches. If we were to simplify this into the "ten priorities for institutional change" we will have defeated our purpose, which is to have these people harness their creativity, skills, and motivation to change their own institution. Additionally, we feel safe in the knowledge that there is no one solution, or question, or direction. There are many possibilities, and we offer a forum for them to discuss the complexity, instead of denying it.

2.2.3. Creativity

Foster creativity by using diversity of worldviews and perspectives in an inclusive way. Use multiple types of activities in addition to reading and discussion, such as drawing, role playing, concept diagramming, game playing, reflective writing, reaction papers, journal writing, in order to keep people actively engaged in seeing the content from new perspectives. Have participants read outside their disciplines or fields, and ensure they listen to and understand the multiple perspectives that others in their diverse groups create. Create activities where the group must create a way to represent multiple views of the same system, and in this way, every diverse view holds value in that it must become part of the whole. Additionally, in order to become part of the group's project, each idea must be understood by the others in the group, or else it could not be represented effectively.

2.2.4. Interpretation

Hold central the act of interpretation and making meaning. It is important for people to realize that the truths they hold on to so tightly have been constructed over years, and often are no longer valid or useful. We make certain that participants understand *we* are not the experts in higher education reform; instead, *they* are the experts. They are the people who will make changes in themselves, their departments, their colleges, and the university. We exist to help them discover options and interpret their possibilities. We do not hold out the "answer" or the "best way." Those are contextual truths at best.

2.2.5. Require reflection

A gift that can be given to faculty or any other employee who feels overwhelmed, rushed, and pressured is a place to go each week where they can think, breathe, and reflect. Just as students do not automatically see the value in reflecting on their learning, so too you might find faculty surprised when you ask them to write out and present what they have learned. Moreover, the very act of writing or speaking what they have learned, and what they plan to do with that new understanding, will help them make new connections. We find this part of learning — reflecting on the issues, how we came to be here, and the possibilities for movement — can make all the difference. It gives space for creativity and insight to bloom.

3. WHAT TO AVOID

It is typical for program developers to be tempted or pressured to do the following:

> grow too rapidly
> preach "the answer"
> pay participants
> problem-solve for the administration

Resist!

3.1. Growing Too Rapidly

When a program becomes successful, word spreads to faculty and administrators (or management). It becomes tempting to "offer" it to more and more people, with the potential for destroying the very characteristics that create success. With collaborative programs centered on work in small groups, an explosion of participants can mean one of two things, neither of which will be advantageous. First, it may mean that the number of small groups grows to a scale where staffing cannot accommodate them. That is, you may find that from six groups of seven to eight people, you now have twelve groups. That will mean that the formative program assessment must change, the number of trained facilitators must increase, and the facilitators will have more difficulty in communicating and organizing themselves. Program coherence will be lost or challenged.

A second possibility is that the structure of the program changes to accommodate larger groups. This is also dangerous in that the nature of the experience in a group of seven or eight is quite different than in a group of twelve. The facilitator will not know all the individuals to the same depth; neither will they know each other. There will be difficulty in having all participate during the same time period, and it will be easier for participants to feel that it is all right if they skip meetings because the group is not depending on them (i.e. there will be enough other people

there, and so it will not matter too much to miss a meeting). We caution that before a program expands, the developers feel secure that they understand what it is about the experience that makes it rewarding for participants. These aspects must be preserved at all costs, even if that means remaining relatively small.

3.2. Preaching 'the Answer'

In programs where it is hoped that people will take what they learn and apply it to situations which are complex and unique, it is vitally important to refrain from reducing complex issues into simple models. People are naturally attracted to things that look simple — like the ten best ways to teach, or the seven sure-fire tips to success. However, everyone is smart enough to look at those lists and critique why they will not or cannot work. We suggest that you should not make the list, but instead create activities where people make and critique their own lists — continually. Our goal is to have people understand what they are intending to achieve, options for exploration, ways to find out if they have been successful, and colleagues to help them plan the next iteration. In this way, we feel individuals and organizations learn and grow. No one can do the learning and experimenting for another.

3.3. Paying Participants

We have been lucky in many ways in that we never had the resources or the belief system that would set up monetary compensation for participation in CCLE or any of our programs. Because we work from job enrichment theories, we believe that the nature of the experience is its own reward. People take what they have learned and use it in their everyday work lives, in teaching, research, and in administration. It changes the way they look at themselves, their roles, their colleagues and their students. This opening up, these new possibilities, would be affected if people were paid for their time with us. We feel that different people might volunteer, and that they would view these discussions as something outside their real job — something extra, added on, not part of. Instead, we desire to infuse a new experience into the "regular" work week. We see ourselves not as offering more work to be done, but as an option to consider for personal and professional growth.

3.4. Problem Solving for the Administration

Finally, it is also common for the administration to see a successful faculty development program as an opportunity to impart their own wisdom to faculty, or to serve out an agenda of problems to be solved. We see that this would be a logical connection for any administrator, and have been very fortunate that pressures applied in this area were momentary and rather light. When a program becomes driven by the administration, it cannot but help buy into the current power structure, the current system of work. If this happens, it not only becomes disingenuous to ask people to creatively re-imagine their work, down to their most basic assumptions, but it probably also becomes near impossible. The more the program becomes bogged down in specific issues to 'solve' beyond those which emerge naturally from the participants, the more it becomes ineffectual. This danger also connects to the issue of safety mentioned early on. If people do not feel safe, respected, and valued, if they know that the agenda is being set from a position of power elsewhere in the organization, they are unlikely to trust, to open up, and to learn.

4. CONCLUSION

In summary, we have found creative implementation of classic job design, organizational learning, and occupational stress literature immensely valuable in helping employees redesign their own work, as well as the policies and procedures at a large state research university. Our implementation of the theoretical frameworks shows that people do respond to meaningful learning and social support in a very positive way. They change their teaching, their research, their attitudes, and their very outlooks. They tell us they are more stimulated and engaged by their work, and are striving in directions they may have never considered previously. The basis in Sociotechnical Systems Engineering has marked overlap with research in adult education, and we feel that large-scale innovation in the cultures and organizational structure of higher education is increasingly likely as practitioners from diverse fields come together to help faculty redesign higher education.

Communication Processes in Small Groups

B. S. Caldwell

Department of Industrial Engineering, University of Wisconsin-Madison, Madison, WI 53706 USA

1. INTRODUCTION

Group performance represents a significant and distinct element of human activity and forms of work processes. Small groups are often created, or evolve, to coordinate, communicate, and coincide information, task allocations, and strategic alignment to complete assignments that are too complex, difficult, or physically distributed for one person to perform effectively alone.

Human-system interfaces for group communication and task performance have a critical role in the design of technologies to support effective and coordinated distributed complex systems. These technology interfaces must facilitate styles of information flow at distinct levels of aggregation, and domains of human activity, which are not required for individual interface designs. For an individual human—machine interface, the coordination of separate tasks and communication between display, actuation, and other feedback systems occurs within the human controller. As task functions are dispersed between group members, technology interfaces must be developed to replace information flow channels which occur in the human nervous, endocrine, or vestibular system. Therefore, an adequate discussion of technology support for group performance must begin with a recognition of the range of group tasks and styles of performance.

2. DOMAINS AND STYLES OF GROUP PERFORMANCE

McGrath (1984) has developed a taxonomy of group tasks that distinguishes conceptual (or cognitive) tasks from behavioral (or conative) tasks, and cooperative from conflict-oriented tasks. Using these distinctions, plus the differences between planning and execution, McGrath created a circumplex of eight distinct types of tasks:

- Planning: creating plans for action
- Creativity: generating ideas for later use
- Intellective: solving problems with an identifiable correct answer
- Decision-making: solving problems where there is no objectively correct answer
- Cognitive conflict: resolving conflicts of viewpoint or perspective
- Mixed-motive: resolving conflicts of interest, relative value, or intention
- Contests: competitive performances against one or more other groups
- Performances: executing specific tasks towards identifiable goals

Group performance and task type distinctions are also described by Sundstrom and colleagues (Sundstrom, DeMeuse, and Futrell 1990), who emphasize demands of coordination based on shared expertise, and task role differentiation or integration between group members. Of course, timescales differ greatly between purely psychomotor synchronization required for coordinated physical performance, and channels that permit the flow of strategic information and exchanges of opinion. Both task type and group composition therefore represent critical dimensions of group task performance that must be defined in order to provide appropriate technology facilitation for group interactions and appropriate information flow.

Timescales and group members' shared expertise or coordinated knowledge place significant constraints on the bandwidth of feasible information exchange in group performance. In addition, the degradation of coordination depends strongly on the demands for synchrony in the information flow, which in turn is based on expectations by group members of appropriate ranges of acceptable delay for the style of communication and type of task performance. The impact of delayed information flow differs on whether communications are based on a synchronous communications model (based on real-time feedback error correction) or an asynchronous model (based on sequential actions or "move and wait" strategies) (Caldwell 1997).

2.1. Dynamics of Group Networks and Information Flow

Shaw (1981) points out that, as the number of group members increases, the number of potential information flow patterns grows. The issue of the network flow patterns between group members is therefore an important structural concern in technology support for group task performance. (This multiplicity of communication possibilities is the primary justification for group dynamics researchers who insist on a minimal group size of three members. Since the number of possible flows varies as $N*(N-1)/2$, the dyadic case (N=2) provides no variation in possible information flow channels.) Coordination and synchronization is therefore limited to network architectures supported by either technology design or group interaction patterns.

Highly centralized networks, where a small fraction of group members must process the majority of messages in the group, have advantages in speed for simple information exchange situations. The multiple linkages of central members make it possible for information to flow quickly to all members of the group with a minimum of delays and distortions. However, the bandwidth capacity of the network as a whole is limited to the processing capability of the more central members. Overloads of information (either due to technology bandwidth constraints or human information processing limits) to a single central position in the group network can cause catastrophic and progressive deterioration of all communications which do not flow exclusively through peripheral network channels.

Decentralized networks are effective in overcoming degradation due to overload or incapacitation of a single group member, and are therefore desirable in many complex systems where multiple task performance options are required. Because there is no single point of coordination in a decentralized network, however, propagation of delayed, distorted, or misdirected information is more likely to cause disorganization or breakdowns

in group task coordination. Group coordination or network centralization must therefore be sensitive to the technology limitations of the human-system interfaces used to sustain task performance, as well as the social interaction limitations of group members' levels of individual expertise, shared experience, and ability to cope with changes in task characteristics or group performance resources relative to task demands.

3. TOOLS TO FACILITATE DOMAINS OF GROUP PERFORMANCE

3.1. Generation, Negotiation, and Choice Tasks

A full census of the population of group tasks which could be supported by information and communication technologies is neither feasible nor within the scope of this article. However, McGrath and Hollingshead (1994) note that the development and evaluation of technologies designed to support group performance does not adequately represent the distribution of task domains described in Section 2 above. They distinguish four types of group information and communication support tools:

- Group Internal Communication Support Systems (GCSS)
- Group Information Support Systems (GISS)
- Group External Communication Support Systems (GXSS)
- Group Performance Support Systems (GPSS)

It should be noted that "performance" in this sense is not equivalent to the "performance" task type of the McGrath (1984) task circumplex. GPSS systems, in McGrath and Hollingshead's description, also include decision support and other electronic tools for supporting meetings in organizations. (Relatively few organizational meeting tasks can be described as "performances" in the domain of sports or surgical team based execution tasks, but may be any of a variety of conflict, generation, or negotiation tasks.)

Both GCSS and GXSS tools are intended to enhance the information processing capability of group members for coordination, both internally and externally, and recognition of temporal factors on information flow. GISS tools are also commonly described as information repositories, databases, or intranets. These tools represent collections of information resources that can be accessed by group members to support shared knowledge and capture the additional experiences of group members as tasks are performed.

3.2. Execution Tasks

Relatively few tools have been developed to support distributed groups conducting coordinated psychomotor performances or execution tasks. Unlike the communication support tools described above, coordinated physical behaviors require information synchronization at the precision of the human nervous system (approximately 200–400 ms for feedback-based psychomotor or sensory tasks). This level of precision functionally restricts the capability of computer technologies to support group-level coordination and performance.

In fact, the trend towards increasing fidelity and display resolution of individual human–computer interfaces increases the difficulty of designing effective distributed synchronous interfaces. Two paths towards developing group-level interfaces have been followed. One path emphasizes "parallel" presentation of the same interface elements to all members of the group, with

simple separations of task allocations according to a sectioning of the single task among group members. This approach corresponds to a more undifferentiated or non-expert model of team performance (Sundstrom *et al.* 1990). Distinct, but coordinated, interface displays pay a much greater performance penalty for increasing interface resolution with limited bandwidth channels. Frequently used methods for increasing interface validity in individual supervisory control or navigation tasks (such as shape rendering, interactive hints, or other computationally intensive display algorithms) can degrade, rather than enhance, performance in distributed group execution tasks requiring psychomotor and sensory performance coordination (Caldwell and Everhart 1998).

4. IMPACT OF NON–TECHNOLOGY FACTORS ON COMMUNICATION PROCESSES

The technological capabilities of group communications systems place distinct bounds on what information flow is possible between group members. It is, however, critical to recognize that non-technology factors, particularly situation constraints and group behavior norms, can more significantly determine the overall effectiveness of a particular communication system implementation. Time available as a task resource or constraint is clearly one element affecting communication processes in groups. Even for cognitive and strategic tasks, communications effectiveness is severely limited if the time required for information flow between group members is long compared to the time available for task performance. (This issue is most clear in feedback-controlled physical execution tasks, where the time available for coordinated display and control information flow is frequently under one second in order to maintain task performance standards.)

Task urgency or the time progression of the group task situation is a factor that may make the same communication technology effective in one task setting and useless in another. Both the lags (elapsed time between initiation of information flow and the start of its receipt) and flow restrictions (the amount of information which can be received and processed through available channels in a unit time) of information exchange between group members can significantly affect task coordination depending on the momentary changes in task demands. Therefore, communication process adequacy must be examined as a dynamic variable in group communication, and not simply on average or aggregate.

Technology appropriateness to support effective group coordination may also be a function of the alternatives available to group members. Several theories have been put forth describing the characteristics which most influence communication media use. No one theory has managed to fully explain differences in medium usage, suggesting that choices are made for a variety of convenience, consistency, or other non-technology factors. When a specific communications channel does not possess sufficient capability to support certain types of information flow, and adequate alternatives are not available, group members will adapt communications patterns to enable coordination and task performance within the constraints of the technology. (The use of ASCII characters as "emoticons" in electronic mail, and the adoption of specialized vocabularies to minimize communication degradation in radio exchanges, are examples of these processes.)

However, group communication is not arbitrarily flexible or elastic to adapt to a technology which is fundamentally incapable of exchanging task critical information in the time and task constraints that define minimal standards for acceptable group communication and task coordination.

5. TOWARDS QUANTITATIVE MEASURES OF GROUP COMMUNICATION VARIABLES

Small group communication and task performance shares many characteristics with other complex engineering systems. Mathematical tools developed to advance the description, design, and prediction of engineering systems have been shown to be effective across a range of physical representations, from fluid and mechanical energy flows through thermodynamic heat transfers and electromagnetic component systems. Although most researchers of group communication and performance would hesitate to suggest that social and organizational processes can be described at the same level of mathematical rigor as engineering technology systems, some progress has been made to describe *patterns* of communication processes in group activity.

Social network analysis techniques have begun to focus on the influence of the organization of links between group members on the response of the group to task demands and communications breakdowns. One measure of link organization is *warp*, which refers to the degree to which communications links are centralized to flow through a small number of critical nodes. The higher the warp measure, the more centralized is the network. As described above, such networks can provide greater efficiency and minimize delays or degradation due to multiple link paths. On the other hand, high warp networks are susceptible to massive breakdown if one of the most central nodes is unable to support the information traffic through it (either due to situational demands or technology or other breakdowns).

Information theory and entropy measures have long been applied to the study of information flow and communication. The original conceptualization of information bits and sender–receiver channels is limited, however, to the flow of data, not the social and experiential human factors which allow a group member to translate data into information. Thus, bits are not the appropriate level of analysis to continue the development of quantitative analyses of information flow and group communication in complex task environments. A more general tool for analyzing the quality and effectiveness of information sharing is *coupling*, which is used in distributed engineering systems analysis to examine the capability of transferring energy from one component of the system to another. As coupling increases, components begin to interact with less loss of energy and less uncertainty of the effect of one component on the other. (Zero coupling indicates that components are functionally independent, and have no direct influence on each other.) Coupling is affected by both the *inertia*, or resistance to change, of the affected components, and the *damping*, or opposition to energy flow, of the medium in which the components operate.

In electromagnetic or fluid flow environments, coupling, inertia, and damping are well-defined and consistently quantified measured variables. As of this writing, strong mathematical analogues to these variables have not been developed or agreed upon in the research literature. Some previous allusions to these types of variables have been made in the psychological literature, including the theories of Lewin (1938) and Gibson (1979). Prescriptive definitions of "the right communication network" are no more likely than accurate and general pronouncements of "the perfect electronic component" or "the universally applicable flow description". In the latter cases, the questions of critical design parameters or optimization criteria are acknowledged as an important element of the engineering design process. Nonetheless, the same mathematical tools are known to apply effectively to those, and other, systems engineering projects. The next major advance in group communication and performance technology design rests in the identification of quantitative measures which can apply effectively to the structure, function, and effectiveness of information sharing and coordinated task performance.

Community Ergonomics Theory: Applications to International Corporations

A. D. Bayeh† and M. J. Smith‡

†Purdue University, Department of Industrial Engineering

‡University of Wisconsin, Department of Industrial Engineering

1. INTRODUCTION

Community ergonomics (CE) was developed from two parallel directions. One came from existing theories and principles in human factors/ergonomics and behavioral cybernetics, which have been applied to assess situations and find solutions at a macro-ergonomic (Hendrick 1986) level. The second direction emerged from the careful and thorough documentation of specific case studies of communities, which in turn led to additional principles and theories with more contextual relevance.

Thus far, CE has been applied at the community level, some of these applications have been documented within the last few years (Cohen and Smith 1994, Smith and Smith 1994, Smith *et al.* 1999). This chapter will examine the applicability of CE at the international level, specifically for corporations engaged in international development and trade. This will be done in two steps. First, the transferability and applicability of CE theories, principles and tools from the local community level to the more global international level of analysis will be examined. Then, CE principles (Smith *et al.* 1999) will be restated so that they can be applied to the international level of analysis.

2. BACKGROUND

Organizations are complex systems which have been defined in terms of their characteristics such as structure (formal and informal), culture, purpose, products and services, climate, workforce composition, leadership, management style, processes, tasks, technology, tools, image, reputation, information flow networks and mechanisms, labor-management relations, geographical context or scope (global, national, regional, local), societal context, and size. Organizations have technical and personnel subsystems that interact to produce outputs. The coordination, integration and combination of these aspects of organizations need to be properly managed to provide effective and efficient operations. This is particularly true for international corporations.

The world has become increasingly more open, taking organizational design principles and management practices to a new level of acceptance and application in the last half of the twentieth century. Simultaneously, this time period has seen struggles for fairness, equality, freedom, and justice for all peoples of every nation. In addition, a more complex global economy has emerged throughout the world. Accordingly, organizations have had to operate within a complex world economy characterized by the following issues, among others: continuous change, a heterogeneous (often international) workforce at all job levels, increased spatial dispersion of physical and human assets, decreased standardization, increased diversification of products and markets, decreased centralized control of resources

and information, uneven distribution of resources, variable performance within and between locales, increased operational and safety standards, and increased susceptibility to global changes in the economic, social, political, and legal conditions. Many organizations have responded to the opportunity presented by the unique openness of the world economy by expanding production and trade worldwide.

In this climate of increased international trade, important issues of social and cultural values need to be carefully examined. Culture, in and of itself, is hard to define in a way in which all its facets and dimensions are appropriately addressed. However, there exists a common understanding and acceptance of what specific culture and cultural values mean. In terms of a global value, there seems to be a universal agreement on the fact that mutual respect and fairness are at the heart of healthy multicultural dynamics. The right to be respected requires showing respect for others and not violating this universal right. The same can be said for fairness, and other considerations such as commitment and responsibility. There is a requirement to be mutually tied so that the welfare of one party is important to other parties' interests.

There is little agreement about what makes effective multicultural organizations. This has led to the emergence of more refined international management practices in response to numerous obstacles encountered when organizations expand abroad or when they transfer processes abroad. Difficulties encountered in growth, expansion, internationalization and globalization are mainly due to the following factors:

- The lack of a process for effective transnational transfers.
- The lack of knowledge of operational requirements and specifications in newly entered markets.
- Ignorance of cultural norms and values in different countries.
- The lack of adaptability mechanisms.
- Low tolerance to uncertainty, ambiguity, change and diversity, etc.

Even though much progress has been made to address some of these issues, there are critical problems that still remain at the organizational level. One of the most important problems in this regard is the lack of a "genuine" corporate commitment to social responsibility with the same intensity as striving for profits. In fact, some managers may believe that social responsibility may conflict with corporate financial goals and tactics. We believe that long-term corporate stability and success (profits) follows from community support for the enterprise and its products. Social responsibility nurtures the mutual benefits for the enterprise and for the community that leads to stability.

We propose that multinational corporations must accept a corporate social responsibility that recognizes the universal rights of respect and fairness for all employees, neighbors, purchasers and communities. Whether these rights are profitable in the short-term, or difficult to attain, such corporate social responsibility is a requirement if global ventures are going to be successful in the long-term. The survivability, acceptability and long-term success of the corporation will depend not only on profits, but also on social responsibility. For this will lead to greater accessibility to worldwide markets. Organizational structure must go beyond the micro-ergonomic and macro-ergonomic levels (Hendrick 1986) to also include the societal (or cultural) level. This will enhance the "fit" between the organization and the economic

markets within which it operates. They must address multicultural design, a comfortable corporate culture, and principles of respect and fairness for employees, customers, and neighbors. This will improve the "fit" with the international "cultures" in which the corporation operates.

3. TRANSFERABILITY CRITERIA

The transferability and applicability of theories and principles are often not universal. This is especially so when an *ergonomic* concept of improving the "fit" is applied, since ergonomic approaches focus on the "unique" characteristics of the environment (culture) and of the person (or the organization) to get the best match. There are key factors that may be considered transferability criteria that determine whether a set of situations is comparable. These comparability criteria are given below.

3.1. Content

This defines what the internal situation is. For instance community characteristics such as learned helplessness, dependency, cumulative "social" trauma (CST), poverty, deficiency in access to and appropriate use of resources affect the potential fit. Often, fundamental improvements must be made in combination before fit can be addressed. \h Table 1 points out some symptom characteristic of settings where CE has been shown to be useful at the community level, and we have expanded this to show how these same symptoms are present at the international level.

3.2. Context

These are conditions external to the situation itself, which are affecting or being affected by the situation. The context captures the environmental, political, social, and economic climate. The context is sometimes highly influenced by religion, social class, political, ethnic, age and gender issues which may dominate the particular place where the situation takes place.

3.3. Process

These are mechanisms describing how the personal, corporate or community situation operates. The process is defined by the mechanisms linking people or corporations to their particular environment, leading to predictable outcomes. Understanding the process is essential in pinpointing crucial points of intervention to eliminate societal hazards or to minimize the negative impact of such hazards.

These transferability criteria may be used to expand CE from the local or community level to the global or international level of analysis and application as shown in Table 1.

4. COMMUNITY ERGONOMICS PRINCIPLES IN AN INTERNATIONAL AND MULTICULTURAL CONTEXT

The principles focus on a goal of social responsibility, fairness and social justice, and do not threaten the prosperity of a company or organization. They are built on the premise that the society and communities in which a corporation operates and from which the corporation generates profits should benefit from the presence of the company. Thus, the corporation should contribute to the development, growth and progress of the local communities. These principles propose a symbiotic relationship between the hosting community or society and the "guest" corporation.

4.1. The FIT Principle

Owing to the diversity of the workforce in multinational ventures

Table 1. Hazards at the community and international levels of Community Ergonomics

Societal Symptom	Definition	Local or Community Level of Analysis	International Level of Analysis
CST - Cumulative Social Trauma	This is the outcome of long term exposure to detrimental societal conditions leading to a cycle of dependency and ineffective coping.	Inner cities with low quality of life, high unemployment rates, low quality of educational, health, security, and social services.	Developing countries with low quality of life, high unemployment rates, low quality of educational, health, security, and social services.
Adverse Societal Conditions	These are the specific detrimental societal conditions in the environment within which people have to function. The severity of the adverse condition determines the likelihood of survival or social proper development.	Communities with high unemployment rates, high crime records, high drug trafficking occurrence, high teenage pregnancies, low education level, low security, health care low income, low skill level, high corruption.	Countries with high unemployment rates, high crime records, high drug trafficking occurrence, high teenage pregnancies, low education level, low security, health care, low income, low skill level, high corruption, political and economic instability.
Societal Isolation	This is the phenomenon that results from segregating, outcasting and alienating groups of people, and treating them with inequity and unfairness.	Inner cities, ghettos, barrios.	Developing countries with little economic power and weak political leadership.
Economic Dependency	Requiring assistance from others. This is the result of needing to survive and seeking help, with no skills or mechanisms to ensure long-term improvement and growth.	Welfare systems, federal funding, unemployment programs, etc. which provide immediate assistance but no survival skills. Once down it;s hard to get up.	International Monetary Fund, World Bank international institutions lending money with high interests and restricted stipulations but no financial management or administrative leadership or knowledge
Learned Helplessness	This is a long-term self-perception of recurrent social isolation and economic dependency that disables people from improving their lives.	Multiple generations of welfare recipients, conformity with the surrounding and observed standard of living as one's highest potential goal.	Countries that are constant recipients of loans and support leading to a perception of disability and helplessness.

and the ongoing trends of today's world economy, accommodations need to be made by companies for a diverse workforce. That is, companies need to design for cultural diversity. Corporations must understand and incorporate the norms, customs, beliefs, traditions and modes of behavior of the local community into their everyday operations. In some communities there will be multiple cultures that need to be included in this process. Often there is a need to strike a balance among the various cultures as they are not always compatible. The corporation's organizational structure and operational style need to be flexible to bridge the gap between the corporate and local cultures. This cultural accommodation will produce commitment to the corporation from employees, customers and neighbors.

4.2. The BALANCE Principle

This is taken from a concept proposed by Smith and Sainfort (1989) which defines the need to find the proper relationship among components of a larger system. Based on this concept we believe that there is a need for balancing corporate financial goals and objectives with societal rights and corporate social responsibility. Companies are a part of a larger community and through their employment, purchasing, civic and charity activities they can influence community development and prosperity. As an integral part of this larger system companies have a responsibility to promote positive balance for the benefit of the community and the corporation. Positive balance often cannot be achieved by optimizing any single or subset of components of an operation such as profits or market share. Rather, the best overall system outcome is achieved by trading short-term optimization for long-term stability by accommodation of all elements of the system including the community.

4.3. The SHARING Principle

Traditionally, a corporation's success has been measured in terms of its financial growth. There are many factors that may lead to this financial growth including the value of the company (stock price), market share, sales, profits and assets. However, there are other factors that are not usually taken into account but will become more critical as social awareness becomes more prominent. For instance, customer loyalty, community support and acceptability of products will be critically related to the corporation's long-term financial success.

For example, if a corporation chooses to invest some of its profits back into the community in ways that are significant to that community, then the corporation may be viewed not only as a business but also as a community partner. Such contributions may take the form of building schools, providing educational scholarships, providing technical training and skill development, giving assistance to small or family owned businesses, or developing community utilities. In giving something back to the community the corporation is developing loyalty to its products and protecting its long-term profitability.

4.4. The RECIPROCITY Principle

This deals with the mutual commitment, loyalty, respect and gain between producers and consumers. It results from the BALANCE and SHARING principles. A bond results from the corporation giving something back to the community, which builds loyalty from the consumers to the company, and eventually leads to a

genuine sense of loyalty from the organization back to the community. In this respect, what might have started as responsibility, will over time become mutual loyalty and commitment. Within the corporate organization, the same phenomenon takes place when the organization shows responsibility towards its employees (producers), who in turn become loyal and committed partners with the corporation.

4.5. The SELF-REGULATION Principle

Corporations should be viewed as catalysts of self-regulation and socio-economic development in host communities. Communities and countries in disadvantaged economic conditions (Table 1) typically show symptoms of learned helplessness, dependency, isolation and cumulative social trauma. Instead of perpetuating conditions that weaken people and institutions, an effort should be made to help people to self regulate, grow, flourish and become productive. In this effort, corporations are very important because they provide employment, training and professional development opportunities that give people the tools to help themselves. Corporations can also invest in the community infrastructure, such as schools, clinics and hospitals, which leads to stronger, healthier and more independent communities in the future.

Through community ergonomics, corporations can help disadvantaged people understand that they have the right to a better, healthier, more productive life. The self-regulation principle asserts that it is in the self-interest of those who have economic privileges and resources to share them with those who do not. For such sharing should produce prosperity and self-regulation, and less need for future sharing. It brings about stability.

4.6. The SOCIAL TRACKING Principle

Awareness of the environment, institutional processes, and social interaction is necessary for people and corporations to navigate through their daily lives, and for communities to fit in the broader world. Clear awareness helps to control the external world and leads to more robust, flexible, open system design. It is important for community members, employees and corporations to be aware of their surroundings to be able to predict potential outcomes of actions taken. Similarly, it is important for corporations to develop a certain level of awareness regarding the workforce, the community, and the social, economic and political environment within which they operate. This includes the cultural values of the people affected by the corporation's presence in a particular community. Considering that change is normal in the global economic arena, it is critical for effective decision making to track this change, and to understand the implications of diversity.

4.7. The HUMAN-RIGHTS Principle

This principle underscores the belief that every individual has the right to respect, a reasonable quality of life, fair treatment, a safe environment, cultural identity, respect and dignity. There is no reason for anyone not to be able to breathe fresh air, preserve their natural resources, achieve a comfortable standard of living, feel safe and dignified while working, and be productive. The term "human rights" implies that people are entitled to these considerations. Communities and corporations should be consciously fair and righteous in achieving their economic goals and objectives. People should not be assigned a difference in

worth based on class, gender, race, nationality, or age. The workplace is a good starting point to bring about fairness and justice in societies where these do not exist as a norm. It is left to the corporations' discretion to use their economic and political power to bring about social change where human rights are neglected.

4.8. The PARTNERSHIP Principle

This proposes a partnership among the key players in the system in order to achieve the best possible solution: corporation, community, government, employees and international links. By doing this, balance may be achieved between the interests of all parties involved, and everyone is treated fairly. In addition, partnership assures commitment to common objectives and goals.

5. CONCLUSION

Operating a business beyond traditional boundaries and entering other cultures and societies should be undertaken with a sensitivity for the needs of the new communities. The essence of internationalization, globalization and multiculturalism is in the culture and climate that the corporation develops to be sensitive to the community and the diversity of the workforce. Just having a diverse workforce in a corporation does not lead to equality or fairness, and it does not ensure that the workplace is receptive or appreciative of diversity or multiculturalism. This includes respect, partnership, reciprocity, and social corporate responsibility towards employees, community and society as a whole. It requires seeking a balance between the corporate culture and that of the community where the business operates and the cultures brought into the company by the employees. In the past corporations have entered new markets all over the world, profiting from cheap labor, and operating freely with little or no safety or environmental liability. However, the level of social awareness has increased all over the world, exposing sweat shops, inhumane work conditions, labor exploitation and environmental violations across the board. The focus as we enter the 21st century will be in doing business with a "social" conscience. By doing this, corporations will become welcome in any part of the world they wish to enter. This is how their products will be sought and accepted, and that is how consumers, employees, communities and societies will come to support businesses so they will remain successful into the future. The key to international business success is not only in just being financially shrewd, but also in balancing economics with social awareness and social corporate responsibility for the community's benefit.

1. INTRODUCTION

The socio-technical complexity of work organization in US society and the pace of technological change and global competition demand new patterns of political, social, economic, community, and industrial organization. While the US Government is faced with the responsibility of designing democratic foundations for economic and work opportunities, it is the human factors and ergonomics professions that must define, design and improve systems of work and social organizations. Failure to view work as the primary determinant of the human condition and as defining the adaptive status of individuals and groups to guide the overall structure of society, may be the fundamental basis of environmental disorder and chaos confronting the US City (Smith 1962). Community ergonomics as a scientific design practice is field-tested and grounded in practical research to redress matters of striking urban poverty. The problems of low self regulatory control, lack of community–environment fit, societal isolation and dependency on government social programs have created a segment of community members who are in extremely dire circumstances.

The USA, as a complex socio-technical society, has experienced a significant decline in the urban neighborhood environment. The decline is reflected in crime, unemployment, deterioration in schools, change in the family unit as an economic social structure, ethnic conflict and expanded demand for State and Federal resources for prisons, mental healthcare, housing and other forms of welfare to correct so called "human defects."

Pioneers in human factors and ergonomics envisioned a broad application of multidisciplinary sciences to benefit society (McCormick 1970). Today, ergonomists are re-evaluating the more recent conceptualizations of ergonomics as narrowly focused to office or industrial work settings (Nadler 1992, Sheridan 1991). The goal of CE is to improve the fit between people and society to achieve higher levels of self-regulatory control and individual effectiveness. A principle outcome is that institutions designed to help the poor are better able to achieve their intended purposes.

Community ergonomics is more than prescriptive; it is always based on the need to achieve implemented solutions through a purposeful problem solving methodology. The process is designed as a decision and action system, with the benefit that the steps necessary for success can be detailed, measured, and adjusted during the activities. The community ergonomist is a trained professional who can manage complex systems in highly turbulent environments. CE as an engineering practice has emerged to confront these new systems realities through the design and organization of work as a social and economic necessity and to improve the compatibility between people, technology, and environments within which people function.

2. THE NEED FOR COMMUNITY ERGONOMICS

The intended missions of institutions such as welfare are no longer justified (Cohen *et al.* 1994, Smith and Smith 1994). Socio-technical reliability is the probability that a given system will perform its intended function for a range of users. The delivery of services and products do not match the needs, desires, or capabilities of those they claim to serve. In effect, people cannot track the dynamics of the missions and objectives of these institutions, and neither can institutions understand the behavior of people effectively to reduce their concerns. The inability of people and societal components to track each other results in severely impacted systems performance and damage for both.

When community ergonomics is applied to the worst urban blight, the assumption is that socio-technical reliability is low and cannot provided for the needs, abilities, and limitations of residents. Defectively designed (ill-fitting) environments trigger behavior that appears contrary to effective and purposeful lifestyles in systems designed for people with stable jobs and safe residential arrangements.

The continued exposure to interactions of individuals with institutions exhibiting low socio-technical systems reliability over an extended period of time, and the resulting human behavior, lead to the development of a definable and observable symptomology. CST is a term to describe, "individuals, groups, or communities [who] have limited control over the environment, are forced into life habits, coerced into interactions in which they are not motivated, and custodial routines which limit self-regulation" (Smith *et al.* 1996). Smith and Smith (1994) describe CST as daily life routines that over gradual time, "produce wear and tear on motivation, skill, and emotional habits leading to emotional, behavioral, and psychosomatic disorders, trauma, and stresses."

An important aspect of the CST concept is that there is nothing inherent about the condition, thus dispelling the notion of poverty based on hereditary (or any other group characteristic). Long term exposure to extreme social hazards is disabling to the point that people loose skills, motivation or resources to self regulate their lives or functionally to thrive in society. These impairments become barriers that limit access to education, employment income, motivation and positive life-effecting choices. One of the major roadblocks impeding people from leading functional and fulfilling lives in isolated urban environments is the lack of access to resources available and services provided.

3. THE PROCESS OF COMMUNITY ERGONOMICS

Community ergonomics is concerned with the improvement of very poor central city environments neglected, but still firmly present in the consciousness of US politics. However, government efforts to improve very poor central city environments have never been well coordinated, systematic or durable.

The process is structured in stages to prevent participants for becoming overwhelmed during the process. Every meeting and activity has defined outcomes that are necessary to achieve

in order to move the process forward. Each stage is comprised of one or more activities, which are action based so that participants do not simply attend meetings passively. The input, output and transformations that are required at incremental stages successfully to implement solutions are specified by using concepts of social tracking and feedback control. Through this action, there is perturbation among the participants that allows for and promotes growth of social tracking relationships. The need to form bonds among the participants requires that members present their ideas as a function of the others in the group. In the end, it is expected that each member can sense their unique contribution to the effort reflected in the overall design of the interface.

The process results in a conceptual understanding of how to guide people in planning and design efforts and helps to explain human behavior in dynamic group situations. For the first time, behavioral cybernetic principles (Smith 1962) are applied in a complex societal setting coupled with an intensive stage dependent approach to problem solving to create a planning, design, and implementation process. Thus, certain transformations occur at certain stages of the planning process in the form of milestones achieved, social tracking bonds established and feedback perceived. Without this understanding and learning, success is limited at the implementation stage. Overall the CE approach is based on purpose satisfaction and the achievement of goals.

4. ACTIVITIES, PURPOSES AND EXPECTED OUTCOMES

The following sections introduce the seven activities constituting the CE process and are adapted from Nadler's Breakthrough Thinking™ (1994). The detailed CE process specifies the decision steps and criteria necessary to achieve the purposes for each activity (Cohen 1997). The process of stages and activities is shown in Figure 1.

4.1. Activity One

The first activity of the process identifies the people necessary to the effort in its current state and defines their roles and responsibilities in the solution finding structure. For the purpose of this activity, it is more important to identify people with skills needed to ensure the successful completion of the solution finding process than simply choosing names of people typically involved in community planning efforts. The expected outcome is to define specific roles and responsibilities of community members and participants. This, in turn, leads to the assignment of appointments to the planning and design team.

4.2. Activity Two

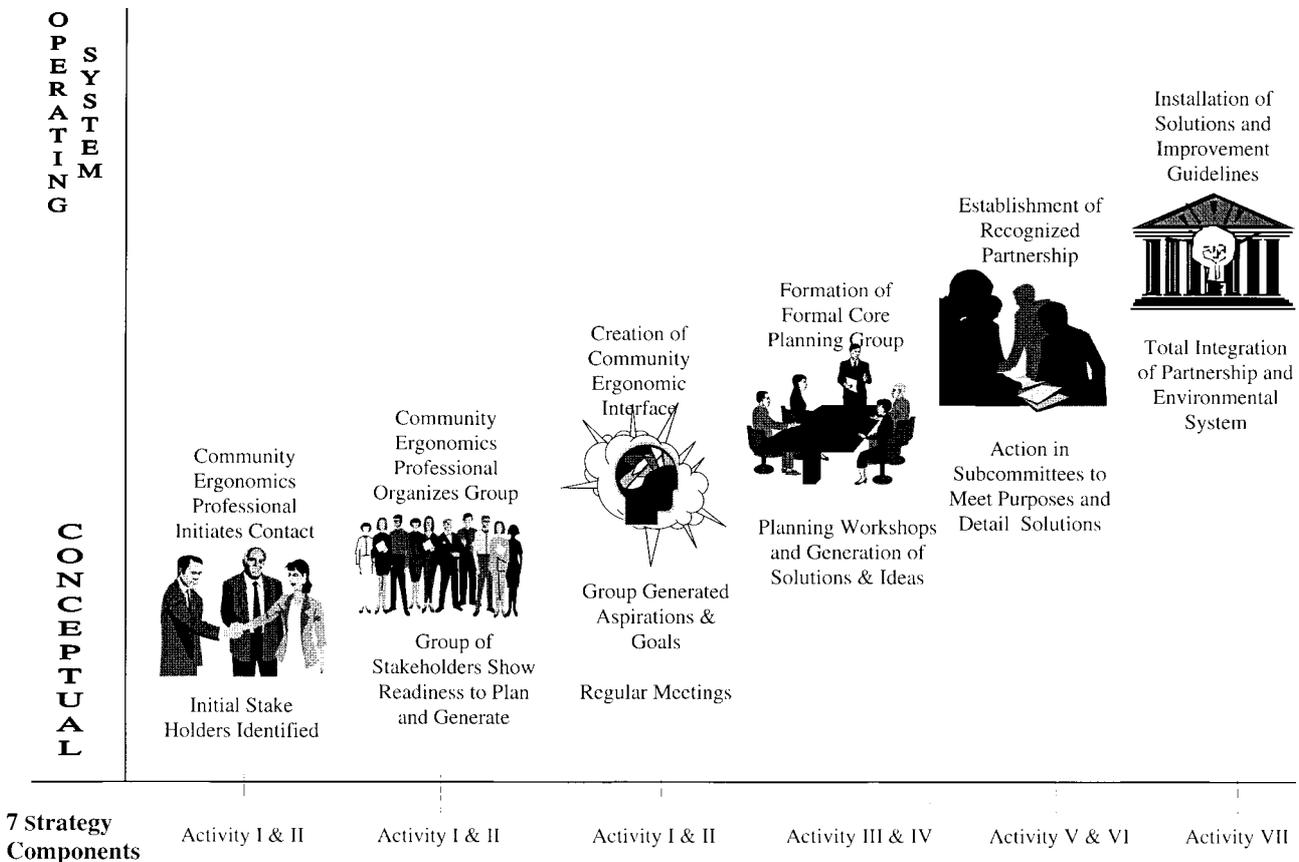
The second activity specifies the issues of concern, aspirations, needs, and goals of the initial planning team. The purpose of this stage is to define perspectives of each member regarding the sub-


Figure 1. Stages of group formation, control and solution accomplishment in the CE process.

stantive issues to be confronted as well as to identify the values and motivations that make these issues troubling to the participants. The expected outcome is to describe the issues, specific problems, and the values and measures associated with each problem. This first planning document functions as the initial guidelines and project history for prospective recruits. It outlines the entire strategy to be pursued, the types of skills and individuals needed, the issues of concern, and aspirations of the initial planning team. It does not specify solutions or detailed ideas. It is generally a conglomeration of concerns and value statements with the intention to coalesce a group of people into a recognized "effort."

4.3. Activity Three

The third activity establishes the purposes for the community activity by establishing the reason for the effort and the things to accomplish. This stage usually occurs some time after the first two stages are well developed and the planning team is firmly established. It is expected that the specifications of what is to be accomplished and the function of the changes sought are determined. However, the methods and solutions to achieve these purposes are not yet specified. The primary purpose of this stage is to determine the scope and level at which the effort will progress. Project participants decide how the project should progress based on the self-regulatory skills they acquire concerning their abilities and the motivations of others.

4.4. Activity Four

The fourth activity establishes the interface solutions and ideas for the selected purpose level. The goal is to organize ideas and suggestions that will eliminate the need to work on the selected purpose. In other words, ideas are sought which lessen the need to work on the purpose because the conditions that require the need are alleviated. The expected outcome is to target a particular solution or set of solutions for the community ergonomics project. The ideas are grouped into major alternatives with specific components that support the central purpose. The selected idea (major alternative) becomes the target interface for the remainder of the effort.

4.5. Activity Five

The fifth activity allows for the development of sufficient details to ensure the initial and continued feasibility of the selected and approved solutions. Using a systems design matrix from Nadler and Hibino (1994), the complex and varied components necessary for solution achievement are detailed. The expected outcome is to specify the solution in this format of elements, dimensions, properties, attributes, and their interrelations.

4.6. Activity Six

The sixth activity defines the implementation and installation strategy for the target system. The purpose is to identify individual and group attributes, change behavior, conditions of readiness and organization attitudes that influence the acceptance and success of the solution details. The expected outcome is the specification of modifications for change in the form of behavior and actions. This stage occurs in tandem with the sixth activity and also concerns the monitoring and adjustments that are inevitably needed with new systems.

4.7. Activity Seven

The seventh activity establishes a system for continuous review of the community ergonomics planning team effort. The purpose is to describe and specify how change and improvement to the community environment interface building will occur. The expected outcome is an interwoven set of future specifications that allow for improvements to the detailed system and a continued search for improvements to meet changing needs. This stage is most concerned with predicting future needs and aspirations.

5. CONCLUSIONS

The operational requirements of decision and action systems resulting from the CE process are specified, produced and measured during the planning and design activities. The community ergonomist, leading the process, is a trained interface professional, capable of engineering and managing complex systems of people, information, organizations and environmental dynamics required to establish social tracking bonds and feedback control within the planning group structure.

The approach provides new specifications of how to achieve solution implementation in extremely difficult and complex planning environments and how it can be measured, explained, taught, and replicated in future efforts. It is not enough to bring people to the same room to investigate problems. The research details how and why positive results can be expected and obtained; it also explains how to predict success or failure in community project situations.

If urban recovery is a real possibility then the first step for community leaders, residents, thinkers, and policy makers is to play a believing game. In order for positive change to occur, everyone involved has to believe that bringing about change is worth the extraordinary effort it requires. However, few effective design solutions exist for the numerous interface problems prevalent in these inner city communities.

The emphasis of CE is not on research, but on planning and design, structuring, creating, and arranging for new facilities to improve the compatibility between the inner city and the urban areas of concern. Within this context, the process is ergonomically managed by using knowledge about human abilities, human limitations and other human characteristics to design community systems, tasks, products, technology and environments.

The CE approach improves the understanding of effective design procedures for confronting the characteristics of systems, products, institutions and human interactions as interdependent phenomena that may contribute to cumulative social trauma and socio-technical reliability problems. The work will contribute significantly to the new realities of human factors and ergonomics by equipping the ergonomics profession to help with immense socio-technical problems emerging in US society and by developing a broad body of research and application.

Economic Models for Ergonomists

M. S. Oxenburgh and P. S. Marlow

77 Ryan Street, Lilyfield, NSW 2040, Australia

1. INTRODUCTION

Economic models can be used to illustrate the benefit of an ergonomics intervention or can be used to assist implementing ergonomics in a workplace.

To introduce better working conditions management will usually require a financial return. This is no different to the engineer wanting new equipment — he/she must show its return in monetary terms. The major difference between the engineer and ergonomist is that the economic models used by the engineer have been long accepted whereas the ergonomist is yet to reach that point. Here we will introduce the concept of economic models and show how they can assist in introducing methods for workplace improvement.

In all economic models certain assumptions are made. These assumptions are usually not susceptible to scientific analysis or proof but are based on experience, common sense and knowledge of what is acceptable to the particular enterprise. Economic assumptions must be clear from the start and the validity agreed to by those involved, at least for that particular workplace.

The differences in culture, organization, financial flow, technology level, capital and intellectual investment will dictate different assumptions between enterprises, even those in the same industrial field. Clearly wide differences in assumptions will exist between governments and private enterprise, between primary industry and manufacture and so on. No one set of assumptions will suit all enterprises.

2. CHOOSING A MODEL

There are several types of economic and accounting models that can be used to analyze the costs and benefits of introducing ergonomics. *Economic* cost–benefit modelling seeks to capture the total cost and benefit of the ergonomic intervention whereas *accounting* models have a more limited scope. For example, traditional accounting systems do not consider the skills of workers to be of monetary value to the company. Therefore spending money to train workers is seen as a cost that cannot be offset.

Accounting seeks to capture only those factors that are seen to directly influence the firm's profit and loss.

A typical accounting model is termed "Return on Investment" (ROI) and is calculated in monetary terms over a defined period:

ROI = income stream produced by investment/cost of
　　　 investment.

The more complex economic cost–benefit models place a dollar value on all aspects (direct and indirect) of cost and benefit. However, in ergonomics it is often impracticable to quantify all the indirect benefits expected from its introduction and thus assumptions must be made. This is particularly the case for intangible factors such as:

- improvements in worker morale;
- reductions in pain and suffering due to fewer or less severe injuries; and
- reductions in usage of health services.

Without capturing the indirect benefits of the ergonomic intervention, the cost–benefit analysis will underestimate total benefits. Other economic models (e.g. costs saved model) do not attempt to quantify these indirect benefits, deeming the risk of over or under estimation to be too great. For instance, where it is anticipated that the ergonomic intervention will save lives, a monetary value for a human life is rarely agreed to by those involved.

Accounting models and economic models both seek to capture costs and benefits over the lifetime of the intervention. This prediction into the future must, of necessity, carry with it a number of assumptions. This can be seen by examining the costs saved model.

The *costs saved* model is one of the simplest cost–benefit models. It is often used where it is not feasible to estimate hidden costs or anticipate fully the benefits flowing from an intervention. The model just examines changes in cost items including costs saved. For a single year this can be calculated as:

$$TC_1 - TC_2,$$

where

TC_1 = current costs
TC_2 = predicted costs after implementation of ergonomics
　　　　 intervention.

A project is considered worthwhile where $TC_1 - TC_2 = 0$.

Once the costs or benefits occur over a period of several years the calculation becomes:

$$\hat{A}\ (e_1 - c_1) + (e_2 - c_2) + (e_3 - c_3) \ldots + (e_n - c_n),$$

where

e_1 = 　present value of the total costs for the ergonomic
　　　　 intervention in the first year
c_1 = 　present value of the total costs for the current system in
　　　　 the first year
n = 　　number of years it will take to pay for the intervention.

The further into the future the project extends, the more uncertainty will be the cost structure and assumptions will need to be made about the *most likely* outcome. Because the value of money changes over time (due to inflation rate, interest rates) it is necessary to make further assumptions about the ways its value will change and build them into the model. This is termed determining the present value of future costs. In a cost–benefit model this is achieved by applying a discount rate to future events.

One of the key assumptions of rational economic theory is that firms will prefer to have a return on their investment today rather than to wait some time for uncertain future benefits; obtaining a return on investment this year is considered to be of greater value than obtaining a return on the investment next year. To reflect this preference for the present, returns on investment received in the future may be discounted by a greater percentage than the anticipated inflation rate. (The percentage chosen is referred to as the *discount rate*).

Thus, the discount rate chosen will reflect not only anticipated

inflation rates but also the firm's culture and values, including their concern about risk. Discount rates and can have a significant impact on the final calculation of cost–benefit. For example, if a firm spends $100 this year to get a return of $110 (110%) this year then the project is clearly worthwhile; if the return of $110 did not occur until the next year then a discount rate would be applied. If the firm used a discount rate of 4% then the $110 return would effectively be worth ($110 – 4%) $105.60; this is still greater than the original investment so the intervention would be considered worthwhile. If the firm used a discount rate of 11% then the $110 return would effectively only be worth ($110 – 11%) $97.90; as this is less than the original investment the intervention would not be considered worthwhile.

As the cost–benefit model becomes increasingly complex it also becomes less and less precise.

A firm may find it easy to calculate the direct costs of a production process, but the indirect costs such as overheads, wages and on-costs may be more difficult to calculate and may need to be estimated. For example, future labor costs require assumptions, which include:

- changes in the labor turnover rate;
- payment to replace staff;
- wages increases; and
- changes in the number of injuries and/or the severity of injuries?

It is *critical* that the assumptions chosen for the cost–benefit model appear reasonable to the management and specifically those persons who will make a decision on funding. In this way there will be agreement that the model gives the *best estimate* for the likely return on investment.

Cost–benefit modeling over multiple year periods are needed where very large and complex interventions are proposed and the intervention takes a considerable time to implement. However, for the majority of ergonomic interventions it is practical to assume that costs are all incurred over a 1-year period and to offset costs against one year of benefits. This simplifies the modeling with many advantages; fewer assumptions are required, the mathematics is more transparent and, with less explanation required, the focus stays on the ergonomics intervention itself.

Unfortunately there is a dearth of models designed specifically to address working conditions. Economic models exist to describe engineering, fiscal and other functions but not for workplace people. Here the Productivity Model will be used to show the general principles of economic models which describe working conditions. The basic assumptions for this model cover:

- *employee working conditions* — namely working hours and productive working hours (paid time at work, excluding paid time for vacation, illness, etc.), wages/salary and on-costs (supervision and administration, workers compensation insurance and taxes, training, recruitment, etc.), overtime and over-employment.
- *productivity factors* — namely quality and quantity of output, error and warranty costs.

3. DATA REQUIRED

From a pool of assumptions, those applicable to the particular ergonomics intervention can be agreed upon and data collected.

Table 1. Cost indicators and how an ergonomics intervention may affect these indicators.

Cost factor	Loss from a calculated 100% efficiency (present situation)	Future value (forecast range for a reduced loss after the ergonomic intervention)	
		minimum achievement	maximum achievement
Example 1.			
Unsuitable equipment	90%	95%	98%

If the loss of 10% in present efficiency is due to unsuitable equipment the gain due to the ergonomics intervention will be in labor costs. If labor costs are $20 per working hour then a gain of 5% in efficiency (the minimum forecast) is $1 per hour or about $1600 per worker per year. If the intervention costs less than this, then the pay-back period will be less than one year.

| **Example 2.** | | | |
| Injury absenteeism | 5 days per employee per year | 2 days per employee per year | 4 days per employee per year |

The productive time is the net working time for which the employee is paid. By reducing avoidable absences, for which wages/salary are still paid, the productive time is increased leading to cost savings. In this example, the ergonomics intervention aims to reduce the injury absenteeism from 5 days per employee per year to between 2 or 3 days per employee per year.

This is a straightforward calculation based on the cost of daily employment multiplied by the number of people involved; this value is compared with the cost of the ergonomics intervention required to achieve this reduction in absenteeism.

| **Example 3.** | | | |
| Reduction of waste | 10% waste of raw materials | 7% waste of raw materials | 5% waste of raw materials |

Waste is the loss of materials during production. The ergonomics intervention seeks to reduce the waste from 10% to between 7% and 5%. The intervention will be financially successful if the savings in waste is greater than the cost of the intervention. In this example there may be extra gains to be made in less energy use, smaller stocks required and less handling of materials.

| **Example 4.** | | | |
| High warranty costs due to poor quality and/or errors | 5% value of produce | 3% value of produce | 2% value of produce |

The ergonomics intervention seeks to improve labor and management skills to overcome the quality deficits and the cost of repairing returned goods. Gains will be in a reduction in labor costs, reduced waste and reduced energy use.

Some of the data required are straightforward and easy to obtain. These include:

- labor items (productive time, wages, on-costs, training, absenteeism, labor turnover, etc.);
- equipment and material costs (equipment failures, waste, errors, etc.); and
- organizational costs (supervisory structure, manning levels, etc.).

Other data are less easy to obtain but, in the experience of the authors, give the greatest return from ergonomics investment. These include:

- productivity (gross output and quality); and
- error and warranty costs.

Where does one get the data? Some can be obtained from the accountant (wages and similar items), some from management (production, waste, errors and warranty costs) and some from the directly involved workers (workplace layout, unsuitable or worn-out equipment).

To assign costs, one can either use the raw figures (wages, absenteeism, cost of labor, value of production, etc.) or one can use a difference value. As the model is a difference model (the difference between the present and an estimated future date) difference values can be based on, for example, labor costs. For example, the ergonomic intervention may be aimed at reducing the time taken to do a particular task; the change would be the difference in time taken between the two tasks.

The present costs are added together and the envisaged reduced costs, due to the ergonomics intervention, subtracted; this value is the "estimated benefit". The total cost of the intervention is calculated (new machinery and installation costs, ergonomics consultant, extra management time, etc.) and is the "cost for improvements."

If one makes the additional assumption that these cost savings occur in one year and that the intervention occurs over one year then the payback period (in years) is:

cost for improvements/estimated benefits.

Table 1 illustrates examples of cost indicators and a forecast of how an ergonomics intervention may affect these indicators.

DEFINITIONS

- *Direct costs* — wages/salary paid to employees, obligatory and other costs (tax, insurance, retirement fund, etc.).
- *Indirect costs* — costs involved in the production of goods or delivery of services excluding the direct costs. It can include supervision, administration and similar personnel costs.
- *Hidden costs* — injury and production/service losses built into the enterprise structure but which are not separately identified.
- *Direct benefit* — identified savings in direct costs and improvements in productivity and/or quality.
- *Productive time* — paid work time used for the production of goods or delivery of a service. It excludes paid time that is not used productively e.g. illness and injury absence, vacations.

1. INTRODUCTION

The manner and level to which ergonomics (or human factors) is taught is important for the progression of the discipline itself, its furtherance among other professions, and the influence it is likely to have on globalization and technological change. Here we briefly indicate the benefits of the inclusion of ergonomics in design practice, review some of the traditional barriers to communication of ergonomics concepts, and lastly consider the manner in which ergonomics may be taught in tertiary, secondary and primary education.

There are two distinct areas of ergonomics that need to be considered:

- Education in the discipline itself, i.e. the *mastery of skills* such as usability assessment, workplace evaluation, the measurement and recommendation of ways in which job related (mental and/or physical) stress may be alleviated. Education to this level will enable one to *practice* ergonomics as a profession, and is traditionally taught at undergraduate and postgraduate level (see below).
- Education for *awareness* of ergonomic factors. Engineers and designers, for example, need to be aware of the function of ergonomics in relation to their own disciplines. In addition we need to consider general education as members of an increasingly complex, large and varied social environment. This is growing in importance as individuals from widely disparate backgrounds can now work together, sometimes without meeting face to face, using ever more rapid, effective and efficient means of communication. Effective working in such an environment requires individuals to understand and be tolerant of others, and to know how to work as a team. Ergonomics, with its emphasis on the importance of human factors and individual differences, can provide a means of unifying diverse curricular activities that might actually help children and adults work together in larger systems.

2. ERGONOMICS IN PRACTICE

To understand the importance of education in relation to ergonomics, it is necessary to appreciate the practice of ergonomics in relation to the disciplines it seeks to inform, namely engineering and design. Well-designed products must be safe, efficient, comfortable and convenient to use, durable, realistically priced, have a pleasing appearance and be pleasurable to use. All of these are human factors issues.

Rapid technological development and the movement towards concurrency in design require that a systematic account of human factors is incorporated as early as possible in the design life cycle i.e. to predict in advance of build who the users are, what their reactions are going to be, and where usability issues will arise.

The complexity of many systems means that it is often impractical or excessively costly to make changes late in the design process. Incorporating ergonomics early into the product design life-cycle has proven benefits in reducing problems with usage, increasing the acceptance and functionality of the finished product and reducing the need for highly expensive re-design.

Attempts to enhance the human factors input into design and engineering have focused on both the product (i.e. ergonomics information) and the process (i.e. the way in which ergonomics can be incorporated into the design process). "Product initiatives" include improving the accessibility of ergonomics information by presenting it in a more designer friendly manner, e.g. in web pages, CD-ROMs, guidelines and research papers which include practical recommendations. "Process initiatives" include the development of tools and techniques tailored to specific design tasks, such as different methods for capturing and communicating user requirements, e.g. through storyboarding, simulation and scenario building and looking at the manner in which this information can be fed into the design process e.g. through the development of ergonomics brainstorming decision support systems (such as the HUFIT Planning Analysis and Specification Toolset and ADECT). Anecdotal evidence would suggest that these initiatives are having an effect.

However, to improve the effectiveness of the discipline one still requires education to:

- train future ergonomics experts in industry and academia; the *practitioners*;
- provide those who are not "ergonomics experts" with an *awareness* of the human issues they should be considering; and
- provide a working environment favorable to the uptake of ergonomics issues.

Below, are the ways in which this is taking place.

3. POSTGRADUATE VOCATIONAL TRAINING

As indicated above, designers and engineers need to consider the human element in their designs at the start of the design process. However, most will have been trained on degree programs that did not consider ergonomics. To some extent an engineer or designer can develop an awareness of the value of ergonomics to their work through the normal process of professional reading. In competitive, niche markets this approach is now often too hazardous. This shortfall in expertise is increasingly being met by postgraduate vocational ergonomics courses, which may form part of a larger post-vocational qualification such as an MSc. Many organizations, especially those in engineering, invest in vocational training to upgrade their work force and to keep their knowledge and skills relevant.

One example of a postgraduate vocational ergonomics course is offered by Loughborough University. Short courses on vehicle ergonomics have been run for the automotive industry since 1981. These are offered either as in-house courses tailored to the specific needs of the company or as open courses attended by people from a variety of companies. Within the automotive industry there is a need for ergonomics training applied to both the manufacturing process and to the design and development of the product.

An example of a postgraduate module at Loughborough is

Vehicle Ergonomics, part of an MSc aimed at engineers. This 5-day residential module includes an introductory lecture on ergonomics and its application to vehicle design and the integration of ergonomics into the design process from concept to customer. Methods used in vehicle ergonomics include the identification, specification and implementation of user requirements, evaluation, the role of simulation, packaging trials, prototyping tools and road trials. Anthropometry in vehicle design is taught as a theoretical and a practical topic including the importance of anthropometry and biomechanics to vehicle design and the application of anthropometric and biomechanics data. It is considered important to give the students an understanding of the methods used to reach ergonomics solutions for themselves rather than being given only ready made solutions. The ergonomics of control and display design covers selection and location of controls and displays, methods of communication, interface and dialogue design and new technology applications. Seat design and the driving package indicate an application of anthropometry and biomechanics and the importance of integrating the driver's workplace into the whole vehicle. A major component of the module is a practical project involving the design and conduct of a user trial with "real" users/customers to tackle a specific aspect of vehicle design such as access and egress or seat comfort.

By the end of the module two things have happened. First, students report that they never before realized how pervasive a topic ergonomics is. Second is a dramatic change in attitude after the project work that involves direct interaction with members of the driving public (their customers and the people they design the vehicles for). The students become very aware that their customers are not like them. They are not all fit healthy young men (only a few students have been women) who are interested in and know about cars. The post-module evaluation often reflects a realization that ergonomics is much more relevant to their work than they originally expected. This is not an isolated example, other organizations also recognize the need for ergonomics training for their work force and courses are provided either by educational establishments or by in-house ergonomists.

It should be noted, however, that concern ergonomists once had that such training would make their role redundant as the designers and engineers would be able to "do the ergonomics" for themselves has disappeared. There is strong evidence that the demand for specialist ergonomics input to design and engineering activities within a company escalates as the designers and engineers recognize the human factors issues for themselves, the extent (or limitations) of their own knowledge, the specialist input the ergonomist can then provide, and the ultimate effect on the end product and customer satisfaction.

4. ERGONOMICS WITHIN TERTIARY EDUCATION

Here we look at ergonomics as taught in UK universities as either a first degree, postgraduate degree, or as part of a degree. Before going into detail we should recognize two areas that have caused difficulty: Firstly there has been a barrier between ergonomics and engineering due to the limited common "language" and the philosophical stances of the disciplines. Secondly, specialist ergonomics degrees tend to recruit students from both a science or design background. This means that courses need to be sensitive to the different backgrounds of the students. This has

not always been the case; e.g. Lombaers (1990) criticized courses that failed to produce well-rounded team players. Students with a science background tended to have little knowledge of product development and had difficulty with the compromising, integrative nature of the design process, whilst those looking at ergonomics from a design background tend to have little knowledge of how to conduct experiments. Recommendations have included:

- Widening the scope of engineering education to include modules in ergonomics, in which the relevance of ergonomics to engineering is outlined and ergonomics information and processes are provided.
- Ergonomics courses offered to all business and technology (and engineering) students with a focus on enabling them to conduct their own human factors investigations.
- Postgraduate level modules in ergonomics (or vocational courses) for those destined for senior management. It is graduates at this level who will be making key decisions.
- Joint degree courses. Besides acting as a scientist, the ergonomist should play a role as a contributing specialized designer with an understanding of the whole process that is being supported. This requires knowledge not only of ergonomics, but ergonomics as it is practiced in a particular industry, for example, product, industrial or automotive design. This can possibly be achieved through modularization and joint degree courses. This has the added benefit of not only having ergonomics applied to the problems faced by a sector of the workplace, but in reducing interdisciplinary communication problems, which all too frequently inhibit co-operative working, and in helping to set joint goals and foster environments in which ergonomics can be used more effectively, especially during the crucial early design stages.
- Training researchers and future teachers as a means of guaranteeing the status of ergonomics among other sciences and humanities and the manner in which it is applied by practitioners.

Some of these are issues that the ergonomics community has taken on board, but some are of a more general nature which can only be addressed through sweeping reforms to the school based approach to tertiary education. Below we look at the manner in which ergonomics is taught at degree level and also how it may be taught as a series of modules in, for example, a design degree. It has been argued (Woodcock and Galer Flyte 1998) that primary and secondary education also need to be considered as possible avenues for making potential students receptive to ergonomics issues. This is reviewed below.

4.1. As an Under- or Postgraduate Degree

Ergonomics, as taught in the UK, may be taken at diploma, degree or masters levels, either as degree in its own right, in conjunction with a related discipline, or as specific modules (options). Here we provide examples of each of these types of courses. For more details of these and courses offered in other countries, see, in the first instance, the Ergonomics Society [http://www.ergonomics.org.uk] or the International Association of Ergonomics [http://ergonomics-iea.org].

The courses, outlined below, have different areas of specialization but meet the requirements of their professional

bodies. These require that students demonstrate knowledge of the principles of ergonomics, and of the relevant human characteristics in the areas of anatomy, physiology, psychology and social organization. It also requires knowledge of how the physical environment affects people and of at least three specialist areas of application selected by the candidate. It requires also evidence that the candidate is able to use statistics, experimental designs, equipment and methods to investigate, modify or design situations an equipment for ergonomic benefits (Centre for Registration of European Ergonomists (CREE) information leaflet). A similar, and much fuller description of the skills and knowledge bases which need to be addressed can be found in the Board of Certification in Professional Ergonomics Handbook (1999).

It should be noted that the professional bodies have different categories of membership. For example, to use the designation, European Ergonomist (EurErg), requires a demonstration of full responsibility in the use and application of ergonomics knowledge and methods in practical situations for at least two years following training.

4.1.1 Masters (MSc) level courses

These are offered by five UK universities. Three offer the course as an MSc: Ergonomics, one offers Work Design and Ergonomics and another a more specialist course in Health Ergonomics. The aims of these programs are to equip students with the requisite ergonomics knowledge needed for them to become professionals recognized by the appropriate professional body for ergonomists (see above), and the necessary expertise to become effective practitioners.

The courses typically run over 12 months (full time) and 24 months (part-time). Assessment is through coursework (normally including a three month research project) and examinations. All courses are strongly supported by industries at local, national and international level, which provide guest visits and research projects for students.

Although each of the courses has its own particular emphasis they all cover basic training needed by a practicing ergonomist. For example, one course offered as a joint program is suited for those who wish to work in an industrial environment, another specializes in the application of ergonomics to problems that occur in health systems such as accidents, ill health and job satisfaction, a third emphasizes the practical applications of ergonomics in for example manufacturing, the health service, computer systems and North Sea oil and gas industries.

As these are masters level courses, the students are likely to be practitioners in a specific industry (e.g. health service, automotive engineering), or have a relevant prior degree perhaps in psychology, physiology or sports science. They will therefore be adding ergonomics competencies to their core professional skills.

4.1.2. Undergraduate degree (BSc) in ergonomics

In the UK only Loughborough University offers a BSc in Ergonomics. This can be taken as a three year undergraduate degree. If this is supplemented by a year working in industry the student will also be awarded a Diploma in Professional Practice. The program fulfills the requirements for full membership of the Ergonomics Society and meets the technical requirements for accreditation as a European Ergonomist.

In terms of the structure of the degree, the first year covers "introductory modules" such as ergonomics and design, anatomy and physiology and basic cognitive psychology; the second year consists of more specialized "degree level" modules such as occupational psychology, thermal environment, organizational behavior and professional practice. For those opting for a four year courses (to gain the additional Diploma in Professional Practice) the third year is a placement one, where the student is in paid employment in a field relevant to ergonomics. This helps to relate academic studies to practical situations and help students to gain an insight into the responsibilities associated with the profession. A close liaison with the university is maintained with the students having both a professional and academic supervisor. Students opting to take this additional year often perform better in the final year and obtain employment more readily after graduation. The final year consists of core subjects such as project work, systems ergonomics and psychology, and optional, more specialized modules such as applied vision, transport safety and human computer interaction.

Discrete areas of ergonomics may also be offered by universities as part of standard joint honors degrees such as Psychology with Occupational Psychology or as modular options. The modularization of degree courses enables students to tailor (within reason) their degree to suit their interests and requirements. For example, modules might occupational, cognitive and environmental ergonomics. These can then be used as an area of specialization when accompanied with core modules, for example in engineering or design. The modular approach to teaching ergonomics is outlined below.

4.2. As a Module in Other Courses

In this section we take as an example the way in which ergonomics can be related to product design degrees, similar approaches may be applied to engineering oriented courses.

As with the incorporation of ergonomics into the product life cycle so it is with incorporating ergonomics into design education: the earlier it is done the more effective and acceptable the outcome. As part of their design education, would-be designers (especially those specializing in industrial design) receive some introduction to ergonomics. Usually this is in the form of a series of lectures or a complete module in ergonomics. At Loughborough University, for example, industrial design students attend a complete module on Ergonomics and Design.

The module syllabus includes both lectures and practical work in which students apply ergonomics principles to the design of everyday objects. The lectures cover topics such as sources of ergonomics information and data and the appropriate application of that data design of displays and controls and their application in a control panel design exercise console and workplace design, tool design, anthropometry and other methods appropriate for workstation design and evaluation, seating, the effect of poor design and musculoskeletal complaints, and methods and tools which can be used to answer new design queries. Other related optional modules are also available such as ergonomics and product design, design of advanced technology systems, and ergonomics and transport.

Ergonomics may be taught by people who are not formally trained in ergonomics but have taken an interest in the subject or by qualified ergonomists either through "service" teaching

where the specialist is not a member of the design department, or by the growing number of ergonomists who are actually part of the design department's complement of staff or by guest lectures from practicing designers or ergonomists. Guest lectures provide a valuable addition to the students' experience in terms of case studies of good ergonomics in practice or examples of how an attention to ergonomics earlier in the design process could have avoided problems such as re-tooling or customer complaints later on. They are also valuable in putting ergonomics firmly into the context of design in real world practice.

The nature of the ergonomics material taught to design students is critically dependent on the approach taken by the person responsible for the subject as there is no agreed content. In the past, and still to some extent at present, ergonomics has primarily been seen and taught as a combination of anthropometry and "knobs and dials." In this approach, which is certainly better than no ergonomics at all, the student designer is made aware of existing sources of ergonomics information (or data) such as Pheasant, *Bodyspace: Anthropometry, Ergonomics and Design* (1986, 1996); Woodson, *Human Factors Design Handbook* (1981) or Sanders and McCormick, *Human Factors in Engineering and Design* (1987) and is urged to refer to these during their design. This encourages the student designer to take account of known ergonomics information particularly physical characteristics such as shape, size, strength and reach.

However, this existing information is not always exactly the information the designer requires for the particular task in hand. For example, reach data may not provide the specific dimension needed for the innovative product under development, or the product may be for a market for which there is only limited ergonomics information on the characteristics and lifestyles of the potential product user population. There is, therefore, a growing trend for student designers to be provided with tools to enable them to gather information for themselves. Design textbooks, such as Baxter, *Practical Methods for the Systematic Development of New Products* (1995), include sections on task analysis and other ergonomics methods. Garner (1991) has produced a book on ergonomics, *Human Factors*, specifically aimed at "A" level and undergraduate design students.

Where ergonomists are part of the design education department their experience in communicating ergonomics to student designers tends to be one of gradual change in emphasis over time. Initially the students simply want to be provided with ergonomics information but gradually, through encouragement, become enthusiastic about a more user-centered design approach. In user-centered design, the potential user(s) of the product is the central focus of attention. This includes using ergonomics methods to more readily understand actual user requirements as well as their physical characteristics and limitations as it not only includes the shapes and sizes, reach and strengths of the range of users, but also requires consideration of the task(s) the product is to support and the environment in which the product is to be used. The environment could be the physical one, for example, the lighting available for seeing the product to use it, the noise environment, for example, to be able to hear a radio in an HGV; it could also be the psychological or organizational environment in which the product is used. What, for example, are the user's expectations for the product based on their previous experience of similar products? Does the organizational environment in

which the product is to be used demand that it has a 'privacy' function for instances where confidential work could be overlooked? It is no surprise, therefore, that all this information is not readily available, yet the failure to provide this specific information has been one of the criticisms continually leveled at the discipline.

Once this latter approach has taken hold on the designer's imagination and practice their own requirements of ergonomics change from simply requiring look up tables, to knowing what questions to ask and how to relate user, task and environmental characteristics to product requirements. This is the basis of user-centered design. Information on the "how to" aspects of using ergonomics methods and tools is still not readily available to design students. Wilson and Corlett's *Evaluation of Human Work: A Practical Guide to Ergonomics Methodology* (1990) covers a great deal more than methods for use in product design, but is primarily aimed at ergonomists who have the expertise to identify the most appropriate method(s) for their particular application. This is where access to an ergonomist in the design education department is of considerable benefit.

Teaching methods employed include lectures on ergonomics principles and information, and individual or group assignments. Typically assignments require evaluation and comparisons e.g. "to evaluate a domestic product such as a kettle for ease of use by the elderly" or "to compare the ease of assembly of two brands of kitchen unit." In completing such assignments students are encouraged to take a user-centered design approach, considering the characteristics of the user(s), the tasks the product is to support and the conditions of use. They are also encouraged to identify design deficiencies as well as the good aspects of the design that should be preserved, and suggest improvements to enhance the product's usability. This encourages a positive as well as a critical approach as it is recognized that ergonomics does have a reputation (now happily diminishing) of only providing designers with negative feedback after product evaluations. To undertake projects of this nature, students require specific assistance with the methods used, such as the design of the evaluation procedure or of a questionnaire.

These assignments are often carried out in groups with the interchange of ideas among the students being seen as a valuable and crucial learning experience, given the nature of the employment they will be seeking after graduation. As the students progress through their design course they undertake a number of design projects, increasing in size and complexity. These design projects differ from the purely ergonomics related assignments described above in that they are primarily focused on product design. In these, considerations of ergonomics have to take place alongside other factors that will influence the final product, such as materials, production process and costs. This is seen as more typical of actual design practice. In these projects, the lecturer tends to act as facilitator, usually on a one-to-one basis with the student. Their role is ensuring that the student takes adequate account of the product's user requirements, refers to existing data or information (so no wheels are re-invented), collects additional user information as needed and undertakes user trials with product prototypes to establish how well potential design solutions meet user requirements. Most importantly, they enable the student to deal adequately with the compromises that will inevitably need to be made in the product development process.

It is only by having a clear understanding of the real requirements of the product users that satisfactory compromises can be made in this process.

The ergonomics input to design education can be seen, therefore, to take two principal forms, the introduction of students to sources of data and information, and the support for user-centered design as part of the whole design process. It is the combination of the provision of ergonomics information and the methods and tools to enable the design student to discover or generate appropriate information for their particular design activity that is the most powerful in design education. It is often only when the designer finds him or herself in a competitive industry that is awake to the market edge that good ergonomics can bring to a product that they see the real relevance of this subject in their design education.

5. ERGONOMICS IN SECONDARY EDUCATION (11–18 YEAR OLDS)

Education is a key factor in the development of any society and should be seen as a continuum, stretching from nursery school, through further and higher education, into the work place and retirement. We see two basic roles for the teaching of ergonomics at school level: general awareness and pre-vocational. General awareness of ergonomic factors is important to us all, if only as users and selectors of products, systems and environments. By understanding something of ergonomics we can become more discriminating consumers and we can set up our working and leisure spaces to greater effect. Going further, an awareness of ergonomics at the critical 16–18 age range can be important in relation to students selecting degree programs in areas where ergonomics are important or possibly choosing to focus on ergonomics as a specific area of study at degree level.

In this section we look at:
- the role ergonomics can play in a curriculum which will prepare learners to take their place in a global society; and
- the extent to which ergonomics is taught as a discipline in its own right.

5.1. Potential for Ergonomics in the Curriculum

Although the introduction of topics in the school curriculum is too slow an agent for change in a modern society, the school phase is critical. In the UK, the National Curriculum (NC) was designed to ensure that all children receive a broad basic education in which they firstly develop an awareness of, and subsequently a capability in specific areas of learning. The two are not, of course, exclusive and are normally seen as part of a continuum where both grow to levels appropriate for the program involved. Here we will review three areas which we believe to be pertinent to education and ergonomics, in terms of curriculum development; namely, the role of information technology, learning about individual differences and team building.

5.1.1. Information Technology (IT)

A review of the current National Curriculum for the UK has acknowledged the vital role of IT awareness. Pupils are required to be ready to respond to the new opportunities and problems that they are going to encounter. These may be summarized as the expansion of communication technologies, changing modes of employment, and new work and leisure patterns resulting from economic migration and the continued globalization of the economy and society.

This may be taken as evidence that general education is becoming inextricably associated with advanced communication technologies such as the web. Children, classes and schools are producing web pages, publishing poems, art work and class experiments, with a view to sharing experiences with their peers in other countries. The only limits to this growth are teachers' ability to guide and integrate these ventures to make them worthwhile learning experiences, and the high cost of the technology involved.

The use of IT in this manner, does indeed open up new vistas for schoolchildren, and should, if fully integrated into the curriculum provide them with greater insights into environmental and cultural differences and similarities. Whereas this has been possible through the use of television and multimedia images, the Internet provides children with the potential to initiate their own interactions. Ergonomics could be used to provide a framework to guide these interactions.

5.1.2. Individual differences

More critically, the proposed changes to the National Curriculum are required to promote equal opportunities and enable pupils to challenge discrimination and stereotyping. This raises a number of issues. First, we can see *general educational* issues associated with using advanced communication technologies such as the web, the globalization of work / leisure and the need to educate children to be sensitive to differences whether they be due to race, gender, religion or ability. Secondly we see *pre-vocational* issues in terms of preparing children for the next phase of training.

The teacher can exploit this diversity as a rich learning environment. In this way ergonomics could be seen to provide uniting glue to disparate projects, in a variety of subjects, as children are taught tolerance and understanding of individual differences at earlier stages in the curriculum.

For example, in the Fostering a Community of Learners approach, Brown and Campione (1996) the teacher acts as a facilitator to children's learning. Staff draw upon the expertise of the students (thereby actively recognizing and valuing diversity) and the wider community. The three main aspects of this are that the children research, share and perform on topic work, so mutual learning, sharing and a division of labor may develop in each group. This implicitly recognizes that individuals possess different skills, that individuals can learn from each other and that these skills can be employed to maximum in effective teamworking

5.1.3. Team working

The ability to work independently and in teams is recognized as a general educational objective from the early teaching of 7–11 year olds, through to graduate programs, for example in engineering. Bertodo (1994) emphasized the personal qualities working in such an environment would require — a breadth of knowledge and understanding, a team player, good communicator and problem solver. These abilities he felt, rank above the more traditional engineering competencies of inventiveness, creativity, rationality and thoroughness. However there are indications that not all school or university staff understand how to organize team-based learning and, particularly

the ergonomics of team working, whether in one team base or remotely using computer equipment.

Developing a team culture and having the ability to rapidly understand and adapt to other organizational structures must be a high priority in research and education, as failure to do so creates barriers to effective international projects. Again, the ability to work and organize team activity is laid down in school, where children work with individuals and groups in their class, across classes for larger joint initiatives, and through the school, e.g. for school plays, and mentoring initiatives, where older children help younger ones with reading. This approach needs to be maintained into tertiary education and through to the workplace.

5.2. Teaching of the Discipline of Ergonomics in Secondary Education

We continue the "reverse engineering" approach to the teaching and learning of ergonomics by looking firstly at the 16–18 age range (mainly "A" level, but also a range of pre-vocational courses such as GNVQs), the majority of whom will go onto tertiary education. We then look at the 11–16 age range that precedes it and, below the primary (5–11) age range.

5.2.1. Advanced ("A") level

The national curriculum in the UK only applies up to age 16. This means that post-16 courses do not have to meet formal requirements in the way they do at 11–16. In the UK, at the time of writing the norm is still very much the traditional three or four "A" levels route despite the fact that it has been heavily criticized in relation to broader approaches such as the International Baccaluriat or Scottish "Highers." Typically students intending to study engineering at degree level in the UK will take "A" levels in Maths, Physics and a third subject such as Further Maths, Geography, etc.

Only in Design and Technology "A" levels is any study of ergonomics made a requirement. However, little detail is given to guide staff by the syllabii produced by examination boards. Currently the Qualifications and Curriculum Authority (QCA) is conducting a major review of national curriculum requirements and qualifications such as "A" level. Their guidelines for "A" level subjects [http://www.qca.org.uk/] indicate that all new "A" level Design and Technology syllabi should also include a section on "planning and evaluating." This will include the use of databases, drawing and publishing and design software with a view to interpreting design data in terms of the properties of materials, ergonomics and nutritional information. Also when the student is developing and communicating ideas, they are required to take into account functionality, aesthetics, ergonomics, maintainability, quality and user preferences.

"A" level science options may occasionally include aspects of human factors. For example "medical physics" options in which the student might look at forces within the spine when a person picks up weights in various postures. Similarly a mathematics teacher may use ergonomics as a basis for project work in statistics at "A" level. The key point is, however, that there is no requirement for this.

A recent survey by Denton and Woodcock (1999) showed that in a sample of over 300 undergraduates on engineering and design programs in a UK university, a large proportion had no experience of ergonomics in schools as 16–18 year olds, unless taking Design and Technology at "A" level. So for many their understanding of ergonomics was very limited.

The overall position showed by the survey was that a student with "A" levels in mathematics or a science may have looked at ergonomics, but it is more likely that they will not. A student with "A" level Design and Technology should have learned something about ergonomics and should have applied this knowledge to project work. However, the older teachers of Design and Technology will not have learned any ergonomics as part of their initial training. Students are dependent on these staff having read up on the subject when it entered these syllabi in the 1970s; not all can be relied upon to have done this. Individually, students may have covered aspects of ergonomics in independent study or where ergonomic data are used to illustrate a certain point in class. It was encouraging to note that a small amount of ergonomics was being taught (and remembered) in other disciplines.

5.2.2. General Certificate of Secondary Education ("GCSE") level

All children are required by the national curriculum to take Design and Technology (in UK) up to the age of 16 and most take a GCSE examination on a subject within that area. The national curriculum (1995 edn) does not make the study of ergonomics explicit in any subject. It does, however, require teachers of Design and Technology to help students to consider "the needs and values of intended users" (*National Curriculum, Design and Technology*, p. 6, para. 3d) or "ensure that the quality of their products is suitable for intended users" (p. 11, para. 3i).

GCSE syllabi tend to be a little more explicit in relation to ergonomics teaching. An example requires candidates to identify and collect data relevant to the product(s) and its users: dimensions, ergonomic and anthropometric data. The survey by Denton and Woodcock (1999) confirmed that up to the age of 16, the majority should be receiving some education on basic ergonomics if design and technology teachers were interpreting the national curriculum and GCSE requirements correctly. There was also evidence that some teachers in science, PE, dance, mathematics and humanities (notably geography) also raised ergonomics in their teaching as well as in the more design related courses. However, this was not the norm, and comprised a very small proportion of the teaching in those disciplines.

Work at "GCSE" level typically involves an understanding of ergonomic principles, and the ability to assess appropriate data (at a very simple level). Children become aware of the differences in people and that products can be designed to suit certain portions of a population and the contribution of environmental factors (such as noise and light) to the product gestalt. Practical exercises can contribute to learning ergonomic principles and developing some capability in applying these principles. In terms of general education (up to 16) we can see potential benefits if children are taught to be aware of aspects of ergonomics. This could increase children's sensitivity to the differences in people, their needs and abilities possibly improving understanding, empathy and relationships between peoples. This awareness could also enable them to become more discriminating purchasers of products or systems in relation to their actual use. This might also act as a market-place lever, forcing manufacturers to design for greater inclusion of users in the first instance.

Crucial to supporting the use of ergonomics in the later Key Stages is the need to develop resource material to support teachers. Such support material could, for instance be in the form of:

- Design projects; where children are encouraged to deconstruct the problem, starting with a consideration of ergonomic problems which could lead to the development of different design solutions, e.g. for forms of seating. These could then be evaluated and compared with the original solutions, and displayed on the Internet for other children to comment on.
- The development of curriculum material on ergonomics which matches the needs, requirements and interests of its users (both staff and students).
- The application of ergonomics tools and techniques (e.g. focus groups, interviews, anthropometric measurements) which take into account the knowledge and skills which need to be acquired at each Key Stage.

6. ERGONOMICS IN PRIMARY EDUCATION (5–11 YEAR OLDS)

Baynes (1992) considers that young children start school already able to design and make, through their everyday interactions with the world. Part of this ability is a concern for users in their designs (whether they be LEGO "people", real or pretend playmates). This might be relatively simplistic, e.g. making sure that the LEGO "person" fits into the house, that the layout of an emergency hospital is satisfactory for both patient and doctor. From a very early are children are aware of what it is like to be excluded from parts of the world; interesting items are placed out of their reach, jars are designed specifically to prevent them from accessing the contents.

Kimbell *et al.* (1996) observed that at Key Stage 1 (age 5–7) children handle user issues "more than at any other Key Stage. They easily empathize with the users of their designs." They are indeed "natural born ergonomists." However, with the progression from primary to secondary school he found a marked change in the way in which user issues are tackled, with users being far more important at Key Stage 2 (age 7–11) than Key Stage 3 (age 11–14). This change in emphasis towards the need to be able to actuate one's creations, rather than take into account and reflect upon user issues in the design, appears to be reinforced through the educational system, and may be one of the reasons of the failure of the discipline to make an impact in design and engineering. A structured understanding of the design activity adopted by young children is necessary for educators and resource developers to understand, support and progress the activities in which children are engaged. This is important if ergonomics and users centered design are to be adequately supported throughout the Key Stages.

7. CONCLUSIONS

Education must be seen as a continuum to be effective. In this chapter we have "reverse-engineered" the general approach to the teaching and learning of ergonomics, though the professional autonomy of the teacher in the UK does allow a wide range of approaches. We have identified the need to see, firstly, ergonomic awareness as an important contribution to general education for all children and students, whatever their intended roles in life. This awareness will assist the individual to be a better discriminating purchaser and a better arranger of working, living and leisure spaces together with an enhanced capacity to work cooperatively with others. Secondly we have identified the need for a "practitioner" strand of ergonomics education growing from that of awareness. This is important to enable engineers and designers to work more effectively and be better able to design products for both general and specific user fields. In addition the engineer or designer will be better able to work with specialist ergonomists when appropriate. Finally the specialist ergonomist will be better able to relate to other specialists and push our understanding of this important filed of human understanding further. Education, at all levels, and as a continuum, is the key.

Enhancing Industrial Performance

H. Kragt† and R. Janssen‡

†University of Technology Eindhoven, The Netherlands
‡Philips Centre for Manufacturing Technology (CFT) Eindhoven, The Netherlands

1. INTRODUCTION

In *Enhancing Industrial Performance: Experiences of Integrating the Human Factor* (Kragt 1995) the realities you can capture by reading the book are:

- Ergonomics/Human Factors should be involved right from the beginning of any design study.
- Human Factors audits in the prototyping phase of any system can "save" the company.
- User participation in all design phases is not a luxury, but a requirement.
- In the organization of large-scale projects the attention to a human-oriented design is of vital importance.
- Last, but not least, realising a good fit between human resources and technical investment is not only a challenge, but vital in many ways.

Corporations worldwide confronting new market demands and intensified competition are responding with infrastructural change and a customer-centred approach. Such initiatives aim for business and manufacturing excellence, and involve enhancing the quality of performance in all areas of client service. Rapid technical change offers new tools to meet market challenges, and multi-skilled employees operating flexible computer-integrated manufacturing systems are central in the struggle for the competitive edge. These multi-skilled employees need also tools to evaluate their workplace(s) from a human factors point of view. Here a self-assessment tool, called Self-assessment Tool Ergonomics and Human Factors (SATEH) is dealt with and related to manufacturing excellence.

2. HUMAN FACTORS IN MANUFACTURING EXCELLENCE

In a world that is continually changing, it is difficult to remain competitive. Companies do everything they can to satisfy changes in customer wishes, in applied technologies and in the strategies which are used to compete with each other. Some companies react by moving the production activities to low-wage countries as quickly as possible, leaving a core of development and other strategic activities behind in the mother country. Others feel they are forced to think about the production activities that have to lead to best class practices.

Thinking about shop-floor activities has attracted an enormous amount of attention at Philips. Van Breukelen (1996) describes the paths that can lead to manufacturing excellence. Suzaki (1993) describes an approach that should make the organization ripe for continuous improvement. Wouters and Hendrickx (1997) plead for a transition from *manu-* to *mento*facturing, by which they mean that there will be no difference in the new organization between those who think and

those who do (the production workers). The workers on the shop-floor must be empowered not only to perform their work, but also to control it independently. The giving of the power to steer themselves to people on the shop-floor is called "empowerment" in the literature (e.g. Suzaki 1993). In the new organization, one makes effective use of the collective wisdom of people. Under the motto "nobody is perfect, but a team could be," self-steering teams have been introduced on the shop-floor in many companies, and with success (Peeters and van der Geest 1996).

This chapter explains how ergonomic design approaches can contribute to the design of production systems on the basis of the first results from a practical case in which SATEH was used.

3. HUMAN FACTORS AND MANUFACTURING EXCELLENCE

The questions arises: "What actually makes a company an excellent enterprise?" On the basis of 20 years experience in the auditing of industrial organizations, van Breukelen (1996) concludes that successful factories have a number of similarities over the complete breadth of the company management. With regard to the flexibility of the production function, excellent factories strive for such things as: short throughput times, small production batches, minimum transport activities and controlled processes.

However, it is not only the technological developments, but also the workers who make a company successful. To be able to use the possibilities of new technologies effectively, people and man–machine interfaces must be regarded as key elements. A company like Philips (Kragt 1995) also recognizes this.

Ergonomic approaches play an important role in the struggle of factories to deliver world-class performances. From the field of ergonomics, a contribution is provided to these excellent performances by placing the task, the person executing task and the task environment of the production system central. On the basis of ergonomic design methods, one tries to (re)-design production systems systematically so that optimum use is made of the possibilities of the human being and his limitations are properly estimated. The models of Döring, Pikaar and Rouse can be mentioned as an example of such methods (Janssen 1997a).

To stimulate the integral vision in production system development from the field of ergonomics as well, a research project has been started at the Philips Centre for Manufacturing Technology, in which the contribution from the human factors engineering discipline has an important position. This project is intended to make the currently used design model more ergonomic. On the basis of a number of practical research projects at Philips factories in Heerlen, Aachen and Eindhoven, we especially looked at the possibilities of integrating the SATEH in the present development approach. Not only is the usability of the tool determined, but also there is an approach developed for SATEH that ties up closely with the thought that the workers on the shop-floor are the people who make a company successful. The results of the research and the mentioned approach are explained below.

Looking back at the term "manufacturing excellence," it has to be mentioned that the struggle for excellent performances demands that management is aware of the situation on the shop-floor (attitude). Here, it is especially important that the production system to be (re)-designed is looked at not only from a technical

vision, but also from logistic, economic, socio-technical and ergonomic perspectives, etc. This demands a holistic/ integral view from both production system designers and users.

4. SELF–ASSESSMENT TOOL ERGONOMICS/ HUMAN FACTORS (SATEH)

4.1. Introduction, Purpose and Background

At the time, Kragt and van der Avort (1994) developed SATEH at the request of the Corporate Industrial Policy department of Philips. Stoppels (1995) improved SATEH and applied it in the Philips factories of Bruges and Nijmegen. In 1996, the present version became available (Kragt *et al.* 1996). This version is being tested at the moment, both in the framework of manufacturing excellence projects at Philips and in various teaching projects of the University of Technology, Eindhoven.

The purpose of SATEH is to enable industrial organizations independently to determine to what extent the (design of a) production system is fitted to the user of the system, the task to be executed and the environmental factors. It is also a tool that,

through its use, can start up an effective discussion, both between members of the organization themselves and with experts. By applying the tool, one obtains:

- An insight in, and knowledge of, the state in which the production system is located in the field of ergonomics/ human factors.
- An indication and prioritization of the areas that need improvement.
- An overview of possible solutions.

The tool supports the drive for manufacturing excellence. It is a further elaboration of the ergonomic/human factors aspect, which is globally specified in the Manufacturing Excellence Self-assessment Tool (Bolwijn *et al.* 1993) by the term "Quality of Working Life." Both tools form an essential component of the policy of Philips in struggle for perfection and fit in the philosophy of continuous quality improvement.

The tool consists of six tables, i.e.:
- Table 1. Design process of work places; given in detail here.
- Table 2. Task contents (see table 2 for details).

Table 1. Design process of work places.

	1	2	3	4	5	Score
1. Orientation	In the design, only the technique is looked at and not the people		In the design, mainly the technique is looked at and hardly the people		Design is oriented on people and socio-technical aspects*	
	Problems are solved by the employees adapting themselves		Problems are solved by changes in design after installation of equipment		Problems are avoided by changes during the design process (e.g. the use of prototypes, simulations, scale models)	
2. Approach	Ergonomic factors are not looked at		Only ergonomic factors are looked at		All ergonomic factors are looked at and included in the design	
3. Design team	One or only a limited number of functions/professions is represented		Several functions/professions represented, little discussion between the numbers		Several functions/professions represented, intensive consultation between the members (integral approach	
4. Participation by the end-users	Absolutely no input from the producions workers		Participation by production workers after important decisions have already been made by the design team		An early and continuous attention on nad by the produciton workers	
	Designer has a different idea of the operation or the use of machines of production systems to the production workers (designer has a different mental model), there is of a misfit				Designer has the same idea of the operation of the use of machines of production systems as the production workers (designer has the same mental model)	
5. Analysis	With the wet finger, common sense		There is only use of a specialist		Process, task and need for information are mapped. Existing faults and wishes of all parties involved are mapped	
	Lack of functional specifications		Functional specifications, made by the designer		Functional specifications are formulated by the designers and users	
6. Introduction	It is unclear who is responsible for the introduction of a (re)-design		It is clear for everyone who has the final responsibility for the introduction of a (re)-design		Everybody involved is aware of his individual responsibility in the introdiction of a (re)-design	
7. Learning ability	Hardly any documentation of earlier experiences		Little documentation of earlier experiences		Complete documentation of earlier experiences. Documentation is used.	
	Nothing has been learned from earlier experiences		Poorly learning organisation. Only parties who are directly involved learn form experiences		Optimally learning organisation	
8. Evaulation	No evaluation		Evaluation with little or no documentation/reporting		Evaluation of both the design process and the results	

Table 2. Graphic profile of SATEH.

Aspects	Criteria	Score 1	2	3	4	5	
1. Design process of work places	1.1 Orientation						1.1
	1.2 Approach						1.2
	1.3 Design team						1.3
	1.4 Participation by the end users						1.4
	1.5 Analysis						1.5
	1.6 Introduction						1.6
	1.7 Learning ability						1.7
	1.8 Evaluation						1.8
2. Task content	2.1 Variety of tasks						2.1
	2.2 Varirty of skills						2.2
	2.3 Completeness of the task						2.3
	2.4 Working speed						2.4
	2.5 Working sequence						2.5
	2.6 Independence						2.6
	2.7 Feedback of skills						2.7
3. Physical activity	3.1 Static load						3.1
	3.2 Dynamic load						3.2
	3.3 Work attitude						3.3
	3.4 Variety of work posture						3.4
	3.5 Lifting techniques						3.5
	3.6 Working position						3.6
	3.7 Energy required						3.7
	3.8 Work place						3.8
	3.9 Tools						3.9
	3.10 Shift work						3.10
4. Mental activity	4.1 Number of mental operations						4.1
	4.2 Concentration						4.2
	4.3 Pressure of time						4.3
	4.4 Stress						4.4
	4.5 Variation between mental and physical activity						4.5
	4.6 Vigilance						4.6
5. Environmental factors	5.1 Lighting						5.1
	5.2 Noise						5.2
	5.3 Vibrations						5.3
	5.4 Climate						5.4
	5.5 Reflections						5.5
	5.6 Cleanliness						5.6
	5.7 Housekeeping						5.7
	5.8 Total comfort						5.8
6. Communication	6.1 Provision of information						6.1
	6.2 Amount of information						6.2
	6.3 Operating equipment						6.3
	6.4 Result of operation						6.4
	6.5 Meters and screens						6.5
	6.6 Visual contact between employees						6.6
	6.7 Oral communication						6.7

- Table 3. Physical activity (see table 2 for details).
- Table 4. Mental activity (see table 2 for details).
- Table 5. Environmental factors (see table 2 for details).
- Table 6. Communication (see table 2 for details).

Table 1 gives the first table from SATEH as an example. It has eight aspects, which are each included as a row. The three columns include descriptions that should be applicable to the relevant aspect. The column on the right, under the figure 5, corresponds with the situation of manufacturing excellence.

The two other columns are under the figures 1 and 3. The person who assesses a work place can also use the score 2 or 4 for those cases where there is a "boundary case." The scores that are thus filled in are graphically represented per aspect in the overview table (see the profile in table 2). By means of this profile, one can quickly get an overview. After all, points that should be candidates for improvement, for example with a score < 3, are immediately noticed.

As will be seen below, it is the intention that several people will make an assessment of the relevant work place. The profiles thus obtained form an important input for the discussion about the work place and the possible improvements to be made.

4.2. A Recipe for SATEH

The use of SATEH gives an insight in the ergonomic strengths and weaknesses of the assessed work place. At least as important as the results is the manner in which the tool is used and how the results are used. After all, ergonomic design means that one takes a critical look at both the design result and the design process, as emphasized by the presence of table 1 in the tool. In this framework, the question arises: "What is (an) ergonomic design?"

On the basis of a literature research into different ergonomic design models by Janssen (1997a), the following definition was made for ergonomic design: "The *systematic* development of a product or system, whereby account is taken of the *requirements, wishes, limitations and possibilities* of the *user* in an *early stage* of the design process and by letting him participate *actively and passively* in the design process ...." Especially the active participation of operators and the application of a clear system in the assessment is of great importance in getting a directed discussion going. These elements are, therefore, given extra attention within Philips in the manufacturing excellence programme.

Taking account of the mentioned elements, the following approach arose in a pragmatic manner:

- Awareness – the ergonomist becomes acquainted with the operators, designers, ARBO (Factories Acts) experts and other interested parties of the factory where the research is being done. The importance of ergonomic research is explained on the basis of the criteria comfort, health, safety and efficiency. This creates the first support for the (ergonomic) changes and improvements.

- Analysis – next, a first impression of the work place is gained by looking at the task and the environment and by talking to the people executing the task. On the basis of this data, the solutions to be chosen can later placed in the light of the task, the performance of the task and the task environment.

- Assessment – by operators, ARBO (Factories Acts) experts, designers and experts, etc., the work place can next be assessed with the aid of SATEH. The scores are visualized in graphs and will later form the first starting-point for the discussion about the work place.

- Interpretation – after the filling in of the tool, the scores can be collected and a first interpretation of the results follows on the basis of a specially developed table. This table gives an insight in the strengths and weaknesses of the work place. It can also be used to determine which factors the fillers-in of the tool do not agree about (lack of consensus), so that special attention can be given to these factors in the discussion.

- Discussion I – in a first discussion, the results are discussed with the fillers-in. Special attention is paid to the factors in SATEH on which there is strong disagreement. The discussion finally results in an accepted overview of the strong and weak points of the work place. This gives the participants a grip on the ergonomy of the work place.

- Re-design – from his knowledge and practical experience, the ergonomist gives the initial start to improvement possibilities with regard to the weak points in the present work place design.

- Discussion II – on the basis of the global improvement possibilities, a discussion is held with the participants about improvement possibilities and solutions regarding the ascertained bottle-necks. Proposals for improvement plans are formulated, in which the responsibilities of the participants are clearly defined.

- Implementation – next, the proposed improvement plans can be implemented. Here, the responsibility is mainly with the operators, designers and ARBO (Factories Acts) experts, etc. The ergonomist mainly fulfils a sounding board function.

- Evaluation – finally, implemented improvements must be evaluated. SATEH can be used again for this, so that one can make a good comparison between the previous and the new situations.

The approach has been successfully applied in the redesign of work places at Philips factories, including Heerlen (Janssen 1997b), Aachen and Eindhoven. As an illustration, the following section takes a close look at the results as have been realised in a Dutch Philips factory. For reasons of privacy, the name of this factory has been omitted.

4.3. SATEH in Practice

The mentioned approach has been followed at a factory of the largest Product Division but one within Philips. The relevant factory produces mainly discrete products for customers in Asia and The Netherlands. It also supplies part of these products to its own development department for tests. The factory also functions as a knowledge centre, whereby knowledge development and transfer are important activities with regard to the product, processes and production tools.

Rising organizational costs, the fall in the dividend on invested capital and a reduction of the profit within the business group to which the factory belongs made the Board of Directors decide to carry out a radical organizational change to be able to safeguard continuing growth and a stable future. In the framework of the mentioned terms of manufacturing excellence, glass wall management (Suzaki 1993) and self-steering teams (van Eijnatten 1996), this led to the introduction of "mini companies" on the shop-floor.

During the introduction of the mini-company project, bottlenecks within the factory organization were discussed with the employees on the production floor. From this, it appeared that one had to fight with several ergonomic problems in part of the production. This resulted in physical complaints from operators and a higher time lost through illness than elsewhere in the factory. A first research project was started from this realization.

On the basis of manufacturing documents, interviews with operators and designers and observations during production hours, the task, performance of the task and the task environment were analysed. Also, the SATEH tool was filled in by three operators, an instructor, a technical assistant, an ARBO (Factories Acts) employee and the ergonomic expert. The scores were then taken together, after which the mathematical average was determined. This gave a first picture of possible bottle-necks for the assessed work place.

The individual scores from which the mathematical average of various factors was composed differed. With some factors from the tool, the lack of consensus appeared to be about the score to be allocated. (For two reasons, one cannot simply express the lack of consensus in the standard deviation: (1) the measurement level of the scale is at best ordinal and (2) the number of observations is small. A solution for this was found in the use of the basis for the spread: differences between scores.) Next, it was ascertained that the calculation of sums of squares about all given scores should give more insight in the factors about which the fillers-in had different opinions (Dijkstra 1997, personal communication). This led to the following table with four cells, in which, on the one hand, on the basis of the average, it can be determined whether the relevant ergonomic factor is strong or

Table 3.

Enhancing Industrial Performance

Table 3. Interpretation table of SATEH sccores.

	There is consensus (sum of squares < $\underline{X}$)	There is no consensus (sum of squares >= $\underline{X}$)
Work place scores well (average ≥ $\underline{Y}$)	**Strength** This cell contains the <u>strong points</u> that one can include in a following Design.	**???** This cell contains points, of which it is <u>not clear</u> whether they are strong or weak. Discussion is necessary.
Work place scores badly (average < $\underline{Y}$)	**Weakness** This cell contains the <u>weak points</u> that one must improve in a following design.	**???** This cell contains points, of which it is <u>not clear</u> whether they are strong or weak. Discussion is necessary.

weak and, on the other hand, whether there is consensus on this point between the fillers-in. With a lack of consensus, the factor is placed in the right of the table and discussion is required.

On the one hand, the strength or weakness of a certain ergonomic factor is determined by the calculation of the average for this factor. This average is compared with a so called threshold value (Y). Y states the minimal required average for a factor. In this way, a principal can determine the desired threshold value of the average himself, fitting in the ARBO (Factories Acts) policy of the enterprise. In the case of manufacturing excellence, a minimum of 3.0 (Y) must be scored on the ergonomic factor. This value was, therefore, kept for the Philips factory mentioned above.

On the other hand, the degree to which there is consensus between the fillers-in about the allocated scores translated to a sum of squares. (Take the following example, in which seven people filled in SATEH: *Individual scores for a certain factor:* 2, 3, 3, 3, 3, 3, 4 – average = 3 and KS = 14 (calculated from the differences of *all* possible combinations of scores!). Here, therefore, the factor scores well on average and one agrees about it (there is consensus about the average). Discussion is not interesting. *Individual scores for a certain factor:* 1, 1, 1, 3, 5, 5, 5 – average = 3 and KS = 168. Here, the factor scores well on average, but one does not agree about it; there is insufficient consensus about the average. Discussion is necessary to be able to explain the difference in opinion and get a balanced assessment.) The higher this sum, the more lack of consensus there is in the individual answers. With the aid of a simple computer program, it can be determined which sums of squares can occur for a given number of operators. In practice, it has appeared that, on the basis of this, a limit for the sum of squares can be chosen (X), whereby sufficient discussion arises without each factor having to be examined separately. With seven fillers-in, this limit was 68 (based on earlier research) and it was, therefore, chosen.

After interpretation of the data by placing the factors in the correct cell, a first discussion was started with the fillers-in of SATEH. Especially the points about which there was a lack of consensus were discussed and, if possible, also assessed, after which an accepted set of good and bad points remained. The results were placed on the appropriate "glass wall." A second session was used to think about solutions; some that could be implemented immediately and with limited impact, others that were suitable for implementation in the long-term. A simple qualitative model was used to give a first picture of the possible

yields of ergonomic interventions (Alexander 1998). As a result of the participation of the fillers-in of the tool in this phase, greater support was created for the improvements. Also, an initial start was given for the formulation of improvement plans to give the actions direction. These plans will again be hung on the "glass wall."

In the near future, the work place will be assessed again, with the aid of SATEH, so that an insight will be gained in the success of the improvements. In that phase, the ergonomist will fulfil a sounding board function.

5. CONCLUSIONS AND RECOMMENDATIONS

The struggle for excellent performances means that, among other things, management is aware of the situation on the shop-floor (attitude). It will have to create conditions whereby such matters as empowerment (see Section 1) of the production worker is guaranteed.

One of the possibilities for realising empowerment is the stimulation of the filling-in of SATEH (see Section 4.1) and presenting the results on the "glass walls" (see Section 4.2). After all, the production floor is the place where the different disciplines meet and where an integral vision about the design and implementation of the production system can be developed. SATEH is powerful because it gives operators the opportunity systematically to evaluate their own workplace and to come up with improvement ideas.

The approach described in Section 4.2 specifies the actual situation of a production system with regard to the ergonomic and human factors. To get to the desired situation, people such as ergonomists must cooperate in the formulation of the programme of requirements for the new situation to be designed. Here, making the extensive literature in this field accessible is a first requirement. We have made a start with this by drawing flow charts, which clearly show the large amount of ergonomic design information in schematic and visual form.

The strength of SATEH is that individual workers start to think about their own work situation and the possible improvements in it. To obtain interpretable group scores from individual scores (shown in clear profiles in table 2), the sum of squares (Section 4.3) has been introduced and successfully applied in the current and other cases. The consensus matrix (table 3) indicates on which aspects there is consensus, and on which aspects discussion is still required. The discussions finally contribute to an accepted idea of the ergonomics of the work place and create stronger support for possible improvements. In practice, the feedback on the shop-floor organization also appears to work well. Profiles, as given in table 2, must be made visible on the production floor next to other performance indicators to continuously stimulate *the improvement* (glass wall management). This also facilitates communication about possible improvements between the people in the factory and, if possible, with experts.

From the practical study, it appeared that ergonomic analyses and solutions must fit in the strategy of the enterprise. Subsequent to "The Philips Way," which includes "The motivation of our people is decisive for the success of the enterprise," the following of a participative approach must be regarded as almost obvious. In the execution of the case in the Philips factory, attention must also be paid to the exemplary function that the relevant factory has with regard to its sister factory in Asia. In this framework,

the knowledge gained of the ergonomic research must be transferred, so that one can learn from each other.

Determining the profitability of ergonomic solutions contributes to its acceptance by management. In the first instance, the economic consequences of ergonomic redesign can be qualitatively mapped. However, it is not always a case of "earning money on ergonomics"; there can be a case of reducing running expenses. Here, it is recommended to look at the ergonomic solutions from a different viewpoint: "Not participating in ergonomics costs money."

The Organization must be "ready" for ergonomic research. This is achieved at Philips by such actions as the education of the management with the aid of three courses: Shop-floor Management, Middle Management and Top Management. In this way, everyone within the enterprise will speak the same language.

Ergonomics and Quality of Life

F. Baptista and P. Moro
Department of Industrial Engineering, University of Wisconsin-Madison, Madison, WI53706, USA

1. INTRODUCTION

Quality of life is an important aspect of one's life, and is composed of two main parts – quality of work life and quality of non-work life. The former refers to an individual's work domain, while the latter refers to an individual's out-of-work domain. If there is quality in both of these components, it is right to say that an individual has quality of life. Lack of quality in one or both components mean that an individual lacks quality of life or has a limited quality of life. One way of increasing someone's quality of life is by increasing each one of the major components – quality of work life or quality of non-work life. Ergonomics, by definition, has the ability to increase someone's quality of work life, and consequently increase the overall quality of life of this individual. Ergonomics can also increase one's quality of non-work life, but the major effect that ergonomics can have in a worker's quality of life is by increasing quality of work life. This chapter aims to discuss ergonomics and its contribution to increasing the quality of life of workers.

2. QUALITY OF LIFE

Quality of life is an important aspect of one's life, and can be understood as the subjective analysis of how healthy, happy and satisfied a person is with his/her life in general. This value judgement will be dependent on the person's culture, education, aim in life and resources, for example, that are available to achieve the person's goals. Quality of life is measured by the use of indicators, such as overall health status (physical and mental), social status, family status (e.g. if married, satisfaction with marriage), leisure time and activities (social life), performance status, general comfort, emotional status and economic status.

Quality of life is a concept. It is the output of a process in which quality of work life and quality of non-work life are the inputs. The transformation here are the interactions between these two input components and the way the worker perceive – through cognitive appraisal – how good or not his/her quality of work and quality of non-work life are. One will have quality of life if quality is found in this person's work and non-work life. Lack of quality in each of these or in both represents a lack of quality of life or a limited quality of life. It is understood that human beings look forward to having quality of life. But to accomplish this, both work and non-work lives should also have quality in them.

Workers have their lives divided by participation in two different domains, which are the domain of work and the domain of non-work. The domains have the ability to affect each other, since the individual that has a life outside the organization is the same individual that has a life inside the organization. The individual brings to work what s/he is experiencing at home, and vice versa.

2.1. Quality of Work Life

Quality of work life can be described as the way an individual perceives and evaluates the characteristics intrinsic to his/her work. This evaluation is subject to the influence of past experiences, education, race and culture. Quality of work life is affected by the characteristics of the organization, workplace, job and tasks the individual performs, by the environment that surrounds the individual, and by other subsystems that exist in the work system. Although quality of work life is also influenced by factors from outside the organization, it is measured by evaluating the level to which people feels good, rewarded, and/or satisfied with their work.

Walton (1975: 92–7) proposed that quality of work life be analyzed by eight major conceptual categories: (1) adequate and fair compensation; (2) safety and healthy working conditions; (3) immediate opportunity to use and develop human capacities; (4) opportunity for continued growth and security; (5) social integration in the work organization; (6) constitutionalism in the work organization; (7) work and the total life space; and (8) the social relevance of work life.

Different researchers have measured quality of work life in many different ways. Some of the variables used to measure it are presented as they have been used in the literature. These measures are: availability of jobs, training, mobility, job security, fringe benefits, earnings, job safety, equitable distribution of wages, job opportunities, job challenge, job satisfaction, job future/career future, job involvement, autonomy, responsibility, advancement opportunities, job control, turnover rate, commitment to the organization, self-esteem, self-actualization, social support, challenge, stress, depression, burn-out, physical health, use of skills, etc. By far, the most used measure of quality of work life has been job satisfaction. It is also accepted that the working conditions affect quality of work life. Measures of these working conditions are, for example, noise, lighting, vibration, fumes, exposure to chemicals and heat/cold.

2.2. Quality of Non-work Life

Quality of non-work life can be described as the way an individual perceives and evaluates the characteristics intrinsic to his/her life outside the workplace. Here, again, previous experiences, education, race and culture affect the individual's appraisal of this domain.

Quality of non-work life has been measured as satisfaction with family life (e.g. marriage, social support, children), leisure activities and hobbies, social life, religious life, self-esteem, self-development, success in life, and financial security to cite some.

Recently, some researchers have looked at the conflict between work and non-work life as a factor that also affects the quality of either work or non-work life and, therefore, the quality of life. Conflict tends to occur when a person is not able to balance the work role and family role. This role conflict can originate from work or from home. Excessive demand from work is, for example, having to work extra hours because of work overload or understaffing, while an excessive demand from home is, for example, having to stay more hours at home due to no child care being available or sickness of a spouse. Conflict can also be caused by excessive demands from both work and non-work domains.

2.3. Final Remark on Quality of Life

The above has shown that the concepts of quality of work life and quality of non-work life are multi-dimensional. Beyond that, the components of each concept are believed to interact constantly. The complexity of the concepts of quality of life, work life and non-work life is evident and has been a challenge to researchers. The use of a systems approach –an approach that looks at all the components and its interactions at the same time, or that acknowledge these interactions and accounts for them during the analysis – is the most adequate way to go about to understand and measure these concepts.

3. ERGONOMICS

Ergonomics is the science or discipline that main goal is to fit, adjust, change, modify the artificial environment human beings work and live in to the limitations and capacities of the human beings. Some examples of how ergonomics accomplishes this goal are: (1) when a new software interface is designed to allow disabled people to use a computer or machine; (2) when new kitchen utensils are designed to allow that elderly people suffering from joint diseases be able to do their chores or still feed themselves more easily and safely; and (3) when a lifting device is designed and built to diminish the intensity and the repetition of movements in a work setting. Ergonomic principles are or can be present in all domains of human lives, from home, to transportation systems, at work or whenever a person is interacting with a machine or device. For example, when one uses an ergonomically designed chair or ergonomically designed controls in a car, one is experiencing the benefits of ergonomics in day-to-day activities.

Ergonomics developed much during this century, and it is acknowledge that its evolution is comprised of three distinct generations. Today, we see applications of all the so-called generations of ergonomics. The first generation was characterized by the design of human–machine interfaces, including control panels, knobs and dials, and the work environment, and it was heavily based on anthropometry. The second generation started with the study of human cognition. It became important to study the cognitive demands of the operator due to the advent of computer technology and its by-product, automation of jobs and tasks. Here ergonomics looks at human–interface design and software design, for example. The macro-ergonomic approach is considered to be the third generation of ergonomics. As proposed by Hendrick (1986) this approach is concerned with ergonomics research, development and application of organization–machine interface technology. It was proposed as a tool that would enable ergonomists to deal with the effects of new technologies in organizations, and consequently their effects on the job.

3.1. Macro-ergonomics

Hendrick (1986: 467) founded macro-ergonomics in the socio-technical systems approach. His definition of macro-ergonomics is: "Macro-ergonomics represents a top-down approach to system design based on a socio-technical systems perspective." Hendrick (1994) also states that the macro-ergonomic approach can satisfy three specific basic criteria for the correct organizational and work systems design, and related design of jobs and human–systems interfaces, which are: (1) be human-centered; (2) use an humanized task approach to function and task allocation; and (3)

adequately consider the relevant socio-technical systems variables in terms of their implications for the design. Macro-ergonomics, due to its conceptualization, has the ability to allow the ergonomist to use different ergonomic approaches and methodologies together, in an aggregated manner, better to design, re-design, change, fit or adjust a system to the human user. Macro-ergonomics helps better to analyze, understand and act upon a system by allowing for a broader understanding of the system being analyzed, which as a consequence increases the odds of having a positive outcome after the ergonomic intervention.

3.2. Using a Macro Framework for Ergonomic Interventions

Moro and Derjani-Bayeh (1996) showed an analytical framework that brings together the micro- and macro-ergonomic approaches, including tools such as participatory ergonomics and ergonomic work analysis under the broader macro-ergonomic intervention. It is believed that the macro-ergonomic approach is the most efficient way of looking into a system (e.g. organization) for the purpose of promoting organizational design, culture and structure changes, as well as new technology implementations. This approach also enriches micro-ergonomic interventions in which it allows the ergonomist to have a broader perspective of the organization and how it works. Macro-ergonomics also allow for the concomitant use of other ergonomic tools that are capable of contributing, in their own way, to the achievement of the goal of the ergonomic intervention. For example, the contribution from ergonomic work analysis (EWA) is the ability to analyze in depth the tasks and activities developed by the employees, while the contribution from participatory ergonomics is that of bringing together employees, supervisors and managers better to understand a work situation and to propose and implement changes. These approaches complement the macro-ergonomic approach and, together, can gather more information on the situation than the macro-ergonomic approach by itself, and also to promote more positive changes in the organization. Of course, these are not the only ergonomic approaches that are available. All other approaches developed in the field, each one in its own way, can contribute to the enrichment of the macro-ergonomic approach and can perform better an analysis of the situation and of all its components.

4. ERGONOMICS AND QUALITY OF LIFE

The contributions of ergonomics to improving one's quality of life will now be addressed. Here, the impact that ergonomics can have on one's quality of work life will be the main focus, since it is still in the work environment that ergonomics can provide major contributions to promote changes that will benefit the individual. Cherns and Davis (1975: 55) stated that "quality of working life permits a focus on a key problem of great significance – the dysfunction in the individual experience between work and the rest of life." One way of interpreting this statement is that the work experience individual's are having are not as positive as the experiences outside the work domain. Another is that the experiences individuals are having in the work domain are negatively affecting the rest of this person's life.

Ergonomics fits perfectly as a tool to help improve quality of work life by definition. Ergonomics has the goal of fitting the task, job and environment to human beings, thus allowing people

to have a better experience, to enjoy their work, to feel that there is quality in what they do and in how they perform their duties. By fitting the human–system interface to the characteristics of men/women, ergonomics is basically increasing the quality of the interaction between the humans and the system. In doing this, ergonomics is helping to increase the quality of the work experience and, consequently, is decreasing the dysfunction between work life and non-work life.

The different ways ergonomics can affect the quality of a worker's life vary from micro- to macro-interventions. Micro-ergonomic interventions are, for example, re-designing a work-station, providing for more ergonomically designed tools and accessories, and re-defining elements of the task to decrease muscular and cognitive demands. This kind of intervention is limited because deals with one or a few workstations or employees, usually in a sector or department. The benefits, although noticed and appreciated by the workers, will not necessarily solve the problem in its totality, since many other organizational characteristics – not accounted for by the intervention – can be playing a role in the situation the ergonomist is intervening on. The ergonomics' literature is full of examples of micro-interventions that increased satisfaction, decreased stress, diminished musculoskeletal problems, reduced turnover rates, decrease injury, etc.

Macro-ergonomic interventions, on the other hand, deal with more characteristics of the system being analyzed. With this kind of intervention, knowledge about the organization structure, culture and future goals is gathered. Together with the use of other ergonomic tools and approaches, the macro-ergonomic intervention can bring benefits like the ones mentioned above as well as benefits from changing the design of the jobs, the structure of the department, the culture of the organization, etc. In this case, the benefits brought about by the intervention are broader and have a greater impact in the situation as a whole. Benefits from this kind of intervention are, for example, a reduction in workload, an increase in control and participation, a reduction in psychosocial stressors, etc. There are many examples in the literature of how such changes benefit the employees.

The magnitude of the impact that the ergonomic intervention has is similar to the magnitude of the intervention itself, and because of that the impact on quality of work life tends to be greater when the ergonomist performs a macro-ergonomic intervention instead of a more limited micro-intervention. Nevertheless, micro- and macro-ergonomic interventions increase the quality of the employee(s) work life by changing job characteristics that are relevant to the concept of quality or work life.

5. IMPLICATIONS

In summary, ergonomics has the potential to affect quality of work life through different types of interventions, from micro to macro. The amount of change that the ergonomic intervention will bring is, of course, dependent on the magnitude of the intervention. A micro-ergonomic intervention will increase the quality of work life of a few individuals in a very limited manner. On the other hand, a macro-ergonomic intervention using participatory ergonomics and other analysis tools will increase the quality of work life of a lot of individuals, and this will happen in a broader manner. Of course, these increases can be more or less significant, depending on the nature of the "situation" and the "solutions" implemented. Nevertheless, it can be concluded that ergonomics can improve the quality of life of workers by improving their quality of work lives.

Forensic Human Factors/ Ergonomics

H. H. Cohen and C. A. LaRue

Error Analysis, Inc., Human Factors & Safety Consultants, 5811 Amaya Drive, Suite 205, La Mesa, CA, 91942-4156, USA

1. INTRODUCTION

Forensic human factors/ergonomics (HF/E) can be defined as the application of the science of HF/E to problems in the legal setting. The central role of the human in systems design is the same as traditional HF/E, as is the role of human performance capabilities and limitations resulting in human error. All that is unique to the practice of forensic HF/E is its application to legal issues, as opposed to other systems.

1.1. Reasonable Care

Another unique definition for forensic HF/E is the science of establishing "standards of reasonable care" in the design, maintenance and use of products, equipment and facilities. Establishing standards of reasonable care is what makes the field of forensic HF/E unique from not only all other applications of HF/E, but from other forensic sciences or disciplines.

Western civil law is concerned with standards of reasonable care. In order to live in modern society we must take precautions to insure that our actions and inactions do not harm other people or their property. *Negligence* theory generally holds all people to the same objective standard, despite their personal shortcomings, using a yardstick, "the man of ordinary prudence." The emergence of this theoretical level of ordinary prudence may be traced to an English case decided in 1837. In that case a man, contrary to his neighbor's advice, built a hayrick in a manner that allowed it to ignite and damage the neighbor's property. The court determined that the question facing the jury was whether the defendant acted as a "man of ordinary prudence" when he constructed the hayrick and not whether he had used his own best judgment (Keeton 1984).

1.2. Areas of Practice

Forensic HF/E has focussed largely on problems of civil, as opposed to criminal, litigation. Moreover, most applications have been directed to personal injury cases involving transportation, premises or products.

1.2.1. Transportation

It is logical that forensic HF/E emerged early to focus on a variety of transportation incidents since such systems design and safety have been studied by HF/E professionals since the field's beginnings. HF/E applications have evolved to include air transport, motor vehicles, industrial and commercial vehicles, rail and water transport, and recreational vehicles. Forensic HF/E cases in this category typically involve collisions between two or more motor vehicles (cars, trucks, etc.), between motor vehicles and individual means of transport (motorcycles, bicycles, etc.), as well as between motorized transport and pedestrians. Many forensic HF/E practitioners are qualified to offer expert opinions on such specific issues as visibility/conspicuity, perception–reaction, attention demand, skill level, human error, impairments to performance and decision-making.

1.2.2. Premises

By far, the largest focus of investigations regarding premises has been directed to the prevention or mitigation of fall injuries. This is not surprising considering the high relative frequency and severity of such incidents, second only to motor vehicle collisions. Specific premises accidents addressed by qualified HF/E professionals include: falls on level surfaces (e.g. slips, trips, missteps, slipperiness, hazard visibility/conspicuity), falls from elevated surfaces (e.g. stairs, ramps, ladders, work platforms, vehicle ingress and egress, handrails and guardrails), biomechanics (normal and disrupted gait, fall dynamics), and information-processing (eye scanning patterns, focus of attention, sensory cues, competing stimuli, user expectations). Typical systems issues in these applications are the design, construction, maintenance and use of the premises.

1.2.3. Products

Forensic HF/E professionals are often called upon to offer expert testimony with respect to issues of products liability. The most commonly addressed areas are alleged product design defects and failures to warn. Product design defects can include a myriad of core HF/E principles affecting a user's reasonable expectations including display–control compatibility, population stereotypes, lack of job performance or decision-making aids, and excessive demands. A large body of HF/E research literature has evolved in recent years concerning adequacy and effectiveness of warnings. Despite one's personal views on the merits of warnings, a growing database specific to forensic HF/E is a positive trend.

1.2.4. Other applications

Litigation in the realm of workplace health and safety (e.g. back injuries, repetitive strain) is, at least in the US, largely limited by workers' compensation laws unless a third party (e.g. a product manufacturer or premises owner) can be implicated. The common concern of other types of cases for the forensic HF/E professional is whether system failures attributed to human error are involved and whether the human error(s) were design or situation-induced and, therefore, preventable through technology.

2. THE PROCESS

Forensic HF/E requires the practitioner to analyze situations involved in litigation and offer opinions that may either support or refute legal theories being pursued. Courtroom proceedings are an adversarial process in which lawyers represent opposing parties; in civil cases, they typically represent either a plaintiff (the injured party) or a defendant (the alleged injuring party). The role of the expert witness is to offer opinions beyond the knowledge of ordinary persons, such as comprise a jury.

The steps typically followed by a forensic HF/E practitioner, with related client feedback, are shown in Figure 1. It should be noted that this process is based on forensic practice in the USA; other jurisdictions may differ.

2.1. Consultation with Client

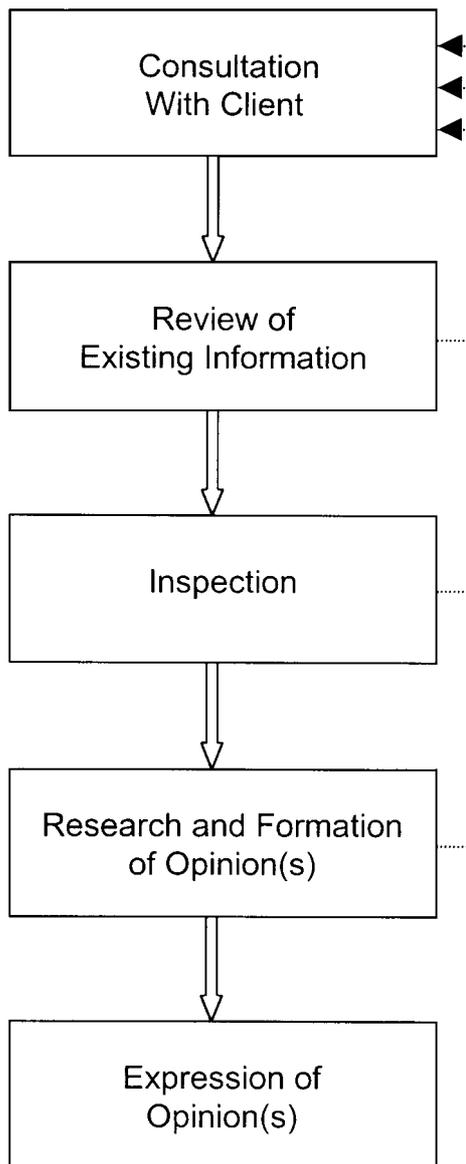
The initial step in the forensic consulting process is a consultation with the client, who is generally an attorney or representative of


Figure 1. Process of forensic human factors/ergonomics

an insurance company. In this initial conversation, the client provides a description of the case and the issues involved. The forensic HF/E professional will want to confirm that the issues in the case are within his/her field(s) of expertise. When an expert stretches his credentials into areas in which he is not qualified, it adversely affects his reputation and credibility, and therefore, the effectiveness of his testimony. The client will want to confirm that the expert has experience and is qualified to offer opinions with respect to the specific issues of the case. Before work on a case begins, generally an agreement regarding fees is made. It is common for the client to pay the expert a retainer, an initial deposit for the expert to begin work on the case.

2.2. Review of Information

As in any scientific endeavor, the first true step is to review the existing information, which in the legal setting is referred to as *discovery*. It is important for the forensic HF/E professional to

review all pertinent discovery in order to understand the relevant background facts of the case.

In a typical case, there is a variety of information available regarding the plaintiff(s) in the form of an incident report, statements, medical records and both written and oral answers to legal questions in the form of interrogatories or depositions, respectively. Other important sources of information are witnesses to the incident and *persons most knowledgeable* about the circumstances who are associated with the defendant(s), such as employees, product designers, or premises managers. This information can also include historical data such as incident reports involving the same premises or product.

Reports and documentation prepared by other expert witnesses involved with the case (e.g. medical doctors, architects, design or traffic engineers, opposing HF/E expert) provide information as to the points both sides of the case will attempt to make.

2.3. Inspection

A very important step in the forensic process is the inspection of the accident location or product involved in the case. Although the purpose for the inspection is to gather as much first-hand data as possible, there are certain points to consider when conducting an inspection for the different types of cases. In all cases, photo-documenting the accident scene or equipment involved is imperative.

2.3.1. Premises case

It is important to measure relevant dimensions at the accident scene (e.g. stair riser, tread and handrail dimensions) depending on the nature of the case. Other testing at an accident location can include coefficient of friction to determine the slipperiness of a walking surface, slope and illumination measurements.

2.3.2. Products case

If the incident involved a product, then the inspection would include an evaluation of the item or exemplar including all controls, gauges, warning labels and guarding. It is also important to review the manuals, instructions and other safety information accompanying the product.

2.3.3. Transportation case

A case involving one or more vehicles would require an inspection of the vehicle(s) and the location of the accident, preferably under similar lighting and weather conditions. Measurements taken typically include scaled dimensions of the accident scene and illumination. A reconstruction of the accident using similar vehicle(s) can also be helpful in determining issues such as visibility/conspicuity, perception–reaction time, and vehicle performance.

2.4. Research and Development of Opinion

It may be beneficial to conduct research prior to developing a forensic HF/E opinion on a case. Research for premises cases could involve determining how similar facilities have handled the design, construction or maintenance issue at question. If a product is involved, research as to the design and safety features of competitors' products can be useful.

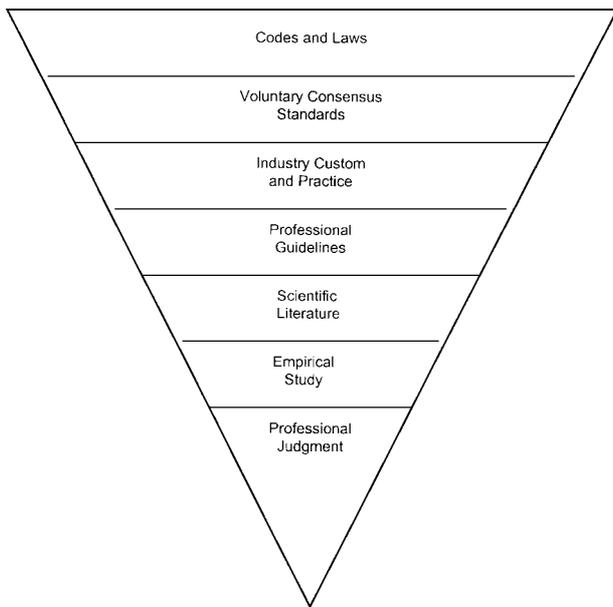
The forensic HF/E professional will integrate all the information gathered from the discovery, inspection and research


Figure 2. Hierarchy of the bases of forensic human factors/ergonomics opinions.

with his/her knowledge and experience to form an opinion. The expert's opinions are further strengthened when s/he can provide a sound authority as the basis for the opinion(s).

There are a variety of authorities on which these opinions may be based, some providing stronger support of the opinion than others, but all acceptable depending on the type of case (Cohen and LaRue 1997). Figure 2 illustrates the hierarchical nature of such opinion bases according to the relative ease with which they can be supported.

2.4.1. Codes and laws

Codes and laws are legal requirements governing a particular jurisdiction. The expert's opinion might be that the situation s/he has analyzed does or does not meet the required provisions of the applicable code. It is rare that the forensic HF/E expert is involved in a court case that has proceeded to the point where there is a clear violation of a local code or law. When this does occur, the issue is typically whether the violation has any causal bearing on the incident or was in effect at the appropriate time. Examples of these types of codes and laws are the Uniform Building Code (UBC) and the federal Americans with Disabilities Act (ADA).

2.4.2. Voluntary consensus standards

This category of opinion basis relies on a group of standards that is not legally binding, but has been arrived at through an industry consensus process by committees associated with standards setting bodies. These organizations include the American National Standards Institute (ANSI), the American Society for Testing and Materials (ASTM) and the International Standards Organization (ISO).

2.4.3. Industry custom and practice

An industry custom and practice is a way of doing business within a particular industry that has evolved over the years, usually based on experience. It is generally not formal and may not even be documented. In some cases, however, these practices may be

formalized as written company policies and procedures that may have evolved from some type of job analysis. These practices can be useful in forming an opinion especially when there is scientific evidence to support the practice and/or research that supports the proposition that it is the customary practice of the industry in question.

2.4.4. Guideline in a professional handbook

Most design-related professions have handbooks that offer design criteria. When none of the aforementioned bases are applicable, a citation from an authoritative professional handbook may be appropriate. Examples commonly used by HF/E professionals include the Illuminating Engineering Society (IES) *Lighting Handbook* (Kaufman and Haynes 1987), Woodson *et al.*'s *Human Factors Design Handbook* (1992) and *The Measure of Man and Woman* by Henry Dreyfuss Associates (1993). The major disadvantage of citing such an authority as the only opinion basis is that the source may not be widely known, especially by the responsible party such as a building owner or manager.

2.4.5. Scientific literature

Because of a background as research scientists, many HF/E professionals feel most comfortable when citing scientific literature as the basis of their opinions. However, the literature cited is typically of very limited circulation, usually far less so than the previously discussed bases. Consequently, citing HF/E scientific literature as an opinion basis may represent information readily available only to the HF/E professional.

2.4.6. Empirical study

Sometimes the issue at hand is not specifically addressed by any documented authority and can only be addressed through original empirical research. In addition to the usual areas of possible impeachment of research studies (i.e. issues dealing with the appropriateness of the experimental design, sample size, bias, confounding, and statistical power) this approach may not always be practical due to time and budget constraints. When feasible, however, research performed to answer specific issues not elsewhere addressed can be helpful in establishing a firm basis for forensic HF/E opinions.

2.4.7. Professional judgment

Sometimes it becomes necessary for a forensic HF/E professional to base an opinion solely on his/her professional judgment and experience when no other foundational source is available. It is helpful where professional judgment is being used as an opinion basis to extrapolate information from previously encountered situations. Generally the more similar the situation is to the current case, the more credible is the expert's opinion. An expert's opinion based solely on his/her judgment is only as good as the experience, credibility and credentials of the expert. Professional opinion is subject to attack, which may include impeachment of the expert's credentials, experience, and testimony in similar cases. Consequently, a legitimate and sometimes necessary basis for expert opinion, professional judgment alone is the hardest to support.

2.5. Expression of Opinion

The field of forensic HF/E requires the practitioner to analyze situations involved in litigation and offer opinions either

supporting or refuting the legal theories being pursued in the case. After the expert has formulated his opinion(s) based on relevant case information, inspections and research, there are a variety of methods in which an opinion may be rendered.

2.5.1. Reports
The first step is usually to provide an oral or, if asked, written report to the client indicating the initial opinion(s) including the strengths and weaknesses of the case. It is important that the forensic HF/E expert present both sides of the case so the client is aware of possible weaknesses. At this point, the client can decide if s/he is interested in pursuing the case further and the HF/E professional can determine if s/he wishes to be named as an expert in the case.

2.5.2. Deposition
A deposition is a formal question and answer period where the opposing attorney has the opportunity to question the designated expert witness under oath. The attorney is most interested in the expert's qualifications, his/her opinion(s), and the bases of the opinion(s). The entire proceedings are typed into a booklet by a court reporter and become part of the case discovery. The testimony carries the same weight as the testimony in a courtroom.

2.5.3. Testimony
If a case does not settle at any point in the legal process, it culminates with a trial before a judge and, typically in the United States, a jury. At this point, the expert witness will be sworn in and questioned by the attorney that retained him/her (direct examination) and the attorney for the opposing side (cross-examination). The cross-examination is usually an attempt to impeach unfavorable testimony. This is typically followed by redirect and recross examination. In some cases an arbitration will be held. An arbitration is a more informal proceeding, similar to a trial, but presided over by an impartial attorney without a jury or court reporter. Unless otherwise agreed, the decision at arbitration is typically non-binding, so the case would continue to trial if the attorneys were not satisfied with the outcome.

3. NEW AND FUTURE DEVELOPMENTS

3.1. Legal versus Scientific Terminology
An issue of increasing concern to forensic HF/E practitioners is the extent to which legal and scientific terminology may differ and the effect this may have on experts' opinions and their credibility. Examples of terms forensic HF/E practitioners are asked to consider in offering opinions include the following: defective, unreasonably dangerous, adequate/inadequate, foreseeable, duty, negligent, open and obvious, reasonable (and prudent) conduct, safe/unsafe, failure to warn, and "beyond a reasonable degree of scientific certainty."

The means for operationally defining constructs has been a cornerstone of HF/E since its very beginnings (Zackowitz and Cohen 1998). It may be argued that operational definitions are essential in order to strengthen the perception of a field's scientific credibility. A true scientific field must have, at the very least, a set of agreed upon terminology and methodologies that are understood by its practitioners and applied uniformly.

3.2. Accreditation and Certification
There is currently a strong movement toward accreditation and certification. Accreditation of academic programs has been established as a means to teach future professionals the core knowledge and skills that define the field of HF/E. As the profession grows toward a distinct knowledge and skill base, it is necessary to be able to demonstrate a minimal standard of professional competency. This is best accomplished through voluntary certification rather than regulatory licensing. A process such as this is taking place throughout the International Ergonomics Association (IEA) federated societies.

3.3. Professional Standards of Practice
Another important endeavor is developing a set of voluntary professional standards of practice. The Code of Practice recently adopted by the Forensics Professional Group (FPG) of the Human Factors and Ergonomics Society (HFES) is reproduced as Figure 3 and is a good first step.

3.4. Forensic HF/E Practice
To date, forensic HF/E practice is largely performed by individual practitioners, working alone. A model our firm has developed follows from more traditional HF/E practice, in that a team of forensic HF/E professionals, each with specialty interests, works within a multidisciplinary network of professionals outside the field, as required by the case. This network of professionals includes design engineers, architects and accident reconstructionists. The evolution of forensic HF/E consulting firms remains a challenge for the future. Another challenge for forensic HF/E practitioners is to continue to publish applied research studies in order to broaden the knowledge base of the practice, as has been well done thus far in the limited domain of product warnings.

Article V – Forensics Practice

Human factors scientists and practitioners do not allow the adversarial system of jurisprudence to affect the quality or integrity of their practice.

Principle 1. Members provide testimony objectively and without bias; their testimony is based on credible data and/or scientific principles; they are prepared to identify the merits and limitations of the data and principles as well as their own capability to interpret those data and apply those principles.

Principle 2. Members avoid impugning the integrity of other expert witnesses without a factual, reasonable, and substantive basis.

Principle 3. Members do not accept fees on a basis contingent on the outcome of the matter.

Principle 4. Members accept that the client is the attorney who engaged them and not the client of that attorney who is party of the suit.

Principle 5. Members avoid discussing the suit with others in a manner that would disclose the caption of the suit or parties involved, absent the permission of the engaging attorney, until the suit is resolved.

Principle 6. Members participating in a suit do not make public statements likely to influence or prejudice the judicial proceedings during their pendency.

Principle 7. Following suit resolution, members do not reveal information detrimental to the litigants' or client's interests, except where they believe silence would breach the greater duty of protecting public health and safety.

Figure 3. Proposed amendment to the Human Factors/ Ergonomics Society code of ethics.

Job Demands and Occupational Health

R. Brauchler and K. Landau

Darmstadt University of Technology, Department of Ergonomics,
Petersenstrasse 30, D-64287 Darmstadt, Germany

1. INTRODUCTION

For many years epidemiological research has been trying to establish the association between stresses at the work place and illnesses suffered by workers. It has been customary to identify the workplace by a job title and the worker's illness by a medical diagnosis. This meant that the data were of only limited use, as no specific information, apart from the job title, was available on the tasks performed by the worker and the resulting stresses and strains.

This method of linking occupation and injury is of very limited usefulness for analyzing the health damage that can occur during a full working life. This type of simple association model ignores a variety of influences from both the occupational and private spheres, leaving a broad spread of residual factors that make it impossible to carry out a meaningful comparison of work stresses and state of health.

There is also the fact that industrial medicine has in the past concentrated mainly on creating information systems for industrial doctors, and has largely ignored the conditions at the work place and the stresses involved there. One reason for this is that the medical experts have frequently lacked the apparatus for determining and defining in ergonomic and technical terms the objective stresses present at the work place independently of the worker himself.

It would thus appear sensible to develop an indicator system for classifying occupational demands and medical diagnoses, not only for individual industrial operations or their departments, but also for whole branches of industry. This could serve as an early warning system in the form of a work-related micro-epidemiology for symptoms or diseases in which work is a contributory factor. There is also the question of how far EDP can be used to assist in the identification of industrial micro-epidemiologies.

2. JOB DEMANDS

2.1. Definitions

The term "job demands" is defined as the general work capabilities that a worker needs to perform a given job. Job demands thus indicate how hard and how difficult the job's work content is. They are complemented by non-job-specific, situative factors, e.g. those resulting from the environment.

At an International Labour Organisation (ILO) conference in Geneva in 1950 the four basic job demands were defined in a highly simplified form as:

- Ability, physical and mental.
- Stress, physical and mental.
- Responsibility.
- Environmental conditions.

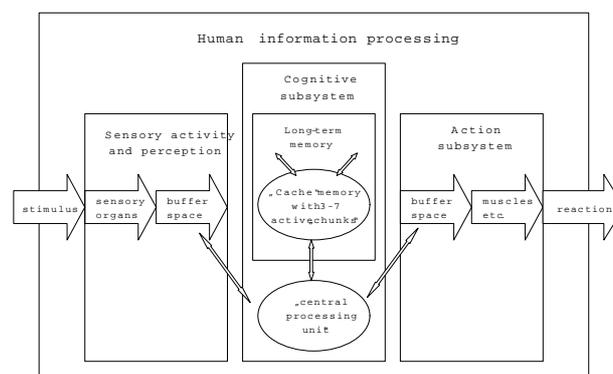
This so-called Geneva Scheme has gained importance over the past 50 years as a basis for the monetary evaluation of work and


Figure 1. A concept of information processing and ensuing human action (Harmon and King, 1986).

for wage structuring. It is, however, too rough to be used for epidemiological purposes. It would be equally inappropriate to try to formulate demands in the form of personal variables, e.g. overall "ability" or "asset" factors like ability to achieve results or to think abstractly.

Job demand data obtained from the sphere of human functioning and reaction are considerably more useful for the purpose of comparing job analyses with occupational morbidity data (Figure 1).

Man possesses a subsystem functioning through sensory activity and perception. The way in which this system is used depends on:

- the type of information involved;
- the sensory organs involved;
- the sensory dimensions;
- the type of recognition (absolute or relative);
- the fine adjustment and accuracy of the information; and
- possible interference factors.

Determination of these variables for a given work system can yield data on job elements which can then be compared with the occurrence of occupational diseases.

The same applies to the human cognitive subsystem. This system has to select and code incoming information, which is then temporarily stored in "buffer memories." The sooner existing information is processed, the sooner is it possible to recall routine motor reactions that require no further cognitive processing. In contrast, in more complex work tasks, the cognitive system cannot rely solely on the short-term buffer memories. It also has to refer to the long-term memory that one could imagine to be structured in the form of scripts or chunks.

After information has been received and processed, the reaction which has been selected as the most sensible one is converted into the corresponding action for which motor processors are used to trigger muscular reactions. The action also has to be organized and directly controlled.

All three of these subsystems of this highly simplified human action model can thus be defined by more or less filigreed job elements that can be placed in relationship to morbidity data. The sum total of the intensity, duration, sequence and timing of these job elements is referred to as workload.

2.2. Analysis Procedures

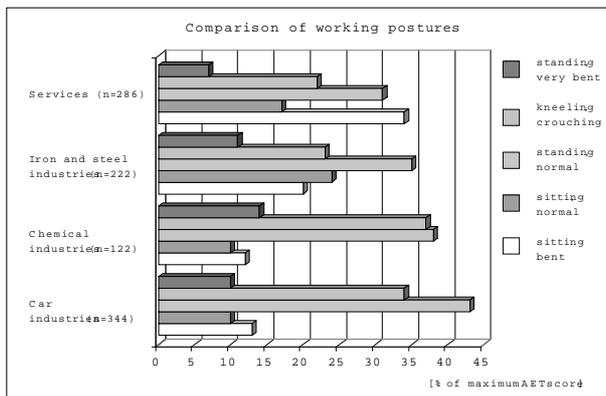
For the statistical treatment of the relationship between job and possible disease it is necessary to have analytical data on demands


Figure 2. **Comparison of working postures in various branches of industry (Landau, Rohmert, 1992).**

and stresses on at least an ordinal scale. Various analytical procedures have been available for many years. The results obtained with them will vary according to the scientific discipline on which they are based (e.g. ergonomics, work psychology, work study, etc.) and the models used. In addition to job demands, these procedures normally collect data on:

- the work object;
- the work tools and materials;
- the work tasks; and
- the actions involved.

For scientific validity purposes we require this type of analytical procedure to:

- be based on a theoretical model (e.g. a work system model);
- record all job demands as far as this is possible;
- be as economical as possible in application, processing and evaluation;
- be standardizable in use; and
- enable a statement on its reliability.

Provided that they meet these criteria, the procedures are in most cases universally applicable and can be used to compare demands in different work systems. This is an essential condition for the epidemiological processing of data on job demands and stresses.

It will not be possible here to review the wide variety of analytical procedures now available. For further details please refer to the synopses published by Landau and Rohmert (1989) or Brauchler and Landau (1998).

2.3. Specimen Result

The following profile diagrams for various branches of industry (Figure 2) are an example of a demand analysis. The procedure used in this case was the AET, which is also described in this book.

This type of profile indicates the actual stress situations arising and can be used as an aid in the interpretation of medical findings and subjective symptoms.

3. OCCUPATIONAL DISEASE

3.1. Definitions

An illness or disease is generally defined as a malfunction of normal vital processes in organs or body systems caused by a pathogenic stimulus. The human and social costs caused by degenerative diseases and the disabilities resulting from them

are becoming an increasingly heavy financial burden in industrialized countries.

The direct and contingent costs caused by occupational disease can be minimized by the improvement of working conditions, but this can only be achieved by proper analysis of the job demands imposed on the worker and the stresses and strains resulting from them. Such analyses can be carried out not only on existing jobs but also on those that are still at the planning stage. This thinking is by no means new. Studies of the overall economic costs of occupational disease undertaken as far back as 1957 resulted in recommendations for increasing industrial productivity by showing greater understanding of the reasons for problems like low worker output, absenteeism and job changes and realization that the workers' behavior in such cases was frequently motivated primarily by health considerations.

The identification and evaluation of risk factors for specific diseases which may, at least partially, be of occupational origin needs to be performed by qualified ergonomists and industrial medical specialists. Whilst the ergonomist is primarily interested in workload or "stress factors", industrial medicine tends to think solely in terms of risk factors. "Risk" in this context is defined as the probability that a worker will contract a disease for reasons related to his or her job. The risk factors thus indicate the calculable health risk to which a worker is exposed as a result of certain activities or elements inherent in his/her job, e.g. physical traumata from lifting heavy loads or cardiovascular disease from the heavy burden of executive responsibility. The risk that these activities or elements could be causal factors behind an occupational disease which manifests itself after a certain period of time can be classified as either relative or absolute. The type and extent of the relevant disease are determined and characterized by the evaluation of subjective symptoms, medical examination and diagnosis. Although this purely medical approach can in some cases help to identify potentially high-risk jobs, a genuine early warning system enabling systematic action to prevent the occurrence of occupational diseases can only be successful if a clear correlation between ergonomic data on job stresses and clinical data on specific diseases is first established.

Although the term "job-related disease" or "occupational disease" has been legally recognized, the legal definition is both too narrow and inadequate and this has led to its being used too loosely. In 1976 the ILO turned its attention to job-related diseases and started an international project with the aim of formulating an exact definition of the term, investigating causal relationships and developing methods of early diagnosis and prophylaxis to reduce the incidence of these diseases. The ILO expert committee met in 1983 to discuss its findings and these were published in ILO Report TRS 714. This report noted the three following different interpretations of occupational diseases:

- They are a subcategory of job-related diseases.
- They have nothing in common with job-related diseases.
- They are the same thing as job-related diseases.

The most commonly held view is that "job-related disease" is a generic term covering not only occupational diseases and potential occupational diseases, but also borderline cases and non-specific occupational diseases. Other interpretations make similar types of differentiation, using "job-related disease" as a generic term for all scientifically recognized but not yet officially recognized occupational diseases, and also for those occupational diseases

which, although scientifically recognized, do not for various reasons qualify for a disability pension and those acute and chronic diseases where occupational stresses may be a contributory factor in either the emergence or the exacerbation of diseases, functional disturbances or merely general indisposition regularly associated with certain work activities.

Yet another interpretation excluded acute diseases altogether and restricted the use of the term to chronic diseases frequently causing temporary incapacitation where there is a clear association with specific job stresses.

The various scientific disciplines working on this problem have now drawn up a list of criteria for classifying a given disease as "job-related." This stipulates that four conditions must be satisfied:

- It must be the result of a specific influence.
- It must affect specific groups of workers.
- The work performed by the group must be the causal influence.
- The morbidity rate for this disease within the relevant group must be higher than the average for the population as a whole.

This definition thus postulates that job-related diseases are triggered or at least exacerbated by specific job demands or combinations thereof. Whether the demand is a major factor or only one of a number of contributory factors is irrelevant.

In the case of occupational diseases, it must normally be proved that a pathogenic influence emanating from a specific noxious substance is present. The question thus arose as to whether it is possible to apply this standard to job-related diseases where the cause/effect relationships between tasks, demands, stresses, strains and disease are frequently complex and may still be unknown. In order to obtain the required proof, it was first necessary to construct a simple basic model for the prediction of job-related diseases similar to that designed by Robert Koch for infectious diseases.

3.2. Models

Koch's model for predicting infectious diseases postulates that a person will become ill when the three basic variables — host, agent and environment — coincide in both time and place under specific conditions. The host would be the person and the agent could, for example, be lead, tobacco smoke or psychosocial factors. Environmental factors bring the host and the agent together and disease results.

In the case of chronic diseases, however, there will not normally be a single causal agent but rather a variety of factors, some of which could be interrelated with the environment.

Although existing knowledge on the etiology of individual job-related diseases is in many cases fairly sketchy, it can be assumed that e.g. time pressure, noise, recurrent dynamic work (undesirable movements or postures, etc.) or static work may initiate a pathological process that subsequently manifests itself as a occupational disease. The multifactorial nature of occupational diseases has prompted several authors to produce models with which to bring together the often-incongruous observations emanating from different sources on these diseases. One general model describing the possible course of the pathological process is outlined below:

The etiology of every occupational disease can be regarded as a classic pathological process consisting of the following elements:

- Causal factors (like job demands and work environment) which may ultimately lead to the emergence of a more or less specific pathological condition.
- In most cases a complex assortment of stimuli influencing the causal factors.
- Reactions of the worker's organism to the stimuli. At a certain point in time these reactions may develop into a manifest disease. Alternatively, the worker may recover or gradually develop resistance to repeated stimuli.

Both the Koch model and the analogous model described above are purely theoretical and there may therefore be problems in applying them in practice. For one thing, occupational diseases may not be the result of a process in which each successive phase can be predicted from the previous one (cf. dynamic modeling with Petri nets in Brauchler and Landau 1991). Second, it is not known in detail how the reparative processes function. Third, the causal relationships between the various factors are unknown.

Causal relationships between occupational stress and job-related diseases may either be dose-related or function on an all-or-nothing basis. Dose-related situations probably apply, for example, in most cases where physical or chemical risk factors are present; the all-or-nothing relationship, for example, in allergies. Only rarely do these causal relationships involve a single factor and one can therefore normally assume that the pathogenesis will be multifactorial. The individual factors can interact in a variety of ways and this again demonstrates the complexity of the problem:

- The causal factors can form a chain with either a fixed or a variable sequence.
- The factors can have an additive or a multiplicative (mutually potentiating) effect.
- A single factor may be insufficient to trigger a reaction on its own; specific combinations may have to be present.
- The individual factors may be pathogenic independently of each other, i.e. the same illness may be caused by several variables.
- The same factor may cause different illnesses.

Where several factors are present, the effect may correspond to the sum of these factors (the additive model), but could also be substantially higher as a result of synergy between the factors (the multiplicative model).

The Enderlein and Heuchert model is an example of the analogous model outlined above and is generally used for the planning and evaluation of analytical epidemiological studies. This model assumes the cause–effect relationship from first exposure to the stimuli until the emergence of the disease to be a fact. To determine the exact effect of exposure to the stimuli, each individual factor capable of causing the disease needs to be taken into consideration. These pathogenic factors are classified into three categories: effect-modifiers, non-confounders and confounders. The confounders distort the pathogenic process by correlating directly with the occupational exposure, e.g. reception of visual information from VDU screens at work followed by several hours of TV at home in the evening. In cases where there is no interaction between the confounder and the occupational exposure, the confounder effect can be eliminated mathematically. Effect-modifiers invariably interact with the exposure. A frequently recurring effect-modifier is, for example, a person's age. In cases where this is relevant, age-specific data

are needed to estimate the effect of the exposure. Finally, there are the non-confounders which do not directly correlate with the exposure but do increase the number of random variables and thus make it necessary to increase the number of spot checks.

4. EPIDEMIOLOGICAL EXPERT SYSTEMS

4.1. Relationship between Stress and Occupational Disease

For the purposes of predicting job-related health risk on the basis of data obtained from job analyses, the stress–strain concept postulated by Rohmert can be expanded to cover general lifestyle e.g. diet, habits, drugs, etc., and also the worker's social situation and general attitudes, i.e. redefinition of lifestyle and social situation. However, the concept needed to be dynamized to make allowance for the high degree of mobility between occupations and workplaces during the course of a person's working life and a system for determining stresses arising at both existing and previous workplaces had to be developed. In short, a model had to be designed in such a way that it could demonstrate the hypothetical association between job demands and occupational disease. It had to take account of:

- the current situation in the person's working and private life;
- the external factors influencing the worker both as a person and an employee (objective influences). These include the stresses arising from job demands and from the work environment, and also stress factors from the worker's private sphere, i.e. non-job-related;
- the worker's redefinition of the job situation. This will be strongly influenced by lifestyle (e.g. diet and habits) and social situation (attainments, aptitudes, skills and ability); and
- the need for dynamization of the model to take into account situations that have applied in the worker's previous professional career and private life.

The use of this type of multi-causal model to prove the hypothetical relationship between those determinants of the job demands causing stresses, strains and ultimately disease, and thus to predict job-related diseases is discussed in greater detail in publications by Brauchler (cf. Brauchler and Landau 1989, 1991,

1992, 1998, Brauchler *et al.* 1990, Landau and Brauchler 1994) (Figure 3).

The above diagram demonstrates clearly that complex calculations and simulation data will be required to relate clinical findings to the potentially relevant causal factors.

4.2. Instruments

The theoretical model now created for establishing causal relationships in occupational diseases and discussed here will, in conjunction with an appropriate indicator system which already exists in prototype form, provide information on industrial micro-epidemiology. The indicator system uses two highly standardized instruments that have been developed for the evaluation of the relevant data collected by industrial medical specialists and work analysts.

The first is a questionnaire for the objective assessment of stresses resulting from job demands. This uses an analytical approach (e.g. the AET method reviewed in this volume).

The second is a standardized questionnaire used for assessment of the worker's health status, habits and social situation at medical checkups. It contains 250 items covering clinical findings, diagnoses and laboratory results, plus sections for recording the worker's job history and stresses experienced in previous jobs and family and social history. The object of this examination is to minimize residual variances in the correlation between the health data and the job stresses.

The data obtained with these questionnaires make it possible to predict health risks with quantifiable accuracy. A database system named Epidemiological and Stress Estimation System ESES for compiling and analyzing this data has been designed and a special evaluation system using profile and cluster analysis, contingency analysis, multi-field panels and cross-cluster analysis (i.e. analyses of results from different, independently evaluated cluster analyses, for example, stress or disease clusters) has been developed (cf. Brauchler and Landau 1994).

The possibility of using stochastic procedures and the network theory has also been examined and the limitations thereby involved have been determined. These examinations have revealed that only rule-induction algorithms derived from knowledge-based systems are suitable for the creation of a prophylactic industrial health system that takes account of both multi-causality and retrospective aspects.

4.3. Prediction of Occupational Diseases

4.3.1. *Algorithm for determining causal relationship*
The use of an epidemiological early warning system for the prediction of job-related or occupational diseases will involve decisions based on theoretical evaluations and the use of established prophylactic methods to simulate the collection and evaluation of empirical data which normally takes place during ongoing routine medical examinations of workers in high-risk jobs. Expert systems are structured to handle problems by processing available data through appropriate algorithms to identify a strategy for prevention of the problem.

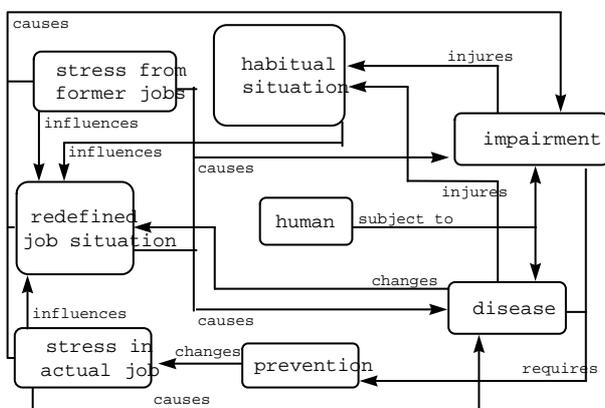
Algorithm-based systems process the potentially pathogenic factors involved in a given job and draw logical conclusions from their knowledge base The prediction system is object-oriented and the conclusions are drawn in the system's second step and based on the assessment of incidence of specific


Figure 3. Possible relationship between stress and occupational disease.

diseases in analogous cases stored in the database. In cases where this predicts a potential health risk, a prophylactic strategy can be deduced from the information in the database. In cases where the there are sufficient similarities with previous cases on which data is available, it is also possible to predict the percentage probability with which a person starting work in a given job will contract a specific disease.

This method will only function correctly if two conditions are fulfilled. First, a detailed, standardized analysis of the case must be carried out. Second, an extensive data bank containing the results of previous investigations must be available for purposes of comparison. The prediction system discussed here fulfils both these conditions.

4.3.2. The ESES-prototype-system

Confirming to the model and the instrument shown in Sections 3.3 and 4.2 two data records (estimated stresses in the job and occupational health data) are linked in the ESES (Brauchler and Landau 1992). When predicting potential health risks in a given case, the user of the ESES-prototype-system will first select a disease, then retrieve the information on the causal factors stored in the database and finally obtain a statement of the potential risk in accordance with the following formula:

> *If* these specific causal factors are present, *then* stress X occurring with intensity Y will cause this disease with a percentage probability of Z.

The method establishes a meaningful link between stress data and clinical data and makes it possible to construct an epidemiological expert system which, in turn, facilitates the design and introduction of preventive measures. In larger companies this can be the responsibility of an expert committee of industrial medical specialists, work analysts, ergonomists and safety officers. In smaller companies lacking the necessary qualified personnel and expert knowledge, employee groups can be formed. The nucleus of an expert system is the knowledge base consisting of facts and rules. In accordance with the basic algorithm, a rule stating that performance of a given job for > 10 years increases the health risk is formulated as a pattern-driven system as follows:

> If << work duration > 10 >> then << health risk (person) = increased >>.

There are two possible ways of creating a knowledge base. The direct or inductive method is by the induction of rules. The authors and designers of the system described here gained experience of this method (Landau and Brauchler 1994) when using the ID3 algorithm to create a knowledge base in which rules are induced from available stress and clinical data.

The second or indirect method of creating a knowledge base can be based on:

- working hypotheses derived from the literature;
- the results of statistical evaluations of stress and clinical data; and
- medical precedents.

To ensure that all available data is used for assessment purposes, a comprehensive knowledge base must include data obtained by this second method.

The data contained in object-oriented systems is stored in the form of large numbers of object–slot–value triplets. The objects, i.e. in this case the test persons from the investigations,

are linked with the type and intensity of the potential pathogenic factors to which they are exposed. The links are established either by rule induction or from one of the three sources listed above under the indirect method.

The knowledge base that can be accessed by the user is built up from available case data, which is stored in another database. In the creation of this database special care is taken to ensure that it is kept dynamic by the addition on new case data and the correction of any errors in existing data.

Data on new cases, i.e. workers who are being checked for potential health risks, are input into the system and compared with the existing case database. The user first classifies the person's present and former stress situation on the basis of the stress and clinical data from the questionnaires described above and with the relevant parts of the epidemiological expert system. The system has appropriate menus for this classification procedure. The input data are then transformed automatically (lack of space makes it impossible to give more details of the transformation procedure here) and the system then calculates the incidence rates for specific diseases. The predictions are presented in the form of percentage probability rates for certain diseases and is supplemented by recommendations for preventive action which may range from redesign of the workplace environment to transfer of the worker another workplace.

It is also possible to use fuzzy set logic in knowledge-based systems to predict associations between stresses and diseases with quantifiable accuracy. Experience with this method is at present meager. Further investigations are necessary before any meaningful conclusions can be drawn.

5. CONCLUSIONS

The main objective of applied ergonomics and preventive medicine in industry is the early identification of job-related deterioration in a worker's condition before serious health damage occurs, and thereby the minimization of the human and social costs caused by degenerative diseases and the resulting disabilities. It is essential to collect all available data on potential health risks at the workplace and to evaluate these to produce a database that can be used to supply answers to ergonomic, technical and epidemiological questions.

Future studies carried out in industry should avoid the error of focusing primarily on achieving maximum cost-effectiveness in the evaluation and interpretation of occupational health and stress data, e.g. by limiting the volume of data collected, and should preferably aim to concentrate more on the multicausality of job-related diseases and on the collection of retrospective data on their causes. This will inevitably involve the use of cost-intensive expert system techniques.

Legal Considerations for the Human Factors Specialist

G. A. Peters

Peters & Peters, 2001 Wilshire Blvd, Santa Monica, CA 90403-5664, USA

1. INTRODUCTION

The human factors specialist is a very likely candidate for some personal involvement with the legal system. It may be rather indirect, such as helping a company lawyer in answering written Interrogatories or Requests to Produce regarding human factors issues raised in a lawsuit. It may be as a company percipient (personal knowledge) witness who has to testify, under oath, at a Deposition or during Trial as to certain factual matters. It could be to assist (inform) lawyers in a lawsuit regarding human factors (liability mitigation), to recommend how to reduce existing human error or fault (liability correction), or to help develop a proposed human factors program within a company (liability prevention). However, the interaction with the law may be more direct and immediate either as a defendant in a lawsuit or when engaging in forensic activities such as that of an expert witness.

2. PERSPECTIVES AND APPROACHES

A proactive or early acquaintance with the legal process is an imperative for several reasons First, learning to understand and deal constructively with unfamiliar legal processes is best accomplished in a calm deliberate manner, whereas attempts at last-minute quick learning, under high stress and personal fear, can result in unintentional mistakes or a simple failure to comprehend the "big picture" and react appropriately to legal proceedings. Second, the old maxim "ignorance of the law is no excuse" has a special legal reality when such personal ignorance results in improper decisions, harmful actions and unnecessary mistakes (such illegal acts are known as errors and omissions). Third, there is a need to translate existing and future legal requirements into engineering specifications, appropriate research protocols and necessary "scientific" data (foundation) that could justify design decisions, technical conclusions and professional opinions. In essence, it is necessary to develop a fundamental understanding of the law so that it can be quickly enhanced when needed.

The *common* (judge made) *law* is based on some fairly universal basic principles whether applied at the community or local, state or provincial, national or international level. Its application is at the professional level involving discretionary or flexible decision-making. Thus, the "worst case" situation should be formulated for use by human factors specialists. The *regulatory, statute, or legislatively derived law* involves a "compliance" or purely technical (non-discretionary) approach in application. However, with increasing world trade and international harmonization of standards, the mere compliance with domestic regulations may not be sufficient. An attempt should be made to comply with the human factors requirements of all relevant, commonly accepted, and appropriate international standards, regulations, and statutes. Thus, a "best universal compliance" approach can help avoid legal complications (minimize legal exposure) for products, systems and services in the immediate future. For example, if there should be prospective legal fault (liability) for an unsafe design, the human factors specialist should determine the best approach to achieve and assure the highest practical level of safety without degradation by controllable human factors deficiencies (Peters 1996a, b, 1997).

3. BASIC CONCEPTS

The concept of *negligence* is central to most legal systems. Fault must be proven before there can be damage (legal redress). In general, negligence is defined as the failure to exercise ordinary or reasonable care, the kind of "due care" which persons of ordinary prudence would use to avoid injury to themselves and others. The exact words of the definition varies from one jurisdiction to another, but is usually read to the jurors by the judge, based on some form of judicially approved Jury Instructions or Charges (in essence, the operative law of the case). The mission of the jurors is to apply the law, as given to them by the judge, to the facts and circumstances of the case (the proof or evidence that has been presented to them).

The defenses to the negligence allegation (absence of due care) include contributory negligence and assumption of the risk. *Contributory negligence* is the kind of fault on the part of the plaintiff that contributes to the causation of the injury-producing event. It may bar or reduce liability. *Comparative negligence* involves the allocation of fault (often by percentage) to each party or all persons involved in causation. The more recent *pure comparative negligence* provides for the allocation of fault, then the assessment of damages in accordance with the degree of fault for all actors (parties and non-parties to the lawsuit). *Assumption of risk* may also bar or reduce liability (fault); however, the risk assumed by the plaintiff usually must be specific (not general) and voluntarily assumed (not coerced). A defense to a violation of a statute, regulation or standard is a good faith *compliance* (evidence of due care), whereas a relevant *violation* may be a rebuttable presumption of negligence (that is, something that must be refuted to avoid a finding of negligence or fault).

Strict liability is based on the allegation that a failure was caused by a "defect" that resulted in personal injury or property damage. A defect may be defined as "excessive preventable risk," a failure to meet "reasonable consumer expectations" or a similar criteria. There may be a new requirement for an *alternative design* that is economically and technically viable, does not introduce some new unacceptable risk and was known, knowable or available at the time of manufacture of the product. Strict liability was intended as a simplification of the proof necessary to sustain a negligence allegation, but in some jurisdictions it may have regressed to closely match traditional negligence causes of action. A *warranty* allegation may be made, where appropriate, or a claim of intentional or negligent *misrepresentation* (where there has been reliance and harm). In fact, there are many possible "causes of action" that are described in various legal publications or can be elaborated by attorneys at law based on their personal experience.

Engineering malpractice (professional liability, errors and omissions, or personal liability) is generally founded in negligence law (absence of due care). The human factors specialist may be personally named as a defendant if the "error" occurred during private practice. If the specialist was corporate employee there

may be legal protection (insulation from lawsuits) so that only the company is a named defendant. This is important as to insurance coverage. However, even though legally protected, bad practice or improper conduct may still have moral or ethical consequences and should be avoided by the exercise of due care. Avoidance is best practiced by the informed professional.

A key concept is *foreseeability*, which means whether the harm could have been predicted, was known or could have been known. The harm might be personal injury, property damage or some environmental problem. This is similar to predictions made in a failure mode and effect analysis, fault tree analysis, risk assessment or task analysis performed as part of the design process and that are relevant to the manufacture, transport, sale, use and disposal of the product, process, system or service. This serves to encourage efforts to identify and prevent defects, discrepancies and unsafe conditions by reasonable risk reduction efforts. *Reasonable* is a frequent and important modifier of legal concepts. Increasingly, formal risk assessment procedures (that include human factors) are detailed in trade practices and international standards.

4. RESIDUAL RISK

During the design process, a conscientious attempt should be made to eliminate all hazards and their associated risks of harm. Rather than rely upon just the subjective judgment of one engineer or department as to what constitutes a safe design, certain analytic techniques, design reviews and system testing may be prescribed. Hazard prevention is paramount, but situations may occur that require supplemental safety devices or the implementation of enforceable safety oriented procedures. In addition, there may be some level of risk that is deemed tolerable or acceptable. This *residual risk* generally requires the use of warnings, instructions and technical communications to alert, inform, minimize or safeguard against avoidable harm to the ultimate user (target of the warnings or possible victim of the hazard). The most common warnings are those found on the labels and packaging of products, material safety data sheets, insertions in owner's or operator's manuals, training instructions, and post sale letters, advisories, recalls and advertisements intended to reach and inform owners and users. It also includes visual and auditory displays, machine or process status indicators, emergency alarms and computer-generated troubleshooting instructions.

These attempts to control residual risk should be the result of a detailed engineering effort, appropriate human factors analyses and testing to determine their effectiveness. The legal issue is often whether proof exists that appropriate warnings and instructions would have significantly influenced relevant user behavior. If they fail to communicate the intended message they are functionally useless. Would proper instructions have increased the use of protective equipment, helped in the choice of accessory or optional safety devices or given a reasonable choice as to risk avoidance behavior? There is considerable scientific, engineering and legal information regarding the design and utilization of warnings and instructions (Peters and Peters 1999).

5. OPINION TESTING

When human factors specialists act as *expert witnesses* they are forced to function within a set of arbitrary rules, a subculture and a value complex of the court system. The conditional and qualified conclusions of an experimental research scientist may be inappropriate in such a system, where "scientific certainty" may be based on only a "more likely than not" criterion for expert opinions and conclusions. The term "reliable," as applied to evidence, may mean simply a credible basis or factual foundation for an opinion. The term "scientific" is generally very broadly defined under the law.

In the past, an expert witness was only someone who seemed able to help the trier-of-fact (judge or jury) reach a better-informed decision (verdict) by providing specialized evidence (testimony and exhibits). The judge determined whether the prospective expert was "qualified" based on credentials and relevant experience. This "gatekeeper" role has been expanded recently to include a focus on "methodology" as well as basic qualification. The trial judge may consider a variety of factors, as to the necessary foundation or reliability of an area of testimony, including peer acceptance, publications, testability and error rates. In other words, just how speculative or believable is the proffered testimony? It is important that jurors' reliance on the testimony can be justified. While this is usually the subject of cross-examination, the trial judge has been given greater responsibility as a gatekeeper to keep out testimony that lacks proper foundation.

The opinions of the human factors expert may be the result of a comparison with some commonly used criterion, the result of a balancing procedure or the result of reference to other information. In the courtroom, the testimony may be that a human error should be categorized as "foreseeable" and an "excessive preventable danger." However, there are some 30 different criteria utilized, specified or recommended throughout the world. Thus, the criterion might be a "reasonable certainty of no harm," the "best practicable means," etc. Common balancing criteria include "cost-benefit," "risk-benefit," and "risk-utility" analyses. In some countries, evaluations may be made in terms of "quality of life for the individual" and "universal design" for all people, all cultures, and all reasonably foreseeable situations. An example might be whether a warning or instruction is "adequate," when a readability test shows it to be at the college level and a review of the work force, to whom the warning is targeted, is it at or below the 6th grade reading level (Peters and Peters 1999).

6. SUBJECT–MATTER HARMONIZATION

Human factors expert testimony does not stand alone. Generally it is interpreted in the context of other testimony from different disciplines or activities. Similarly, in a company design context there are different academic disciplines, terminology and general knowledge being utilized. The effectiveness of the human factors expert, engineer or specialist depends on whether there has been sufficient harmonization as to the general factual context of the situation, the body of commonly used pre-existing knowledge, and the language (terminology) used for communication in the arena being used for the presentation of human factors knowledge.

There is a remarkable amount of highly specialized information available as background context or general subject-matter content, much of it is written by human factors specialists. There are books on slip and fall, driver vision and perception, alcohol and drug impairment, forensic aspects of highway safety, warnings and instructions, traffic control devices and accident

reconstruction for automobiles, trucks, bicycles, motorcycles, boats, snowmobiles, aircraft, trains, construction equipment and pedestrian accidents. There are company manuals for design, manufacture and testing. There are numerous trade publications and an unbelievable number of standards (including many that focus on human factors). These are a very efficient and low cost means for the rapid acquisition of background information and very helpful in the harmonization process (Peters and Peters 1984–93).

There are less widely used information sources, such as the neuropsychological assessment tests such as the Halstead–Reitan Battery, diagnostic criteria (DSM-IV) and trauma symptom checklists that may augment, supplement or help to explain the human factors testimony, report or communication. Similarly, socio-technical evaluations may be made of local cultures for jury selection and improved advocacy communication. These may be available from other expert witnesses or document files. However, the prime source of specific information for the human factors specialist should be from the experiment-based data, conclusions, principles and information contained in peer-accepted periodicals, transactions and books. An important caveat

is that the trial lawyer, plaintiff or defense may have access to such information to utilize during cross-examination for one purpose or another, so be prepared to some degree. In other words, an attempt should be made to translate the human factors or other information into a context that is acceptable and understandable to the target audience. Subject-matter harmonization may be the key to credibility.

Low-cost Ergonomics Improvements

T. Kawakami

Institute for Science of Labour, 2-8-14, Sugao, Miyammae-ku, Kawasaki, Kanagawa 213, Japan

1. MOMENTUM OF THE LOW-COST IMPROVEMENT

Ergonomic improvements are sustaining and growing action in the place where people are at work. How to support the peoples' improvement initiative is the real agenda for ergonomics. Ergonomic improvements, which can be done at low-cost, have been playing vital roles to strengthen such peoples' improvement initiative in different countries and regions (Kogi *et al*. 1988). Low-cost improvement actions mobilize self-help efforts of workers and managers and cultivate sustaining and growing action. This is why low-cost improvements are essential in ergonomics. Visible achievements are always strong drive force for accelerating the further improvement action.

Cost constraints on upgrading ergonomic standard are commonly seen in many workplaces in different countries. Often important ergonomic improvement ideas are blocked by lack of financial initiative. Low-cost improvements have provided the way to break such cost barriers. Many ways to upgrade the working conditions in various ergonomic areas at low-cost have been paved and contributed to stepping up the existing ergonomic conditions in various workplaces. Even in large-sized enterprises having better financial background, low-cost improvements have been a key issue for increasing the workplace initiative for sustaining action.

2. WORK IMPROVEMENT IN SMALL ENTERPRISES (WISE) PROJECT IN THE PHILIPPINES AND THE ROLES OF LOW-COST IMPROVEMENT STRATEGY

Low-cost improvement strategy played fundamental roles in the Work Improvement in Small Enterprises (WISE) project in the Philippines from 1994 to 1996. The WISE project, technically assisted by the International Labour Organization (ILO) and financially supported by the UN Development Programme (UNDP), was aimed at joint improvements of working conditions and productivity in Philippine small enterprises (Batino 1997). Special emphasis was placed on building on local practice and focusing on existing achievements at low-cost in the Philippine workplaces. WISE identified nine priority technical areas for the improvement including: (1) materials storage and handling, (2) work-station design, (3) productive machine safety, (4) control of hazardous substances, (5) lighting, (6) premises, (7) welfare facilities, (8) work organization and (9) environmental protection. During the 3-year project periods of WISE, 2060 action ideas were proposed by the owners and workers in the participating small enterprises and as high as 1724 proposals (83.7%) were actually implemented at low-cost. Among the nine technical areas, 364 improvements were in materials storage and handling while 134 in workstation design. Ergonomics improve-

ments were the priority area for upgrading the working conditions and productivity.

Typical low-cost improvements carried out in WISE were:
- In "materials storage and handling," introduction of push carts, mobile racks, clear and marked passageways, even floors, multi-level shelves for storage, materials containers, hoists and conveyors
- In "work-station designs," adjusted work height, foot platforms and work item holders, placing frequently used tools and materials within easy reach of workers, jigs and fixtures for holding items, hanging tools and fixed tools, "home" for each tool, chairs of correct height with a sturdy backrest.
- In "productive machine safety," safety guards to moving parts, feeders, labels and signs, regular machine maintenance, clearly visible and easily reached emergency controls.
- In "control of hazardous substances," using safer substituting materials, decreasing the amount of hazardous substances in use, isolation of dust, chemicals, noise or heat out of the workplace, installing screens or partitions to reduce the harmful effects of dust, chemicals, noise or heat, providing workers with safety information of hazardous substances in use.
- In "lighting," maximal use of skylights, painting ceilings and walls in light color, local task lights, elimination of direct glare.
- In "premises," labels for chemical containers, covered containers for organic solvents, paints and glues, increased natural ventilation by having more openings, heat protection of the factory building, appropriate use of personal protective equipment, local exhaust ventilation, safe wiring connectors, fire extinguishers, emergency exits.
- In "welfare facilities," cool and safe drinking water, toilets designated separately for men and women, washing facilities, resting corners, hygienic place for eating meals, first-aid equipment, recreation and game facilities.
- In "work organization," job rotation to avoid monotonous and repetitive nature of work, buffer stock for allowing self-paced work, layout rearrangement for smoother flow of work between different work-stations, insertion of frequent short breaks.
- In "environmental protection," installing a gauge to water valve for saving, decreased amount of chemicals used, reuse or recycling of waste materials.

It was noteworthy that low-cost improvement actions carried out in WISE encouraged the workplace people to mobilize all available materials and skills for ergonomic changes. For example, drum cans and materials containers were made into pushcarts for moving heavy materials. Waste steel bars and wood pieces were used for establishing storage shelves or canteen tables. It was possible for many workers and factory owners to contribute to generating such improvement action by using their skills like carpenter's or welder's. Their practical experiences for developing tangible outputs in upgrading their own working conditions at low-cost have apparently enhanced their sense of participation and increased confidence of sustaining their action. Subsequent follow-up studies showed evidence that low-cost improvements carried out by the local people provided ergonomic benefits such as reduction of local muscular loads, decreased heart

rates during the work and shortened production time (Kawakami and Batino 1998).

3. EXTENSION OF THE LOW-COST IMPROVEMENT STRATEGY

In Thailand, the low-cost improvement programs learning from WISE have frequently been applied. The Occupational Health Training and Demonstration Center belonging to the Thai Ministry of Public Health trained managers and workers in four small enterprises in Samut Prakarn province in the south to Bangkok as a pilot intervention program (Tandhanskul *et al.* 1994). Practical training tools such as action checklists, slides showing local good examples and group work dynamics were used for the training. The follow-up visits to the participating factories after the training counted 63 improvements in multiple technical areas. It was noted that 22 improvements were carried out at no cost and another 23 cost < US$20. Budget limitation was not an absolute barrier for upgrading their working conditions. After confirming the visible benefits by low-cost ergonomic solutions, budget allocation for installing more expensive facilities for upgrading working conditions were facilitated in the participating small enterprises. The Thai Ministry of Public Health has been applying this ergonomic low-cost improvement program to other provinces and increasing the coverage.

The low-cost improvement approaches have been applied to the agricultural sector in Vietnam (Khai *et al.* 1996). Learning from local good examples and applying an action checklist, a variety of the improvement in agricultural working conditions have been attained. This program was named as the Work Improvement in Neighbourhood Improvement (WIND). The WIND program had two unique features. First, WIND is aimed at the application of ergonomic principles for the joint improvements in both living and working conditions. Second, WIND encouraged equal participation of male and female farmers to the improvement action. A follow-up study confirmed 88 improvements by the 20 pairs of husbands and wives who had participated in the pilot training course. The areas of the improvements implemented were: ergonomic kitchen and eating facilities; safe drinking water and sanitary facilities; improvements in work and housing environment; home economy planning and income generation; transporting agricultural product and child care. Among the 88 improvements, 20 could be done at no cost and another 37 < US$10. Ergonomic improvements such as changing methods of carrying heavy agricultural products, or newly designed kitchen facilities with appropriate height could be implemented in collaboration of men and women. It was confirmed that multi-faceted improvements relating to both living and working conditions in the agricultural sector in developing countries were possible using inexpensive, available local resources.

The low-cost improvement strategy have been breaking the cost barrier and facilitated continuing improvement action in industrially developed countries such as Japan as well as industrially developing countries. Large-scale enterprises having better financial sources have also experienced that the low-cost solutions could promote the active shop-floor participation and initiate growing ergonomic improvement action. The common steps taken in the low-cost improvement strategy consist of:

- learning from existing wise solutions and ready-to-use information;
- performing a walk-through survey with an action checklist for identifying feasible low-cost improvement options;
- organizing group discussion for proposing workable improvement ideas and increasing the sense of participation of all people in the workplace;
- finding the low-cost ways for stepping up the existing conditions first rather than aiming at complete solutions;
- implementing improvements by mobilizing available local resources and skills and confirming the improvement benefits; and
- sustaining and increasing participatory actions by regular walk-through and other practical activities.

4. CONCLUSION

The low-cost improvement strategy has provided local workplaces in different countries with large opportunities of participation and motivation. Application of sophisticated ergonomic risk-assessment methods needs experts and equipment. The sophisticated methods are useful for the improvement, but not always available for many local workplaces in different countries and regions. Conventional expert-centered ergonomic approaches have produced valuable recommendation for upgrading their working conditions, but they do not necessarily increase the initiative of the local workplace people. The low-cost improvement strategies apparently have an advantage for supporting locally growing improvement initiative. The sophisticated ergonomic improvements using expert-centered high technology would powerfully contribute to the ergonomic improvement when the low-cost strategy enhanced the dynamic improvement initiative of the local workplace people. It should be noted that the low-cost improvements relying on the local wisdom and initiative are never the second class improvements but the first priority decision for going beyond the existing standards to meet the people's changing needs.

Management Perspectives for Workplace Ergonomics

C. F. Dillon

University of Connecticut School of Medicine, USA

1. INTRODUCTION

Ergonomics is the examination of human characteristics and abilities as they impact the design of equipment and jobs. Applied ergonomics aims to improve workplace efficiency, safety and well being. Management is the art of utilizing all available resources to accomplish a given set of production tasks in a timely and economical manner. This article provides an overview and perspectives on management roles in implementing workplace ergonomics programs. Business rationales and need for workplace ergonomics programs, and strategies pertinent to implementation are discussed from a management perspective.

2. GUIDING CONCEPTS AND ISSUES

2.1. The Spectrum of Workplace Injury

Historically workplace injury and safety concerns focused on acute injury, that is, injuries happening suddenly, and with a single obvious cause — for example, accidents from slips and falls, or overt physical trauma resulting from unsafe equipment. Adequate attention to such an obvious problem area came only over an extended time period. The development of scientific ergonomics, and the recognition of "cumulative trauma disorders" or chronically developing workplace musculoskeletal injuries attributable to multifactorial causes provides a more comprehensive perspective of the overall impact of the everyday configuration of working conditions, but, from a management point of view, seemingly adds a new layer of complexity to an already difficult situation. The reality, however is that both acute and chronically developing injuries have always characterized the working environment.

There are existing examples of excellence in corporate safety and loss prevention programs, and such industry leaders have generally experienced less difficulty in integrating the newer ergonomic concepts and technologies into their ongoing work process. Even at this late date, however, the implementation of site specific comprehensive company safety programs to address practical safety concerns relating to acute injury is far from uniform. For companies without a tradition of organized workplace safety efforts, the useful assimilation of ergonomic technology and perspectives to deal with chronically developing musculoskeletal injuries is at best problematic.

The existence of a broader spectrum of workplace injury is unwelcome news and it is understandably difficult for some business managers to accept. Skepticism has been fueled by a public and sometimes very partisan debate about the nature and extent of the problem both within business and public sector and in scientific circles. Business managers should know, however, that the essence of science is critical thinking and debate. On any specific issue, a diversity of opinion typically exists, and it is the overall balance of evidence from multiple studies that should be routinely employed as a benchmark. Current expert scientific consensus (National Research Council 1998) validates a wider view of the spectrum of both acute and chronically developing workplace injury. Further, both workplace and population-based surveys typically indicate that the prevalence of workplace injury is much larger than that ever reported to existing workers' compensation systems by at least an order of magnitude (Morse *et al.* 1998).

For the typical company, therefore, a large pool of individuals with work-related injury typically exists, and only a small portion of this is evident as reported workers' compensation claims. An obvious management fear is that to address such a situation properly, an expanded scope of spending for workers' compensation claims will be required, an unwelcome additional allocation of already scarce economic resources. This is not a new problem in the workplace, however, and the salient question to ask is how the costs associated with this wider spectrum of workplace injury is currently being paid by companies and their employees. The answer, in the typical case, is that there is substantial cost shifting to private medical insurance or other available benefit programs, and to the employee's own economic resources. Indirect costs associated with such injuries are difficult to determine, but are estimated at two to ten times the direct costs paid by workers' compensation.

A company's economic burden that may be engendered by the presence of adverse acute and chronic ergonomic hazards probably includes important contributions to such non-medically-related outcomes as increased absenteeism, rates of personal illness, employee turnover, and decrements in employee morale commitment and productivity. Although the magnitude of problems varies by company, such ergonomic-related factors appear to be widely pervasive in industry: at issue for each management team is whether there is value in rethinking the current system, and whether a more organized management approach based on ergonomic technology integration would be a more effective approach to deal with problems that may exist.

2.2 Historical and Traditional Ergonomic Views

In the early twentieth century, physical workload was a primary concern in the workplace, and the issue of physical fatigue was addressed primarily to increase productivity. Comprehensive motion time studies were wedded to this approach with the aim of creating optimal task organization and efficiency. Historically, general physical workload has been reduced in industry, a process enhanced by mechanization, although notable exceptions to this rule exist to this day. Despite such reductions, musculoskeletal injuries continued to be reported, and it was clear that the then existing injury risk concepts needed revision. Risk assessments made on the basis of whole body exposures were refined to stresses applied to local anatomic areas, and guidelines were further refined. Local estimates of magnitude and duration of local applied forces, postures, repetition rates, and task cycle recovery times were made. An appreciation of the hazards posed by prolonged static posture exposures with selective adaptation of muscle groups developed. These strengthened scientific approaches, while providing improved general understanding; however, with few exceptions, they have not yet provided highly precise guidelines for safe, permissible ergonomic exposure limits comparable, for example, to those currently available for industrial

chemical exposures. In an important sense, ergonomic recommendations, therefore, need to be tailored to the individual case.

2.3   Non–biomechanical Injury Risks

Considerable data has accumulated to indicate that worksite injury risk factors may be broader in scope than the traditionally described physical and biomechanical stresses. There is evidence suggesting that work organizational factors may be pertinent to musculoskeletal injury risk, either as effect modifiers amplifying the effects of purely physical risk factors, as factors that influence the frequency of reporting of workplace injury, or as primary risk factors in and of themselves. This means that a company's work organization and culture, and labor relations issues, will be pertinent to finding solutions for ergonomic problems. Many of such factors are under management control. For example, management controls the pace of production which powerfully influences repetition rates for physical factors. Viewed in this manner, injury resulting from workplace risks may be considered variable costs related to production and sales volumes. Factors such as piecework incentives, limited potential for job rotation, and extensive overtime emerge in many studies as risks for injuries. The possibility that incentives for higher production rates may produce more injuries and other undesirable outcomes, such as an increased rate of defective products and product returns, implies that net productivity is not always synonymous with greater production rates.

Current research indicates that the perceived support of supervisors and co-workers, and employee decision latitude in job performance are all important factors influencing injury rates. Discrepancy between workers and management with respect to their overall assessment of the safety of the workplace is also a very powerful injury risk. Variables consistently associated with lower injury rates in major studies are good working relationships between management and employees, an active role of management in safety programs, lower turnover and higher seniority of the workforce, and company commitment to ongoing safety training incorporating ongoing monitoring of unsafe behaviors and safety audits (Shannon 1998). These types of risk factors are not those associated with traditional engineering solutions to ergonomic problems, but appear to be emerging as powerful predictors of workplace injury. There are important implications for management, especially in the current rapidly changing business environment. For example, in a setting of staff integration in a merger or of planned staff reductions in downsizing, what practical steps can be taken to maintain supervisory and co-worker support systems? Ergonomic factors may have traditionally exerted more subtle influences on the structure of work organizations. For example, current worker seniority systems may have evolved in part as an adaptation to workload, in part functioning to decrease biomechanical exposures on longer-term employees in an organization.

2.4   Applications and the Sufficiency of Ergonomics

Ergonomics has been criticized for not offering pat, definitive solutions to workplace problems. Like all sciences, ergonomics has a body of theory and methodology. While bench lab and engineering research both powerfully contribute to ergonomic theory, ergonomics is, in an important sense, an observational science, meaning that such controlled experimentation is rarely possible in real-life industrial settings. Observational sciences depend on systematic observation of naturally occurring phenomena, and therefore have the handicap that multifactorial situations must be analyzed in toto, without direct control over pertinent causal variables. This is a similar situation to economics, medicine, or even business management. Observational, like experimental, sciences operate by building progressively more adequate explanatory theory; however, all theory, however well documented is considered provisional in the sense that future research is expected to eventually supersede and improve current ones.

Ergonomic theory, as currently developed, represents a powerful available technology, and is rapidly improving. It is currently capable of solving many important problems, though not all the problems one would wish. It will grow still more powerful as time and experience accumulates. Specific business applications of ergonomic theory and technology, however, must be individualized by site, and usually are not superior to the training and experience of those chosen to implement them. Business managers are often concerned about open-ended ergonomic commitments — i.e. they want to know, on a one-time basis, when sufficient attention to ergonomics has been given. If products, production processes, the workforce, and the general business environment were static and ergonomic science fully mature, there might in fact be an ultimate single solution to a company's ergonomic needs. Applied ergonomics, however, is a *process*, and not a fixed goal. Further, it is just one component of a complex, ongoing business process. The appropriate level of a company's attention to ergonomics must be continually rationalized according to an individual company's needs and ongoing local situation assessments, and continued improvements in ergonomic technology.

2.5   The Workers' Compensation Experience

Day-to-day experiences and difficulties with individual workers' compensation injury cases are a compelling reality to managers and businesses. Workers compensation injury management is an important, obligatory focus for management. In the workplace, ergonomics often becomes synonymous with a company's workers' compensation injury experience. As we have seen, this is not altogether true. Ergonomic factors do affect the safety of the workplace, and hence the likelihood of reported injury, but there is good evidence that substantial numbers of work-related injuries are never reported through the workers compensation system. Although they routinely provide important information on prevailing workplace risks, it is also possible that reported injuries may be somewhat unrepresentative of those generally occurring in a production setting, a factor which may introduce bias into plans using workers' compensation injury data to remedy pertinent workplace problems. Also, other important adverse outcomes exist, including employee job dissatisfaction, and effects on absenteeism, personal illness rates, productivity, employee turnover, and production quality problems. Insurance tracking and regulatory scrutiny of industry workers' compensation injury experience, however, in many respects virtually defines the ergonomic debate in both the public and business sectors. Thus, while important information is provided, it can nonetheless be a

narrow and somewhat limited perspective on the overall scope of workplace problems. The workers' compensation experience, however, represents a permanent fixture of the business landscape.

Both government regulators and business ultimately have a similar goal: to reduce workers' compensation injury to a minimum, given current knowledge of ergonomic technology. Government regulators typically perceive workplace injuries as a widespread and pervasive problem, and, based on available research data, feel that industry in the main has been too slow in addressing what is an obvious problem. A central theme is that regulators have used reported workers' compensation injuries to leverage what they see as needed general reform. On the business side, workplace injury is often perceived to be the exception, rather than the rule. Such injuries, and associated workers' compensation reports are often viewed as unpredictable aberrancies arising out of the exigencies of circumstance, with insurance purchased as a remedy for such unpredictable "acts of God". Injuries occurring are seen as somewhat expensive, inconvenient divergences from the everyday production process. There is some suspicion that the very existence of workers' compensation insurance benefits sets up a target for dishonest employees. For individual businesses, the psychological and personnel issues surrounding specific cases is viewed as substantial and a resource drain. An important facet of the business perspective on workers' compensation is that it can be highly individualistic, and thinking on this issue may be heavily influenced by a company's prior experience with individual "high profile" cases. Regulators are generally removed from the daily rigors of the workplace, which can contribute to ideological conflicts with business management. Details of the day-to-day reality of dealing with workers' compensation cases, however meaningful and compelling to business, are less important for regulators who generally hold to a population-based view, where individual experience on average is the principal consideration. From this perspective, the presence of generic, shared ergonomic risks surface as general industry problems to address, and experiences and risks common among injury reports are emphasized.

There are humanitarian and practical necessities to treat workers' compensation injuries when they occur. The frequency of reported injuries may wax and wane, with periodic lulls in reporting tending to reinforce the notion that injuries are the exception rather than the rule. Episodic increases in reported injury rates are dispiriting, especially for responsible managers routinely accustomed to success in other business activities. An intuitive response is to seek improved medical care for those injured. As it currently stands, therefore, the workers compensation injury experience has been heavily medicalized. For many companies, this scenario represents a form of "casualty bias." It should be obvious that medical management of workers' compensation injuries alone, however well perfected, cannot in and of itself be expected to "solve" the workers' compensation problems while pertinent causal workplace risks remain unaddressed. Rather, one must seek to learn from the injury experience, abstracting out lessons that will redress root causes in both the individual and the generic case, and then apply these lessons to production situations generally, so as to prevent future problems from developing, thereby managing the overall level of ergonomic risk. Medical providers treating injured workers must therefore not simply seek to alleviate suffering, but should be routinely expected to provide feedback to employers on the likely biomechanical causes for the observed injuries. The workers' compensation injury experience, therefore, loses substantial value if not coupled with ongoing workplace ergonomic assessments. Managers need to ask themselves with each injury if something new was learned from an ergonomic point of view, that is useful and productive. If this is not the case there is an obvious problem, and difficulties are virtually certain to continue.

3. PLANNING FOR ERGONOMICS

3.1. The Situation Assessment and Ergonomic Management Information Systems

A key question is the relationship, if any, of ergonomics initiatives to company profitability. To understand this question, it is necessary to assess accurately a company's existing current net liabilities, if any, including the scope of both reported and unreported injuries, and estimates of the true costs involved, including workers' compensation and the magnitude of cost shifting to other benefit plans. The magnitude of associated indirect costs should also be estimated. A key management problem, therefore, is to develop a reliable, informative, ongoing "management information" system to provide this ergonomic situation assessment. Traditionally, such situation assessments have been performed using reported workers' compensation data, but, as is already apparent, this results in a somewhat biased underestimate of the typical situation at hand.

The management challenge to develop more reliable ergonomic information systems can be approached in several ways. Businesses typically prefer passive acquisition of data (reviews of existing injury reports and benefits databases) fearing that data collection via active surveys of employees will produce more problems than any information gained may be worth. Planned, active data collection, through selective audits, surveys, or planned surveillance systems, however, is recognized usually to provide a higher quality of information. Naturalistic data collection, for example, by periodic management walk-throughs of plants can also be extremely useful. At a minimum, situations that should typically trigger workplace ergonomic assessments or monitoring include injuries, significant job work process, or task changes, plant equipment refitting, changes in equipment design or the purchase of new equipment, processes or facilities. Ergonomic risk assessments in these typical high risk situations are indicated in order to prevent ergonomic hazards from being inadvertently introduced into the workplace. Follow-up monitoring should be planned to allow feedback control over process and strategy revisions.

3.2. General Economic Perspectives

Conceptually, ergonomics is not a variable expense item in the external business environment, such as the cost of raw materials, that rightfully needs to be managed to the minimum. Nor, despite externally imposed government regulations, does ergonomics represent an external environmental force over which companies have little or no control, such as the prevailing economic conditions, or competitive developments within an industry sector. Rather, ergonomic practices are in fact incorporated into a firm's internal level of operating efficiency, which, in business models, typically represents a directly controllable cost. Ergonomic successes and failures are hence already built de facto

into existing production lines and operating budgets. As this has not typically been done in a systematic rationalized way, current company operating budgets may therefore hide inefficiencies which have heretofore eluded proper evaluation. Operative models for ergonomics in business must therefore move away from postures of denial (ergonomics as an external business environmental factor), and beyond the somewhat individualistic workers compensation model (a "write off" of the individual case as an internal overhead expense), towards a view of ergonomics as an integral part of the production and work organizational environment.

An important business consideration is the effect of ergonomic changes made on marginal productivity. In current business rationalization, each factor in production, including ergonomic ones, receives investment in proportion to its contribution to the production process. Given this operational paradigm, it can be seen that ergonomic changes can provide a return on investment, be economically neutral, or in fact represent an economic liability. In an era of increasing production rates and price competition, management fears are that ergonomic initiatives may constitute a threat to production via reduction in marginal profitability, putting a product "at risk," or even jeopardizing the continued existence of a product line. The skill of the management team and workforce, however, largely determines the economic success or failure of workplace ergonomic innovations, as is the case with developments in production capabilities generally. Such potential threats to marginal productivity appear to be poorly appreciated by many regulators, who tend to view corporations from the perspective of their total size and assets, rather than regarding them as decentralized and diversified entities. Often, from the regulatory point of view, marginal productivity theory appears to hold potentially beneficial ergonomic changes hostage to short-term profitability in the local production context.

3.3. Management Formulation of Ergonomic Programs

General guidance for overall conceptualization of management responsibilities in establishing systems for management of workplace musculoskeletal disorders has been provided in the recent peer reviewed ANSI draft consensus standard (ANSI 1996). Policy in the ergonomic area needs to be developed at the senior board level, and strategic planning coordinated with the existing corporate planning cycles. Major planned ergonomic interventions, for example, should be timed to coincide with new capital equipment acquisitions or annual shutdowns for maintenance and retooling. The management group responsible for organizing a company ergonomics strategy should represent a powerful guiding coalition: ideally, it should incorporate both elements of senior and departmental management and establish accountability, identify existing and needed resources, including experienced ergonomic consultants who can benchmark process operations against ergonomic best practices in industry generally and provide new options for the local ergonomic context. Management should further establish operational assignments, work practices, and responsibilities. Training and communications issues are significant: ergonomics issues typically require education to achieve "buy in" by management and

employees. The overall aim is to achieve an ongoing corporate infrastructure to monitor and respond to ergonomic issues.

Senior management roles include concept validation and facilitation of planned programs, including dealing with key blockers or obstacles to process change. While regulatory thinking places total and direct legal responsibility for workplace safety and ergonomics on businesses and their management, the practical business reality is that supervisors and workers on the shop floor have a direct, major day-to-day responsibility for implementation and success of ergonomics programs. These individuals should also participate in on-site planning of specific ergonomic changes by virtue of their practical experience and the necessity to have their "buy in" for any planned innovations to work. The power for success in workplace ergonomic programs is therefore, to a large extent, inherent in the work group itself, and will be affected by the existing climate of labor relations. Management has authority to institute changes in work practices and policies, and can strategize, lead, and furnish improved technologies, but, in the end, does not itself do ergonomics. There is, therefore, an inherent structural discrepancy between legal and actual practical working responsibility for ergonomics improvements. Guidelines are available for the development of worksite ergonomics programs on an operational level (NIOSH 1997).

Key requirements for success of ergonomic programs, therefore, include senior management planning and commitment, experienced ergonomic input, and supervisor and employee participation. Flexibility is necessary as iterative solutions are frequently required before final solutions are discovered. Major initiatives should be piloted before general introduction. Ergonomic plans must be in synchrony with both short- and long-term corporate goals and plans. The financial and production impacts of ergonomic changes should be continuously documented, and any planned interventions should be appropriate to the level of risk determined by prior situation assessments. Long-term maintenance of a coherent ergonomic initiative in a rapidly changing high production environment, with frequent organizational changes, should be considered.

3.4. Ergonomic Benefits and Cost Opportunities

For many companies, ergonomic cost opportunities exist. In situations where ergonomic and safety issues are poorly managed, insurance costs for worker's compensation represent one such opportunity cost. In fact, some workers' compensation insurers seek out high-risk companies with relatively poorly managed ergonomic and safety programs as an obvious opportunity to profit. Insurance ratings are typically held to prevailing, relatively high levels, while structured workplace safety/ergonomic and improved medical interventions are applied. Over a 2–3-year horizon, enterprising insurers can realize up to 50% profit against premiums ratings in a poorly managed situation.

In the realm of purchasing, many companies have found that, as a direct result of ergonomic assessments, specific standard equipment designs are preferable in terms of productivity, employee safety, and comfort. Standardization in purchasing contracts emphasizing ergonomically preferred products can represent a significant cost opportunity and also puts market forces into play as suppliers recognize ergonomic design as a customer-perceived added value in product differentiation. (It

should be recognized, however, that a certain percentage of individuals will predictably fall outside customary workstation design specifications, and will not be well served by this strategy.) When major capital equipment is purchased specifically to reduce musculoskeletal injuries, proper installation and employee training should be assured, and satisfactory warranties obtained, to help assure the equipment performs as expected.

Employee job satisfaction is an important intangible. From the point of view of employees themselves, general working conditions are a significant concern, and a primary factor in motivation, job satisfaction, and turnover. Ergonomic factors, as they may contribute to prevailing working conditions, are potentially of significance. In most major surveys, working conditions, surprisingly, typically rank somewhat above wages as factors of importance to employees. Development of a company's level of ergonomic sophistication relates not only to internal product stewardship, but can also be useful in product development and differentiation in the marketplace; ergonomic features represent value-added enhancements to products. Ergonomic knowledge can also function to reduce a company's consumer liability risks.

4. SUMMARY

Workplace ergonomics is a substantive issue worthy of management attention. Each management team must make its own positive assessments of need based on objective evidence and minimizing the exigencies of the individual workers' compensation case. An impartial perspective is required to develop and maintain the appropriate level of ergonomic sophistication, skills, and resources in a rapidly changing business environment. The scope of ergonomic problems varies by industry, by individual company, and over time. Some level of problems exist generally in industry, with some companies having major difficulties, and others little trouble. In an era of mature, highly competitive markets and shortened product life cycles, a central question for business is whether there exists a profitable basis for ergonomic technology integration. This question needs to be answered in the individual case. Investments are continually being made in this area, either on a planned, rational basis, or in an unplanned, de facto manner. Those making investments on a strategic basis will be more likely to profit from the experience, and are less likely to leave potentially important uncontrolled ergonomic factors operating in the production environment.

Production Standards and Performance Feedback: a Strategy for Improving Worker Productivity and Satisfaction

B. Das

Department of Industrial Engineering, Dalhousie University, Halifax, Nova Scotia, Canada

1. INTRODUCTION

In repetitive production tasks, the improvement of worker productivity and satisfaction is a major concern for management. Such tasks are often considered as monotonous, boring, and fatiguing, and this in turn may have a detrimental effect on worker satisfaction, job attitudes, and absenteeism. Furthermore, there may be adverse consequences on the physical and mental well-being of workers. The nature of such work often results in muscular tiredness due to stressing specific muscles and the concentration needed to perform a task. The application of suitable strategies to improve worker productivity and satisfaction, especially in repetitive industrial tasks, is therefore of the utmost importance.

A goal is a predetermined standard of success and end result. Goal or standard setting is believed to motivate operators in task performance through directing attention, mobilizing energy expenditure, and prolonging effort. The positive effects of goals on worker performance have been well established. Research studies have demonstrated that specific difficult goals lead to higher levels of performance than "do your best" or easy goals (Awdia *et al.* 1996; Locke and Latham 1984; Phillips and Gully 1997). However, some recent studies have indicated that the typical positive effect of specific difficult goal assignment may not hold for the performance of novel complex tasks (Gilliland and Landis 1992.

Feedback affects performance by motivating adjustment to work output, reinforcing response pattern and direction towards goal. It has been found effective in learning situations and in improving an individual's motivation in performance (Wofford and Goodwin 1990). For goal-setting to be effective, feedback is a necessary condition. Studies have shown that goal-setting with feedback is superior to goal-setting or feedback alone (Das 1982a; Erez 1977).

The goals can be either assigned or set participatively with the worker. Research studies have shown inconsistencies regarding the superiority of participative versus assigned goal-setting (Ludwig and Geller 1997). Some studies indicate that participatively set goals lead to better performances than assigned goals (Latham and Yulk 1975; Latham et al. 1978), while others have given the opposite results or effects (Dossett *et al.* 1979; Latham and Steele 1983). Worker participation in decision-making is the primary means of obtaining commitment to productivity and lowering resistance to change (Latham *et al.* 1994).

Worker satisfaction is an emotional reaction in terms of value responses. Both job content and context factors affect worker satisfaction on the job. Research studies on goal-setting have shown that difficult or hard goals generate less satisfaction and overall acceptance of tasks than easy goals, but that specific difficult goals produce more interest and less boredom than "do-your-best" goals (Kim and Hamner 1976). Locke and Latham (1984) showed that although hardest goal tasks produced the highest performance, they also resulted in the lowest degree of worker satisfaction. Performance feedback gives operators information about their actual performance which can be used by them for action. When feedback is present, it often — but not invariably — elicits a positive response that tasks are interesting and less tiring; it has also been found that worker satisfaction can improve significantly when a specific goal is provided with feedback (Das 1982b; Das and Shikdar 1990).

Monetary incentive is believed to have a positive impact on worker satisfaction, although in the laboratory setting there was no apparent effect on worker productivity and satisfaction (Das 1982a, 1982b). Task success also appears to be directly related to worker satisfaction: Hamner and Harnet (1974) found that subjects who exceeded their reference operators' performance were more satisfied that those who did not.

Goal setting and performance feedback are believed to have a positive impact in making the work more challenging and interesting, and less boring, creating more job attention especially in a repetitive production task. In addition, a task performed at an ergonomically designed workstation is likely to be less fatiguing (Das 1987).

In respect of assigned and participative goal-setting, it is generally believed that participation in goal-setting has a positive impact on worker satisfaction, although some studies have reported that satisfaction declined in both assigned and participative goal-setting conditions (Latham *et al.* 1978, Latham and Yulk 1976): Ivancevich (1976) reported that participative goal-setting was not superior to assigned goal-setting in terms of worker satisfaction.

Most of the studies in the past employed simulated or relatively simple tasks and goals were set arbitrarily or based on an operator's past performance; measured standards were not used. Consequently, the question of "how hard is hard" cannot be defined precisely. For the most part, studies dealt with worker performance, and worker satisfaction was seldom considered. Systematic controlled studies have seldom been performed with a repetitive manufacturing task employing measured standards under an ergonomically designed manufacturing work system to determine the effects of goal-setting and performance feedback, singly or jointly, on worker productivity and satisfaction.

In dealing with the production situation, the term "production standard" is often employed rather than "goal setting". The main objective of this article is to discuss the application of production standards, performance feedback, and monetary incentive for the purpose of improving worker productivity and satisfaction in a repetitive production task.

2. EFFECTS OF PRODUCTION STANDARDS AND FEEDBACK, SINGLY OR JOINTLY, ON WORKER PRODUCTIVITY AND SATISFACTION

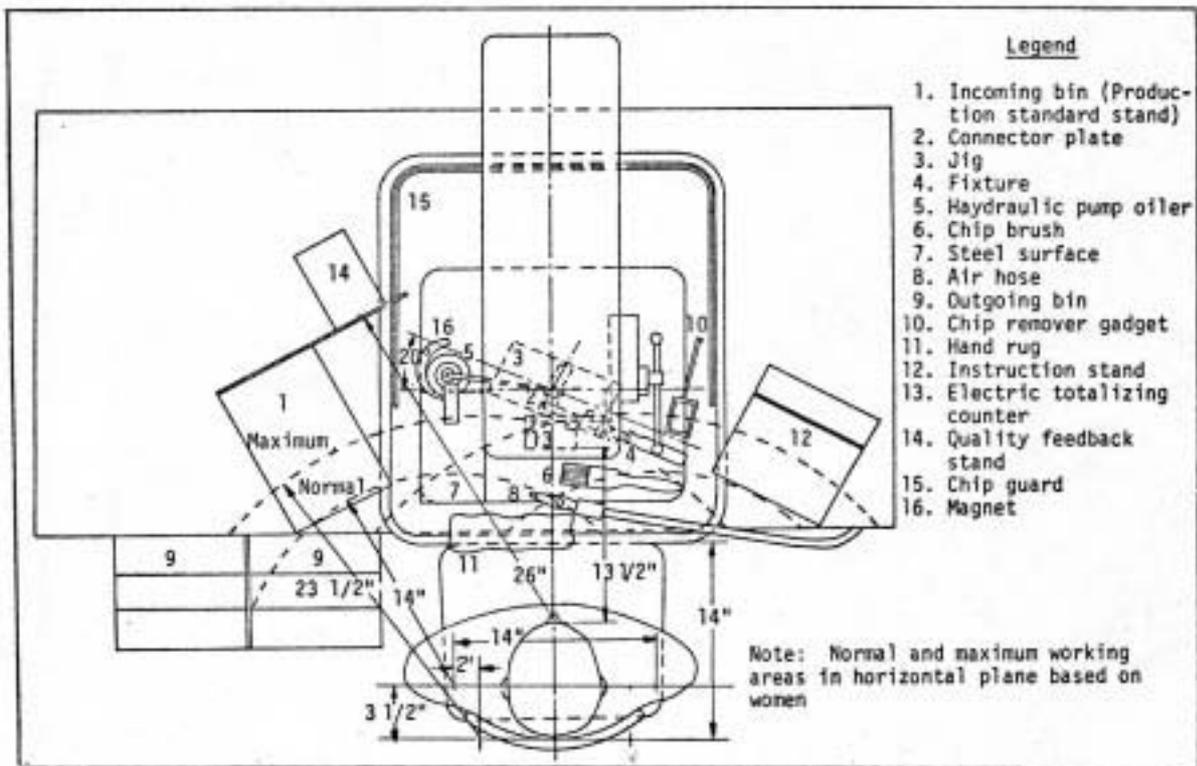
For this study, a drill press operation was chosen to represent a


Figure 1. Workplace layout of drill press operation.

realistic repetitive manufacturing task. The task involved an operator drilling four holes into a previously prepared steel plate while he or she was in a seated position. A power feed drill press with jig and fixture was used to produce connector plates in the Machine Tool Laboratory, North Carolina State University (Figure 1).

The production standards were determined by means of methods–time measurement (MTM). The production/time standard for the operation was 240 holes/hour (100% normal). The percentage of cycle time that was machine controlled was 52%. The hard production standard was determined on the basis that external work elements would be performed at a pace of 130% of normal standard to achieve an overall production standard of 112% of normal or 268 holes/hour. An electric totalizing counter was used to provide quantity feedback and the production quality feedback was presented in terms of percentage of good holes drilled in a unit time. Appropriate ergonomic principles and data were employed to facilitate the design of a manufacturing work system (Das 1987).

The operators (56) were trained individually for one hour in the task performance and asked to perform the same task for another hour under a specific work condition. There were seven groups consisting of eight participants in each group. The seven groups were subjected to the following work conditions dealing with production standard (PS) and production feedback (PF):

(1) No PS/PF (Control)
(2) PS: 100% normal
(3) PS: 130% normal
(4) PF: Quantity
(5) PF: Quantity and quality
(6) PS: 130% normal + PF: Quantity and quality

(7) PS: 130% normal + PF: Quantity and quality + Monetary Incentive (MI): 1:1, piece rate.

Worker productivity was determined in terms of production quality (number of holes) and quality (number of good holes) output. Worker satisfaction scores were determined by employing modified Job Diagnostic Survey (JDS) scales (Hackman and Lawler 1971; Hackman and Oldham 1975). The modified JDS scales included the following job or work dimensions:

(1) skill variety
(2) task identity
(3) task significance
(4) autonomy
(5) production feedback
(6) production standard
(7) working conditions
(8) pay

Each participant was asked to answer the questionnaire, which consisted of 18 questions on a seven-point Likert-type scale, regarding his or her perception of the various job attributes that were actually present.

2.1. Production Standards

The provision of an assigned specific quantitative or 100% normal production standard had no significant effect on worker productivity, but had a significant positive effect on worker satisfaction. The hard production standard of 130% normal had no significant effect on worker productivity, but had a highly significant positive effect on worker satisfaction. The assigned hard production standard failed to generate a high level of effort from the operator. The non-acceptance of the assigned hard

standard by 37% of the subjects (Group 3) was probably responsible for such results.

2.2. Production Feedback

Quantity feedback had no significant effect on quantity output, but had a significant positive effect on quality output. Consequently, definitive conclusions could not be made regarding the overall improvement in worker productivity. This work condition had no significant effect on worker satisfaction. Quantity and quality feedback had no significant effect on worker productivity, but had a highly significant positive effect on worker satisfaction.

2.3. Combination of Production Standard and Feedback

The provision of a hard production standard in combination with quantity and quality feedback had a highly significant positive effect on worker productivity and satisfaction. The increases in quantity and quality output were 12.84% and 14.46% respectively, compared to the control group. The average increase in worker satisfaction score was 7.66, compared to the control group. This work condition was far superior to the hard production standard or the quantity and quality feedback alone in terms of worker productivity and satisfaction.

2.4. Combination of Production Standard and Feedback and Monetary Incentive

The conclusions stated above were found to be equally true when the operators were given the same experimental condition as before along with monetary incentive (1:1, piece rate for good holes only with a guaranteed base rate of $3.50 per hour, Group 7). However, a comparison of groups 6 and 7 showed that the monetary incentive had no significant effect on worker productivity, but had a significant negative effect on worker satisfaction. The possible reasons for such results were the perception of the participants that the monetary incentive was inadequate and the investigator was enticing them to high performance levels with insufficient monetary incentive.

3. DETERMINATION OF THE SPECIFIC PRODUCTION STANDARD WITH FEEDBACK TO MAXIMIZE WORKER PRODUCTIVITY AND SATISFACTION

This study was conducted in the machine shop, Technical University of Nova Scotia (Shikdar and Das 1992). Basically, this study employed a similar task and methodology to the previous study. The participants in this study were also college students who were paid $5.00 per hour. For the participative standard, the participant was asked by the investigator to decide upon a production standard above 100% normal that he or she would like to attempt. It was pointed out that operators in the past generally performed between 100% and 150% of normal.

Fifty-six operators participated in this study. The seven groups, with eight participants in each group, were given the following experimental conditions:

(1) No PF/PS (control)
(2) PS: 100% normal + PF
(3) PS: 130% normal + PF
(4) PS: 140% normal + PF

(5) PS: 150% normal + PF
(6) PS: participative + PF
(7) PS: 140% normal + PF + MI

It should be noted that production feedback (PF) included both quantity and quality feedback.

3.1. Assigned Normal Standard and Feedback

The incorporation of an assigned normal (100%) standard and feedback (Group 2) had a significant positive effect on quantity output, but no significant effect on quality output. No conclusive inference could be made, therefore, with regard to the overall improvement in worker productivity, although this work condition had a highly significant positive effect on worker satisfaction.

3.2. Assigned Hard Standard and Feedback

The provision of an assigned hard standard of 130% normal and feedback led to a significantly better performance than an assigned 100% standard and feedback, but no significant difference in worker satisfaction was found between the two work conditions. The incorporation of a still harder assigned standard of 140% normal with feedback led to a further improvement in worker productivity when compared to the provision of an assigned hard standard of 130% normal and feedback. The increases in quantity and quality output for Group 4 were 14.42% and 9.48% respectively, compared to the control group. No significant difference in worker satisfaction was found between the two work conditions. For Group 4, the average increase in worker satisfaction score was 4.00, compared to the control group.

The further increase in the assigned hard standard (150% normal) with feedback failed to increase worker productivity when a comparison was made with the provision of an assigned hard standard of 140% normal and feedback. In fact, a significant deterioration in performance took place. Again, no significant improvement in worker satisfaction was found.

3.3. Participative Standard and Feedback

A comparison between Groups 6 (participative standard + feedback) and 4 (assigned 140% normal + feedback) showed that the worker productivity of the latter group was significantly better than the former. Consequently, the assigned standard of 140% normal (with feedback) is regarded as the best standard for the present repetitive manufacturing task. The provision of a participative standard and feedback was not superior to an assigned normal or hard standard and feedback in terms of worker satisfaction.

3.4. Combination of Best or Assigned 140% Normal Standard and Feedback and Monetary Incentive

The provision of monetary incentive along with an assigned 140% normal standard and feedback (Group 7) had a significant improvement in quantity output when compared to the provision of an assigned 140% normal standard and feedback (Group 4), but the quality output deteriorated significantly. The probable reason for such an outcome could be that the subjects were working faster to reach the (quantity output) standard and did not give adequate attention to maintenance of quality level. Considering both quantity and quality output, the assigned hard

standard of 140% normal with feedback proved to be the best condition for improving worker productivity in this task.

The difference in worker satisfaction score of 1.61 between Groups 7 and 4 was not significant. Hence, monetary incentive had no impact on worker satisfaction. The possible reason for such result was the lack of opportunity to earn a substantial monetary gain in one hour of production time.

4. APPLICATION OF PRODUCTION STANDARDS, PERFORMANCE FEEDBACK AND MONETARY INCENTIVE IN INDUSTRY TO IMPROVE WORKER PRODUCTIVITY AND SATISFACTION

A large fish processing industry was selected to conduct the study (Shikdar and Das 1995). The selected task was a perch fish trimming operation, a highly repetitive production task (Figure 2). The task involved trimming and/or sorting perch fillets into four different product sizes. The work cycle time varied from 3 to 5 minutes. The cycle time involved processing one pan of incoming fillets of about 20 lb. The workers were unionized.

The existing method of operation was standardized for the purpose of the investigation. MTM was used to determine the normal (100%) production standard. The hard standard was set at 140% of normal. The participative standard (above 100% normal) was set by workers individually in consultation with the investigator. Performance feedback was provided in terms of production output (lb/hr, % of normal standard) every two hours on a feedback card in graphical form. Monetary incentive was based on a company policy (1 : 0.6).

The 48 participants (male and female), who had at least 6 months' job experience and a minimum of 7th grade education, took part in the study on a voluntary basis. The exact method of operation to be followed was explained to them. Operators were trained for one day to familiarize them with the standardized method. The participants were randomly assigned to six work groups with eight participants in each group.

The groups received the following work conditions with respect to PS, PF and MI:

Figure 2. Fish trimming workplace layout (all dimensions are in centimeters).

(1) No PF/PS (control)
(2) PS: Assigned 100% normal + PF (quantity and performance level)
(3) PS: Assigned 140% + PF
(4) PS: Participative + PF
(5) PS: Assigned 140% + PF + MI
(6) PS: Participative + PF + MI

The participants worked under the work conditions for 10 days over a ten-month period. Worker productivity was measured in terms of production output (lb/hr) and converted into percentage of normal standard. Worker satisfaction scores were determined by employing the modified JDS scales that included the following job or work dimensions:

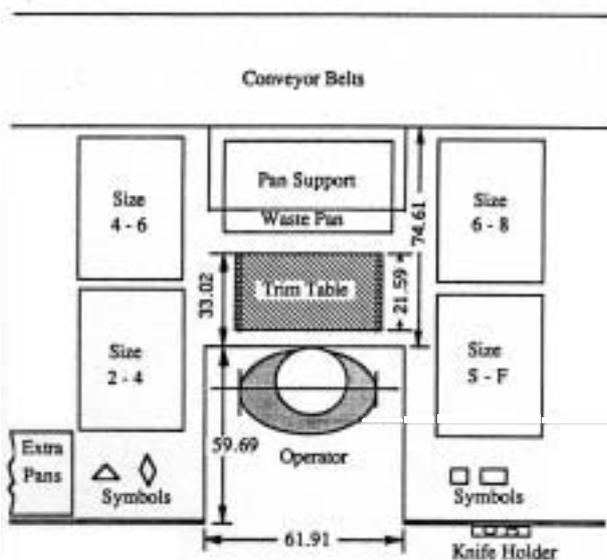
(1) skill variety
(2) task identity
(3) task significance
(4) autonomy
(5) production standard
(6) performance feedback
(7) working conditions
(8) pay
(9) promotion
(10) supervision
(11) co-workers

Each participant was asked to answer the questionnaire, which consisted of 24 questions on a seven-point Likert-type scale regarding his or her perception of the various job attributes that were actually present.

4.1. Assigned Production Standards and Performance Feedback

The provision of an assigned normal (100%) standard with feedback (Group 2) was significantly superior to the control group. The improvement in worker productivity was 12.5% compared to the control group. The assigned hard (140%) standard with feedback (Group 3) improved worker productivity significantly beyond the normal standard with feedback. The worker productivity improvement was 8.9%. A comparison between Groups 2 and 1 showed that the provision of an assigned normal production standard and feedback had a highly significant positive effect on worker satisfaction. The provision of an assigned hard standard (140%) with feedback (Group 3) was significantly better than Group 1. No significant difference was found between Groups 3 and 2. Stated otherwise, an assigned hard standard with feedback did not improve worker satisfaction over an assigned normal standard and feedback.

4.2. Participative Production Standard and Performance Feedback

The participative standard with feedback (Group 4) was significantly better than the assigned hard (140%) standard with feedback. The improvement in worker productivity was 19.1%. A comparison between Group 4 and 1, showed that the provision of a participative standard with feedback improved worker satisfaction significantly. Highly significant differences were found between Groups 4 and 2 and Groups 4 and 3. Worker satisfaction for the participative condition was significantly better than the assigned normal (100%) or assigned hard (140%) standard conditions. Participation in setting a standard or decision making probably lead to a higher level of worker satisfaction.


4.3. Monetary Incentive in Combination with Production Standards and Performance Feedback

The monetary incentive when combined with (1) an assigned hard (140%) standard and feedback (Group 5), and with (2) a participative standard and feedback (Group 6), produced further improvement in worker productivity compared to conditions (1) and (2) without monetary incentive. The respective worker productivity improvements were 14.7% and 8.3%. The provision of monetary incentive in conjunction with participative standard and feedback provided the maximum improvement in worker productivity of 57.9%, when compared to the control group.

As disclosed by the comparison of Groups 5 and 1, the provision of monetary incentive in conjunction with an assigned hard standard and feedback had a highly significant positive effect on worker satisfaction. However, no significant difference was found between Groups 5 and 3. Consequently, monetary incentive had no effect on worker satisfaction. A comparison between Group 6 (participative + feedback + monetary incentive) and Group 1 showed that worker satisfaction improved significantly as a consequence of a participative standard with feedback and monetary incentive. There was a significant negative difference in worker satisfaction between Groups 6 and 4. In other words, monetary incentive had a significant negative effect on worker satisfaction when provided with a participative standard and feedback.

5. SUMMARY AND CONCLUSIONS

Only the combination of an assigned hard production standard (130% normal) in the presence of production feedback on quantity and quality had a significant positive effect on both worker productivity and satisfaction. The increases in quantity and quality output were 13% and 15%, respectively, compared to the control group. The provision of an assigned hard standard alone failed to improve worker productivity; however, it had no adverse impact on worker satisfaction. The incorporation of quantity and quality feedback had no significant effect on worker productivity, but had a favorable impact on worker satisfaction. Monetary incentive added no incremental performance or satisfaction gain.

A progressive increase in the assigned standards (100%, 130%, 140%, and 150% normal) with feedback (quantity and quality) improved worker productivity significantly up to the provision of an assigned standard of 140% normal and feedback. The maximum increases in quantity and quality output were 14% and 10%, respectively, compared to the control group. No further improvement in worker productivity resulted as a consequence of an assigned harder standard of 150% normal and feedback. The provision of a participative standard with feedback was significantly inferior to an assigned 130% normal standard and feedback in terms of worker productivity. The provision of assigned and participative standards with feedback improved worker satisfaction significantly. No significant difference in worker satisfaction was found among the standards and feedback conditions. Monetary incentive had no beneficial effect on worker productivity and satisfaction.

An assigned normal (100% standard with feedback improved worker productivity significantly in industry. The assigned hard (140%) standard with feedback improved worker productivity

significantly beyond the normal standard with feedback. The participative standard with feedback was significantly superior to the assigned hard standard with feedback. The monetary incentive when provided with the hard and participative standards along with feedback improved performance significantly further. The maximum improvement in worker productivity was found for the monetary incentive, participative standard, and feedback condition. The improvement was 58% compared to the control group. The provision of assigned normal, assigned hard, and participative standards with feedback improved worker satisfaction significantly in a repetitive production task when compared with the control condition. The participative standard with feedback proved to be significantly superior to other work conditions in terms of worker satisfaction. Monetary incentive added no incremental satisfaction gain.

1. INTRODUCTION

The emergence of macro-ergonomics has strongly contributed to the increasing interest in psychosocial work factors in the ergonomics field (Hendrick 1991, 1996). Work factors can be categorized into the individual, task, tools and technologies, physical environment and the organization (Smith and Carayon-Sainfort 1989). They can also be described as either physical or psychosocial (Cox and Ferguson 1994). The importance of psychosocial work factors in the field of ergonomics emerges from several considerations (Carayon and Lim 1998).

Physical and psychosocial ergonomics are interested in the same job factors. For instance, job rotation and job enlargement are job design strategies aimed at improving psychosocial work factors (increased task variety) and physical factors (reduced exposure to high physical load).

Physical and psychosocial work factors are related to each other. For instance, high work pressure may induce physical stressors, such as increased work pace and repetitiveness.

Psychosocial work factors play an important role in physical ergonomics interventions (e.g. participatory ergonomics).

Physical and psychosocial work factors are related to the same "outcome," for instance, work-related musculoskeletal disorders (see article on "Applications of Community Ergonomics").

2. DEFINITIONS

Within the past decade, the role of psychosocial work factors in ergonomics has gained much popularity. However, the term "psychosocial work factors" has been used "loosely" to define and represent many factors that are "a part of," "attached to" or "associated with" the individual. Some would consider what has been traditionally termed socio-economic factors such as income, education level and demographic or individual factors (e.g. age and marital status) as part of the psychosocial factors. To understand psychosocial factors in the workplace, one needs to take into account the ability of an individual to make a psychological connection to his or her job, and thus formulating the relationship between the person and the job. For instance, the International Labour Office (ILO 1986) defines psychosocial work factors as "interactions between and among work environment, job content, organizational conditions and workers' capacities, needs, culture, personal extra-job considerations that may, through perceptions and experience, influence health, work performance and job satisfaction." Thus, the underlying premise in defining psychosocial work factors is the inclusion of the behavioral and psychological components of job factors. below, we will use the definitions proposed by Hagberg et al. (1995) because they are most highly relevant for ergonomics.

Work organization is defined as the way work is structured, distributed, processed and supervised (Hagberg et al. 1995). It is an "objective" characteristic of the work environment, and depends on many factors, including management style, type of product or service, characteristics of the workforce, level and type of technology, and market conditions. Psychosocial work factors are "perceived" characteristics of the work environment that have an emotional connotation for workers and managers, and that can result in stress and strain (Hagberg et al. 1995).

Psychosocial work factors are multiple and various (Cooper and Marshall 1976), and are produced by different, interacting aspects of work. The Balance Theory of Job Design (Smith and Carayon-Sainfort 1989) proposed a conceptualization of the work system with five elements interacting to produce a "stress load." The five elements of the work system are: (1) the individual, (2) tasks, (3) technology and tools, (4) environment and (5) organizational factors. The interplay and interactions between these different factors can produce various stressors on the individual which then produce a "stress load" which has both physical and psychological components. The stress load, if sustained over time and depending on the individual resources, can produce adverse effects, such as health problems and lack of performance. Research and practice in the field of work organization has demonstrated that considering only a small number of work factors can be misleading and inefficient in solving job design problems. According to the Balance Theory, psychosocial work factors are multiple and of diverse nature. Table 1 shows a selected sample of the many different dimensions of jobs (e.g. job demands, control, social support) that have been studied extensively. Furthermore, each dimension is made up of different facets that define and operationalize that particular dimension. For example, as shown in Table 1, the dimension of job demands consists of various facets, such as quantitative workload, variance in workload, work pressure and cognitive

Table 1.   Selected Psychosocial Work Factors and their Facets

1. Job demands	quantitive workload
	variance in workload
	work pressure
	cognitive demands
	emotional demands
2. Job content	repetitiveness
	challenge
	utilization and development skills
3. Job control	task/instrumental control
	decision/organizational control
	control over physical enviroment
	resource control
	control over work pace: maching- pacing
4. Social interactions	social support from supervisor and colleagues
	supervisor complaint, praise, monitoring
	dealing with (difficult) clients/customers
5. Role factors	role ambiguity
	role conflict
6. Job future and career issues	job future ambiguity
	fear of job loss
7. Technology issues	computer-related problems
	electronic performance monitoring
8. Organizational and management issues	participation
	management style

demands; the dimension of job content includes repetitiveness, challenge on the job and utilization of skills.

3. MEASUREMENT OF PSYCHOSOCIAL WORK FACTORS

From the ergonomics point of view, the purpose of examining psychosocial work factors is to investigate their influence on and role in worker health and well-being. Thus, psychosocial work factors can be considered as predictors (i.e. independent variables) while worker health and well-being serve as the dependent variables or outcomes. The most often used method for measuring psychosocial work factors in applied settings is the questionnaire survey. Difficulties with questionnaire data on psychosocial work factors are often due to the lack of clarity of the definitions of the measured factors or poorly designed questionnaire items that measure "overlapping" conceptual dimensions of the psychosocial work factor of interest. Measures of any one facet typically include several items that can be grouped in a "scale." Reliability of the scale is often being assessed by the Cronbach a score method in which the intercorrelations among the scale are items are examined for internal consistency. In general, it is recommended that existing, well-established scales be used to ensure the "quality" of the data (i.e. reliability and validity) and to be able to compare the newly collected data with other groups for which data has been collected with the same instrument ("benchmarking").

The level of objectivity/subjectivity of the measures of psychosocial work factors will depend on the degree of influence of cognitive and emotional processing. For example, ratings of work factors by an observer cannot be considered as purely objective because of the potential influence of the observer's cognitive and emotional processing. However, ratings of work factors by an outside observer can be considered as more objective than an evaluative question answered by an employee about his/her work environment (e.g. "how stressful is your work environment?"). On the other hand, self-reported measures of psychosocial work factors can be more objective when devoid of evaluation and reaction (Kasl and Cooper 1987). Any data can be placed somewhere on this objectivity/subjectivity continuum from "low in dependency on cognitive and emotional processing" (e.g. objective) to "high in dependency on cognitive and emotional processing" (e.g. subjective) (see article on "Survey Design").

Presented are three different questionnaires that include numerous scales of psychosocial work factors. Validity and reliability analyses have been performed on all three questionnaires. Two questionnaires have been developed and used to measure psychosocial work factors in various groups of workers or large samples of workers: (1) the NIOSH Job Stress questionnaire (Hurrell and McLaney 1988), and (2) the Job Content Questionnaire (JCQ) (Karasek 1979). The NIOSH Job Stress questionnaire is often used in the Health Hazard Evaluations performed by NIOSH. Translations of Karasek's JCQ exist in many different languages, including Dutch and French. The third questionnaire, the University of Wisconsin Office Worker Survey (OWS), was developed to measure psychosocial work factors in office/computer work (Carayon 1991). It covers a wide range of psychosocial work factors of importance in office and computer work. In addition to many of the psychosocial work factors

measured by the NIOSH Job Stress Questionnaire or Karasek's JCQ, the OWS measures psychosocial work factors related to computer technology, such as computer-related problems (Carayon-Sainfort 1992). The OWS questionnaire has been translated in Finnish, Swedish and German. For all three questionnaires data exist for various groups of workers in numerous organizations of multiple countries. These data can serve as comparison to newly collected data and for benchmarking. Numerous other questionnaires for measuring psychosocial work factors exist, such as the Occupational Stress Questionnaire in Finland (Elo *et al.* 1994) and the Occupational Stress Indicator in England (Cooper *et al.* 1988). Other questionnaires are listed in Cook *et al.* (1981).

4. PSYCHOSOCIAL WORK FACTORS AND WORK ORGANIZATIONS

The role of "psychosocial work factors" in influencing individual and organizational health can be dated back to the early days of work mechanization and specialization, and the emergence of the concept of division of labor. Taylor (1911) expanded the principle of division of labor by designing efficient work systems accounting for proper job design, providing the right tools, motivating the individuals, and sharing of responsibilities between management and labor, and sharing of profits. This is known as the era of Scientific Management in which scientific methods measure work objectively with the objective of improving its efficiency. An analysis of psychosocial work factors in the Scientific Management system reveals that skill variety is minimal, workers have no control on the work processes, and the job is highly repetitive and monotonous.

In the next step of development in the Job Design field, we see the emergence of the Human Relations movement (Mayo 1945) which raised the issue of the potential influence of the work environment on an individual's motivation, productivity, and well-being. Thus, job design theorists incorporated worker behavior and work factors in their theories. The two theories of job enlargement and job enrichment formed the basis for many job design theories thereafter. Job enlargement theory emphasized giving a larger variety of tasks or activities to the worker. While this was an improvement from the era of Scientific Management, the additional tasks or activities could be of a similar skill level and content: workers were performing multiple tasks of the same "kind." This has been called "horizontal loading" of the job, as the opposite of job enrichment, which focused on the "vertical loading" of the job. Job enrichment aims at expanding the skills used by workers, while at the same time increasing their responsibility. Herzberg (1966) defined intrinsic and extrinsic factors (or motivation versus hygiene factors) that are important to worker motivation, thus leading to satisfaction or dissatisfaction, and psychological well-being. Intrinsic factors are related to the work (or job) conditions, such as having additional control over work schedules or resources, feedback, client relationships, skill use and development, better work content, direct communications, and personal accountability (Herzberg 1974). Extrinsic factors are related to aspects of financial rewards and benefits and also to the physical environment. Herzberg indicated that extrinsic factors could lead to dissatisfaction with work, but not to satisfaction, while intrinsic factors could increase

satisfaction with work. In a way similar to Herzberg's job enrichment theory, the Job Characteristics Theory (Hackman and Oldham 1976) focused on specific characteristics of the job (i.e. skill variety, task identity, task significance, autonomy and feedback) in combination with individual characteristics (growth need strength) which can determine personal and work outcomes.

The Sociotechnical Systems Theory recognized two inter-related systems in an organization: the social system and the technical system. The main principle of the Sociotechnical Systems Theory was that the social and technical systems interact with each other, and that the joint optimization of both systems can lead to increased satisfaction and performance. The social system focused on the workers' perception of the work environment (i.e. job design factors) and the technical system emphasized the technology and the work processes used in the work (e.g. automation, paced systems, and monitoring systems). It was Davis (1980) who provided a conceptual framework and a set of principles that formulated the Sociotechnical theory. His framework called for a flattened management structure that would promote participation, interaction between and across groups of workers, enriched jobs, and most importantly, meeting individual needs. The Sociotechnical Systems Theory proposed a new form of work organization: semi-autonomous work groups (Trist and Bamforth 1951). Recently, various forms of teamwork have been proposed and applied, from temporary teams (e.g. quality circles, project teams) to permanent teams (e.g. semi-autonomous work groups, self-managed teams).

Other trends in businesses include the widespread development of quality improvement strategies, such as Total Quality Management (TQM). TQM can involve important changes in the way work is organized (Smith *et al.* 1989). TQM can lead to positive and/or negative changes in psychosocial work factors (Sainfort *et al.* 1997). In addition, a basic principle of Total Quality Management is employee participation, which is considered as a positive psychosocial work factor.

The development of Information and Communication Technology (ICT) has also contributed to the emergence of new forms of work organization, such as telework and teamwork via computer-mediated communication. Telework or working at home is most common for clerical workers performing routine transactions and for autonomous professionals (e.g. writers, designers) (Sproull and Kiesler 1991). In terms of psychosocial factors, there are potential positive and negative aspects of ICT that can influence quality of working life and health. ICT can have both positive and negative effects on work demands. One example is in the context of telework or remote work. On the one hand, telework allows for increased control over work pace and variability of workload. It has been found, however, that electronic communication and telework have led to feelings of not being able to get away from work and to the augmentation (rather than substitution) of regular office hours (Sproull and Kiesler 1991, Phizacklea and Wolkowitz 1995). The work place and the home are one in the same, and constant access to technology eliminates time boundaries for work. Although there is a potential negative impact in terms of work demands, the freedom and flexibility offered by telework is a major advantage, especially for individuals with children and other non-work responsibilities (Phizacklea and Wolkowitz 1995). The ability to schedule work around other crucial responsibilities increases job

control and helps to reduce role conflict. Remote work does, however, lead to decreased social interaction with work peers and sometimes decreased career mobility because of the lack of informal, social networks developed within the organization (Sproull and Kiesler 1991).

Jobs in which people use ICT may require high mental effort. Some types of computer-mediated tasks may increase information-processing requirements and place great demands on attention, decision-making, and memory. Increased levels of cognitive demands due to ICT have been shown to influence employee stress and health (Lindstrom and Leino 1989, Czaja and Sharit 1993, Yang 1994). Studies have shown that several types of cognitive demands can be generated from the use of ICT: (1) great amount of information given in a certain unit of time, (2) abstract information being presented on the screen and (3) difficult and concurrent tasks being performed at the same time. In addition, the characteristics of the ICT, such as variability of system response time, can affect human's physiological and psychological responses. Cognitive demands can be increased when the system response time is poor and the nature of workflow is not transparent to the workers. In other words, unpredictable demands and interruptions of workflow caused by system breakdowns may be difficult to deal with because of the disruptive effect on cognitive control process. Overall, cognitive demands are associated with job characteristics such as intensity of computer work, the type of communication, and high speed/functions of computers. The implementation of ICT in work organization can lead to greater demands on cognitive resources in terms of memory, attention, and decision-making that may have a negative impact on worker health and work performance.

The positives and negatives of ICT are ultimately not inherent to the technology itself, but rather are effects of the organizational structures and policies (i.e. work organization) under which the technology resides (Smith *et al.* 1981, Sproull and Kiesler 1991, Carayon and Lim 1994). New computer-based technology has prompted some managers to reinforce hierarchical organizational structures by controlling information exchange, blocking certain channels of communication and enhancing surveillance (e.g. electronic performance monitoring). The same technology has prompted other managers to initiate a new management style characterized by a flexible, continuous learning work environment and culture to support information sharing and participation in decision-making (i.e. decision/organizational control). One of the biggest challenges of the future for organizational design and management will be to design for maximizing the positive and minimizing the negative potential aspects of ICT and its implementation in different types and forms of work.

5. CONCLUSION

It is important to recognize the multiplicity and variety of psychosocial work factors. According to the Balance Theory, various aspects of the different elements of the work system (i.e. the individual, task, technology, organization and environment) and/or of the interactions among the elements of the work system can be positive and negative from a psychosocial point of view. Psychosocial work factors have been shown to influence quality of working life and health, and therefore are important to consider in the ergonomic design of work. Finally, recent trends in businesses, e.g. team work, TQM and Information and

Communication Technology, have seen the emergence of new forms of work organization which can have both positive and negative psychosocial work factors. To prevent negative effects on people, we need to (re)design work to remove as much as possible these negative psychosocial work factors.

Social Policy and Industrial Development

K. Vanwonterghem

CERGO International, Zavelvennestraat 64, B-3500 Hasselt, Belgium

1. INTRODUCTION

Ergonomics as a discipline focusing on the design and redesign of the "active human" systems is concerned with the living quality of human kind. It aims to bring equilibrium between human activities and environmental conditions that would increase human potential. A well-balanced "human-at-work" system (work in the widest sense of its content) should create conditions of acceptable risks with respect to occupational health and safety, and assure the human well-being, in combination with satisfactory efficiency of the human activity.

The above goals of ergonomics should be also valid in industrially developing countries (IDC), but many obstacles may destabilize development of human-oriented policies. Wars, threats of wars, revolts, riots, ethnic conflicts and general insecurity create climates in which the risks of loss of life and degenerating human integrity are put against human well-being and adequate quality of life. As the first priority should be striving for peace and avoiding conflicts, the knowledge and experience of ergonomics should be used to prevent such conflicts and to protect the working population.

A major obstacle to improving the quality of life is an impact of the non-controlled industrialization on the socioeconomic system of developing countries, especially as they strive to join the global economy. A need to develop and increase regional and local economies has to be balanced against the consequences of moving from the informal sectors and small size companies, where workers are often self-employed family members, including women and children with low educational background, to a well-organized industrial organization.

The expectance of such an evolution is an increased life quality, better housing facilities and living conditions, and increased financial means, which should serve to bring the social status to a higher level for all citizens. The underlying benefit should also be an improved health and safety. However, as shown by economically emerging regions in South America and Africa, the industrial development does not always bridge the gap between the wealthy and underprivileged populations. Such a gap becomes a global issue, and even in South East Asia and China, where economic growth is strong and sustained, many problems evolve. Whereas the living standards raised drastically for the privileged population, others (less fortunate) follow similar purchasing trends, buying technical gadgets such as sophisticated video systems or mobile phones, etc., while the essential values of health and safety are put aside to the lower priority level.

2. ERGONOMICS AND INDUSTRIALIZATION

In the industrialized world, there is a strong need to stimulate productivity to cope with the production costs, and the very expensive social security systems. One of the reasons for investing in developing countries is to approach those economies that need further development, but can also provide cheap labor and low, or nonexistent, social cost. The dominant strategy is often based on direct transfer of high tech systems, knowledge and experiences to developing countries. These new technologies (at least new for the IDC), such as advanced production systems, are imported and implemented as they are being used in the country of origin, where first priority is to increase system productivity within the shortest time possible. The responsibility to get the production system going is a true challenge for the local management that often puts priority on the technical development. Human, as part of the production process, is regarded as a technical tool, and classified as the necessary cost factor.

In this evolution, workers are trained to fulfill their tasks, while health and safety matters are handled through organizational techniques and formal working standards, procedures and legislation. Because of the fact that the directives are transferred along with the equipment and machinery, the IDC's often receive existing (international or national) standards. By classifying these formal prescriptions as valid in IDC, just because they are valid "over there" (in the industrialized countries) and, because of lack of knowledge that hinders productivity, other essential policy items are often neglected, denied or applied abusively.

The above industrializing principles may work for an undetermined time. This is because human beings have extremely powerful adaptation skills that lead to development of new cultures, i.e. the "industrial cultures", in a short period. The step from a farmer to a production worker in a semiautomatic electronic assembly plant may sometimes take only a few months. However, only few can take full advantage of this new situation. The remaining majority is often split into different categories, with some people just accepting the situation and others frustrated with unfulfilled ambitions. Drastic changes may also cause a social shock alienating, even separating, those who can follow the new possibilities from their "old" community.

3. ERGONOMICS AND SOCIAL POLICY

It is difficult to assess the impacts of expatriation, seasonal labor in neighboring regions or countries, learning to live with changing values, the introduction of new technologies in a daily life, respecting the variety of social structures (gender differences, elderly, social position), contacts with foreign cultures, the introduction of women's liberation, less rigid religion rules, the enlarged possibilities for leisure, or transfer of goods, drugs and other "created" needs, on the human well-being. Given the above, it is remarkable to see how local people bridge the distance between the rural-agricultural activities and the mechanized high-tech industrial activities. But developing an industrial culture is an ongoing process that takes time. In Europe, for example, it took ~200–300 years, during which health and safety evolved via experience, leading to the development of prevention policies.

Bridging the above gap is difficult because of the complexity of new working conditions. The superficial introduction of new technologies without taking into account the relevant human factors, is often ineffective and results in a high social cost. In the economic context, it can be observed that unemployment and the degree of workforce availability on the market are closely

related to the level of investments targeted for improving working conditions. Increased turnover rates and absenteeism illustrate these effects.

The divergent needs of industrialization and social development indicate that these problems cannot be solved by any single or universal method, that money does not cure everything, and that economic development must consider the social and human dimensions. Industrial development should also take into consideration the history, the reality of existing social systems of each country or region, and should pay respect to the fundamental values on which the culture is based on. These basic values, as is the case for the industrially developed world, are founded on factors such as life and professional expectances, socioeconomic and cultural status, and personal needs. They will steer the adaptation process of individuals and groups.

Risk-coping strategies, conscious or unconscious, are determined through the subjective interpretation of the acceptable risks, of feelings of comfort/discomfort, satisfaction, happiness, and the expected rewards. Ergonomics can help in the development of risk assessment methods, practical problem-solving measures, and the establishment of priorities at the micro- and macroeconomic levels.

The experiences of the developed industrial world should be utilized to help to create sustainable development in the newly industrializing countries. While "knowledge transfer" is the key, care should be exercised in practical implementation of such knowledge. Fortunately, it is believed that most of the basic ergonomics knowledge needed is already available in the IDC. This is because many professionals graduated from universities of the industrialized world. Furthermore, the global information networks keeps them informed about the current trends and new developments. The real problem, however, is translating the available knowledge and experience into a sustainable policy. In many developing countries there is a lack of national and regional prevention programs, and there are no necessary structures to bring them into the effective applications. This limits many of the experts as only individual actions are often possible. There are, for example, no prevention-oriented records of the useful health and safety solutions, and the experts are not, or only exceptionally, involved or consulted on the industrial and economic issues.

For these reasons, ergonomics in many IDC is seen as an interesting discipline, but one that remains limited to the academic cocoon. Furthermore, no funds are available to support the ergonomics programs, although the health and safety programs exist and are strongly supported. The "preventive" capacities of ergonomics at the early system design stage, before the advent of diseases and accidents, are not yet commonly recognized. The ultimate vocation of ergonomics is direct contacts with the shopfloor, as this is the place where prevention is most effective.

4. ERGONOMICS AND EDUCATION

The crucial challenge for ergonomics in IDC is to bring about an awareness about the risks, and ways to reduce their consequences in industrial practice, as well as providing the knowledge, both theoretical and practical, at all levels of society. Therefore, ergonomics should focus its activities in IDC on three basic types of activities, namely research, consulting, and training and education.

4.1. Research

With the concern to bring ergonomics as a theoretical and practical tool in IDC, ergonomics should join the economical world which evolves into an information-led system, in which communication becomes crucial for development. The existing techniques of telecommunication, such as the use of computers and the Internet, allow for sharing all the necessary knowledge between experts to increase their capacities. Is this the solution for ergonomics? Possibly but, as mentioned before, practical implementations have to take place in the real factories and workplaces. To realize this, the gap between the academic and practical problems must be bridged, and both the fundamental and applied research should be stimulated.

It is of great importance to agree about a common research methodology in ergonomics. This would create reliable, interpretable and comparable data that would ensure that all external factors are well described and/or measured. The assessment of such data should be put in the context of individual human reactions to the selected phenomena under study, and validated statistically for groups of individuals occupying the same activities. The human physiological, psychomotor and mental reactions, including objective and subjective experiences of the exposed workforce, should be measured to evaluate tasks, organization and environmental issues.

Knowledge about the specific capacities and differences in characteristics of the local workforce is very much needed. Therefore, where possible, local data banks about the anthropometric, biomechanical, physiological and psychomotor issues should be established. Some countries have developed their own basic data. Such data is also some are available from the International Labor Office and the World Health Organisation.

To fulfill the research requirements, skilled teams of ergonomists should be trained in the applied research methodology and data processing. Such teams should be able to operate nationwide as the specific problems are typically very large. Owing to the high complexity of the involved issues, the required expertise should be set at an academic level in one of the ergonomics-related disciplines, with an understanding of the multidisciplinary involvement of other disciplines. Such research teams should have strong interaction with, and the feedback from, industrial partners.

4.2. Consulting

The short-term projects (from a few days or weeks to the maximum of 6 months) should focus on actual problems occurring in industry. Project objectives should be formulated by industry, and assessed at various management levels as well as by workers at the shop-floor level. The teams should use a practical approach by identifying the problem, indicating its importance, formulating specific improvement measures (task, organization and environment), setting priorities by assessing the potential impact on the exposed workers, and following up implementation as a project evaluation.

Experts with good technical skills in developing and evaluating the technical and organizational aspects of the projects are needed. However, such practical skills are often absent in most of the industrially developing countries. Therefore, one of the first priorities should be to establish local training networks to fill up this gap. The trainers must have an appropriate

background in the ergonomics discipline, as well as close contacts with the industry and workers. They should serve as the bridge between the industry and academic world.

4.3. Training and Education

In terms of the required basic knowledge that is needed to realize such projects, ergonomics must be introduced at all levels of society, from the workshop floor up to the academic and political world. This should be done with the elementary principle that applying such knowledge in practice is essential for sustainable economic development.

At present, some attempts have been made to bring the basic knowledge in ergonomics to the workers at the shop-floor level by means of a series of "roving seminars" and "training for trainers" workshops, designed to reach bigger population in a short time. The main criticism of such attempts is that they typically use work design examples that originate in the industrialized world, instead of providing design solutions that meet local conditions and needs.

Similar phenomena can be seen at the academic level. In many cases, qualified ergonomists who graduated at universities in the developed countries, move back to their native universities. They often teach advanced (theoretical) material, having very limited industrial experience relevant to the local needs, and very few contacts with industry to teach practical implementation of their knowledge. The absence of managing structures and appropriate policies often leads to efforts which are not suitable for industrially developing countries because they are "too academic", removed from reality, and too expensive.

It should be noted here that the longer one is studying abroad the more s/he is alienated from the economic and social realities of the native country. Knowledge acquired in the developed world often does not match the limitations in the local financial mechanisms, advanced technology, slowly changing industrial policies, and the national standards and legislation.

5. CONCLUSIONS

The promise of ergonomics often relies on the belief in social, industrial and economic efficiencies. Therefore, if national authorities do not create a climate for sustainable development, all investments, new technologies, and efforts to improve working and living conditions may remain an interesting option for the academic exercise. An example of the above situation is the recent (February 1999) workshop organized in Thailand about the health and working conditions in South East Asia (Physical Workload and Heat Stress). About 20 experts participating in this workshop came to a conclusion that, even in a tropical area,

very little is known about the impact of heat on health and human behavior. To handle the issue for the working population, there is a tendency to introduce an ISO standard (WBGT, ISO: 7243) by legislatures in various IDC.

While the above may be a worthwhile strategy, two European Union-sponsored research projects (conducted in Thailand and Indonesia) concluded that there was an important difference in the physiological responses of the workers from the western world compared with South East Asia. These cardiocirculatory and thermoregulatory differences lead to the conclusion that particular attention should be paid to the assessment of physical workload. By strictly following international standards, without reference to the local thermoregulation capacities or physical characteristics of the local population, some unintended risks can inadvertently be introduced to the workers.

Sustainable development only can be realized by appropriate training and education in combination with fundamental and applied research, as well as practical consulting as a long-term growth factor. The local and national authorities have the responsibility to facilitate implementation, through political programs, of practical guidelines and directives. The quality of the ergonomic measures must be developed by pragmatic and scientific research. Management must recognize and understand the impact of the problem on the affected worker population, and make practical interventions or accept guidelines as needed.

The final goal is to combine the political world with the forces of economy and science in saving the human being's work and improving quality of life. As stated by James D. Wolfensohn, President of the World Bank: "There is no simple solution. Infrastructure capacity, agriculture and industrial productivity, economic policies and human investments are all essential, but none in itself is adequate to generate broad-based growth. Instead, we are learning that the most effective development strategies strike a balance among economic, social, financial and environmental factors. *The best begin and end with the dignity of every human being*" (*Herald Tribune*. 21 June 1999).

As for "economics of ergonomics" there is no single, simple solution. Developing, implementing and applying ergonomics knowledge on a large scale in industrially developing societies takes a long time before successful results become obvious. These may not even be recognized as a result of the economic or ergonomic program. However, ergonomics, in its multidisciplinary approach to "man-at-work" systems, has great potential to contribute to the socioeconomic growth of the industrially developing countries.

Socially Centered Design

1. INTRODUCTION

System design and the individuals who contribute to this activity have evolved to reflect the salient concerns of successive eras. The laboratory engineer as the principal designer has evolved into a team of designers including psychologists, social scientists and anthropologists. These latter additions to the design team are confronting the problem of designing for groups of users and organizations. This has led to socially centered design, which is concerned with "border issues," i.e. design variables that reflect socially constructed and maintained world views which both drive and constrain how people can and will react to and interact with a system or its elements. Socially centered design is a medial-ergonomic design that fills the void between traditional system centered design (i.e. macro-ergonomic design of the overall organization and work system structure, as well as process interfaces with the system's environment, people and technology) and contemporary user-centered design (i.e. micro-ergonomic design of specific jobs and related human–machine, human–environment and user system or software interfaces) (Stanney *et al*. 1997). Specifically, socially centered design takes a holistic approach to design, broadening the narrowly defined technical focus of past design approaches by considering users as their performance is influenced by their knowledge and understanding of the social context in which they perform their work. Following this design approach, naturalistic observation of human behavior as it is influenced by situational, contextual and social factors is used to assist in the formulation of system designs.

Socially centered design assumes that by taking into consideration organizational and social factors, such as informal work practices and shared artifacts, the system design process will be enhanced. This presupposes that social interaction is orderly and can therefore be understood. Goguen (1994) suggests that system designers can achieve this understanding by developing a sense of the intrinsic categories and methods (i.e. informal processes) members of an organization assign themselves during their interactions. In particular, participatory observation in which designers become immersed in and interact with target user populations in their natural work setting can be used to gain such understanding. Further, socially centered design recognizes that the roles and responsibilities of workers are situated (i.e. emergent rather than individualistic, local to a particular time and place, contingent on the current situation, embodied in a physical and social context, open to revision, and vague), being defined in relation to the social interaction in which they occur.

2. THE SOCIALLY CENTERED DESIGN PROCESS

The socially centered system design process begins with a contextual inquiry to determine the user, product, task and environ-mental parameters potentially influencing system design (Stanney *et al*. 1997). This investigation will generally involve some form of direct observation such as field studies or ethnographic observation. It is critically important that this observational period be conducted in an unbiased, non-leading manner (Nardi 1997). Designers are expected to become immersed in one or more communities of practice to observe, record and analyze what users actually do in applying artifacts to achieve goals. While such participatory observation leads to great insights, designers should avoid modifying the behavior of those observed by refraining from asking leading questions, or imposing biases where their perspectives differ from those being observed. In applying techniques like interviews, focus groups, detailed questionnaires or by measuring specific aspects of work performance, the immersed designers seek to adopt the user's frame of reference or view of reality to understand the how and why of artifact use. Once completed, the most common mistake of such observational studies is to overextend the interpretation of the results. Thus, it is essential that the rich abundance of observational data obtained be filtered, organized and interpreted in the larger context of the technology and science in which the artifacts exist.

3. SOCIALLY CENTERED DESIGN VARIABLES

The socially centered design variables for which data are accumulated during observational studies comprise those input or contextual variables that are expected to influence group processes (Stanney *et al*. 1997). These variables include the context itself, both as a global or comprehensive factor and the separate component variables that collectively comprise the context: artifacts, cooperative task activities, organizational structure, situational factors and interpersonal characteristics.

The context in which an activity is performed has both physical (e.g. locational and sensory cues) and social elements (e.g. presence of, relationship to and expectations of other individuals) that provide opportunities for or constrain individual behavior, particularly due to the schema (i.e. general purpose representations of concepts, situations or ideas) that develop over time.

Artifacts are the designed and created objects (e.g. paper and pen, computers) or systems (e.g. traffic lights, Internet) that humans apply and use to influence the world around them. Individuals within a given community generally use artifacts in particular ways according to past insights, common intuitions, shared understandings and activities, and current or recent experiences (Brown and Duguid 1994). Over time, however, different communities may develop "border" or non-central uses for peripheral or secondary attributes characteristic of particular artifacts. These border uses will likely be unique to a given community and may arise when functional fixedness is overcome by a perceptive user with a novel problem. While in the past these issues were recognized, their influence on design were generally thought to be inconsequential due to the tendency of artifacts to remain stable over time and populations of consumers (Stanney *et al*. 1997). With the de-massification of today's competitive market, however, designers have been forced to offer many customized products instead of a few standardized ones to cater to narrow demographic segments scattered in regional markets. The result is there may no longer be a guarantee of artifact continuity to include border uses. In turn, shared practices may not

be easily maintained, especially if customization is extended downwards to the individual user so that only a very few common core or border attributes exist to support member coordination of the community's internal behaviors (Gaver 1994). Such circumstances highlight the need for embracing socially centered design practices.

In organizational settings, cooperative task activities generally define or reflect the job or objective that artifacts are used in whole or part to accomplish. The influence of the task factor on group performance, when this is mediated in some manner by technological artifacts, manifests itself in terms of the degree to which effective group performance depends on both the transmission of information about the task and transmission of information about the values, interests, and personal commitments of group members (Hollingshead and McGrath 1995). These factors and the effectiveness with which system designs or artifacts support their performance can be identified via the observational studies of socially centered design.

The organization or group within which an activity is performed significantly affects the appropriateness of a system design. To implement plans and achieve common objectives, group members and the systems that support them must create and maintain meaningful relations (i.e. norms, power relationships, status relationships, cohesiveness and group density) which can be identified through observational studies. Thus, organizational requirements emerge from a system being placed in a social context and its associated group relations rather than those deriving from the functions to be performed or the tasks to be assisted (Dobson et al. 1994).

Situational characteristics reflect the various social networks and relationships that exist among group members, as well as the maturity of the group (e.g. just formed versus well established) (Stanney et al. 1997). In particular, cultural situational differences (e.g. collectivistic versus individualistic) are particularly influential in social and work settings, which in turn is reflected in the behavior of the members of these cultures.

Interpersonal characteristics (e.g. dominance, friendliness, authoritarianism, field-articulation, gender) reflect the attitudes, behaviors and motivations of individual group members. Groups whose members have compatible personalities tend to be more cohesive, more efficient and more productive than groups with incompatible members.

These socially centered design variables may not be readily noticed or recognized by designers as important without a contextual inquiry, yet they can influence the effectiveness of system and product design. Thus, through observational studies global context can be identified and the genre of artifacts that may be used to achieve particular goals (both central and border) within a certain range of situational conditions for a community of users are recognized. This information can then be used to design systems and products that directly meet users needs and are genuinely easy to use. There are several different methods used to elicit this information.

4. SOCIALLY CENTERED DESIGN TECHNIQUES

Socially centered design techniques reflect the methodologies applied to acquire data about users and their work context and related artifacts (Stanney et al. 1997). These techniques elicit identification of artifact attributes for both core and border uses and specify whether they facilitate, slow or impede activities; the scope and nature of relationships among individuals and the manner in which particular artifacts support these relationships; and how work, communication and information flow are mediated (Hollingshead and McGrath 1995). Several different techniques have been used in an attempt to elicit such contextual information.

4.1. Group Studies

Socially centered design can use a modified version of traditional sociological group studies, where predictive theories or even designers' intuitions are formulated and situationally tested in a variety of contextual settings (Stanney et al. 1997). This can be a timely and resource intensive approach.

4.2. Ethnographic Studies

The ethnographic approach identifies work practices and organizational interactions through anthropological studies of the work setting (Stanney et al. 1997). Ethnomethodology examines how competent members of an organization coordinate their behaviors, specifically in delimiting the categories, methods and artifacts used to render their activities intelligible to one another (Goguen, 1994). Ethnographic studies have two general focuses: (1) the moment-to-moment interactions of observational participants or (2) more global, longer-term activities such as how artifacts are used to distribute and regulate knowledge, communication and action, as well as identification of the personal objectives, beliefs, principles and practices of those observed (Nardi 1997).

The ethnographic approach often involves participatory observation in which designers intensely observe and interact with the cultural activities, belief systems, rituals, institutions and artifacts of those under observation. Using this approach, designers and intended users of the system or product develop a shared understanding of the nature of the work or activity to be performed, the users' needs in performing this activity, and the contextual components which support the completion of the activity. This mutual understanding is deeply tied to the context in which the work or activity is performed. Thus, design solutions based on the ethnographic approach may not generalize to other situations.

4.3. Cooperative Work Studies

Cooperative work studies involve observational investigations of groups working cooperatively in their natural social and cultural setting (Stanney et al. 1997). In general, the group under observation collaborates on a common goal that requires communication (either face-to-face or mediated exchanges) to support goal achievement, and who thus must in some manner coordinate their work activities. With this approach, structural variables reflecting the group (e.g. size, composition, interactions, internal processes) and external situational factors that reflect the natural environment are identified and used to inform the design process.

4.4. Anthropomorphic Studies

Anthropomorphic studies generally examine human-to-human communication patterns and then try to emulate these relationships in the design of interactive systems. The focus is to identify

the schema (e.g. communication modes, cognitive strategies) through which people perform activities or tasks.

5. APPLYING THE SOCIALLY CENTERED DESIGN APPROACH

Interactive system designs are more commonly being derived from contextual inquires, with more traditional design techniques being reserved for evaluation and refinement of the ensuing designs. Further, as advancing technologies emerge, designers must struggle with the issue of how to generate new innovative technological artifacts that meet users' requirements. The techniques of socially centered design may prove to be instrumental to this developmental process. In particular, socially centered design approaches are advantageous in the exploratory design stages before an initial design concept has been identified (Nardi 1997). At this stage, the information generated from observational studies can lead to creative design solutions that would likely have never been rendered without such insights. These approaches are also useful once a formal prototype has been generated when observational studies can focus on the intended users interacting with the system or product in its operational setting.

As for where socially centered design will have the greatest utility, the current surge of consumer products provides numerous opportunities. For example, while multimedia currently focuses on the technological integration of several input and output media, a socially centered approach would redirect focus from the media, which is transitory in nature, to the context in which this media is applied, uncovering its work practices, artifacts and environmental and cultural factors (Stanney *et al.* 1997). Socially centered design may prove to be particularly influential in the design of emerging interactive networks, particularly for interactive television (I-TV). Designers of I-TV, who are freed from the need to create media that appeals to the masses, will need to tap into the lives of their viewers to identify their unique skills and interests if they are to capture targeted audiences. The techniques of ethnographic studies will be well suited to such investigations. In addition, the emerging virtual environments (VE) technology is inherently more social than past non-interactive technologies. VE users are immersed in a particular context or virtual world, with its own set of interactive artifacts and situational characteristics. For such interactive products and systems to be effectively developed, the assumptions that designers make concerning the types of users who will adopt these systems, the types of tasks to be performed and the environmental character-istics in which these activities will be done become critically important. The effectiveness of such designs may thus heavily rely on the techniques of socially centered design.

6. CONCLUSIONS

System and product designers have come to the realization that it is not what a product or system can do that defines success but how well users can accomplish intended tasks with the aid of the product or system. Yet users are known to have idiosyncratic usage patterns that are not readily foreseen by designers. The challenge is to identify the artifacts, cooperative task activities, impact of organizational, cultural and situational factors, as well as the interpersonal behaviors that influence the effectiveness of a given system or product design. Failing to comprehend or consider these factors may make the acceptance and adoption of new system level solutions very unlikely or difficult at best. Socially centered design techniques can be used to systematically elicit an understanding of contextual factors and integrate this knowledge into the design process, thus providing a grounding framework within which a formal design can evolve.

Sociotechnical Analysis of Work System Structure: Applying Empirical Models of Sociotechnical System Elements

H. W. Hendrick

Hendrick and Associates, Englewood, CO 80111, USA

1. INTRODUCTION

In order to systematically analyze the dimensions of a given work system's structure, we first must understand what those dimensions are. As we then shall see, utilizing empirically developed models, knowledge of the specific sociotechnical characteristics of a given work system can be used to analyze and optimize these dimensions for that work system.

2. THE STRUCTURAL DIMENSIONS OF WORK SYSTEMS

The organizational structure of a work system can be conceptualized as having three core dimensions. These are *complexity, formalization,* and *centralization* (Robbins 1983). Complexity, in turn, has two major dimensions: *differentiation* and *integration.*

2.1. Complexity: Differentiation

Work system structures employ three common types of differentiation: *vertical, horizontal,* and *spatial.* Increasing any one of these three increases a work system's complexity.

2.1.1   Vertical differentiation

This refers to the of the number of hierarchical levels separating the chief executive position from the jobs directly involved with the hands on work. Too much vertical differentiation for a given set of sociotechnical system conditions increases communication, coordination, and control problems, thus decreasing efficiency. Too little also decreases efficiency because of a lack of adequate coordination and control.

2.1.2 Horizontal differentiation

This refers to the degree of departmentalization and specialization within a work system. Horizontal differentiation increases complexity because it requires more sophisticated and expensive methods of control. In spite of this drawback, specialization is common to most work systems because of the inherent efficiencies in the division of labor.

The two most common ways to determine whether or not a work group should be divided into two or more departments are the degree of commonality of *goals* and *time orientation* To the extent that subgroups either differ in goals, or have differing time orientations, they should be structured as separate departments. For example, sales persons differ from R&D employees on both of these dimensions. Not only do they have very different goals, but also the time orientation of sales personnel usually is *short*

(one year or less), whereas it usually is *long* (three or more years) for R&D personnel. Thus, they clearly should be departmentalized separately, and usually are. (Robbins 1983)

2.1.3   Spatial dispersion

This refers to the degree an organization's activities are performed in multiple locations. There are three common measures of spatial dispersion: (1) the number of geographic locations comprising the total work system, (2) the average distance of the separated locations from the organization's headquarters, and (3) the proportion of employees in these separated units in relation to the number in the headquarters. In general, complexity increases as any of these three measures increase.

2.2. Complexity: Integration

Integration refers to the number of mechanisms designed into a work system for ensuring communication, coordination, and control among the differentiated elements. As the differentiation of a work system increases, the need for integrating mechanisms also increases. This happens because greater differentiation increases the number of units, levels, etc. that must communicate with one another, coordinate their separate activities, and be controlled for efficient operation.

Some of the more common integrating mechanisms that can be designed into a work system are formal rules and procedures, committees, task teams, liaison positions, and system integration offices. Computerized information and decision support systems also can be designed to serve as integrating mechanisms. Vertical differentiation, in itself, is a primary integrating mechanism (i.e. a manager at one level serves to coordinate and control the activities of several lower-level groups).

For a given work system's sociotechnical characteristics, too many integrating mechanisms stifle efficiency, and too few result in inadequate communication, coordination and control. Either too few or too many usually will increase costs and decrease productivity.

2.3. Formalization

Formalization refers to the degree to which employee decision discretion is limited by explicit job descriptions, extensive rules, and clearly defined procedures covering processes. Ergonomists can contribute to formalization by designing job, machine, and software interfaces so as to standardize procedures and allow little opportunity for operator decision discretion. By the same token, these interfaces can be ergonomically designed to permit greater flexibility and scope to employee decision-making.

2.4. Centralization

Centralization refers to the degree to which formal decision-making is concentrated in a relatively few individuals, group, or level, usually high in the organization. When the work system structure i`s highly centralized, lower-level supervisors and employees have only minimal input into the decisions affecting their jobs (Robbins 1983). In highly decentralized work systems, decisions are delegated downward to the lowest level having the necessary expertise.

Work systems carry out two basic forms of decision-making, *strategic* and *tactical*, and the degree of centralization often is quite different for each. *Tactical* decision-making has to do with the

day-to-day operation of the organization's business; strategic decision-making concerns the long range planning for the organization (Hendrick 1997).

3. SOCIOTECHNICAL ANALYSIS OF THE STRUCTURAL DIMENSIONS OF WORK SYSTEMS

The analysis of a work system's structure and related processes involves consideration of three major sociotechnical system elements that interact and affect optimal work system design. These are the (1) *technological subsystem,* (2) *personnel subsystem,* and (3) *relevant external environments* that permeate the organization and upon which its survival and success depends. Each of these elements has been studied in relation to its effects on the three organizational design dimensions of *complexity, formalization, and centralization,* described earlier, and empirical models have emerged. These models can be used as macroergonomic tools in analyzing and developing or modifying the design of a given work system.

3.1. Technological Subsystem Analysis

Technology, as a determinant of work system structure, has been operationally classified in several distinctly different ways that are useful in analyzing work system structure (e.g. see Hendrick (1997) for a summary of these). Perhaps the most generalizable and widely validated model of the technology-work system structure relationship is that developed by Perrow (1967).

3.1.1. Perrow: knowledge-based technology

Perrow's model uses a *knowledge-based* classification scheme. He begins by defining technology as the action one performs upon an object in order to transform the object. This action requires some form of technical knowledge. Using this approach, Perrow identified two underlying dimensions of knowledge-based technology. The first of these is *task variability*, or the number of exceptions encountered in one's work. The second concerns the type of search procedures one has available for responding to task exceptions, or *task analyzability*. These search procedures can range from "well defined" to "ill defined". At the "well defined" end of the continuum, solving problems can be accomplished using rational-logical, quantitative, and analytical reasoning. At the "ill defined" end there are no readily available formal search procedures. Instead, one must rely on the experience, judgement, and intuition of the decision-maker. Dichotomizing these two dimensions yields a two-by-two matrix having four cells. As shown in figure 1, each cell represents a different knowledge-based technology.

1. *Routine* technologies have well defined problems with few exceptions. They lend themselves to standardized coordination and control procedures and, thus, are associated with high formalization and centralization and moderately high vertical differentiation. Mass production units typify this category.
2. *Non-routine* technologies have many exceptions and difficult to analyze problems. As a result, these technologies require the flexibility that comes from being highly decentralized and having low formalization. Combat aerospace operations would be an example.
3. *Engineering* technologies have many exceptions, but can be

Figure 1. Perrow's knowledge-based technology classes

handled using well-defined rational-logical processes. Consequently, they lend themselves to moderate centralization, but require the flexibility that is achievable through low formalization. Engineering design firms or units typify these technologies.
4. *Craft* technologies involve fairly routine tasks, but problem solving relies heavily on the experience, judgement, and intuition if the individual craftsperson. Decisions thus must be made by those having the particular expertise. This requires decentralization, low formalization, and usually works best with low vertical differentiation.

3.1.2. Other technological considerations

During the 1980s and 1990s, major advances were, and continue to be made, in computer and communications technology. Two forms of this technology have major implications for work system design: these are advanced information technologies (AIT) and computer integrated manufacturing (CIM). AIT has tended to facilitate decentralizing operational or tactical decision-making, while enhancing the efficiency of centralized strategic decision-making (Bedeian and Zammuto, 1991). Computer-based AIT links employees electronically, thus enabling them to better participate in the tactical decision-making process. As a result, AIT enhances the efficiency of decentralization and greater employee professionalism (see 3.2.2 below). In addition, AIT enables lower level personnel to have a greater indirect influence on strategic decision-making. This occurs because they often are the ones who select and filter the information and structure the data bases that form the input for the highly centralized strategic decisions.

CIM, by its very nature, results in a very high level of integration of workflow processes and, thus, a high level of interdependence among differentiated units. This interdependence increases the need for designing in effective integrating mechanisms across functional units. In addition, CIM often increases the need for market-based unit grouping (e.g. project or product task team grouping) — especially during the product design phase (Bedeian and Zammuto 1991).

3.2. Personnel Subsystem Analysis

At least three major personnel subsystem characteristics are critical to an organization's work system design. These are (1) the *degree of professionalism*, (2) *demographic characteristics*, and (3) *psychosocial aspects* of the work force (Hendrick 1997).

3.2.1. Degree of professionalism

Formalization can take place either on or off the job (Robbins 1983). When done on the job, formalization is *external* to the

employee. The rules, procedures, and human-system interfaces are designed to limit employee *discretion*. This typically characterizes unskilled and semi-skilled positions, and is what is meant by the term "formalization". Professionalism, on the other hand, creates *internal* formalization of behavior through a socialization process that is an integral part of education and training. Thus, from an ergonomics design standpoint, there is a trade-off between formalization of the work system and professionalization of the jobs that comprise it. If the work system is designed to allow for low formalization and, thus, considerable employee discretion, jobs and related human-system interfaces need to be ergonomically designed to require persons with relatively greater professional training or education. In summary, in the absence of formal decision rules and procedures, employees need to have the necessary professional knowledge and skills to make the decisions. Most often, it is the need to have employees that can deal with unanticipated or unique situations that creates the need for low formalization and more highly professionalized jobs.

3.2.2. Demographic factors

The demographic characteristics of the workers that comprise the organization's personnel subsystem can interact with the work system's design. Those that are most striking within the USA are the (1) "graying" of the work force, (2) age group differences in the value system of workers, (3) broadening of the cultural diversity of the work force, and (4) increase in the number of woman in the work force.

Graying of the work force. Since the mid-1970s as the post-World War II baby boom bulge moves through their working careers, the average age of the work force has been increasing at the rate of about 6 months per year. As a result, we now have a more experienced, mature and better-trained work force than existed in the 1970s and before. In fact, according to the bureau of labor statistics, since the mid-1970s the number of persons with post-high school education in the labor force has doubled. If employees are to feel fully utilized and remain motivated, work systems must accommodate to this change by becoming less formalized and decentralizing more of the decision-making - particularly where high formalization and centralization traditionally have characterized the work system's structure.

Value system shifts. Based on extensive longitudinal studies of work force attitudes and values, Yankelovich (1979) noted that those workers born after World War II have very different views and feelings about work than their predecessors. He further noted that these conceptions and values would have a profound effect on work systems. Yankelovich refers to this group of workers as the "new breed". This "new breed" of workers has three common principal values that distinguish them from those of the mainstream of older workers: (1) The increasing importance of leisure, (2) the symbolic significance of the paid job, and (3) the insistence that jobs become less depersonalized and more meaningful. When asked what aspects of work are more important, the "new breed" person stresses "being recognized as an individual", and "the opportunity to be with pleasant people with whom I like to work" (Yankelovich 1979). In terms of work system design, these values translate into a need for less hierarchical, less formalized, and more decentralized organizational structures; and for an attendant greater

professionalism to be designed into individual jobs and human-system interfaces then found in traditional bureaucracies. In short, work system design characteristics that allow for greater individual recognition and respect for an employee's worth. They also can enhance meaningful social relationships on the job.

Cultural diversity. In a number of urban areas in the USA and elsewhere, such as the Los Angeles Basin, immigration has resulted in work forces that are far more culturally diverse than existed several decades ago. It now is apparent that unless organizations accommodate to this diversity, it will adversely affect employee motivation and commitment. Much of the accommodation required has to do with changing organizational cultures to be more inclusive. Decentralizing some aspects of decision-making to allow greater employee involvement and control appears to be one structural change that can facilitate this accommodation process. This can include the use of participatory ergonomics in designing or modifying work systems.

Women. Although women have been entering the work force in progressively increasing numbers, there is no clear indication as to how these demographic changes will, or should affect work system design. The one possible exception is that, as women have moved into traditionally male positions, they have tended to emphasize the importance of modifying work systems and jobs so as to allow for greater social interaction and more flexible work hours.

3.2.3. Psychosocial factors

Harvey, Hunt, and Schroder (1961) have identified the higher-order structural personality dimension of concreteness—abstractness of thinking, or *cognitive complexity* as underlying different conceptual systems for understanding reality. In general, the degree to which a given culture or subculture (1) encourages by its child-rearing and educational practices an *active* exposure or openness to learning from new experiences or *diversity*, and (2) through affluence, education, communications media, transportation systems, etc, provides *opportunities* for exposure to diversity, the more cognitively complex the persons of that culture will become. An active exposure to diversity enables persons to develop new conceptual categories and sub-categories in which to store experiential data, or *differentiation;* and to learn new rules and combinations of rules for *integrating* information and deriving deeper, more insightful conceptions of problems and solutions. Persons who experience an active exposure to considerable diversity thus develop a high degree of conceptual differentiation and integration, or *abstract* functioning. Conversely, relatively closed-minded approaches to new experiences and/or a lack of exposure to considerable diversity leads to a more limited development of differentiation and integration in one's conceptualizing, or *concrete* functioning.

Concrete functioning consistently has been found to be characterized by a relatively high need for structure and order and for stability and consistency, a low tolerance for ambiguity, closedness of beliefs, absolutist thinking, authoritarianism, paternalism and ethnocentrism. Concrete persons tend to interpret their world more literally and statically than do abstract persons. They tend to see their views, values, norms, and institutional structures as relatively static and unchanging. Conversely, abstract adult functioning is characterized by a low need for structure and order and stability and consistency, a high

tolerance for ambiguity, openness of beliefs, and relativistic thinking. They also demonstrate a greater capacity for empathy and related strong people orientation; consequently, they are less authoritarian, paternalistic, and ethnocentric. Abstract persons have a dynamic conception of their world and *expect* their views, values, norms, and institutional structures to change. (Harvey *et al.* 1961).

Not surprisingly, relatively concrete work groups and managers function best in work systems characterized by moderately high vertical differentiation, centralization and formalization; and in which the structure and processes are unambiguous and relatively slow to change. In contrast, cognitively complex or abstract persons prefer more dynamic work systems, characterized by relatively low levels of vertical differentiation, formalization, and centralization.

3.2.4. Personnel subsystem implications for future work system designs

Much of the available data on personnel subsystem determinants of work system design comes from attitude surveys and projections from psychosocial and demographic studies. In spite of their somewhat tenuous nature, there is considerable convergence of these data: They point to a need for work systems of the future to be as vertically undifferentiated, decentralized, and lacking in formalization as their technology and environments will permit. Given the rapidly developing trend towards highly dynamic virtual organizations, and attendant work systems, this indication is most fortunate.

4. EXTERNAL ENVIRONMENTAL CHARACTERISTICS

Both the survival and success an organization depends on its ability to adapt to is external environment or, more specifically, to its *relevant task environment*. Relevant task environment refers to that part of the firm's external environment that can positively or negatively influence the organization's effectiveness — the organization's critical constituencies.

4.1. Types of External Environments

Some of the most common types of external environments to which organizations must adapt are as follows.

- *Socioeconomic*. Particularly the degree of stability, nature of the competition, and availability of materials and qualified workers.
- *Educational*. Especially the availability of facilities and programs, and the educational level and aspirations of workers.
- *Political*. Particularly the degree of political stability and the governmental attitudes toward (a) business (friendliness

versus hostility), (b) control of prices, and (c) welfare of industrial workers.
- *Cultural*. Social status system, and values and attitudes held towards work, management, etc., and the nature of trade unions and union-management relationships.

4.2. Environmental Uncertainty

Of particular importance to work system design is the fact that all specific task environments vary along two highly critical dimensions: *Change* and *complexity* (Duncan 1972). Degree of change refers to the extent to which a given task environment is dynamic or remains stable over time. The degree of complexity refers to whether the components of an organization's specific task environment are few or many in number (i.e. does the company interact with few, or many government agencies, customers, suppliers, competitors etc.?). These two environmental dimensions of change and complexity, in combination, determine the *environmental uncertainty* of an organization. Figure 2 illustrates this relationship for four different levels of uncertainty.

With a high degree of uncertainty, a premium is placed on an organization's ability to be flexible and rapidly respond to change. With low uncertainty, maintaining stability and control for maximum efficiency becomes paramount for survival. The greater the environmental uncertainty, the more essential it is for the work system's structure to have relatively low vertical differentiation, decentralized tactical decision-making, low formalization, and a high level of professionalism among its work groups. In contrast, highly certain environments call for a comparatively high level of vertical differentiation, formalization, and centralization, such as historically are found in classical bureaucracies. Today, most large and/or high technology corporations are operating in highly dynamic and complex environments.

5. INTEGRATING THE FINDINGS

In weighting the results from the analysis of each major sociotechnical system element for a given work system, if we assign a weighting of '1' to the technological subsystem results, we would assign a rating of approximately '2' to the personnel subsystem results, and a weighting of approximately '3' to the external environment analysis. Based on the literature, this roughly approximates the relative importance of each in determining the design of work systems.

It also is important to note that, once the characteristics of the overall work system have been determined and installed; jobs and related human–machine and human–software interfaces need to be modified, as necessary, to harmonize. For example, if low formalization and decentralized tactical decision-making characterize the desired work system, then the individual jobs

Degree of complexity	Degree of change	
	Stable	Dynamic
Simple	Low uncertainty	Moderate uncertainty
Complex	Moderate uncertainty	High uncertainty

Figure 2. Environmental uncertainty of organizations.

will need to be designed or modified to require the necessary knowledge and skills to carry out necessary evaluations and make sound decisions. Similarly, information and, as required, decision support systems would need to be designed to provide the necessary information and support. Training programs also may need to be designed or modified to bring employees up to the required level of professionalism. By the same token, procedures may need to be modified to make them less formalized and allow for greater flexibility of action.

Sociotechnical Systems Theory: the Sociotechnical Systems Model of Work Systems

H. W. Hendrick

Hendrick and Associates, Englewood, CO 80111, USA

1. INTRODUCTION

The sociotechnical systems model of work systems was developed empirically in the late 1940s and 1950s by Trist and Bamforth (1951) and their colleagues at the Tavistock Institute of Human Relations in the UK. Follow-on research by Katz and Kahn and their colleagues at the University of Michigan's Survey Research Center, and by many others, served to confirm and refine the sociotechnical systems model. The basic tenets of sociotechnical systems theory, and the coining of the term *sociotechnical systems,* can be traced back to the classic studies by Trist and Bamforth relative to the effects of technological change in a deep seam Welsh coal mine (DeGreene 1973).

2. THE TAVISTOCK STUDIES

Prior to the introduction of new machine technology, the traditional system of mining coal in the Welsh mines was largely manual in nature. The work was carried out by small teams of miners who functioned relatively autonomously. To a large extent, control over work was exercised by the group itself. Each miner could perform a variety of tasks, thus enabling most jobs to be interchangeable among the workers. The miners derived considerable satisfaction from being able to complete the entire "task". Further, through their close group interaction, workers could readily satisfy social needs on the job. As a result of these work system characteristics, the psychosocial and cultural characteristics of the workforce, the task requirements, and the work system's design were *congruent.*

The technological change consisted of replacing this more costly manual, or *shortwall*, method of mining with mechanical coal cutters. Miners were no longer restricted to working a short face of coal. Instead, they now could extract coal from a long wall. Unfortunately, this new and more *technologically-efficient longwall* system resulted in a work system design that was not congruent with the psychosocial and cultural characteristics of the workforce. Instead of being able to work in small, close-knit groups, shifts of 10 to 20 men were required. The new jobs were designed to include only a narrowly defined set of tasks. The new work system structure severely limited opportunities for social interaction, and job rotation no longer was possible. The revised work system required a high degree of interdependence among the tasks of the three shifts. Thus, problems from one shift carried over to the next, thereby holding up labor stages in the extraction process. This complex and rigid work system was highly sensitive to both productivity and social disruptions. Instead of achieving the expected improved productivity, low production, absenteeism, and inter-group rivalry became common (DeGreene 1973).

As part of follow-on studies of other coal mines by the Tavistock Institute (Trist, Higgin, Murray, and Pollock 1963), this conventional longwall method was compared with a new, *composite* longwall method. The composite work system design utilized a combination of the new technology and features of the old psychosocial work structure of the manual system. As compared with the conventional longwall system, the composite work system's design reduced the interdependence of the shifts, increased the variety of skills utilized by each worker, permitted self-selection by workers of their team members, and created opportunities for satisfying social needs on the job. As a result of this work system redesign, production became significantly higher than for either the conventional longwall or the old manual system; and absenteeism and other measures of poor morale and dissatisfaction dropped dramatically (DeGreene 1973).

Prior to the Tavistock studies, there was a widely held belief in *technological determinism*. It incorporated the basic concept of Taylorism that there is one best way to organize work. It was a belief that the "one best way" for designing the work system is determined by the nature of the technology employed. Based on the Tavistock Institute studies, Emory and Trist (1960) concluded that *different organizational designs could utilize the same technology*. As demonstrated by the Tavistock studies, the key is to select a work system design that is compatible with the characteristics of: (a) the people who will constitute the personnel portion of the system; and (b) the relevant external environment; and then to (c) employ the available technology in a manner that achieves congruence.

Although any given technology can utilize different work system designs, technology, *once employed in the system*, often constrains the subset of possible work system designs. This has become even more evident with the introduction of computers and related automation into managerial, administrative, production, logistical, marketing, and other facets of our modern complex systems. With this progressively increasing automation, it has become increasingly important to determine first the optimal *macroergonomic* design of the work system before fully proceeding with the micro-ergonomic design of human–machine and human–software modules, subsystems, and interfaces. At least *conceptually,* a top-down macroergonomic approach is essential to insure that the "dog wags the tail", and not visa-versa.

3. JOINT CAUSATION AND SUBSYSTEM OPTIMIZATION

Sociotechnical systems theory views organizations as open systems engaged in transforming inputs into desired outcomes (DeGreene 1973). *Open* means that work systems have permeable boundaries exposed to the environments in which they exist. These environments thus permeate the organization along with the inputs to be transformed. There are several primary ways in which environmental changes enter the organization: through its marketing or sales function, through the people who work in it, and through its materials or other input functions (Davis 1982).

As transformation agencies, organizations continually interact with their external environment. They receive inputs from their environment, transform these into desired outputs, and export these outputs back to their environment. In performing this transformation process, work systems bring two critical factors to bear on the transformation process: technology in the form of

a *technological subsystem*, and people in the form of *a personnel subsystem.* The design of the technological subsystem tends to define the *tasks* to be performed, whereas the design of the personnel subsystem primarily prescribes the *ways* in which tasks are performed. The two subsystems interact with each other at every human–machine and human–software interface. Thus, the technological and personnel subsystems are *mutually interdependent.* They both operate under *joint causation*, meaning that both subsystems are affected by causal events in the external environment.

Joint causation underlies the related sociotechnical system concept of *joint optimization.* The technological subsystem, once designed, is relatively stable and fixed. Accordingly, it falls to the personnel subsystem to adapt further to environmental change. Because the two subsystems respond jointly to causal events, optimizing one subsystem and fitting the second to it results in sub-optimization of the *joint work system*. Consequently, maximizing overall work system effectiveness requires jointly optimizing *both* subsystems. Thus, in order to develop the best possible fit between the two, joint optimization requires the *joint design* of the technical and personnel subsystems, given the objectives and requirements of each, and of the overall work system (Davis 1982). Inherent in this joint design is developing an optimal structure for the overall work system (see Sociotechnical analysis of work system structure).

3.1. Joint Optimization vs. Human–centered Design

At first glance, the concept of joint optimization may appear to be at odds with human-centered interface design. It might seem that human-centered design would lead to maximizing the personnel subsystem at the expense of the technological subsystem and, thus, to sub-optimization of the work system. In fact, this has proven not to be the case. In human-centered design, the goal is to make optimal use of humans by the *appropriate* employment of technology so as to optimize jointly the capabilities of each, and their interfaces. When a human-centered design approach is not taken, invariably the capabilities of the technological subsystem are maximized at the expense of the personnel subsystem. In recent decades, this often has been exemplified by automating and giving the human the left-over functions to perform, which sub-optimizes the personnel subsystem and, thus, the total work system. To achieve the appropriate balance then, joint optimization is operationalized through (a) joint design, (b) a human-centered approach to function and task allocation and design, and (c) attending to the organization's sociotechnical characteristics (see Sociotechnical analysis of work system structure).

4. THE SOCIOTECHNICAL SYSTEM ELEMENTS

As is inferred above, the design of a work system's structure and related processes involves consideration of three major sociotechnical system components that interact and affect optimal organizational design. These are the (1) *technological subsystem,* (2) *personnel subsystem,* and (3) *relevant external environments* that permeate the organization.

Beginning with the Tavistock studies, cited earlier, a consistent finding — and one fundamental to sociotechnical system theory — is that the four basic sociotechnical system elements are

mutually interdependent. If any characteristic of one of the four elements is changed, it will affect the other three. For example, if one changes some aspect of the personnel subsystem, it will impact on the technological subsystem, the work system's interaction with the external environment, and the structure and/or processes of the work system. It is of critical importance for ergonomists if these impacts on the other sociotechnical system elements and their interfaces are not anticipated and planned for as the impacts are likely to be *dysfunctional* and affect the work system in unanticipated and sub-optimal ways.

5. WORK SYSTEM HARMONIZATION AND ORGANIZATIONAL SYNERGISM

A widely accepted view among system theorists and researchers is that all complex systems are synergistic: that the whole is more than the simple sum of its parts. Thus, like biological and other complex systems, sociotechnical systems should be synergistic. Theoretically, because of this synergism, the following should tend to occur in our complex work systems.

5.1. When Work Systems Have Incompatible Designs

When work system structures and processes are grossly incompatible with their sociotechnical system characteristics, and/or jobs and human-system interfaces are incompatible with the work system's design, the whole is less than the sum of its parts. Under these conditions, we can expect the following to be relatively deficient: (1) productivity, especially quality of production, (2) accident rates, lost time injuries, and adherence to safety standards and procedures, and (3) motivation, related aspects of job satisfaction, and perceived quality of work life (e.g. psychosocial comfort, stress, etc.).

Further, these detriments may be greater than a simple sum of their parts would indicate.

5.2. When Work Systems Have Compatible Designs

When, taking into account its particular sociotechnical system characteristics, a work system has effectively been designed macroergonomically, and that effort has been carried through to the micro-ergonomic design of jobs and human–machine and human–software interfaces, then the work system design is *harmonized.* As a result, synergistic functioning becomes possible; and system productivity, safety, employee satisfaction, commitment, and perceived quality of work life will be much greater than the simple sum of the parts would indicate.

5.3. Implications for the Potential of Organizations

Assuming the above two propositions are true, then a fully harmonized sociotechnical system has the potential to improve productivity, scrap rates, safety, health, employee motivation and commitment, and the quality of work life *exponentially* rather than linearly. Instead of the 10% to 25% improvements in these system effectiveness measures that many ergonomists have experienced from their successful micro-ergonomic interventions, we should see improvements of 50% to 90%, or more (Hendrick 1986). As has been documented with actual cases (Hendrick 1996) this prediction is proving to be accurate.

Telework

A. Buessing

Department of Psychology, Technical University Muenchen, Munich, Germany

1. INTRODUCTION

The first pioneers of teleworking worked in the 1970s. However, telework was not widely accepted at that time; rather it was rejected by some because it was associated with simple homework or with day laboring.

Why is telework on the upswing these days? The increase of information and knowledge work connected with a rapid growth in performance and network capability and an enormous decline in the cost of technology allows for new qualities of telework (e.g. Andriessen and Roe 1994). Globalization, increase of international competition and a consumer-oriented market demand for new flexible forms of organization (modular, distributed, virtual) into which telework as an "any-time-any-place" form of work organization easily can be integrated. New ways of living that result from a dissolution of core family structures, an increase of female employment and an individualization of biographies add topicality to the contract between work, family and leisure, and let the work-family challenge become a relevant field for organizations.

2. TELEWORK: FORMS, PENETRATION AND POTENTIAL

2.2. Forms of Telework

Many phrases have been coined to describe forms of work known as telework: telecommuting, remote work, distance work and, of course, telework are the popular ones. "Telework" is preferred here as it places emphasis on work being done at distance rather than placing emphasis on commuting. Besides the well-known home-based version, telework covers a wide range of different forms of work organization.

A consensus among the different approaches seems to be that telework is a media-supported distributed work process which is spatially decentralized. Based on selected criteria, some essential *forms* of telework can be differentiated (Wigand *et al.* 1997):

According to spatial factors one can distinguish between *home-based* telework, *center-based* telework (satellite, neighborhood offices, telecentres), *mobile* telework and *on-site* telework, which takes places at the location of the customer.

In terms of time factors one can classify in *full-time* telework and *alternating* telework (e.g. between home and central office).

Contractual rules can be applied to differ between, for example, telework based on an *employment* or *freelance contract*.

With regard to technical links one can make a difference between *asynchronous off-line work*, more or less synchronized information exchange and *synchronous on-line-work*.

From a broader perspective telework is part of a media supported telecooperation process (Wigand *et al.* 1997) among distributed employees, organization units and organizations including telemanagement ("media supported distributed coordination") and teleservices ("media supported distributed provision of services", e.g. telebanking, teleshopping, telemedicine, etc.).

2.2. Penetration and Potential of Telework

Today telework is a widespread form of work. However, peculiarities are found in its organization among different countries according to differences in culture, geography, economy and societal background. Therefore, and because of the different terms and definitions in use, estimations of telework penetration usually are not very reliable.

The USA is considered the mother country of telework. According to recent data it leads with ~11 million teleworkers, which represents ~9% of the labor force in 1997 (http://findsvp.com/prls/pr97/telecomm.html). In Europe telework is also a fast spreading form of work organization. The 1998 European Information Technology Observatory (EITO; http://www.fvit-eurobit.de/eito) provides data for the European telework penetration based on the TELDET study from 1994 (Korte and Wynne 1996). According to this study there is a total of ~1.5 million teleworkers in Europe, which equals a penetration rate of 1% in 1994 (in comparison in 1994 USA = 4.54% and Canada = 3.5%). However, among the 15 countries of the European Union (EU) one finds large differences. Five countries range above the average (Sweden, Finland, UK, Ireland, The Netherlands) while all 10 others countries fall more or less below this average of 1%. More recent data, for example for Germany, however indicate a strong progress in telework dissemination during the past couple of years: results from a 1997 study show a that ~0.875 million teleworkers, which would be ~2.4% in Germany at that time.

Estimations of telework potentials are even more vague than penetration figures. While the growth of telework in the USA between 1995 and 1997 reflected an estimated annual rate of 15% (which equals to an extrapolated rate of ~12% of the labor force in 2000) the European Commission sees ~10 million teleworkers, which is ~7% for the EU in 2000.

3. TASKS, QUALIFICATIONS, COSTS AND BENEFITS OF TELEWORK

3.1. Tasks under Telework

To a large extent telework today is *knowledge work*; it is carried out by qualified personnel, specialists and knowledge workers. Tasks like programming, management, research and development, steering and supervision of technical processes are in the focus of interest. Though, one finds all kinds of jobs under telework: counseling, consulting, management, marketing, monitoring, research and development, "project-based organization" type of telework where teleworkers are involved in different projects and different roles (e.g. consultant, trainer, salesman, information broker). Only a small proportion among teleworking tasks represent secretary and personal support functions because they require frequent and high rates of communication and tuning. Therefore, most appropriate are those tasks that need little regular and especially not much cooperation and spontaneous personal face-to-face communication.

3.2. Qualifications for Telework

In the beginning telework was dominated by low skilled work, fragmented and easily controllable working tasks, typical for word processing or data input. Since then a shift to more or less sophisticated *qualificational demands* under telework took place. While high work fragmentation and strong external control still can be found today's teleworking jobs cover a wide range of

demands, autonomy, necessary skills and qualifications, often reaching a high level of job enlargement and job enrichment.

Moreover, the *upkeeping of qualifications* is of importance: for people who are bound to the household because of family obligations or by being handicapped, telework is a chance to avoid dequalification or to keep up with the progress of new qualificational demands (Büssing 1998). Under such circumstances telework quite often functions as a bridge over to a "regular" non-telework job.

Self-leadership is considered a key qualifications of successful teleworkers. But the step away from being guided and led requires new competencies because insufficient qualification for self-organization and self-control can lead to time pressure, overtaxing, stress and reduced quality. Especially telework with its flexible working time arrangements and relatively high time sovereignty stands for more responsibilities and requirements in dealing with time because leaving the "golden cage" of standardized working times and the defined distinction between working and leisure time also implies the loss of organizational rules with all its relieving moments.

3.3. Costs and Benefits of Telework

From the companies point of view telework increases productivity and contributes to advantages in competition. For example Gray *et al.* (1993) report of increases in productivity of 40–70% in the USA. Cost reduction results from a saving of space, lower rent and running costs, and a decrease in labor costs, for example, by hiring personnel from areas with lower income level or by cutting back additional labor costs, e.g. for overtime work.

While it is fairly easy to measure cost reductions it is quite difficult to estimate benefits and economic potentials of telework. An important benefit of telework is the increase of efficiency through a more flexible and autonomous organization of work and through a concentrated and uninterrupted way of working. Another aspect of economic relevance are nearness and orientation towards customers due to decentralization and flexibility of teleworking. Moreover, telework allows a better use of human capital. According to many studies teleworkers show higher work motivation, satisfaction and overall well-being which is reflected in an increase in productivity, reduced absenteeism and turnover. Finally, telework seems to be a good way of binding qualified personnel especially in cases of family obligations (e.g. birth of a child, demands for care) and change of residence.

Besides cost reduction and benefits telework may cause new costs itself. These costs are to a large extent so called transaction costs (i.e. costs for new methods of coordination and management); however, it is also found that additional expenditure for hardware and software, payments for telecommunication and refunds for running costs especially when telework is home-based.

From the *employee* point of view telework allows a spatio-temporal independence of work and non-work, and, therefore, telework creates chances to integrate and balance work and private life. This provides opportunities for persons with family obligations, handicaps and limited mobility, and flexibility who otherwise would not be able to participate in the labor market. However, telework also gains attractiveness for regular job holders because telework permits a self-regulated and individualized work organization and working time, some time sovereignty, a reduction

of stress caused by commuting and an increase of family satisfaction. An important advantage of telework is seen in an improved quality of leisure. That is, no loss of time when changing between work and private activities and higher personal work efficiency under telework increase the actually available amount of private time, while time sovereignty ensures time for private activities at the right moment.

Besides these benefits teleworkers are regularly faced with some potential disadvantages. For example, they have to deal with the difficult demarcation between the different spheres of life, a stronger involvement in family affairs during working time, a loss of organizational transparency and a loss of resources like social support from colleagues, secretary assistance, informational support etc.

4. CHANGES IN ORGANIZATION, WORK AND PRIVATE LIFE UNDER TELEWORK

4.1. Changes in Management

Many organizational changes are associated with the introduction of telework: changes in human resources, structure, management style, culture, technology and tasks (Chapman *et al.* 1995); changes in the *style of management* are among those crucial for the success of telework. In most cases it is the middle management that has to deal with this new form of work organization, and their interests and actual possession of responsibility, hierarchy and control will undergo further change. The implementation of telework demands new ways of supervision and leadership according to the network system of telecooperation. To deal effectively with the organization of telework managers need — more than ever before — social and communicative competencies with respect to interpersonal relation and use of media to be able to build up trust, integration and identity; and, as a part of this process they have to accept the role of coaches and resource managers.

Moreover, and this is one of the important alterations, managers have to delegate many of their typical tasks to the teleworkers, e.g. coordination of dates, meetings, working time scheduling, information management. Therefore, the step from leading to *self-leadership of teleworkers* is ambivalent for management: it leads to less demands and a relief on the one side but on the other side it goes along with feelings of loss and uselessness; these feelings in turn may lead to reduced commitment, a lack of readiness and even reactance.

Under telework *management by objectives* and task-oriented management focusing on results instead of input and processes becomes the important way. And this forces managers to become more detailed and obliged, and to direct their communication more carefully to goal setting.

4.2. Changes in Work Motivation

A spatio-temporally flexible form of work organization like telework increases demands for *intrinsic motivation* on the side of the employee. Different work orientation of teleworkers compared to employees working at central offices are ascribed by van Sell and Jacobs (1994: 85): satisfied teleworkers are intrinsically motivated by their job and the challenges of their tasks while "office programmers derived most of their satisfaction from managing others and from having status in the office hierarchy."

However, it is known that work orientation and work satisfaction are also dependent on the social context (e.g. organizational climate), on the social support and on the feedback and appreciation of colleagues and superiors. Therefore, by accounting for motivation and satisfaction telework should be organized in a way that sufficient time and opportunities are available for task-related communication and exchange as well as for social contact in the central office.

4.3. Interrelation between Work and Private Life

There are many aspects of the intertwining of telework and private life to be mentioned (Büssing 1998). Therefore, we restrict to two important ones: the increased compatibility between work and private life by means of time sovereignty on the one and the reduced demarcation between the two spheres of life on the other side. In comparison with all other groups of employees teleworkers report the lowest time pressure and the highest degree of usability of free time according to the demands from family, children and friends. The multiple loads and the rhythms of family, spouses, children and all kinds of institutions (e.g. kindergarten, school, authorities) can more easily be matched. Moreover, they can make use of private activities not only during the evening, rather private life is much more equally distributed across a day. This is the good side. The bad side is the increased and hardly controllable spilling over of problems, conflicts and stress from telework to private life, and vice versa. With quite a few implications: for example children and other family members have to be urged not to interrupt and disturb, teleworkers miss the "switch off" and relaxing from work at home as well as from family responsibilities at work, role conflicts arise more often, and self-management takes a lot of time. However, altogether many studies find a better balancing between work and private life especially for those groups of teleworkers which need to closely coordinate their spheres of life because of young children and other indispensable family obligations.

5. FUTURE OF TELEWORK

The future of telework is difficult to forecast because present research has not yet developed models and theoretical approaches to explain the various impacts and outcomes of the different forms of telework and so far most of the research is on a relatively low methodological level (e.g. van Sell and Jacobs 1994). Besides advances in technology and work organization the future of telework depends largely on the readiness of companies as well as on the readiness, needs and attitudes of potential users (Handy and Mokhtarian 1996). Although we find many indications that demands and needs for telework tend to grow we know fairly little about the specific factors which support these tendencies.

First of all one can not be certain of the development of telework: will it follow the home or the center-based line of organization? Like in the past the dominating form of telework in the future will very likely be differ from country to country dependent upon geographical, economic, social and cultural circumstances. However, center-based telework can avoid or restrict potential disadvantages of home-based telework like for example social isolation, deficits in communication and cooperation, and incomplete working tasks without loosing some of the advantages of a highly flexible form of work organization close to the place of residence (Stanek and Mokhtarian 1998). Second, we lack specific knowledge about interaction and communication under telework, and their influence on trust and social relationships to colleagues, superiors and customers. Third, we need to know much more about changes of values and attitudes in work and family under telework to forecast its future. What we know by now is that telework not only leads to a dissolution of actual boundaries between work and non-work but also to a disintegration of symbolic confines between the areas of life with all their — quite often conflicting — implications for performance, appreciation, esteem on the one side and relaxation, social presence, and feelings of security on the other side (Büssing 1998).

In any case, the intra-organizational penetration of telework will be limited by transaction costs; especially the cost of coordination will make the practice of telework unreasonable beyond certain levels of dissemination. It is more likely that in the future telework will become an element of *telecooperation* of inter-organizational networks, networks of self-employed etc. as well as of *virtual organizations* of any kind (Wigand *et al.* 1997). This telecooperative embedding of telework will produce new challenges for both, management and teleworkers, and it will lead to new ways of communication, organizational cultures and identities.

Trade Union Approaches to Workplace Improvements

J. Lund

School for Workers, University of Wisconsin-Extension, Madison, WI 53703, USA

1. INTRODUCTION

Labor unions are institutions whose primary function is to represent the interests of their members at both the micro- (enterprise) and macro- (societal) level. Unions receive the bulk of their operating income from membership dues and must receive policy and expenditure authorization from the memberships. Ergonomics is rapidly becoming a major Labor union issue, although not in any uniform fashion and approaches to ergonomics differ widely at both the macro and micro-levels.

At least four variables impact the ergonomics approach a labor union will develop: (1) employer acceptance of repetitive stress injuries (RSI) as work-related and compensable under workers' compensation regulations or statutes; (2) union member support for ergonomics relative to their other concerns (e.g. wages, job security, other working conditions); (3) employer willingness to invest resources in ergonomic improvements and to involve the union in that process; and (4) public policy (laws, regulations) concerning ergonomics. Obviously, all four variables are interrelated: some deal solely with the micro-level while others operate within both micro and macro-levels.

Here, we will briefly explore how these four forces together with union structure and function, interact to determine what approach a labor union will take vis-à-vis ergonomics. In doing so, we will briefly describe the policy environment and the actors themselves and how these factors and the environment interact to determine the menu of ergonomic approaches available to unions.

2. VARIABLES AFFECTING CHOICE OF UNION ERGONOMICS APPROACHES

2.1. Employer Recognition that an Ergonomics Problem Exists

The employer's first step toward correcting ergonomic hazards is to recognize that they are a workplace problem. While they may be costly to acknowledge because of legal liability under worker compensation law, they are also costly to ignore because of their negative impact on productivity and employee morale. According to the US AFL-CIO, RSI in the US account for > 700 000 cases annually, or about one-third of all serious reported injuries costing an estimated $7000–30 000 per case for a potential annual cost of $20 billion (AFL-CIO 1997). (Gathering truly comparable and comprehensive international data on the extent and costs of RSI is complicated by a number of factors, particularly the lack of a commonly accepted definition of RSI and a universally accepted list of RSI injuries and illnesses which are compensable. Notwithstanding the above, several trends can be discerned: (1) the number of RSI is increasing. The Australian Commonwealth

Banking Corporation reported an increase in 275% of the number of RSI from December 1983 to November 1994 (Melhorne 1998). RSI occurrences have increased by 100% in the UK from 1989 to 1993 (TUC 1996); (2) the proportion of RSI to total reported occupational injuries and illnesses is growing as evidence from the province of Ontario (Ashbury 1995), in Sweden, where musculoskeletal injuries account for every fourth accident; in France, they account for > 50% of occupational illnesses (Euro Review 1994); and (3) the cost of compensating RSI is substantial. In the UK, RSI injuries cost ~£1 billion (TUC 1996) and in New Zealand, where in 1989, NZ$16 million was paid in compensation to 6200 RSI sufferers (Beadle and White 1992).) Unions may be able to make the economic case for employer ergonomic interventions by aggressively pursuing RSI work injury cases at the same time they engage the employer in discussion about the total cost of such injuries.

2.2. Labor Union Recognition of the Problem

Labor unions cannot function at the micro-level without some form of recognition of the union's representative status from the employer; they may be able to function only at the macro-level but will then be able to influence micro-events indirectly. Winning and maintaining this representational status is the first objective of a Labor union (in some cases, ergonomic issues may be a key to successful union recruitment of new members). This may be likened somewhat to a hierarchy of needs. The next basic needs the union must fulfill are the job and economic security of the union's members. If members are at risk of losing their jobs or if wages are about to be drastically cut, no Labor union is about to launch a full-blown ergonomics campaign in the workplace. Next, the union may have other more pressing safety and health issues, particularly protection from traumatic injuries. A union representing timber cutters is more likely to direct its limited resources on protecting its members from being struck by falling trees and limbs or being cut by power saws *before* it will launch an attack on the underlying causes of Raynaud's syndrome. Union members may be reluctant to embrace ergonomics (a higher order need) if it negatively affects lower order needs; if it is necessary to mechanize jobs to reduce the risks of highly repetitive work, with resulting job loss, unions or their members may actually oppose ergonomics. On the other hand, some national- and international-level labor organizations have developed ergonomics policies and programs for their members. (By way of example, the Trades Union Congress in the UK has published *Five Steps at Your Workplace* which focuses branch unions on workplace RSI surveys, attempting to cost out RSI, analyzing jobs and workstations for RSI risk factors and other actions (TUC 1997). The International Labor Office guidelines also recommend performing workplace surveys using a checklist aimed at identifying risk factors and what corrective actions can be taken (Rosskam 1997). Unions may also use government-developed or -sponsored checklists and guidelines, such as a *Guidance Note for the Prevention of Occupational Overuse Syndrome in the Manufacturing Industry* developed by Worksafe Australia (National Occupational Health and Safety Commission 1996).)

2.3. Employer Mobilization to Action

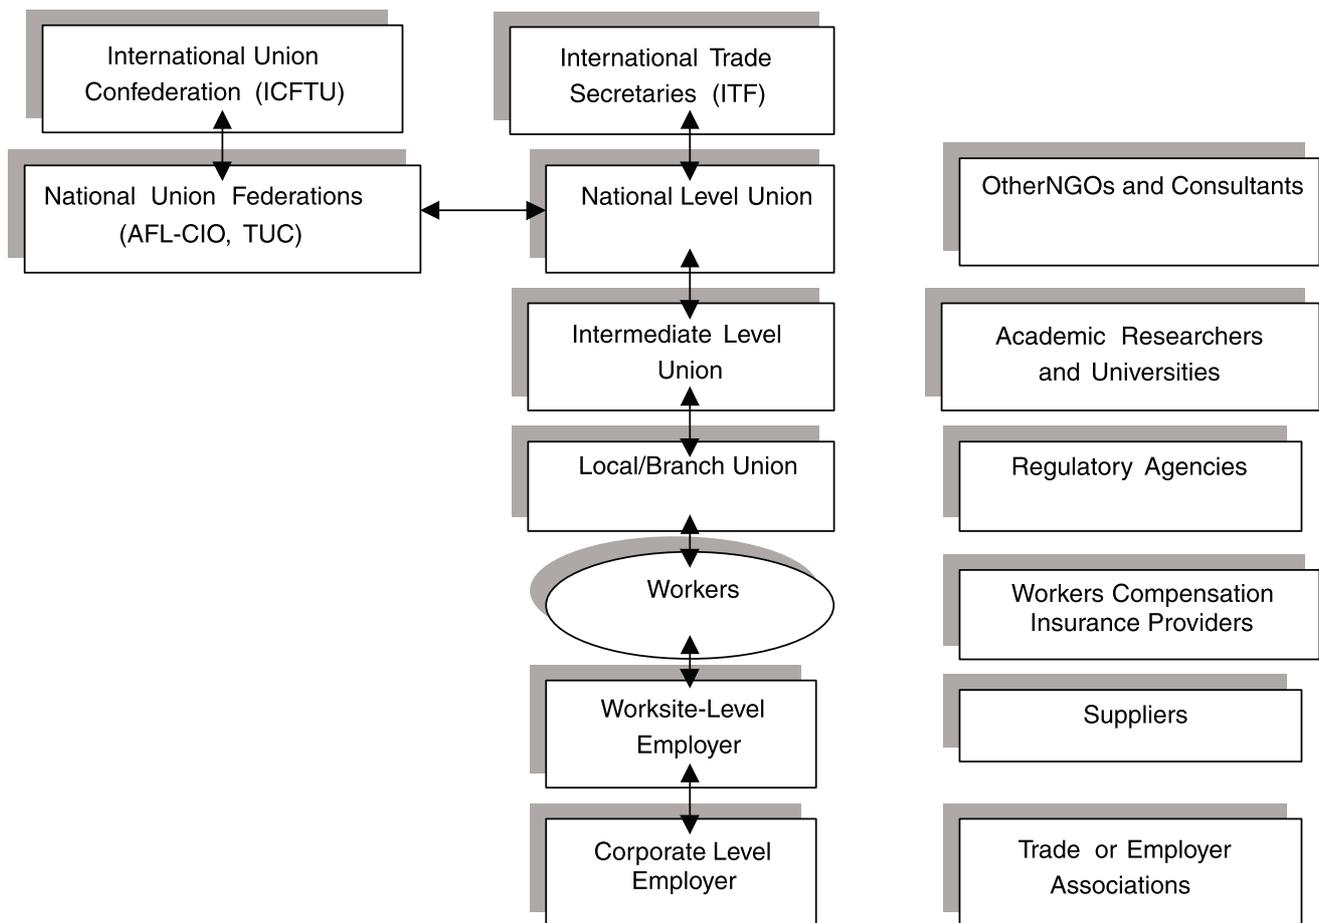
Assuming the threshold employer acceptance of the work-relatedness of RSI, unions must gauge the willingness of the


Figure 1. Schematic of actors.

employer to shift resources towards the identification and reduction of RSI risk factors; the profit motive or other strategic employer goals may drive employer reluctance to allocate what the union or workers feel are adequate resources to address the problem. Unions can play a very key role in both negotiating a larger allocation of resources as well as in enhancing the effectiveness of any employer risk reduction effort, but as management the employer must agree to commit resources in the first place. Employer willingness may be due in part to pressure from public policy in the form of mandatory standards, voluntary guidelines or perhaps pressure from third parties (Figure 1) such as a workers' compensation carrier, corporate officers, suppliers or customers. Employer willingness to commit may also be based in part upon the cost burden generated by RSI injury compensation and its impact on profitability. Unions may be able to focus the employer's attention in this area by persuasion or negotiation, or use of regulatory rights (e.g. filing complaints with regulatory agencies or claims for workers' compensation).

2.4. The Role of Public Policy

Public policy can play a significant role in determining the union's approach to ergonomics. Public policy may require the employer to identify and correct ergonomic problems via mandatory standards or voluntary guidelines; to compensate workers for various types of RSI; for the employer to consult with the union on what hazard identification and correction measures to deploy; or public policy may do none of the above. Unions may use

whatever policy exists and seek to change policy to meet its needs. The former can be a micro and/or a macro-effort, while the latter will generally be a macro-strategy.

Taking these four variables into account, the ideal environment for formulating an ergonomic approach for a labor organization would occur when the employer recognizes the existence of RSI problems and injured workers receive fair compensation; where the union and its members make ergonomics a high priority; where the employer commits significant resources to reducing RSI risk factors and is willing to collaborate closely with the union and where public policy supports and encourages such joint labor-management action and where both parties are able to build alliances with other third parties for assistance (insurance carriers, employer associations, suppliers, the government and universities). Generally, most cases will fall short of this ideal. Unions may analyze where shortcomings exist and develop appropriate strategies to achieve their ideal. A favorable macro-public policy can greatly assist unions in formulating an effective ergonomic approach; an unfavorable macro-public policy forces unions to focus on a more micro-level strategy, one workplace or industry at a time, with widely varying results.

3. ACTORS AND ENVIRONMENT

Labor unions are typically constituted both at the branch (workplace) and industry (national) level, although some organizations have intermediate levels at the regional or state

level. Internationally, many national level unions constitute International Trade Secretariats (ITS) such as the International Transport Workers Federation, which provide transnational research and support services to their affiliates. Unions also reach across branch and industry divisions to form federations, such as the American Federation of Labor-Congress of Industrial Organizations (AFL-CIO), Canadian Labor Congress (CLC) or LO (Landsorganisajonen in Norway, Sweden or Denmark). Internationally, there is a "federation of federations," the International Confederation of Free Trade Unions (ICFTU). National unions and their federations may also participate in a tripartite body (composed also of government and employer representatives) the International Labor Organization (ILO) headquartered in Geneva. These international bodies, the ILO in particular, make recommendations and conventions on a variety of subjects relating to safety and health, including ergonomics.

As Figure 1 suggests, employers are also organized at the branch (enterprise) level as well as the industry and national (corporate) level. Employers may also belong to employer associations that also may provide policy guidance and research in the areas of occupational health and safety.

There are a variety of "third parties" who can have a direct bearing on the union's ergonomic approaches, both at the macro- and micro-levels, which are shown to the right side of Figure 1.

Equipment suppliers and vendors can greatly assist unions and employers by developing ergonomically correct tools, workstations and other products which meet ergonomic criteria and reduce the risk of injury. Several branch unions in the US warehouse industry together with their employers have had success in convincing suppliers to reduce the weight of products stored in warehouses and to add better handles so as to reduce the risk of lifting injuries (obviously a more macro-level approach would have affected more workplaces). Other unions representing timber cutters have entered into direct dialog with power saw manufacturers to reduce the risk of vibration-induced white finger (Raynaud's syndrome). Telecommunications workers who install equipment are now entering into direct dialog with hand tool designers. Tool and equipment designers are motivated by the potential of increased sales and, depending upon national laws; the possibility of product liability suits if they fail to produce a safe product. Lawsuits against keyboard manufacturers in the U.S. may not have produced a jury verdict, but have resulted in at least one out-of-court settlement and a number of re-designed keyboards.

Workers' compensation insurance providers also have a role to play and may be important allies in formulating a union approach to ergonomics. In the USA, for example, many states require that these carriers offer "loss prevention" services to the enterprises to whom they provide workers' compensation insurance. Because of the significant increase in RSI, these carriers have a significant stake in reducing the number of injuries through ergonomic interventions. Several US unions have been able to work, at the branch level, with these carriers who provide training and technical assistance, and form a "tripartite" relationship with collaborating employers. Obviously, unless the employer is willing to enter into such an arrangement, unions cannot access these carriers since it is the employer, not the union, who is paying for the workers' compensation coverage.

Governmental agencies may also be a potential player in the union's ergonomics approach. At the macro-level, unions may lobby for mandatory standards requiring employers to develop and implement ergonomic interventions or to provide some form of compensation for RSI. The government may also sponsor or fund research identifying RSI risk factors or corrective measures. In the USA, the National Institute for Occupational Safety and Health (NIOSH), part of the Centers for Disease Control, has an Ergonomics Branch that conducts field evaluations of ergonomic problems at the request of unions or employers and it publishes a number of resources designed to reduce injury risk. It published a guide to reducing lifting injuries (NIOSH 1992) and many other helpful publications. In addition, the US Occupational Safety and Health Administration has, since the late 1970s, funded union and employer hazard recognition and abatement training efforts which have included ergonomics (OSHA's "New Directions" grant program). At the micro-level, union ergonomics approaches may utilize the government safety and health or labor inspectorates to enforce mandatory ergonomics standards, where they exist.

Universities and colleges may also provide important elements to union approaches to ergonomics. First of all, many universities in North America provide labor education services to unions, such as the University of Wisconsin's School for Workers, which at 75 years is the oldest university-based labor education program in North America. This school and many others have provided considerable ergonomic training and technical assistance to unions and employers in the USA In addition to such training and technical assistance, many unions have turned to university-based researchers to assist them in documenting the existence of RSI risks in their workplaces. Work by the University of Wisconsin-Madison's Department of Industrial Engineering has assisted the Communications Workers of America in documenting many RSI problems among video display terminal operators; the University of Michigan has assisted the United Autoworkers union similarly with the automobile industry. Building close relationships with labor unions is advantageous also to university researchers because of the access to workers and workplaces it affords.

Finally, there are other "non-governmental organizations" (NGO) which are potential players in a union ergonomics approach. This includes political parties who can assist unions in formulating policy at the macro-level, professional associations of occupational physicians, physical therapists and lawyers and in the USA, "Committees on Occupational Safety and Health" or "COSH groups." The latter are composed of many community activists, as well as health professionals and attorneys who can provide research and technical assistance to unions. One such example is the Massachusetts Center on Office Technology which helps workers, including those not represented by unions, in obtaining compensation for RSI and sponsors legislation and training programs.

Using the above set of actors and the four variables, it is possible to construct a model that can predict union approaches to ergonomics. The ideal case, as stated earlier, is where all four variables are positive. Where they are not, at least five scenarios can be discerned; these scenarios are described in more detail in Figure 2. As a general proposition, unions seeking to develop an ergonomic approach will turn both to public policy and to the third parties listed in Figure 1 to change the variable(s) from a negative to a positive value.

Figure 2. Union ergonomics scenarios and approaches.

Scenario	Description	Possible union approaches
Employer will not accept nexus between RSI injuries risk factors	Employer denies apparently valid compensation claims for RSI injuries filed by workers or has a policy announcing it will not compensate any or all RSI	• Sponsor/lobby legislation at state or national level to recognize some or all RSI as compensable or seek to change regulations concerning compensability with or without a coalition of like-minded third party groups • Using university, union and/or government researchers, document the extent of RSI and their relationship to work-related risk factors • Seek to work more closely with workers compensation carriers for more active involvement in risk factor reduction • Conduct membership awareness concerning RSI and their work-relatedness • Build alliances with NGO such as lawyers and medical providers who can provide assistance in documenting work relatedness and securing compensation
Union will not make ergonomics a priority	Union leaders and/or members see ergonomics as less pressing that other 'lower order' needs or union leaders	• Conduct training programs for officers, leaders and members to build awareness and review case studies of other unions • Document the extent and severity of the problem • Exchange information with other unions (national, international) about their response to similar situations
Employer will not commit adequate resources to address reduction of RSI risk factors	Employers are willing to recognize the problem, but not to address adequate resources to correct the problem	• Union can seek to negotiate the design of the RSI program • Union can start its own independent RSI program to document problems, attempt to secure intervention on a case-by-case basis and if not timely action, secure outside government intervention • Union can intervene with governmental agencies, universities, trade associations, suppliers and workers compensation carriers to provide low cost or free assistance • Union can turn to governmental enforcement agency to pressure compliance • Union can work with other third parties to start pressure campaign • Unions can develop their own model ergonomics programs or sponsor guidelines developed by others
Employer will not accept union as a collaborator in risk reduction program	Employer is committing to a risk reduction program but does not want significant union involvement	• Union can intervene with corporate organization of the employer • Union can petition for government intervention • Union can use other case studies as justification • Union seeks to negotiate a solution through collective bargaining

4. CONCLUSIONS

Before developing an ergonomic approach, labor unions must carefully examine the environment and actors and evaluate the four variables described above. At the micro-level, unions must determine employer acceptance of the work-relatedness nexus of RSI and employer willingness to reduce RSI risk factors and to accept the union as a collaborator in this process. Unions must also look within themselves to determine how much of a priority to assign to ergonomics. At the macro-level, the union must determine what support for RSI injury compensation and employer response to ergonomics problems are underwritten by public policy. To the extent that employer resistance is present on the first and third variable, unions need to shift attention to working with third parties as shown in Figure 1; the union may also need to combine forces with other unions and third parties to bring about a change in public policy. At the same time, employers need to better understand the environment in which unions operate and recognize the resources that can be brought to bear from such third parties. Unions by and large would prefer to work collaboratively with the employers at the micro-level, but where this is not possible, unions can and should have no difficulty in building alliances with third party groups and developing their own *independent* ergonomics approach.

Types of Organizational Designs

H. W. Hendrick

Hendrick and Associates, Englewood, CO 80111, USA

1. INTRODUCTION

As described elsewhere in this encyclopedia, sociotechnical analyses can be carried out to help determine the optimal level of various structural dimensions to design into work systems. These include the degree of vertical and horizontal differentiation, the kinds and numbers of integrating mechanisms, where various kinds of decisions should be made, and the extent to which formal rules and procedures should direct activities and constrain decision-making. Ultimately, in designing work systems, these factors must be integrated into an overall structural form. A variety of *types* of structural forms have been successfully developed and used in organizations. Each has its advantages and disadvantages. The issue then, is to select the structural form with characteristics that best fit a given work system's needs.

There are four general types of organizational structure that are most commonly found. These are (1) classical *machine bureaucracy*, (2) *professional bureaucracy*, (3) *matrix organizations*, and (4) *free form designs* (Robbins 1983). It should be noted that large, complex organizations often do have relatively autonomous units with different overall forms. As a general rule, the smaller the organization, the greater is the likelihood that it will have a single overall type of work system structure.

2. CLASSICAL OR MACHINE BUREAUCRACY

This classical form of work system has its roots in two streams of thought: *Scientific management* and the *ideal bureaucracy*. Scientific management began with the work of Fredrick W. Taylor in the early 1900s. Although heavily influenced by Taylor's concepts, the classical bureaucratic design was actually conceptualized by Max Weber at the beginning of the twentieth century. Collectively, Taylor's and Weber's theoretical principles resulted in what today is known as the *machine bureaucracy* type of organizational structure. Its basic structural characteristics are as follows (Robbins 1983).

1. *Division of Labor.* Each job is narrowly defined, and consists of relatively routine and well-defined tasks.
2. *A well-defined hierarchy.* A relatively tall, clearly defined, formal hierarchical structure in which each lower office is under supervision and control of a higher one. Tasks tend to be grouped by function. Line and staff functions are clearly distinguished and are kept separate.
3. *High formalization.* Extensive use of formal rules, procedures, and detailed job descriptions to ensure uniformity and to regulate employee behavior.
4. *High centralization.* Decision-making is reserved for management. Employees have relatively little decision discretion.
5. *Career tracks for employees.* Members are expected to pursue a career within the organization; and career tracks form part of the work system design for all but the most unskilled positions.

2.1. Advantages

The primary advantages of the machine bureaucracy are efficiency, stability, and control over the work system's functioning. Narrowly defined jobs with a clear set of routinized tasks enable individuals to know their own function and the roles of others better, minimize the likelihood of error, require comparatively few prerequisite skills, and minimize training time and costs. Formalization ensures stability, control, and a smooth integrated pattern of functioning. Centralization further ensures control, reduces the education and training requirements for employees, and further enhances stability.

2.2. Disadvantages

There are two major disadvantages to the machine bureaucracy form of work system. First, this form tends to result in jobs that fail to utilize adequately the mental and psychological capacities of the workers. Thus they are lacking in intrinsic motivation. Second, these work systems are inherently inefficient in responding to environmental change and non-routine situations.

2.3. When to Use

Machine bureaucracy can be used when (1) system operations are repetitive or otherwise can be routinized, (2) the relevant external environments are comparatively simple and stable or predictable, or (3) the education and skill levels of the available personnel are relatively low.

To the extent that the above stated conditions do not exist, one of the other three forms of work system structure is likely to be more effective.

3. PROFESSIONAL BUREAUCRACY

Professionalism can be defined as the degree of training and education required by the design of specific jobs and related human–system interfaces. The professional bureaucracy is designed so as to rely on a relatively high degree of professionalism in the jobs that comprise the work system. Its differs from the machine bureaucracy design in that jobs are more broadly defined, somewhat less routinized, and allow for greater employee decision discretion (Robbins 1983). Accordingly, there is less need for formalization and *tactical* decision-making is decentralized. As with machine bureaucracies, positions are grouped functionally, are hierarchical, and *strategic* decision-making often remains centralized.

3.1. Advantages

As compared with the machine bureaucracy form of work system, there are at least three major advantages to the professional bureaucracy. First, professional bureaucracies can effectively cope with complex environments and non-routine tasks more efficiently. Second, jobs tend to be intrinsically motivating and better utilize the mental and psychological capabilities of employees. Third, they require less managerial tactical decision-

making and control, thus freeing management to give greater attention to long-range planning and strategic decision-making.

3.2. Disadvantages

They are not as efficient as machine bureaucracies for coping with relatively simple, stable environments. They require a more highly skilled work force and attendant greater training time. Thus, both salaries and training costs are relatively higher. Control is less tight and efficient. The distinction between line and staff functions is often less clear. The management skills required tend to be more sophisticated (i.e. a greater reliance on tolerance for ambiguity, and on persuasive and facilitation skills rather than on a simple and direct authoritarian style.

3.3. When to Use

A professional bureaucracy form of work system is to be preferred when the external environment is fairly complex and/or somewhat unstable, and there is an available applicant pool of professionalized workers. It is less optimal than machine bureaucracies for highly repetitive operations with a simple stable environment; or if the available management pool is highly authoritarian and concrete in its functioning.

4. THE CONCEPT OF ADHOCRACY

Although truer for machine bureaucracies, a major disadvantage of both forms of bureaucracy is that they tend to be inefficient in responding to highly complex, dynamic, or uncertain relevant external environments. In response to this shortcoming, two more recent forms of organization have evolved. These are the *matrix* and *free form* designs. Collectively, these two are known as *adhocracy* designs. An adhocracy can be described as a rapidly changing adaptive system organized around problems to be solved by groups having diverse professional skills. In terms of their structural dimensions, adhocracies are characterized by moderate to low complexity, low formalization, and decentralized decision-making (Robbins 1983). Because these work systems are staffed primarily by professionals, horizontal differentiation tends to be high. In contrast, vertical differentiation tends to be low. This low vertical differentiation reflects the low need for supervision because of the high level of professional staffing. Instead of formal rules and procedures, flexibility and rapidity of response are emphasized. It is for this reason that a high level of professionalism and an absence of administrative layers are needed.

4.1. Advantages

Adhocracies trace their roots to the task forces of World War II. The military created ad hoc teams to perform specific missions, and then disbanded them when the task was completed.

Team members' roles were flexible and often interchangeable. Sub-units would be added or deleted as required. These features enabled the teams to react quickly, efficiently, and creatively to a dynamic environment, and thus be highly effective. These are the same characteristics and resultant advantages that characterize modern adhocracies. When the primary organizational need is to be adaptive and innovative, and respond rapidly to changing situations and objectives, and when these responses require collaboration of persons possessing different specialties, the adhocracy forms of organization are more effective than the bureaucratic (Robbins 1983).

4.2. Disadvantages

All adhocracy forms have at least three major disadvantages: (1) *conflict*, (2) *social and psychological stress*, and (3) *inherently inefficient structures* (Robbins 1983).

4.2.1. Conflict

Since boss–subordinate relationships tend not to be clear, the lines of authority and responsibility are ambiguous. Thus, conflict is an integral part of adhocracy.

4.2.2. Psychological and sociological stress

Because of the dynamic nature of their environment and tasks, the structure of teams or units is temporary and work role interfaces are not stable. By contrast, the establishing and dismantling of human relationships is a slower psychosocial process that is stressed any time there is significant organizational change. Concrete functioning employees especially are likely to find it difficult to cope.

4.2.3. Inherent inefficiency

By comparison with bureaucracies, adhocracies lack both the precision and expediency that comes with routinization of function and structural stability. Accordingly, adhocracy designs are to be preferred only where these inefficiencies are more than offset by the gains in efficiency in terms of responsiveness or innovation.

5. THE MATRIX DESIGN

The matrix design is the most widely used form of adhocracy. It combines departmentalization by function with departmentalization by product line or project. As with bureaucracies, functional departments exist and tend to be lasting. Unlike bureaucracies, members of the functional departments are farmed out to project or product teams as new projects or product lines develop; and the combined technical expertise of the individual departments is required. When the need for a given department's professional input to the interdisciplinary team is no longer required, or when the level of effort reduces, employees return to their "home" department or transfer to another team. The product or project manager supervises the team's interdisciplinary effort, but each team member also has a functional department supervisor. Thus, the matrix design breaks the fundamental design concept of bureaucracy of *unity of command*.

5.1. Advantages

Matrix designs afford the best of two worlds: the stability and professional support of depth of functional departmentalization and the interdisciplinary response capability of ad hoc teams.

5.2. Disadvantages

In addition to those characteristics of all adhocracy designs that cause problems, the major disadvantage of matrix organizations is that employees must serve two bosses: their functional department head, who tends to be relatively long-term oriented and somewhat remote from the team member's immediate tasks, and the project team director who tends to be short-term oriented but immediate to the employee's present tasks. Serving two masters with overlapping supervisory responsibility and different

goals, responsibilities, and time orientations creates conflict and can disrupt organizational functioning.

A second major problem for the employee is that, when assigned too long to a project, he or she may have difficulty keeping technically current and may lose contact with his or her functional department. These consequences can both adversely affect the employee's career.

5.3. When to Use

The matrix organization is particularly well suited for responding to complex and dynamic external environments where both interdisciplinary responsiveness and providing for functional depth in individual disciplines are considered essential. Since many high technology organizations exist in these kinds of environments, the matrix form of work system is widely used.

6. FREE FORM DESIGNS

Of the four general types of organizational structure the *free-form* design is the newest and most rapidly growing. In its purest form, the free-form work system resembles an ameba — it continually changes its shape in order to survive (Szilagyi and Wallace 1990). The *raison d'être* of free form designs is responsiveness to change in very highly dynamic, complex and competitive environments.

In free-form systems, the functional departmentalization of bureaucracies is replaced by a *profit center* arrangement. Profit centers are results oriented and are managed by teams. Collectively, they constitute the work system. Free-form designs are characterized by very low formalization and vertical differentiation and highly decentralized decision-making. Very heavy reliance is placed on professionalism as expressed through participation and autonomy. As with matrix organizations, project teams are created, changed, and disbanded as required to meet organizational goals and problems. To function effectively in these work systems, managers and employees alike need to possess a great deal of personal flexibility, tolerance for ambiguity, and ability to handle change.

6.1. Advantages

The single major advantage of free-form designs is the ability to respond to highly competitive, complex, and dynamic relevant external environments with speed and innovation. This is the very purpose for which they exist.

6.2. Disadvantages

The free-form work systems have essentially the same units within disadvantages as matrix adhocracies, only to a greater extent. They thus require a highly professionalized work force to succeed.

6.3. When to Use

The free-form work systems can be used when (1) the organization's success or survival critically depends on speed of response and innovation, and (2) a highly professionalized work force and management pool are available. These features tend to characterize small to medium-sized high-technology organizations, and semi-autonomous, rapid prototyping "outlaw" large bureaucratic organizations, operating in highly dynamic, complex and competitive environments.

6.4. New Variations

The combination of new technological advances and the need to respond to complex, uncertain environments has led to new adhocracy forms of organization. Of these, two of particular note are the *modular* and *virtual* forms.

6.4.1. Modular organizations

The modular organization outsources non-vital functions while retaining full strategic control. Outside sources may be used to manufacture parts, handle logistics, and perform maintenance, housekeeping, or accounting activities. Structurally, the "organization" is a central hub surrounded by networks of outside suppliers and specialists. Modular parts readily can be added or taken away, as the situation requires.

6.4.2. Virtual designs

The virtual type of organizational structure is characterized by a continually evolving network of independent companies — suppliers, customers, and even competitors — to pursue common strategic objectives. These are linked together to share skills, costs, and access to one another's markets (Dees *et al.* 1995). In contrast to the modular firm, which maintains full strategic control, participants in the virtual firm give up part of their control and accept interdependent destinies. A virtual organization need not have a central office, organization chart, or hierarchy. Participating firms in a virtual organization may be involved in multiple alliances. They may form a virtual organization to attain specific strategic objectives, and then disband when those objectives are met. A major advantage of the virtual organization is ability to respond quickly to opportunities in a highly dynamic environment. Each subunit firm brings a particular set of competencies to the alliance, thus creating a more competitive, yet highly flexible entity.

Methods and Techniques

Activity and Other Sampling Methods

J. R. Buck

Department of Industrial Engineering, University of Iowa, Iowa City, IA 52242, USA

1. INTRODUCTION

Sampling is a term typically used in industry to distinguish random or periodic observations from continuous observations. As an alternative to continuous observation, sampling has both advantages and disadvantages. On the advantage side, sampling is usually much less costly to perform. But it does have the disadvantage that results can be incorrect when sampling is improper. The key point in sampling is summed under the question, "can one obtain an accurate condition of the situation during a brief or at least short-term observation?" Unless an affirmative answer can be given, sampling should not be considered. It was that key observation that Tippett, the originator of activity analysis, made when he listened to the knitting mills in the midlands of England in the early 1930s. He noted that a momentary listening to the mills would disclose whether the machines were working properly. He called the sampling technique "ratio delay," and one occasionally hears that term yet today.

The most common form of industrial sampling is the case in which momentary observations are made at randomly determined times. This methodology is typically referred to as "work sampling" or "occurrence sampling." The basis of this methodology is simply binomial or Poisson sampling, which are well described in many books on statistics. In its simplest form, an event either occurs at an observation or not, and if that event occurs on 40% of those observations one would expect the event to occur with that frequency plus or minus sampling errors. Forty percent of 10 observations clearly has a much lower statistical precision than 40% of a 1000 observations. That precision is determined by the statistical confidence interval from the sampling.

There are many applications of activity analysis including: assessing the fraction of time that unproductive activities are occurring, machine interference studies in which one attempts to identify the relative frequency of various interference, setting time standards, and determining how various people spend their time. In most of these situations there is an advantage of identifying the high-frequency tasks as those can affect overall effectiveness the most and even small improvements there can make considerable improvement. Hence, activity analysis can be a useful tool in problem solving.

There are numerous variations of sampling used in activity analysis in addition to elementary random sampling. One is periodic sampling such as making observations every M minutes. If someone needs to be aboard a moving vehicle (e.g. plane, ship, car, bus), a high density of periodic observations can be very effective. In the 1950s, Christensen flew with the US Airforce and made observations of activities that the crewmember performed over the flight using periodic observations. He was investigating how crewmembers spent their time and if some of the activities were necessary. They ended up reducing some of the paperwork and reducing the crew size. About the same time MacFarland and Mosley observed bus drivers' hands and feet during the but trip to determine the frequency of left- and right-hand hand and feet movements. Their concern was whether these hand and feet activities were balanced between the left and right sides. As a result, they recommended an automatic shifting system for buses. The only real danger in a periodic set of observations is when the period selected is similar to the fundamental period of activities being observed.

2. TRADITIONAL ACTIVITY ANALYSIS

Activity analysis has traditionally consisted a person who is not part of the activity observing it, classifying the activity being observed, and recording it at each randomly selected points of time. These points of time are during a prescribed period. When a total of N observations are to be made during that period, the manager of the study needs to select N random numbers, order them in size and map those N numbers onto the period (Figure 1). Each random number should have enough digits so that each of the N can be unique. The remaining analysis follows the theory of binomial sampling. Poisson sampling is also used but infrequently.

2.1. Binomial Sampling

In basic binomial sampling, an event either occurs or not. If it occurs q percent of the time and N randomly timed observations are made, one would expect to see the event occurring on Nq observations. But with random sampling the actual number of observations will be more or less with a standard deviation of

$$V(X) = \sqrt{Nq(1-q)}$$

If X is the actual number of events observed, the probability of observing precisely that number is:

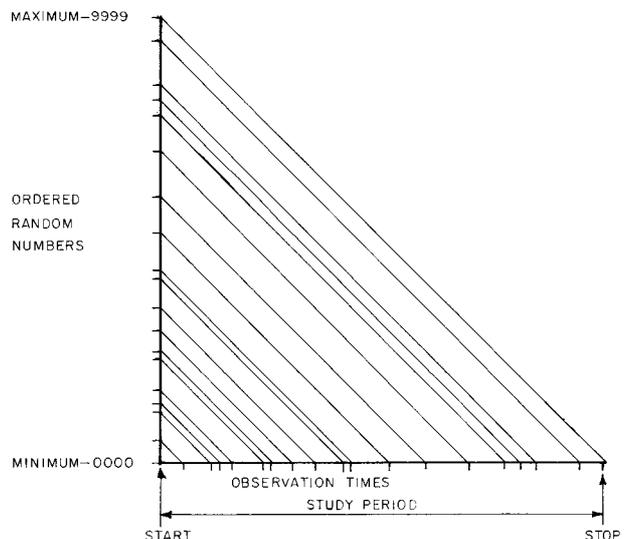
$$p(X) = \frac{N!}{X!\,(N-X)!}\; q^X (1-q)^{N-X} \tag{1}$$


Figure 1.

for

$$0 \leq X \leq N$$

To find a confidence interval for q corresponding to the actual observations made, an integral of equation (1) over for the lower tail error and over q'' for as the upper tail error so that the sum of the two errors equals the confidence limit. However, that procedure is not as simple as recognizing that the binomial resembles the normal (Gaussian) distribution when , according to Dr Abraham Wald of Columbia University. To equate the binomial to the normal distribution, one should first recognize that the standardized normal deviate is:

$$Z_\alpha = \frac{X - \mu}{\sigma} \qquad (2)$$

Assuming that the binomial is being represented by the normal distribution, let us replace the normal mean m with the binomial mean Nq and replace the normal standard deviation σ with $\sqrt{Nq(1-q)}$ so that equation (2) becomes:

$$Z_\alpha = \frac{X - Nq}{\sqrt{Nq(1-q)}} \qquad (3)$$

Now dividing equation (3)'s numerator and denominator by $N > 0$:

$$Z_\alpha = \frac{[X/N - q]}{\sqrt{q(1-q)/N}} \qquad (4)$$

Note that the numerator of equation (4) describes the difference between the actual fraction of the time the event occurs q from the expected occurrence. Let the maximum acceptable difference between the actual q and the expected q be denoted as the acceptable error e. Solving equation (4) for N yields:

$$N = \left[\frac{Z_a}{e} \right]^2 q(1-q) \qquad (5)$$

When Z the normal standardized deviate for the desired confidence interval, say 1.645, 1.96 or 2.58 for 90, 95 and 99% confidence intervals respectively, the satisfying N shows the sample size that meets the confidence interval requirements for the specified error e. q can be estimated from the sample as

$$X/_N = q$$

Consider the numerical example where a 90% confidence interval and an error of 1% is acceptable in an activity analysis. Suppose that q is estimated as 30%. An appropriate sample size is:

$$N = \left[\frac{1.645}{0.01} \right]^2 0.3(1 - 0.3) = 5682 \text{ samples}$$

If during the sampling one finds that the estimated q differ from 0.3, for example, after 4000 observations, $X = 1120$, a better estimate of q is 1120/4000 = 0.28. Replacing 0.30 with 0.28 yields a smaller required sample size of 5455 samples. Repeating this calculation later in the sampling will allow the manager to assure a sample size that meets a desired confidence interval.

It should also be noted that nomographs are available for roughly approximating the sample size by entering the desired confidence interval and an acceptable error size relative to the random variable q.

2.2. Applications of Traditional Activity Analysis in Problem Solving

In plant maintenance operations a report of some malfunction or problem occurs and people go to the site. They diagnose the complaint, and send an individual or crew to perform the need maintenance or repair. Sometimes several crews are involved such as carpenters, plumbers and/or electricians. The manager of maintenance may be concerned with the effectiveness of the organization and ask for an activity analysis of the maintenance operations specifically looking for causes of being non-productive. Some of those causes occur when the crews are travelling to the work-site, waiting for spare parts, technical information or assignments, or experiencing delays due to interference within a crew or interference between different crafts. The specific improvements to be made depend upon the fraction of occurrences of these different causes of non-productivity. If travel is a large fraction, decentralization of maintenance should be considered. Delays due to spare parts, technical information or assignments implies the need to improve the support activities dealing with these three aspects. Interference within a crew may require crew composition or leadership and interference between crews involves crew scheduling.

Another application of traditional sampling occurs when a particular worker group is in short supply and management is considering aids for these workers in terms of assistants. An example may be nurses in a hospital. If management is to aid these nurses, they must find out how they spend their time in terms of activities that can be aided. If the activity analysis finds out that a very large amount of their time is spent in distributing bed-clothing to the rooms, this task may be handed-off to another group in the hospital that has extra time or some new personnel can be added to perform that activity.

An application of activity analysis in industry is determining the normal time required for a particular assembly operation. In this case, an activity analysis can be performed to see the fraction of time spend assembling this particular item. That time fraction coupled with other data allows one to determine a normal time (i.e. a time requirement for only performing the task, neglecting any time spent for personal needs, or resting from fatigue, or time lost due to failed support activities. The additional data needed are the total time worked as shown in the time records and the total number of assemblies performed. If only only a few persons performed the observed assembly activity, additional information of the speed of those persons observed is also needed. Numerous sources claim that the activity analysis procedure for estimating normal times are far less costly than traditional time study and that the accuracy is better because daily and weekly variations are factored into the data. Also many people report greater worker acceptance.

2.3. Some Speciality Forms of Sampling

There are several other forms of sampling that need to be identified for completeness. One is stratified sampling which is a procedure whereby sampling frequencies are apportioned to specified parts of the system. This technique is used for better representativeness or for greater precision on more important system features. Cochran (1957) describes this form of sampling in detail. It is used infrequently but some situations make it desirable.

Another form of sampling is where the external observer doing the sampling not only identifies the ongoing activity but also rates the speed of the observed person relative to the mythical "standard operator." Those estimated performance rates are often assumed to be normally distributed and the activity identifications as binomial. Hence, two analyses are usually made of such data. The technique is often referred to as "rated work sampling."

Another variation in activity sampling is to have the persons being observed to be their own observers. This sampling can be performed with a random reminder device that emits a signal at random points in time and at that time the person is supposed to enter the type of activity that is going on at time. Often, they are asked to denote where it took place and in some cases why. One source of random reminders is made by Divilbiss Electronics (Champaign, IL, USA). This form of sampling is particularly useful when outside observers might interfere with regular operations or when people under observation move from location to location extensively or dependent on variational factors so that outside observers would not be likely to know where the activities are going on.

3. PARAMETER MAPS

A useful graph in activity analysis is a parameter map of the statistical distribution being used. Parameter maps are simply rectilinear graphs where each axis represents a parameter of the probability distribution being used and plots on the graphs are the values of specific statistics. For example, rectangular distribution from parameter a to parameter b has a probability density function of:

$$p(x) = (x - a)/(b - a), \tag{6}$$

and the mean and variance statistics in terms of those parameters are:

$$E(x) = (a + b)/2 \tag{7}$$

$$V(x) = (b - a)^2/2. \tag{8}$$

The parameter map of this distribution is a rectangular graph with the x-axis representing parameter a and the y-axis representing parameter b. Isocontours of a specific $E(x)$ are straight lines of a unit slope from the upper left to the lower right starting at the y-axis at $y = 2E(x)$ and ending at the x-axis at $x = 2E(x)$. Variance isocontours start at the y-axis at $\sqrt{2V(x)}$ and this isocontour line increases linearly in an amount equal to a:

$$B = [2V(x)]^2 + a. \tag{9}$$

And Figure 2 describes this parameter map for this rectangular distribution.

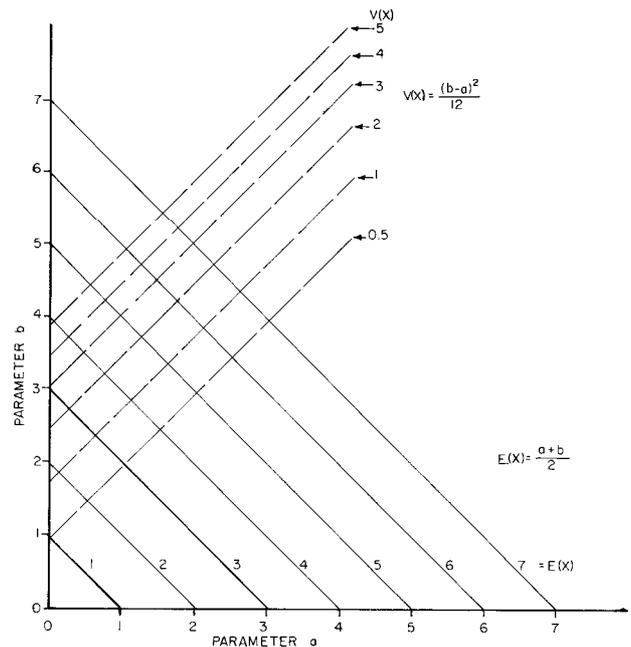
Parameter maps are available for other distributions. One of particular importance, as will be shown below, is the beta


Figure 2.

distribution (of the first type) which has a probability function of:

$$p(q) = \frac{(a + b + 1)!}{(a - 1)!(b - 1)!} \, q^{a-1} (1-q)^{b-1} \tag{10}$$

where the parameters of this distribution are a and b. It follows that the mean and variance of the beta in terms of the parameters are respectively:

$$E(q) = \frac{a}{a + b} \text{ and } V(q) = \frac{E(q)[1 - E(q)]}{a + b + 1} = \frac{a}{a + b} \left[\frac{b}{a + b} \right] \frac{1}{a + b + 1} \tag{11, 12}$$

When estimates are available for the mean and variance, those estimates can be equated to equations (10) and (11) and solved simultaneously to find parameters a and b. It also follows that the mode of the beta (i.e. q that maximizes p(q)) is:

$$M(q) = \frac{a - 1}{a + b - 2} \tag{13}$$

Any two of these three statistics can be estimated to find parameters a and b. It follows that when the mean is fixed at $E(q)$, a contour of all combinations of parameters a and b that produce an equivalent mean fit the relationship.

In a similar vain, the contours for a constant mode $M(q)$ and variance $V(q)$ are defined by their respective relationships of:

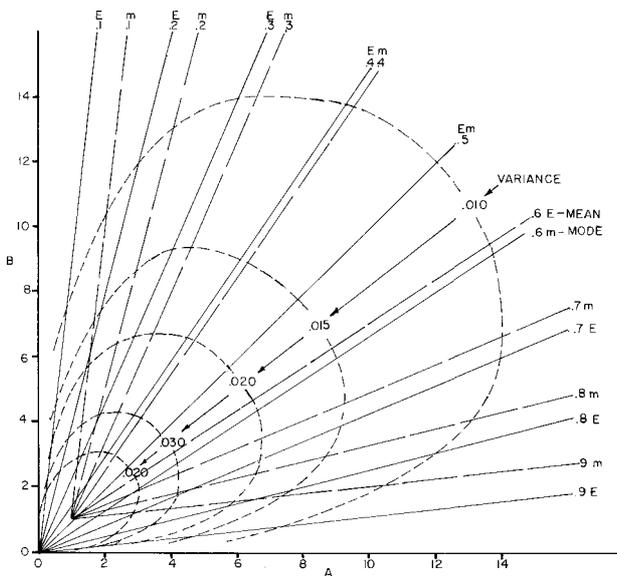
$$b = \frac{a - 1}{M(q)} - a + 2 \text{ and } b = \frac{E(q)[1 - e(q)]}{V(q)} - a - 1 \tag{14, 15}$$


Figure 3.

Figure 3 provides a parameter map for the beta distribution showing all three statistics. Note that when $q = 0.5$, $E(q) = M(q)$ and so the mode and mean follow the same contour in that case. As q gets < 0.5, the mean is lower than the mode and as q gets > 0.5, the mode is lower than the mean. Also, both the mean and mode begin at $[a = 1, b = 1]$. Another important observation is that the constant variance contour curves around the map, emanating from the origin $[a = 0, b = 0]$ and returning there but crossing all $E(q)$ and $M(q)$ contours. Moreover, constant variance contours with smaller constant are farther from the origin.

4. SEQUENTIAL BAYESIAN ACTIVITY ANALYSIS

This type of activity analysis uses the binomial as does most traditional activity analysis but it starts off and ends up a bit differently. Bayes' theorem is the basis for this technique and this theorem states that an existing probability distribution can be modified under new evidence to a corrected posterior distribution. Accordingly, the starting basis of this Bayesian version of activity analysis may start with a prior distribution p(q) which may be a beta, as shown in equation (10). This prior distribution should be one that best fits the supervisor's or manager's current perception of the situation at the start. If neither of them have any prior knowledge, find some else who does. In a last resort, select a beta with $a = 1 = b$; an extremely conservative beta equivalent to the rectangular distribution where all variables q from 0 to 1 are equally likely. Thus, to start, one needs to estimate the expected value of the random variable q and the variance of q as envisioned at the start. One way to do that is to take estimates of $E(q)$ and $V(q)$, find the contours of these estimated statistics on the parameter map of Figure 3, trace those contours until they cross, and then find the parameters a and b that simultaneously match both. That beta distribution is the *a priori* or "prior" distribution. A second way is to insert these estimated statistics into equations (9) and (10) respectively and solve simultaneously. Results will be the same either way.

4.1. Can People Estimate Statistics Subjectively with Reasonable Accuracy?

The discussion about Bayesian activity analysis is briefly interrupted here to focus on an important question about starting

this analysis when the only available data are determined subjectively held by the people in the organization. Since Bayesian analysis can start with a model that is based on subjective estimates, it seems questionable that accurate final results can occur if the beginning is inaccurate.

A wide variety of studies was summarized by Sheridan and Ferrell (1970s), who have shown a few cases where people are presented with a relative frequency of an event and asked to estimate the fraction subjectively. Those studies demonstrated that people are accurate in their estimation but their precision is

for relative frequencies of q from ~25 to ~75%.

Above or below those limits precision deteriorates. So it is unreasonable to request greater precision than ~5% or to ask for relative frequencies that are very high or low.

4.2. Second Step in Sequential Bayesian Activity Analysis

As stated above, the first step is in establishing a prior beta. The second step involves sampling. Use binomial sampling by making N' observations, where N' is a comfortable day or half-day sample size. In reality, N' is the number of samples to be taken before updating the posterior distribution. During those N' observations ($N' > 0$), find X' events (observations when a particular activity is ongoing) through binomial sampling. It then follows through Raiffa and Schlaifer's (1961) conjugate distribution theory that:

$$A = a + X' \quad \text{and} \quad B = b + N' - X' \qquad (16, 17)$$

where A is the corresponding parameter of the posterior distribution and B is similarly the second parameter. The mean and variance of the posterior is:

$$E(q') = \frac{A}{A + B} \quad \text{and} \quad V(q') = \frac{E(q')\left[1 - E(q')\right]}{A + B + 1} \qquad (18, 19)$$

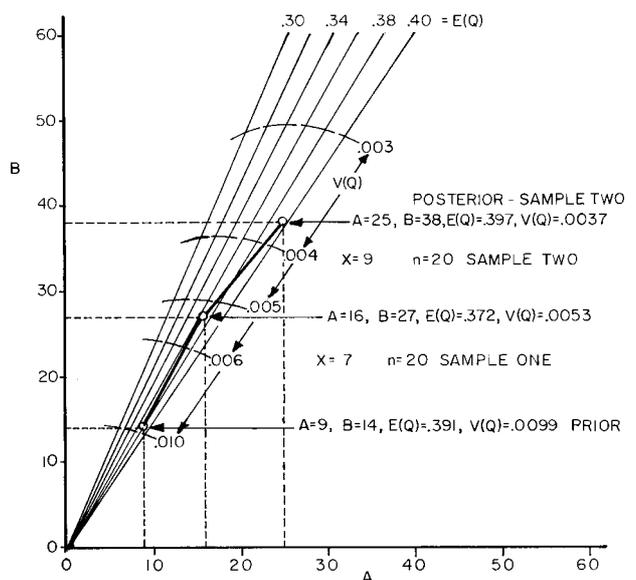
With respect to the beta parameter map, the prior distribution was at the point $[a,b]$ and the sampling moved one's knowledge


Figure 4.

about the situation to be represented as the point [*A*,*B*]. If further sampling is contemplated, that posterior point becomes a prior point to the next episode of sampling. In this way sampling evidence causes the prior distribution (as represented by the point [*a*,*b*]) to the posterior distribution (as represented by the point [*A*,*B*]). With more sampling, there is an incremental change following the same routine but with the prior point as the last sampling's posterior. Figure 4 illustrates the sequential chaining of points along a path on a parameter map from the initial prior to successive posterior points.

4.3. Numerical Example

Suppose that the prior beta has an estimated mean of 1/3 and a variance equal to 0.008 (or . . .). $\sqrt{V(q')} = 0.0891$). It follows from equation (18) that $2a = b$. From equation (19) one can calculate . $\frac{1}{3}\binom{2}{3}$ By substituting $2a$ for b in the last equation, one calculate $a = 8.93$ or ~9. Since $b = 2a = 18$. If 10 samples were made and the event was observed three times, $N' = 10$ and $X' = 3$ so that the posterior parameters are $A = 9 + 3 = 12$ and $B = 18 + 10 - 3 = 25$. The posterior mean is $E(q') = 12/(12 + 25) = 0.324$ and the variance is:

$$V(q') = \frac{0.324(1 - 0.324)}{12 + 25 + 1} = 0.00577$$

Note the reduction in variance from 0.008 to ~0.006.

4.4. How Does One Know When to Stop?

One can stop when one is satisfied, but if a statistically acceptable basis for stopping is desired, one should continue until the confidence interval of q is sufficiently small. Statistical sufficiency is determined by a stated acceptable error e and a specified probability that the error is not greater. The confidence interval for a beta distribution is, $q_1 \le E(q') \le q_2$ where the maximum acceptable error is $e_1 \le E(q') \le q_1$ and $e_2 \le q_2 - E(q')$. It is important to recognize that the beta distribution is not symmetrical about the mean $E(q')$ so that the lower interval does not necessarily equal the upper interval. If there is particular concern about being too small but less about being too large or vice versa, e_1 and e_2 may differ. A short table of beta confidence intervals are found in a number of sources (Schmitt 1989). Knowing parameters A and B, one can look up the confidence interval in Table 1.

Linear interpolation is usually an acceptable approximation if the parameters are between a pair in Table 1, but such interpolation is not simple unless one of the parameters is a tabled value.

Tabled confidence intervals for the beta distribution are really Bayesian high-density intervals that are defined at equal ordinates at the endpoints and an integral between endpoints equal to 0.90, 0.95, or 0.99 in the cases shown here. Please note that the mean $E(q')$ is not a midpoint between endpoints.

Table 1. 95% confidence interval table to find

a	b		
9	11	0.241	0.661
9	11	0.145	0.462

An alternative approximate method requires one to compute the skewness of the posterior distribution which is:

$$\alpha_3 = \frac{2(B - A)\sqrt{A + B + 1}}{(A + B + 2)\sqrt{AB}} \quad (20)$$

Once the skewness and variance are determined, the equation for the proper confidence interval and for the lower or upper partial confidence interval can be found and the standardized partial confidence and full confidence intervals computed. Each standardized full or partial confidence interval is a regression equation of tabled values so the resulting equations consist of a constant plus three terms: skewness, 1/*A** or 1/*B**, and the square of skewness, each with a coefficient. The standardized partial confidence interval at the 90% level is:

$$\frac{\sqrt{V(q')}}{E(q) - q_1} = 0.605 - 0.0437\,\alpha_3 - 0.0156\,\frac{1}{A^* \text{ or } B^*} + 0.0997\,\alpha_3^2$$

This particular regression equation had a squared coefficient of determination $R^2 = 0.98$ that shows that 98% of the variance in the tabled data was explained by the equation. Also shown, a mean squared error of prediction is 0.00000145, so the approximation is quite good. Whenever a blank is shown, that term does not need to be used. After the values are inserted and calculations are made, one equation computes:

$$\frac{\sqrt{V(q')}}{E(q') - q_1}$$

and the other:

$$\frac{\sqrt{V(q')}}{q_2 - q_1}$$

Note that the right hand side of the first equation is K and the second is K' so that:

$$E(q') - q_1 = \frac{\sqrt{V(q')}}{K} \quad \text{and} \quad q_2 - q_1 = \frac{\sqrt{V(q')}}{K'} \quad (21,22)$$

It easily follows that equations (22) − (21) = $q_2 - E(q')$

4.5. Numerical Example

Consider the case where $A = 120$ and $B = 240$ where the mean $E(q') = 1/3$ and the variance is $V(q') = 0.0006156$ and the SD = 0.2481:

$$Skewness\,\alpha_3 = \frac{2(240 - 120)\sqrt{361}}{362\sqrt{120(240)}} = \frac{4560}{61433.44} = 0.07423$$

$$\alpha_3^2 = 0.27245$$

The 90% confidence full and partial interval equations are:

$$\frac{0.0006156}{0.3333 - q_1} = 0.605 - 0.0437(0.07423) - \frac{0.0156}{120} + 0.0997(0.07423)^2 = 0.602176$$

$$\frac{0.0006156}{q_2 - q_1} = 0.301 + \frac{0.0155}{120} + 0.0321(0.074227) = 0.303512$$

Since

$$\frac{0.0006156}{0.602176} = 0.333 - q_1$$

it follows that $q_1 = 0.3323$

$$\frac{0.0006156}{0.303512} = q_1 \, 0.3323$$

and $q_2 = 0.33434$.

This makes the 90% confidence interval from 30.35 to 33.43% with 2.98% below the mean and 0.1% above.

While this is only an approximation but the regression $R^2 = 0.98$ at least and the mean MS of prediction error was at most $.0^4 145$.

4.6. Managing a Sequential Bayesian Activity Analysis

In sampling, the number of observations made each day is a management decision. More samples per day speeds up the study so that the results are available earlier but there are fewer daily variations so that the study's representiveness is decreased. Deadlines need to be met, however, and so managers must make a tradeoff between meeting deadlines and being more representative.

Available observers is an important resource for managing activity analysis studies and every observation an observer makes requires an amount of time for the person to leave the office and go to the observation site and return. The workday divided by the sum of the travel plus observation time represents the maximum possible number of observations made per day per observer less allowances for personal time and conflict. Those allowance are likely to be 10% or more. Sometimes managers have more assistance available and they can increase the rate of sampling. However, managers must be careful when increasing the sampling rate that more samples are not taken at only specific days of the week or hours of the day, as those increases can bias the study if the ongoing activities are not uniform over time.

A feature of sequential Bayesian activity analysis which can aid managers as they plan sampling activities in the future is to look ahead to see where the study is likely to meet the imposed conditions to complete the study. In most studies several different activities are under observation and so any critical activities are likely to occur less than 50% of the time. Accordingly, the beta distribution relative to each critical activity will likely have a long right tail and a mean well below 50%. The resulting confidence interval will probably have a larger $q_2 - E(q')$ interval than the interval $E(1') - q_1$ that are the acceptable errors at the study completion. Those maximum errors are approximately $2\sqrt{V(q')}$.

Consequently, find $V(q')$ which equates management's maximum error. That $V(q')$ contour and the intersecting $E(q')$ contour provides an estimated stopping point along the study path as plotted on the parameter map and it can be located as the expected posterior point $[A,B]$. If the current state of sampling is at the point $[a,b]$, the path of the remaining part of the study should follow near the isomean contour. Figure 5 presents a parameter map with these points marked out. If an equilateral triangle with legs parallel with the two axes is constructed from the current point $[a,b]$, the two legs will go from that point horizontally to $[a + n, b]$ and vertically from the current point to $[a, b + n]$. The satisfying value of n is the expected number of added samples needed. If n divided by the normal rate of sampling per day will exceed the deadline, it is clear that a greater sampling rate is required or a larger error may have to be accepted. Figure illustrates this look-ahead feature. This concept provides a look-ahead basis for better study management.

Another aspect for study management is to view daily plots on a parameter map and inspect for either strange behavior or specific patterns that do not conform to the statistical assumptions. One such case is the trend of constant change in the $E(q)$ over time. Binomial sampling is based on a constant q.

4.7. Other Bayesian Sampling

There is a development of Bayesian Poisson that is similar to the binomial sampling above which is given by Buck *et al.* (1995). Also, computerized systems for these Bayesian approaches are available from Phan Gia of the University de Moncton, New Brunswick, Canada.

5. FINAL REMARKS

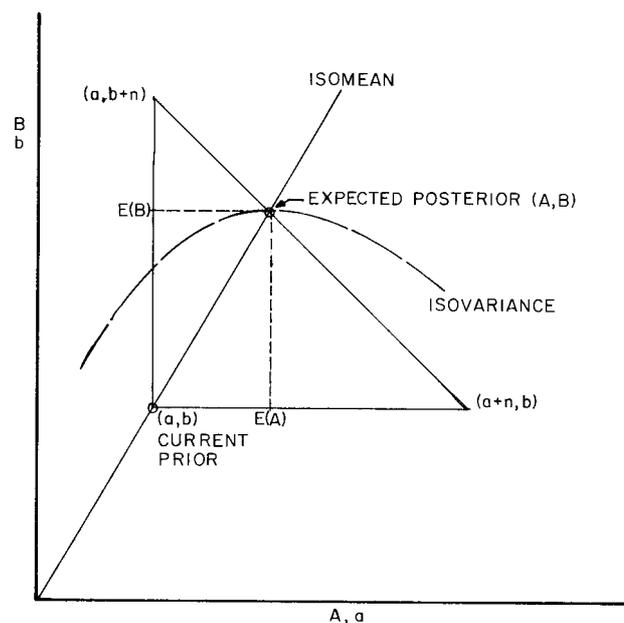
Activity sampling (or work sampling) is an observational approach to finding out how people spend their time. Typically it is


Figure 5.

performed with outside observers who look and classify the ongoing activity but in some cases the performing people can simply record their activity at random point of time. At the end of the study, the percentages of time the people spend on each specific activity can be estimated with reasonable accuracy and precision, depending upon the sample size. Traditional sampling techniques have been either binomial (Bernoulli) or Poisson sampling. The former is far more common and illustrated above. Also shown was Bayesian activity sampling and some of its advantages.

AET Ergonomic Job Description Questionnaire

K. Landau

Institute of Ergonomics, Darmstadt University of Technology,
Petersenstrasse 30, 64287 Darmstadt, Germany

1. INTRODUCTION

The origins of the AET (Abeitswissenschaftliches Erhebungsverfahren zur Tätigkeitsanalyse; ergonomic job analysis procedure) date back to a study (Rohmert et al. 1975) ordered by the German government to investigate discrimination against women at work with respect to pay. A job analysis procedure was required that allowed a detailed investigation of workload and strain within a given work system. At that time there was no job analysis procedure that could readily be used, although the position analysis questionnaire (PAQ) of McCormick *et al.* (1969) seemed to provide a basis for the psychological items.

Starting from that particular research project, the AET (Landau et al. 1975, Landau, 1978, Rohmert and Landau 1979, 1983) has been continuously developed over the last few years and applied in different industrial situations to analyze a wide range of shop-floor and management jobs (a total of about 7000 job analyses).

The AET has been developed for the universal analysis of work systems, the content of work ranging from "production of forces" to "production of information". The procedure can be used for selection, placement, training, job classification, rehabilitation, job design, occupational medicine, work safety, etc.

2. JOB ANALYSIS

This article describes job analysis as a subsection of a comprehensive system of work studies that covers the analysis of the individual components of person-at-work systems as well as the description and scaling of their interdependences. Job analysis starts from a model of work activity and assesses all relevant aspects of

- the work object
- the work resources
- the working environment
- the work tasks
- the work requirements

with regard to stress and strain considerations. Therefore, the basis of our understandig of job analysis is composed of the theoretical model of the person-at-work system and the concept of the simultaneous distinction and interdependence of stress and strain.

3. APPLICATIONS OF JOB ANALYSIS

The concept of job analysis as a universal "wideband" method allows the solution of quite a variety of practical and scientific problems. Applications are possible in the following fields:

1. Analysis of requirements and work design
   - Workplace documentation (e.g., for the investigation of accidents and analysis of industrial safety)
   - Work design
   - Design of work resources
   - Systematic reduction of stress
2. Industrial organization
   - Preparation of organizational changes
   - Design of work sequences
   - Organizational work design and work structuring
   - Organization of shift hours and rest allowances
3. Personnel management
   - Personnel recruitment
   - Personnel selection and placement
   - Integration of handicapped persons and other groups into the company
   - Basic and advanced education
   - Work evaluation and remuneration
4. Vocational counseling and research
   - Health status in different job classes
   - Job classification with respect to requirements
   - Vocational counseling and information.

According to work scientists, the main advantage of job analysis is its usefulness in adapting the work to the worker by constructive and methodical work design, and in adapting the worker to their work by adequate education, exercise and selection. In particular, the systematic application of job analysis procedures can either completely replace extremely expensive physiological investigations or at least restrict them to small bottleneck situations.

4. THE AET PROCEDURE

AET is oriented towards the elements and flows of the person-at-work system.

It has three parts (Table 1):
- Part A: analysis of the person-at-work system
- Part B: analysis of tasks
- Part C: analysis of demands

Besides the usual statistical requirements of an analysis procedure, a fundamental problem arises over theoretical justificationæasking for the selection of characteristics within the outlined classification of the procedure and for the scale level of the selected characteristics.

Particularly when selecting the items, it is important to consider the following basic facts:

- It is not possible that a fully completed catalog of items can be expected as part of the selected theoretical concept, especially in view of the economy of the procedure.
- Only those items which are important for numerous person-at-work systems should be included.
- The selection of items implies a certain judgment; hence "author-specific traits" influence the system of analysis, e.g., experience, standards of values, opinions.

So as the selection of the theoretical model forms the basis of the procedure, the selection, scaling and description of items within this model entails a series of subjective assumptions. However, these assumptions are acceptable as long as several analysts achieve reliable results by applying the procedure.

Parallel to the development of AET, an attempt was made to limit the subjective influences on the construction of items by using an iterative procedure development with respect to the experience of company specialists and ergonomists.

If one acknowledges the subjective, author-specific influence on the selection of a theoretical model substantiating AET on the

Table 1. Contents of the AET

PART A: WORK SYSTEM ANALYSIS

1. Work objects
   1.1 Material work objects
   1.2 Energy as work object
   1.3 Information as work object
   1.4 Human beings, animals, plants as work objects
2. Equipment
   2.1 Working equipment
       2.1.1 Equipment tools
       2.1.2 Means of transport
       2.1.3 Controls
3. Work environment
   3.1 Physical environment
       3.1.1 Environmental influences
       3.1.2 Dangerousness of work and risk of occupational disease
   3.2 Organizational and social environment
       3.2.1 Temporal organization of work
       3.2.2 Position in the organization of work sequence
       3.2.3 Hierarchical position in the organization
       3.2.4 Position in the communication system
   3.3 Principles and methods of remuneration
       3.3.1 Principles of remuneration
       3.3.2 Methods of remuneration

PART B: TASK ANALYSIS

1. Tasks relating to material work objects
2. Tasks relating to abstract work objects
3. Person-related tasks
4. Number and repetitiveness of tasks

PART C: JOB DEMAND ANALYSIS

1. Perception
   1.1 Mode of perception
       1.1.1 Visual
       1.1.2 Auditory
       1.1.3 Tactile
       1.1.4 Olfactory
       1.1.5 Proprioceptive
   1.2 Absolute/relative evaluation of perceived information
   1.3 Accuracy of perception
2. Decision
   2.1 Complexity of decision
   2.2 Pressure of time
   2.3 Required knowledge
3. Action
   3.1 Body postures
   3.2 Static work
   3.3 Heavy muscular work
   3.4 Light muscular work, active light work
   3.5 Strenuousness and frequency of movements

selection of items and on the determination of scale levels, codes and aids of classification, then one must also recognize the need to include technical criticism to achieve a progressive development of AET. The goals of the iterative AET development consisted of increasing its accessibility to the users while safeguarding or improving the statistical quality criteria.

The development of AET was oriented towards certain groups of users. Besides addressing ergonomically trained researchers and practitioners, it also addresses ergonomists. And AET is also aimed at industrial psychologists, representatives of labor and management, etc.—people who are interested in its results but who may not actually apply it.

AET part A describes the person-at-work system. The description and scaling refers to the objects of work and to the equipment and the working environment. The objects of work are analyzed under material, energy and information aspects. When a person is an object of work, it is essential to investigate the characteristics of that person's group. Finally, the qualities of material objects of work (like raw materials) are analyzed. The equipment, the work instruments (e.g., tools and implements) and other operating materials (e.g., hardware and software) are of interest. In this case the ergonomic system of classification is completed by technical aspects. The analysis of the environment is related to the physicochemical conditions in the workroom, the organizational and social working conditions and the principles and methods of pay.

There are 36 items for working and operating materials, 50 for the physical, organizational and social working conditions and 24 for the economic working conditions.

The object of investigation is the human activity in the person-at-work system; this is composed of the tasks which have to be carried out. The tasks stem from the purpose of the person-at-work system. In this sense part B of the analysis procedure represents a link between the tasks to be fulfilled and the resulting demands exerted on the working person. So the analysis of the person-at-work system is followed by the task analysis; this is carried out using 31 items subdivided according to the objects of work.

Task analysis is followed by demand analysis. Here the items are chosen to maximize the number of body functions considered. This is true for the function of power and energy generation in the different organs (stress during postural work and static work, heavy dynamic work and active light work) as well as for the functions of perception, decision and action in different mechanisms of information processing. The classification depends on deciding which area is required for receiving information, making decisions and taking actions. In demand analysis one distinguishes between the demands of reception of information (17 items), the demands of information processing (8 items) and the demands of information output or activity (17 items).

5. OBSERVATION INTERVIEW

The analysis of the job is done in the form of an observation interview, which means the necessary analytical data is collected first by observation of the job and working environment and second by interviewing the incumbent and the incumbent's superior (Figure 1).

Each AET item consists of a question outlining the state of affairs to be grasped and indicates the code for classifying this item. Sometimes examples are given as classification aids. The explanations clarify the questioning of the AET characteristic in view of extent, delineation and classification, but they cannot be taken as a complete and binding instruction for the rating. The classification of characteristics can only be done by using the corresponding code. The different codes are as follows:

- *Significance code (S)*: The importance or significance of this aspect for the task should be estimated in relation to other tasks or activities. Use a range from 0 to 5.
- *Duration code (D)*: This is based on a shift lasting eight hours. Eight hours is assumed even if the incumbent is a part-time worker, allowing comparisons between the work content of

jobs with different shift hours. Use a range from under one-third of shift time to whole shift time.

- *Frequency code (F)*: This code characterizes the temporal distribution and position of stress sections. Use a range from 0 to 5.
- *Alternative code (A)*: The alternative code only asks about the presence of a characteristic. Enter 1 if the work characteristic in question does apply; enter 0 if not.
- *Exclusive code (E)*: The exclusive code is always related to only one specific question, e.g., multiple properties of a working instrument. Use a range from 0 to 5.

An AET analysis in the field is directly followed by the coding of the AET items. This coding has to be done on a standard form or in direct dialogue with the computer. The time required for an observation interview is usually 1 to 3 hours, depending on the analyst's practical experience, the type of job and the repetition rate of work processes.

6. AET EVALUATION

The evaluation of AET codings has to provide answers to the following questions:

1. What are the differences in the jobs regarding work content, objects of work, work instruments, workplace, working environment and work organization in different branches of industry, different enterprises, different departments, different wage groups?
2. What are the differences in the job characteristics of jobs requiring different education and job-related training?
3. To what extent do the job characteristics of native and foreign workers differ?
4. To what extent do the job characteristics of industrial employees, office workers, executive personnel and government workers differ?
5. Which jobs are particularly similar or differ markedly in view of different strain-relevant stress components?

For interrelated and basic requests, the best solution is through using univariate evaluation methods which are supplemented by a series of multivariate methods. For univariate methods it is possible to use well-known procedures of descriptive statistics and profile analysis. Appropriate multivariate techniques are cluster analysis, discrimination analysis, factor analysis and multidimensional scaling.

Having obtained the item group scores in the form of profiles, they can be used to give a graphic survey of the extent or the duration of stress experienced during the execution of jobs or groups of activities. This type of evaluation is known as profile analysis (Figure 2).

Running down the chart are the characteristics of the

workplace and the types of demand, and the horizontal bars show the maximum AET classification in percent.

Job analysis procedures are often criticized because of their unsuitability for a wide range of applications. But it is a costly business to develop universally applicable job analysis procedures. The optimal solution is to make the procedure as universal as possible within the financial limitations imposed. Universality is defined here as suitability for the interpretation and generalization of data obtained from different investigations, different sectors of industry or different companies.

Basic Ergonomics Checklists

K.Kogi

The Institute for Science of Labour, 2-8-14, Sugao, Miyamae, Kawasaki, Kanagawa, Japan

1. THE PLACE OF ERGONOMICS CHECKLISTS

Ergonomics checklists are widely used to evaluate ergonomics-related conditions of plans, designs, systems, equipment, facilities, and existing conditions of work and life. Various checklists have been developed for different purposes, usually as a tool for prioritizing action plans in ergonomic design or redesign, comparative studies, and training. In an ergonomics checklist, a selected number of items are presented in the form of a list with yes/no reply boxes or other types of noting down the evaluation result for each item. Such a checklist has an obvious advantage of taking into account important items relevant to the check purposes. A checklist for workstation design, for example, presents check items related to work space, layout, postures, controls and displays, varied operations, work outputs, physical environment, and work organization. In this way it helps its users go through relevant ergonomic aspects of workstation design.

From the results of applying a checklist, we can know items which are relevant or marginal for the work situation under consideration. We use the checklist results to improve the original designs or existing conditions. There are two basic types of ergonomics checklists. Differences in the design concept of these two types are listed in table 1.

The first type presents a list of items that should be analyzed and evaluated by the checklist users. These items are presented in order to evaluate whether each item under analysis is appropriate from ergonomics points of view. Often, certain evaluation criteria are described so that the checklist users can see if these criteria are met. For example, the checklist users are asked to see if "all controls related to a particular function or operation or having sequential relations are grouped together," then the reply may be yes or no, or alternatively to indicate which groupings of controls are satisfactory or unsatisfactory. The same item may be mentioned in a checklist as "grouping of controls," meaning that the checklist users should see if controls are adequately grouped. This first type checklists may be called "analysis checklists."

The second type presents a list of actions that could be taken to improve the existing designs or conditions. Usually, typical remedial actions are presented so that the checklist users can select those items which are useful to improve the conditions under consideration. In order to assist the users, actions that are relatively easy to take are given. For example, the checklist users are asked whether they propose an action so as to "place frequently used materials, tools and controls within easy reach" or "make displays and signals easy to distinguish from each other and easy to read'. This second type checklists may be called "action checklists." An example of such checklists is presented in *Ergonomic Checkpoints: Practical and Easy-to-implement Solutions for Improving Safety, Health and Working Conditions* (International Labour Office 1996). In this publication, developed jointly by the International Ergonomics Association (IEA) and the International Labour Office (ILO), each checkpoint is presented in the form of a low-cost improvement action. The attached checklist presents each action followed by a question "Do you propose action?" with reply boxes for "no", "yes" and "priority". The last box "priority" is for ticking if the reply is "yes" and if that action should be given priority in the user's opinion.

The design of an ergonomics checklist depends largely on the purpose of its use. Analysis checklists are suited for inventory purposes so that the users can check important aspects of a job, a workplace, or worker tasks from ergonomic points of view or check specific design aspects. For example, the Position Analysis Questionnaire (PAQ) (McCormick 1979) and the Ergonomic Job Analysis (AET) (Rohmert and Landau 1985) comprise items required for assessing job performance as a whole. Such checklists are particularly useful for knowing problem areas and comparing different jobs or workplaces.

Action checklists as represented by one incorporated in the IEA/ILO Ergonomic Checkpoints are useful for prioritizing practical improvement actions and for training in identifying practical improvements. By selecting those actions in the list which are applicable for improving the existing work situation, the users can compare selected practical improvements so as to find priority actions covering major areas or specific aspects of the work situation. Action checklists are not necessarily aimed at presenting all the relevant aspects, but guiding the users in finding applicable improvements and developing their own ideas. Action checklists are thus particularly useful in initiating improvement plans and in action training.

2. AREAS COVERED BY ERGONOMICS CHECKLISTS

Ergonomics checklists are to assist users in making informed decisions to enhance efficiency at work, safety and health, and physical and psychological well-being of people at work or using facilities or equipment. Many checklists therefore covers broad areas so that the users can examine work systems as a whole and identify necessary improvements. The selection of areas covered by each checklist depends on the specific approaches taken. Ergonomics checklists proposed to analyze work systems usually try to cover major areas of job characteristics, whereas there are

Table 1. Design concept of two main types of ergonomics checklists

	(a) Analysis checklist	(b) Action checklist
Purpose	Ergonomic job analysis orwork systems evaluation	Finding practical improvements in work systems or situations
Check items	Features of a job or a work system to be considered in better design	Actions to be taken to improve existing conditions
Check procedures	Examining whether given criteria are met or the item is satisfactory	Considering whether given actions can be proposed
Outcome	Analysis report identifying items requiring improvement	Priority actions to be taken for immediate imporvement
Emphasis	Profiling jobs or work systems by listing their important aspects	Practical nature of actions listed including simple solutions

Table 2. Examples of areas covered by analysis checklists (in parentheses are the number of items listed)

(a) Position Analysis Questionnaire (PAQ)	(b) Ergonomic Job Checklist (AET)	(c) Human Factors Checklist for air traffic control systems
Information input (where/how one gets information on the jobs to perform) (35)	The man-at-work system (work objects, tools and equipment, environment including physical, organizational, social and economic conditions) (143)	General (subsystems, necessary information) (10)
Mental process (information-processing and decision-making in doing the job) (14)		Visual displays (general, visual alerts) (66)
		Auditory alerts (general, speech messages) (29)
		Cognitive workload (general, automation) (58)
Work output (physical work done, tools and devices) (50)	The task analysis (different kinds of work object such as material and abstract objects, worker-related tasks) (31)	Data entry procedures (general, commands and command execution, menus, error messages and and user guidance (63)
Interpersonal relationships (36)		Data entry devices (general, keyboards, touchscreens, trackballs, grip devices, mice graphics, pushbuttons, pedals) (46)
Work situation and job context (Physical/ social contexts) (18)	The work demand analysis (elements of perception, decision and response/ activity) (42)	
Other job characteristics (work schedules, job demands) (35)	The supplement (body postures, movements in assembling)	Workstation design (user-centered design, control-room seating, communications equipment, environment (68)
		Human factors planning (30)

many other checklists covering only selected specific areas important for the intended improvements. As a result, general-purpose job analysis checklists such as the PAQ and AET have some common areas. Specific-purpose checklists such as traffic control systems checklists or products checklists may be designed to cover selected areas in detail. Examples of areas covered by analysis checklists are shown in table 2.

The PAQ has six major divisions consisting of information input, information processing, work output (physical work, tools and devices), interpersonal relationships, work situation and job content, and other job characteristics (work schedules and job demands). The AET consists of three parts dealing with the man-at-work system (work objects, tools, equipment and work environment), the task analysis, and the work demand analysis. Such a job-oriented approach is useful for undertaking task inventories and job analysis by considering important aspects of the given complex job tasks.

As shown in table 3, action checklists contrast in this respect with these analysis checklists. The checklist of the IEA/ILO Ergonomic Checkpoints mentions low-cost actions for various aspects of work activities, workplace facilities and equipment, working environment and work organization. The Work Improvement in Small Enterprises (WISE) checklist, developed for use by small enterprise owners/managers (Thurman *et al.* 1988) is used in checking small workplaces in order to identify simple improvements. In both these checklists, a special emphasis is placed on building on local practice and on low-cost solutions that are applicable immediately by using locally available skills.

Both checklists are accompanied with guidance about how to make simple improvements in low-cost ways.

New types of design support checklists devised for various ergonomic design purposes have diversified structures. Many such checklists are used for computer-aided design from ergonomics points of view. For example, a design support checklist for computer-aided designs (Aaltonen and Mattila 1998) consists of questions about layout design, mechanical design (location of equipment and controls, structural strength), control design, electrical design, maintenance design and installation design. Usually, these checklists belong to analysis checklists and are based on essential standards for ergonomic design. With the aid of these checklists, designers can document the standards used for the object in question.

3. THE PRACTICAL USE OF ACTION CHECKLISTS

The practical nature of checklist use is important. The users of the checklists expect to be able to have an overview of the ergonomics-related aspects of the work systems or objects considered for the purpose of identifying required improvements. Therefore, checklists should not be too long or too extensive. Analysis checklists tend to be long, and their users should devise appropriate ways of using them for their own purposes, for example, concentrating on certain aspects or trying to have a quick overview. Action checklists are easier to handle since they are relatively short. Action checklists can be used to initiate workable ideas by learning from the presented examples of actions. When action checklists are used in the course of a walk-

Table 3. Technical areas covered by typical action checklists

(a) IEA/ILO ergonomic checkpoints	(b) Work improvement in small enterprises checklist
Materials storage and handling (21)	Materials storage and handling (5)
Hand tools (15)	Workstation design (7)
Machine safety (20)	Machine safety (5)
Workstation design (15)	Control of hazardous agents (6)
Lighting (10)	Lighting (6)
Premises (heat, ventilation) (7)	Welfare facilities (5)
Control of hazardous substances and agents (6)	Premises (heat, noise, fire, passageways, wiring((7)
Welfare facilities (13)	Work organization (5)

through round, going through selected work areas or workstations, the time required for completing a checklist should be 30–60 minutes. Longer time can be used for analysis checklists, but we should keep in mind that lengthy check procedures may not be widely applied.

The format of checklists varies greatly. The reply entries are usually for yes/no, satisfactory/unsatisfactory or step-wise evaluations (for example, 1–5). There are both quantitative and qualitative criteria in using analysis checklists, and the users need to be guided about how to apply these different criteria. Items with quantitative criteria are clearer about evaluations to make, but not always relevant to the situation under consideration. As a rule, the checklist users should be allowed to make quick decisions based on the gained knowledge and their own experiences. The way each check item is presented is important in this respect. Each item should be clear about what aspects are to be checked. It is better to include clues for making quick judgment. For example, a question such as "Are displays and controls compatible with easy understanding and reactions?" is rather difficult to respond to quickly, while a question such as "Are controls color-coded for identification?" is easy to answer. Action checklists are thus easier to respond to as they mention practicable actions such as "use markings or colors on displays to help workers understand what to do."

The best way to use ergonomics checklists is to use them in group work. It is even better to plan the use of a checklist jointly and then apply it in the form of a joint inspection or a joint walk-through round. Each participant may fill in the checklist based on individual judgment. The results of checklist application can be discussed by small groups. Group presentations may follow if some groups join in the checklist application. We should try to summarize the results of such group discussions and agree on priority proposals for improving the work systems or objects checked.

Practical support for applying checklists is also important. The checklist users should be familiar with the work systems or objects to be checked. Knowledge and experiences in ergonomics principles are further necessary, and training in the use of checklists is needed. Such training can be combined with initial checklist exercises so that the users can learn how to use the checklist by doing themselves. Guidance materials and manuals on ergonomic principles and improvement actions are useful. Such support is effectively given when the checklist application is done by group work.

4. USEFUL CHECKPOINTS

Often, new checklists are designed for the specific purposes of the checklist users. This is encouraged as in this way the users can learn how to examine the various ergonomic aspects and how to utilize the check results. In designing new checklists, a compiled pool of "checkpoints" can be used as a database from which the checklist users can select those items which are applicable in their specific circumstances. The compiled points can also be used to get hints about new items to be added in the checklist by getting hints from these points. Table 4 gives examples of checkpoints useful for designing new checklists.

5. CHECKLISTS AS DESIGN AND TRAINING TOOLS

Ergonomics checklists are in the process of development. It is useful to exchange experiences in constructing and applying checklists. The design of new checklists adjusted to the checklist users' purposes is encouraged. This is important since the way work systems or facilities are used is increasingly varied on account of developing information technologies, flexible work systems, aging, and, increasingly, diversifying human needs.

One should note the shortcomings of general-purpose checklists in applying them to various situations. While knowledge about ergonomic standards is developing, there is a general lack of ergonomics norms and protocols of evaluation which are readily applicable in analyzing the varying aspects of work and objects. The evaluation of ergonomics aspects by

Table 4. Examples of useful checkpoints (from the IEA/ILO "Ergonomic Checkpoints")

Materials handling	Clear and mark transport routes.
	Use carts, hand-trucks and other wheeled devices or rollers when when moving materials.
	Use mechanical devices for lifting, lowering and moving heavy materials.
Hand tools	Provide a "home" for each tool.
	Use vices and clamps to hold materials or work items.
Machine safety	Make different controls easy to distinguish from each other.
	Use marking or colours on displays to help workers understand what to do.
Workstation design	Adjust the working height for each worker at elbow level or slightly below it.
	Allow workers to alternate standing and sitting at work as much as possible.
Lighting	Provide local lights for precision or inspection work.
	Relocate light sources or provide shields to eliminate direct glare.
Premises	Isolate or insulate sources of heat or cold.
	Isolate or cover noisy machines or parts of machines.
Welfare facilities	Provide drinking facilities, eating areas and rest rooms to ensure good performance and well-being.
	Provide a place for workers' meetings and training.
Work organization	Combine tasks to make the work more interesting and varied.
	Set up a small stock of unfinished products (buffer stock) between different workstations.

applying a checklist is based often on subjective assessment and subject to the lack of precision. We should keep in mind the limited scope of checklist results. It is important to understand the role of ergonomics checklists and use them as one of a range of practical evaluation tools for conducting social dialogue between employers, workers, users, and others concerned.

Two important uses of ergonomics checklists are in human-centered design and in training. In assisting designers in evaluating work situations and objects, ergonomics checklists can play a vital role. There are thus interesting proposals of design support checklists. Computer-aided application of such checklists is also developing. Design-support checklists usually contain ergonomics principles or standards useful for designers. The checklist users can use relevant check items and get useful advice about improving the specific aspects under consideration. The designers should use checklists as advisory tools in a flexible manner.

Another important use of ergonomics checklists is their application in education and training in ergonomics. Checklists help trainees to study complex interactions between the working situations and human characteristics in a more or less systematic manner. Analysis checklists are useful for training in standardized ergonomic analysis. Action checklists are useful for training in ergonomics interventions in local situations. Low-cost ideas contained in action checklists can motivate trainees to look for local solutions with practical benefits.

In using ergonomics checklists as design and training tools, the combined use of other information materials and databases is effective. Handy manuals, design standards, improvement guides, best practice stories, and illustrations or photographs of good examples are particularly effective. The use of checklists can be constructive when the checklist users pay due attention to data collection, learning through good examples and action-oriented interventions.

Biomechanical Modeling of Human Strength

D.B. Chaffin

Department of Industrial & Operations Engineering and Biomedical Engineering, University of Michigan, Ann Arbor, MI 48109-2117, USA

1. INTRODUCTION

Human strength is characterized by many experts as the maximum force or torque a well-motivated person can demonstrate for a few seconds without fatigue (i.e., with a minimum rest of at least one minute between repeated exertions). Many factors modify the resulting strength values. Some of the most important factors are as follows:

- Personal attributes
  - strength conditioning and genetics
  - gender
  - size (anthropometry)
  - age
- Task attributes
  - force direction (lift, push, etc.)
  - posture
  - speed of motion

Because these factors interact in a complex fashion, and the effect of each is only empirically known for some factors, biomechanical models have been proposed and used to assist in predicting the strength capability of a specified population of people (older men, small women, etc.) in a variety of ergonomic design scenarios.

2. WHY MODEL HUMAN STRENGTHS?

Besides the obvious curiosity people seem to have about strength (strength and aerobic training programs are big business), the major interest seems to come from a growing concern by employers for the following reasons:

- Manual exertions remain an essential part of many jobs today. It is believed these types of exertion account for a disproportionate number of serious injuries, mostly to the musculoskeletal system. Based on a Department of Labor Survey of work-related injuries and illnesses, overexertion accounted for 27% of injuries and illnesses in 1994. The direct medical and wage replacement costs associated with these injuries and illnesses are estimated at $15-20 billion dollars annually, with administrative and other indirect costs possibly quadrupling the total costs.
- When a job includes manual exertions, it is a job that often becomes difficult to staff, due to the large variability that exists in the strength performance capability of the working population. In fact a normal, healthy, mixed gender population of workers may have strength variations greater than 10:1 (Chaffin *et al.* 1999). If a manual task in a job is found to be particularly difficult for older workers, women or physically impaired individuals, legal remedies may mandate changes in the job to eliminate the discriminatory task, particularly if it is not an essential function in the job.

3. BASIC BIOMECHANICS OF STRENGTH PREDICTION

The musculoskeletal system can be viewed as a series of levers (bones) and mechanical actuators (muscles). The muscles produce a tendency for the bones at each joint to rotate. The magnitude of this tendency to rotate is called the rotational moment at a joint. During any physical exertion the muscles that surround each joint contract to produce moments in response to any external forces or torques required as one attempts to perform a manual task. Essentially at each joint a simple balance must be achieved between the moments produced by the muscle contractions and the moments caused by body segment weights and other external forces (e.g., hand loads). Mathematically this balance is expressed

$$M_j = S_j$$

where

M_j = the external moment at each joint

S_j = the maximum moment that can be produced by the muscles at each joint, (i.e., the muscle strength at a joint) normally specified for a particular population subgroup

The values for M_j normally depend on three general requirements:

- The load (force) acting on one's hands (weight lifted, push force, etc.).
- The posture one is in when performing the maximum effort.
- The size (anthropometry) of a person being considered for the task.

Given data describing each requirement, the moments at each joint can be easily computed using Newtonian mechanics, wherein external forces acting on the human body are multiplied by the perpendicular distance from the point of action to the joint. Population joint range-of-motion statistics are often consulted to assure that a given posture does not exceed the normal mobility at each joint. Figure 1 is a typical biomechanical model of a person used for computing major joint moments during exertions.

The joint moment strengths S_j are obtained by population measurements using standardized strength testing methods. Population values have been developed for most major muscle functions; remember that muscle strength moments vary over the range of motion for a joint. Thus joint angles must be known to predict S_j values. In fact, because muscles often span two joints, the angle at adjacent joints must be considered in predicting S_j values. A synthesis of values for S_j from the moment strength studies is presented in Chaffin *et al.* (1999).

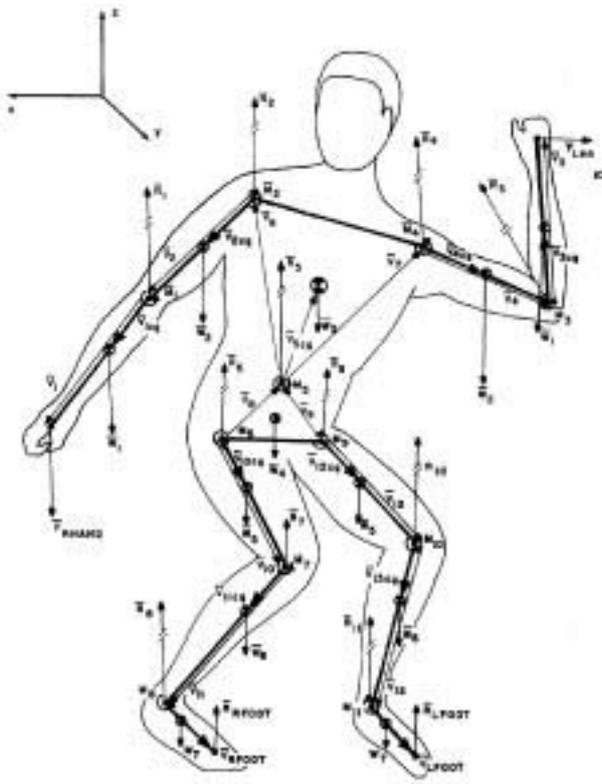
Many calculations are needed to estimate the M_j and S_j values, so computer programs were developed for this purpose. The sagittal plane strength prediction program was first programmed in 1968 by Chaffin and was used to evaluate lunar exploration manual task simulations for NASA in the early 1970s. Nowadays it is known as the 2D static strength prediction program (2DSSPP). A three-dimensional version, known as the 3D static strength prediction program (3DSSPP), was written in 1975. It compares the population strength capabilities with 24 different muscle joint strengths, and allows asymmetric exertions involving one or both hands to be evaluated. The logic used in these programs is described in Figure 2.


Figure 1. Three-dimensional distance, force and moment vectors used in the 12-link biomechanical model for strength prediction (Chaffin and Erig 1991)

In addition to using the muscle strength moments at each joint to predict the percentage of a population able to perform a specific exertion, the external moment loads at the lower back and feet are used to determine hand exertion forces that would either raise the risk of low back injury or of falling, respectively.

Thus strength models have become quite robust in their ability to evaluate high exertion tasks of many types.

4. STRENGTH MODEL VALIDATION AND LIMITATIONS

Three different validations of static strength prediction models have been performed over the years. In the first validation Garg and Chaffin (1975) had 71 male air force personnel perform 38 different maximum arm exertions (lifts, pushes, pulls, etc.) in a variety of arm/torso postures while seated. They found the predicted strengths were highly correlated with the group strengths when performing the 38 upper body tasks ($r = 0.93$ to 0.97). Chaffin *et al.* (1987) simulated 15 different whole-body exertions in the sagittal plane which were also performed by both men and women volunteers from a variety of industries. In some of these tests over 1000 people performed the exertions, though on average about 200 people performed each. Comparison of the 2DSSPP with the group strength data revealed a very high correlation ($r = 0.92$). This same study also included 3DSSPP simulations of 72 different one-arm exertions performed by five male army personnel. The correlations ranged from $r = 0.71$ to 0.83. But in this latter comparison, exact postural and bracing conditions were not available to use in the simulations. This and the small sample ($N = 5$) may have contributed to the lower correlations.

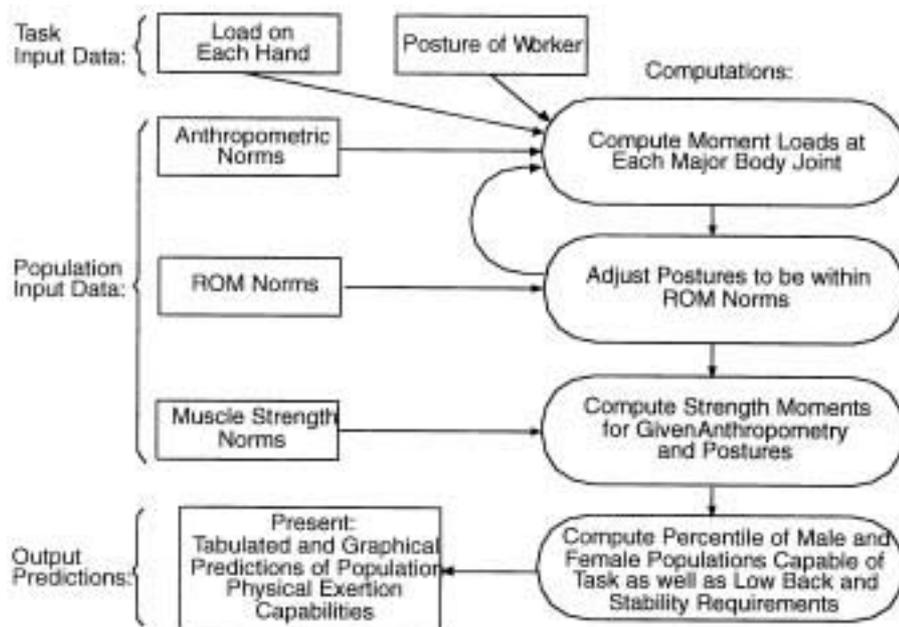
The last validation involved simulations of 56 one- and two-handed, whole-body exertions in 14 different symmetric, bent, and twisted-torso postures (Chaffin and Erig 1991). The simulation results were compared with the group strengths of 29 young males. Photographs from several views were available to assist in replicating the computer-rendered postures used by these subjects. The results indicated that if care is taken to assure the postures used in the model simulation are the same as the postures chosen by people performing the exertions, the prediction error


Figure 2. Biomechanical logic used to predict whole-body static exertion capabilities for given postures, hand force directions and anthropometric groups

standard deviation will be less than 6% of the mean predicted value.

At present the strength norms used as joint moment limits in the models are based on male and female populations who are relatively young (18–49 years). To improve the models further, I am now gathering strength values for older populations. In this regard, one comparison involving 98 men and women with a mean age of 73 years, showed a major decrease in strength performance in certain muscle functions. When these decreases were included in the 3DSSPP population database, it was found that some exertions which could easily be performed by younger people were predicted as impossible for most older people (Chaffin *et al.* 1994).

Perhaps the biggest limitation in strength prediction is that no dynamic models have been formulated or validated. Since many high exertion, manual tasks require a specific speed of motion (e.g., keeping up with a fast-paced production line) and since strength capability can vary significantly with movements, it is imperative to develop dynamic biomechanical models and dynamic strength data that improve future ergonomic evaluation methods.

5. USABILITY OF CURRENT STRENGTH PREDICTION TECHNOLOGY

To make them useful, the existing biomechanical models had to be easy to implement and easy to use on personal computers. Over the last 25 years several research engineers and computer programmers at the University of Michigan's Center for Ergonomics have worked to accomplish this goal, which resulted in the first 2D static strength prediction program licensed in 1984 by the university's Technology Management Office. This was followed in 1989 by the licensing of the first 3D static strength prediction program.

Figure 3 shows the main screen of the SSPP. The input values (i.e., body link angles, hand forces, and anthropometry) are shown in the upper left quadrant. A diagram depicting the body posture, the hand location, and the hand force direction, which are used as inputs, is depicted in the upper right quadrant. The predicted percentage of the male and female population having sufficient strength to perform the designated exertion (in this case lifting a 44 lb stock reel) is shown in tabular and graphical form in the lower left quadrant. The back compression force predictions for

men and women performing the 44 lb lift is shown in the lower right quadrant. In this situation, from inspection of the percent capable predictions (lower left), it is obvious that hip strengths are the most limiting muscle group strengths (only 66% of women and only 87% of men have sufficient hip strength to lift the 44 lb reel). Incidentally, these values are below that recommended by NIOSH, which believes jobs should accommodate 99% of men's strength and 75% of women's strength (or 90% of a mixed gender population). The lower right quadrant shows that the L5/S1 compression forces on the lumbar spinal disks of 924 and 845 lb are above the 770 lb recommended by NIOSH.

6. DISCUSSION

The existing biomechanical models are neither complete nor accurate for all types of exertion. If there are fast movements combined with maximum strength exertions, the static models will overpredict the population's capabilities. Where it is difficult to grip an object being manipulated, the models will overpredict the population's capabilities. For an older population, the models will overpredict its capabilities. These are issues that are being addressed by other biomechanics researchers. As improved biomechanical models and population databases are developed, they will be incorporated in subsequent versions of the program.

The important thing is that a great deal of information on population variability for strength and low back failure is now accessible in a form which can improve future job designs. I hope this chapter will help interested parties to understand the rapidly developing technologies needed to further improve manual tasks in industry.

Biomechanics of Low Back: Guidelines for Manual Work

S. M. McGill

Occupational Biomechanics and Safety Laboratories, Faculty of Applied Health Sciences, Department of Kinesiology , University of Waterloo, Waterloo, Canada N2L 3G1

1. INTRODUCTION

Some of the well intended guidelines provided to workers to reduce the risk of low back injury often recommend to: "bend the knees and keep the back straight"; never jerk a load - lift slowly and smoothly"; "adjust your chair to keep the back upright and the hips, knees, and elbows at 90 degrees". These continue to be proliferated despite the fact that very few manual jobs can be performed by "bending the knees", and in fact some of these well intended guidelines can actually increase the risk of injury! Workers know this, and often return to their former habits. There is a need to examine the evidence to justify recommendations that reduce loading on the tissues at risk and develop recommendations that are applicable to a wide variety of workplace situations.

Having just indicated that "reducing the load on tissues at risk" is a laudable objective, a caveat is required here. While it often is common "wisdom" to direct effort to always reduce the demands of a job, some jobs may need to be made more demanding. Optimal occupational health requires some loading, but not too much. Too much of any one activity will lead to troubles, even sitting too much, standing too much, lifting too much, etc. However, some lifting, sitting, and standing is necessary to maintain health from the tissue and motor control level through to enhancing health at the systems level.

This chapter aims to integrate scientific evidence to build a foundation for the formation of a set of guidelines intended to reduce the risk of low back injury in a wide variety of occupational situations, ranging from heavy lifting to sedentary activities. Since some of these guidelines are based on recent research findings, they remain tentative until their efficacy under field trial is proven or disproven.

2. REDUCING THE RISK OF LOW BACK INJURY: ISSUES AND EXPERIMENTAL EVIDENCE

It is not the intent here to describe the detailed process of investigation of spine function and injury mechanisms in living workers. The interested reader is directed to McGill, 1997 for more information on this process. Rather, this section constitutes a discussion of some recent research findings as they relate to the issue of formulating guidelines for manual exertion for task assessment and implementation by ergonomists.

2.1. Should One Avoid End Range of Spine Motion During Exertion?

It is recognized that very few lifting tasks in industry can be accomplished by "bending the knees and not the back". Furthermore, most workers rarely adhere to this technique when repetitive lifts are required — a fact which is quite probably due to the increased physiologic cost of squatting compared with stooping. However, a case can be formulated for the preservation of neutral lumbar spine curvature (i.e., the natural relaxed curve observed when standing) while lifting, (specifically avoiding end range limits of spine motion about any of the 3 axes). This is a different concept than "trunk angle", as the posture of the lumbar spine can be maintained independent of thigh and trunk angles. Specifically, there has been much confusion in the literature between trunk angle or inclination, and the amount flexion in the lumbar spine. Bending over is accomplished by either hip flexion or spine flexion or both. It is the issue of specific lumbar spine flexion that is of importance here. Normal lordosis can be considered to be the curvature of the lumbar spine associated with the upright standing posture.

Using the tissue load distribution perspective, the following example demonstrates the shifts in tissue loading, predicted from our modelling approach, which has quite dramatic affects on shear loading of the intervertebral column and lends insight into the stoop-squat issue. First, the dominant direction of the pars lumborum fibres of longissimus thoracis and iliocostalis lumborum are noted to act obliquely to the compressive axis of the lumbar spine producing a posterior shear force on the superior vertebra. In contrast, the interspinous ligament complex acts with the opposite obliquity to impose an anterior shear force on the superior vertebra. Suppose a worker holds a load in the hands with the spine fully flexed sufficient to achieve myoelectric silence in the extensor muscles (reducing their tension), and with all joints held still so that the low back moment remains the same, then the recruited ligaments will add to the anterior shear to levels well over 1000 N, which is of great concern from an injury risk viewpoint. However, when a more neutral lordotic posture is adopted, the extensor musculature is responsible for creating the extensor moment, and, at the same time, will support the anterior shearing action of gravity on the upper body and hand-held load. Disabling the ligaments by avoiding full flexion greatly reduced shear loading. (For a more comprehensive discussion see McGill, 1997.)

The scientific evidence appears to point to the following positive effects if one lifts while avoiding full lumbar flexion: conscious control of lumbar musculature is retained, reducing shear load on the facet joints and providing neurological protection not present if one depends on passive tissue to support the load; the disc is loaded more uniformly permitting all of the annular fibers to share the stress rather than disabling some.

2.2. Should One Lift or Perform Extreme Torso Bending Shortly After Rising from Bed?

The diurnal variation in spine length together with the ability to flex forward has been well documented. Over the course of a day, hydrostatic pressures cause a net fluid out flow from the disc resulting in narrowing of the space between the vertebrae which in turn reduces tension in the ligaments. When laying down at night, osmotic pressures exceed the hydrostatic pressure causing the disc to expand. It has been estimated that disc bending stresses increased by 300% and ligament stresses by 80% and concluded there is an increased risk of injury to these tissues when bending forward early in the morning.

2.3. Should One Lift Immediately Following Prolonged Flexion Postures?

Prolonged flexion causes spine tissues to creep such that stresses accumulate with progressive tissue deformation over time which will lead to damage (see McGill, 1997). This is of particular importance for those individuals whose work or movement patterns are characterized by cyclic bouts of full end range of motion postures followed by exertion.

These data suggest that the spine has a memory, since the mechanics of the joints are modulated by previous loading history. Before lifting, following a stooped posture, or after prolonged sitting, a case could be made for standing or even consciously extending the spine for a short period. Allowing the disc nucleus to "equilibrate" and ligamentous tissues to slowly regain their rest length and stiffness reduces the risk of damage.

2.4. Should Intra-abdominal Pressure be Increased While Lifting?

It has been claimed for many years that intra-abdominal pressure (IAP) plays an important role in support of the lumbar spine, especially during strenuous lifting. This issue has been considered in lifting mechanics for years and, for some, has formed a cornerstone for prescription of abdominal belts to industrial workers and also has motivated various abdominal strengthening programs. Many have advocated the use of intra-abdominal pressure as a mechanism to reduce lumbar spine compression.

In fact increased IAP is produced with abdominal wall musculature activity which has actually been shown to increase spine compression. However, it appears that the spine prefers to sustain increased compression loads if intrinsic stability is increased. An unstabilized spine buckles under extremely low compressive load (e.g. approximately 20N). The geometry of the musculature suggests that individual components exert lateral and anterior–posterior forces on the spine which perhaps can be thought of as guy wires on a mast to prevent bending and compressive buckling. As well, activated abdominals create a rigid cylinder of the trunk resulting in a stiffer structure. Thus it appears that increased IAP, commonly observed during many activities including lifting, as well as in those people experiencing back pain, does not have a direct role to reduce spinal compression but rather is an agent used to stiffen the trunk and prevent tissue strain or failure from buckling.

2.5. Should Abdominal Belts be Prescribed to Manual Materials Handlers?

Readers are directed to the chapter on this topic in this textbook by McGill.

2.6. Should Workers Adopt a Lifting Strategy to Recruit the Lumbodorsal Fascia?

Studies have attributed various mechanical roles to the lumbodorsal fascia (LDF). In fact there have been some attempts to recommend lifting postures based on LDF hypotheses. Suggestions were originally made that lateral forces generated by internal oblique and transverse abdominis are transmitted to the LDF via their attachments to the lateral border. This lateral tension was hypothesized to increase longitudinal tension, from Poisson's effect, pulling in the direction of the posterior midline of the lumbar spine causing the posterior spinous processes to move

together resulting in lumbar extension. This proposed sequence of events formed an attractive proposition because the LDF has the largest moment arm of all extensor tissues. As a result, any extensor forces within the LDF would impose the smallest compressive penalty to vertebral components of the spine. However this hypothesis was examined by three studies which used quite different methods, all published about the same time, and which, collectively, questioned its viability. Given the confused state of knowledge about the role, if any, of the LDF, the promotion of lifting strategies based on intentional LDF involvement cannot be justified at this time.

2.7. Should the Trunk Musculature be Co-contracted to Stabilize the Spine?

The ability of the joints of the lumbar spine to bend in any direction is accomplished with large amounts of muscle co-activation. Such co-activation patterns are counter productive to generating the torque, necessary to support the applied load, in a way that minimizes the load penalty imposed on the spine from muscle contraction. Yet it has been recently documented that cocontracting torso musculature acts to stabilize the spine and prevent buckling (Cholewicki and McGill, 1996).

2.8. How Do People Hurt their Backs Picking Up a Pencil?

While injury from large exertions is understandable, explanation of how people injure their backs performing rather benign appearing tasks is more difficult — but the following is worth considering by the ergonomist. Continuing the considerations about stabilization from the previous section — a number of years ago, we were investigating the mechanics of power lifter's spines while they lifted extremely heavy loads using video fluoroscopy for a sagittal view of the lumbar spine. During the execution of a lift, one lifter reported discomfort and pain. Upon examination of his vertebral motion, one of the lumbar joints (specifically, the L4/L5 joint) reached the full flexion calibrated angle, while all other joints maintained their static position (2–3 degrees from full flexion). This is the first observation that we know of reported in the scientific literature documenting proportionately more rotation occurring at a single lumbar joint than at the other joints: the spine buckled! It would appear that this unique occurrence was due to an inappropriate sequencing of muscle forces (or a temporary loss of the normal motor control pattern). This motivated the work to investigate and continuously quantify stability of the lumbar spine throughout a reasonably wide variety of loading tasks (Cholewicki and McGill, 1996). Generally speaking, Cholewicki noted that the risk of such an event was greatest when there are high forces in the large muscles with simultaneous low forces in the small intersegmental muscles (a possibility with our power lifter) or when all muscle forces are low such as during a low level exertion. Thus, a mechanism is proposed, based on motor control error resulting in temporary inappropriate neural activation, that explains how injury might occur during extremely low load situations, for example, picking a pencil up from the floor following a long day at work performing a very demanding job.

2.9. Are Twisting Lifts Particularly Dangerous?

Twisting of the trunk has been identified as a factor in the incidence of occupational low back pain but the mechanisms of risk require some explanation. Some hypotheses have been based on an inertia argument in that twisting at speed will impose dangerous axial torques upon braking the axial rotation of the trunk at the end range of motion. Twisting has indeed been documented to damage the disc annulus and possibly the posterior ligaments if the joint is fully flexed prior to twisting.

Certainly the mechanisms of injury from torsional loads applied under twisting conditions remain inconclusive. However, it is clear that the increase in compressive load on the spine is dramatic if a comparatively small amount of axial twist torque is required in addition to the dominant extensor torque. These differences result from the difference in co-activation of the trunk musculature, combined with small moment arms in many cases, to generate the moments of force required. It appears that the lumbar spine pays dearly in order to support even small axial torques when extending during the lifting of a load.

2.10. Is "Lifting Smoothly" and Not Jerking the Load Always the Best Advice?

We have all heard that a load should be lifted smoothly and not "jerked". This recommendation was most likely rationalized on the basis that accelerating a load upwards increases its effective mass by virtue of an additional inertial force acting downwards together with the gravitational vector. However, this may not always be the case as it is possible to lift a load by transferring momentum from an already moving segment. The concept of momentum transfer during lifting which is a skill and feature of many skilled workers is known as the "kinetic lift". For example, if a load is awkwardly placed, perhaps placed on a work table at a distance of 75 cm from the worker, a slow-smooth lift would necessitate the generation of a large lumbar extensor torque for a lengthy duration of time — a situation that is most strenuous on the back. However, this load could be lifted with a very low lumbar extensor moment or quite possibly no moment at all. However, if the worker leaned forward and placed his hands on the load, with bent elbows, the elbow extensors and shoulder musculature could thrust upwards initiating upward motion of the trunk to create both linear and angular momentum in the upper body (note that the load has not yet moved). As the arms straighten, coupling takes place between the load and the large trunk mass (as the hands then start to apply upward force on the load) transferring some, or all, of the body momentum to the load causing it to be lifted with a jerk. This highly skilled "inertial" technique is observed quite frequently throughout industry and in some athletic events such as competitive weight lifting but it must be stressed that such lifts are conducted by highly practised and skilled individuals — the body momentum must be generated prior to the transfer to the load. In most cases, acceleration of loads to decrease low back stress in the manner described is not suitable for the "lay" individual when conducting the lifting chores of daily living. There can be no argument that reduction of the extensor moment required to support the hand load is paramount in reducing the risk of injury and that this is best accomplished by keeping the load as close to the body as possible.

2.11. Is Sedentary-seated Work Harmful?

Epidemiological evidence has documented the increased risk of disc herniation of those who perform sedentary jobs characterized by sitting. This has motivated occupational biomechanists to consider the duration of sitting as a risk factor when designing seated work in the interest of reducing the risk of injury. A recently proposed guideline has suggested a sitting limit of fifty minutes without a break, although this proposal will be tested and evaluated in the future. Further, the notion of making sitting a "dynamic task" with regular posture changes is gaining favour rather than the conventional textbook description of the ideal sitting posture being an upright torso with hips and knees to 90 degrees. Still, there is no substitute for regularly standing up from the chair — answering the phone for example provides such an opportunity.

2.12. What About Walking: Fast and Slow Occupational Gait?

Studies of walking mechanics have documented that slow walking ("mall walking") results in static muscle activity and spine loading while fast walking produces cyclical loading and unloading. This may explain the relief experienced by some from fast walking while slow walking exaggerates symptoms. Further, spine posture during standing and walking is quite different from the sitting posture supporting the recommendation to change from sitting to standing regularly.

3. TENTATIVE RISK REDUCTION GUIDELINES FOR OCCUPATIONAL INJURY

The following recommendations have been summarized from the biomechanical rationale developed in the previous section. Some are consistent with what has been advocated for years, while others contradict longstanding notions that were based on flawed, or unavailable, biomechanical understanding. They are more versatile and widely applicable than the commonly used instruction of "bend the knees — not the back" to reduce lifting stresses. These recommendations may have the potential to reduce tissue loads during the performance of a wide range of industrial exertion tasks and they are able to accommodate all tasks including those outside of the sagittal plane. Furthermore, the exact instructions issued to a specific worker should not be taken verbatim from the following list, but rather the biomechanical principle should be explained in a language and terminology which is familiar to the worker. In addition, often successful job incumbents have developed personal strategies for working that assist them in avoiding fatigue and injury. Their insights are the result of thousands of hours of performing the task and they can be very perceptive — attempts should be made to accommodate them.

3.1. Recommendations for Safer Work – A Tentative List

1. First and foremost, design work that facilitates variety.
   - Too much of any single activity leads to trouble. Relief of cumulative tissue strains are accomplished with posture changes, or better yet, other tasks that have different musculoskeletal demands.

2. Avoid a fully flexed or bent spine and rotate trunk using hips (preserving a neutral curve in the spine).
    - Disc herniation cannot occur.
    - Ligaments cannot be damaged as they are slack.
    - The anterior shearing effect from ligament involvement is minimized and the posterior supporting shear of the musculature is maximized.
    - Compressive testing of lumbar motion units has shown increases in tolerance with partial flexion but decreased ability to withstand compressive load at full flexion.
3. Choose a posture to minimize the reaction moment on low back so long as #2 is not compromised.
    - Neutral lordosis is still maintained but sometimes the load can be brought closer to the spine with bent knees (squat lift) or relatively straight knees (stoop lift). The key is to reduce the moment which has been shown to be a dominant risk factor.
4. Allow time for the disc nucleus to "equilibrate" and ligaments to regain stiffness after prolonged flexion (e.g. sitting or stooping) and do not immediately perform strenuous exertions.
    - After prolonged sitting or stooping spend time standing to allow the nuclear material within the disc to equilibrate and equalize the stress on the annulus, and allow the ligaments to regain their rest length and provide protective stiffness to the lumbar spine.
5. Avoid lifting or spine bending shortly after rising from bed.
    - Forward bending stresses on the disc and ligaments are higher in the early morning compared with later in the day (at least 1 hour after rising) causing discs to become injured at lower levels of load.
6. Prestress system even during "light" tasks.
    - Lightly co-contract the stabilizing musculature to remove the slack from the system and stiffen the spine, even during "light" tasks such as picking up a pencil (Cholewicki and McGill, 1996).
    - Mild co-contraction and the corresponding increase in stability increases the margin of safety of material failure of the column under axial load.
7. Avoid twisting and the simultaneous generation of high twisting torques.
    - Twisting reduces the intrinsic strength of the annulus by disabling some of its supporting fibers while increasing the stress in the remaining fibers under load.
    - Since there is no muscle designed to produce only axial torque the collective ability of the muscles to resist axial torque is limited and may not be able to protect the spine in certain postures.

- The additional compressive burden on the spine is substantial for even a low amount of axial torque production.
8. Exploit the acceleration profile of the load (rather than "always lift slowly and smoothly").
    - This is only for highly skilled individuals performing repetitive tasks.
    - Dangerous for heavy loads and should not be attempted.
    - It is possible that a transfer of momentum from the upper trunk to the load can start moving an awkwardly placed load without undue low back. Possibly, the viscoelastic property of biological material will safely absorb a momentary high load required to bring the load close to the trunk which reduces the reaction moment.
9. Avoid prolonged sitting.
    - Prolonged sitting is associated with disc herniation.
    - When required to sit for long periods, adjust posture often, stand up, at least every 50 minutes, and extend spine and/or walk for a few minutes.
    - Organize work to break up bouts of prolonged sitting into shorter periods that are better tolerated by the spine.
10. Consider the best rest break strategies.
    - Workers engaged in sedentary work would be best served by frequent, dynamic breaks to reduce tissue stress accumulation (for exercises documented to spare the spine, see McGill, 1998).
    - Workers engaged in dynamic work may be better served with longer and more "restful" breaks.

Bivariate Anthropometric Design for Work Spaces and Products

J.G. Kreifeldt and K. Nah

Department of Mechanical Engineering, Tufts University, Medford MA, USA

1. INTRODUCTION

Fitting a work space or product to human geometry often requires that two or more of the human's anthropometric variables be accommodated simultaneously. For example, consider the simple bivariate problem in Figure 1 in which the overhead spacing (H) AND the knee clearance (K) are to be chosen so that together they may accommodate some desired percentage (e.g. 50%) of the design population. Approaching this or any other multivariate problem as a series of independent univariate ones can result in the accommodated percentage being severely incorrect because of the correlation between the variables.

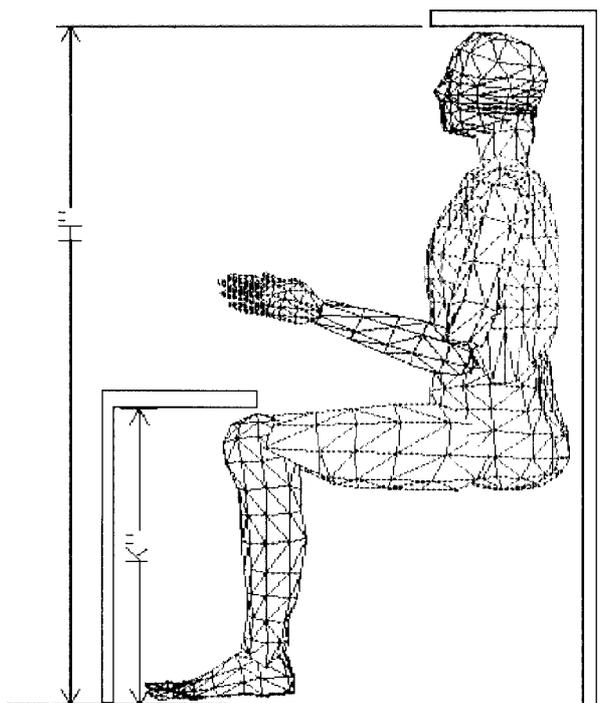
This article will present a set of graphs and tables which simplify five types of bivariate design problems for specifying a pair of design values to accommodate some desired percentage of the population. Among the assumptions used in preparing the tables and graphs are that: (1) the relevant anthropometric dimensions of the user population are normally distributed, and (2) a given accommodation percentage can be achieved using equal or complementary percentile values of the anthropometric values in a manner to be explained.


Figure 1. A simple work space design problem.

2. BACKGROUND

Ordinarily, a bivariate (or generally a multi-variable) design problem must be approached using the appropriate bivariate (multivariate) distribution. In the above example, the bivariate distribution for sitting knee height and sitting stature would be needed. Such a bivariate distribution for normally distributed variables would be expressed as the following equation in which if 'X' stands for the sitting knee height then Y stands for the sitting head height, ρ_{XY} is the correlation betwen the two variables and 'm' and 'σ' stand for the means and standard deviations of the variates.

$$p(X, Y) = \frac{1}{2\pi\sigma_X\sigma_Y\sqrt{1-\rho^2}} \exp\left[-\frac{1}{2(1-\rho^2)}\left[\left(\frac{X-m_X}{\sigma_X}\right)^2+\right.\right.$$

$$\left(\frac{Y-m_Y}{\sigma_Y}\right)^2-2\rho\left(\frac{X-m_X}{\sigma_X}\right)\left(\frac{Y-m_Y}{\sigma_Y}\right)$$

In the problem given, the knee space and overhead space dimensions must be selected so that 50% of the population has knee heights AND sitting heights simultaneously less than these two values. In bivariate (and multivariate) design, there are an infinite number of pairs of values which will satisfy this requirement. (Although this may seem to complicate the problem, this actually is a strength of the multivariate approach because it can result in considerable design flexibility.) The approach presented here reduces the infinite number of choices by using the reasonable assumption that the selected values expressed as percentiles will be either equal or complementary depending on the problem type. This will be clarified in the following. The general approach for selecting the appropriate values of the variates in the example may be visualized in Figure 2 which represents a scatter plot of 2000 pairs of these two variables in which each point represents a particular person's pair of values.

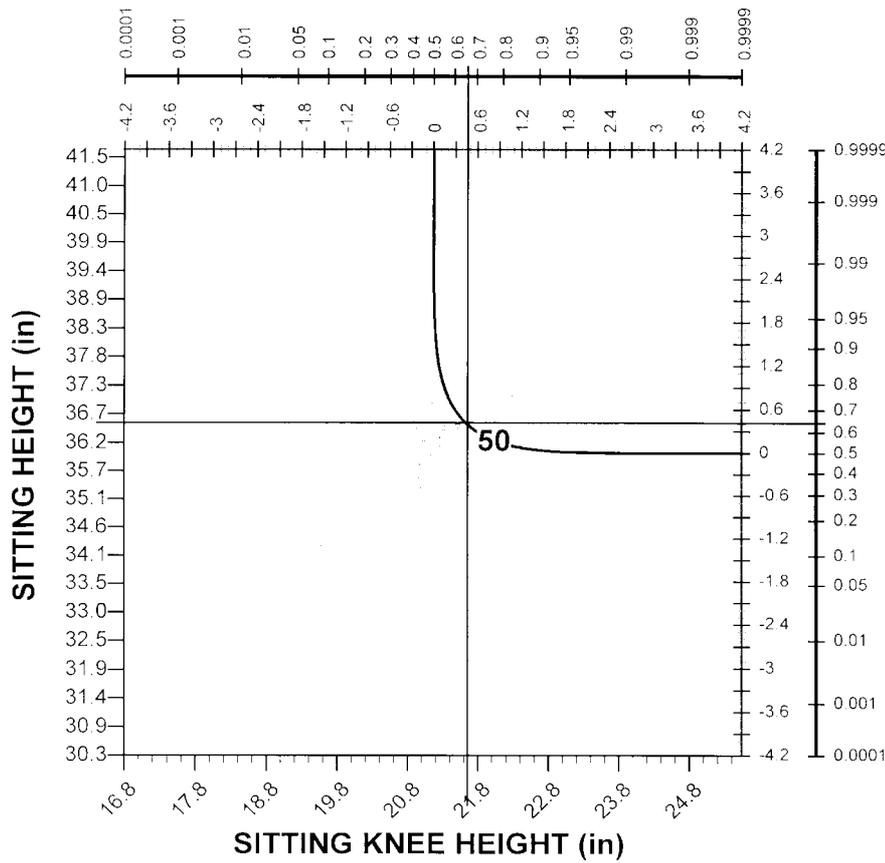
The correlation between the values is 0.4. The figure has the measurement values on two axes and the z transformed values and equivalent GAussian percentiles (as a fraction) on the opposing axes. The general approach to the example problem is to select a value ("cut-off") for each variate so that 50% of the pair values are simultaneously less than those two values. These would then be the values to use for the respective design values. However, *any* point (pair) on the 50% contour shown superimposed on the scatter plot is a possible candidate pair. That is, a set of orthogonal lines (defining the cut-off values) through any point on the contour will contain 50% of the scatter points in the lower left quadrant of the crossed lines. In order to make a universal and rational choice of a single one from the infinity of possible point pairs on the contour, one can select that point which produces equal percentile (or z) values for the two variates. This point actually turns out to be the point of symmetry where a diagonal passes through the contour as well as lying on the best fit linear interpolation line to the bivariate data. Therefore, for the sample problem, the defining sitting knee height and sitting height are 21.4" and 36.6" respectively, meaning that if the K = knee space = 21.4" and H = head space = 36.6" in Figure 1 are at least these values, then these dimensions will accommodate at least 50% of the population. To generalize this problem for all normal bivariates with a correlation of 0.4, the


Figure 2. A bivariate scatter plot showing actual, Z and cumulative fractional values.

corresponding normalized values or the corresponding percentile values for this example would be: z = 0.43 or 66.6% for either variate. Obviously, any accommodation percentage could have been set such as 95% and the procedure would be the same.

3. METHODOLOGY

In order to generalize this to any pair of normally distributed variables with any bivariate correlation coefficient, the cumulative form of the normalized bivariate distribution can be back solved for the pair of equal z values (z_{eq}) which produce the desired percentage for the problem. The value of z_{eq} which solves the following equation produces the values in question in which P = the desired percentage and ρ = the bivariate correlation coefficient. The value z_{eq} can be found by a root solving algorithm. This procedure will be exemplified for the problem of Figure 1.

The normalized bivariate normal distribution is given in equation (2) where the triplet (z_x, z_y, r) refers to the two normalized normal variates and their bivariate correlation coefficient respectively.

$$p(z_x, z_y, \rho) = \frac{1}{2\pi \sqrt{1-\rho^2}} \exp[- \frac{(z_x^2 + z_y^2 - 2\rho \, z_x z_y)}{2(1-\rho^2)}]$$

Doubly integrating equation 2 from -∞ to values of (z_x, z_y) produces the fraction (or percentage if multiplied by 100) P of the distribution which has z values less than this pair of values. This is expressed

in equation (3) where the integrand is the normalized bivariate Gaussian distribution shown in equation (2).

$$\int_{y=-\infty}^{y=z_y} \int_{x=-\infty}^{x=z_x} p(x, y, r) \, dx \, dy = P$$

There are an infinite number of such (z_x, z_y) pairs defining the constant fraction (or percentage) values such as shown in Figure 1. To find the unique pair of z values which are equal and which produce the desired cumulative fraction, the z values are set equal to zeq as in equation (4) and 'back solved' by any root finding algorithm. This is done repeatedly for various values of 'P' and P in order to generate the graphs and tables for this paper.

$$\int_{y=-\infty}^{y=z_{eq}} \int_{x=-\infty}^{x=z_{eq}} p(x, y, r) \, dx \, dy = P$$

4. PROBLEM TYPES

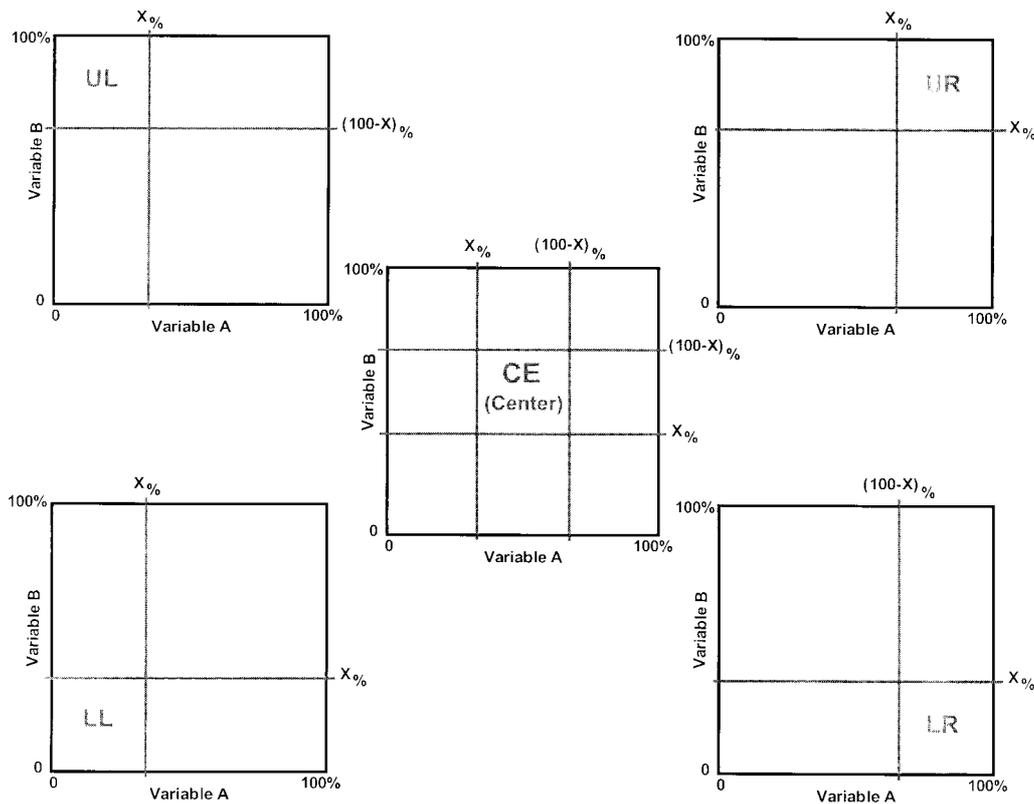
Before providing these graphs and tables, we also consider the five typical generalized accommodation problems. These can be readily pictured as in Figure 3 showing five common accommodation problems as viewed on a bivariate plot of two variates normalized as their percentiles.


Figure 3. A bivariate chart showing five common accommodation problem types.

Given any desired percentage to be enclosed in one of the five areas, this article supplies appropriate values for the two variates expressed as 'z' values appropriate to equal or complementary percentile values. For example, for a specified percentage to be enclosed in the Lower Right (LL) section, the appropriate percentile values would be given as X and its complement as (100-x) both expressed as the corresponding Z and -Z values. The problem will define which variable to call A or B. Z values are given in the graphs and tables because of the need to convert ultimately to physical values, while percentile descriptions are used because of their clarity in explaining the theory.

The shape of Figure 3 can be considered a square because the axes are expressed in percentiles ranging from 0–100% and each of the five defined problem areas is also square because of the use of the equipoints to define the cut-off values. Thus, regardless of the percentage of the population to be included in one of the five given problem areas, the cut-off values will intersect on the ascending or descend diagonal.

This article uses the following nomenclature to distinguish the five problem types.

4.1. Type 1 – LL (Lower Left)

This refers to problems similar to Figure 1 in which both variates must be simultaneously less than some pair of values.

4.2. Type 2 – LR (Lower Right)

This refers to problems in which one variate must be greater than some value while the other is less than some other value. This problem is solved by a complementary pair of percentile values expressed as 'x' and 100-'x'). For example, consider specifying the sitting height and body weight of a manikin to be used to evaluate the adequacy of the height of a head restraint in

an automobile seat. Logic suggests that people with a *tall sitting stature* (head height above their seat) and a *light weight* are most at risk from a head restraint which is too low for them when sitting on a cushioned seat as this would cause them to sit higher than heavier people for that sitting height. Following a decision as to what percentage of people to allow at risk (e.g. 5%), it then follows that the sitting height and weight for the manikin must be specified. This problem can be solved by specifying the relevant percentile 'x' for the sitting height and its complementary percentile (100 - 'x') for weight which achieves the desired 'at risk' percentage given the bivariate correlation between sitting height and weight for the design population. The percentiles can then of course be converted into the appropriate sitting height and weight. If the height of the head restraint is designed to provide support at least for the manikin so designed, then only those who have a sitting height greater than the design sitting height and a weight less than the design weight are put at risk.

4.3. Type 3 – UR (Upper Right)

This refers to problems in which both variates must exceed some values. For example, it might be desired to find an arm length and a standing height which are both exceeded by only 5% of the population. Although Figure 3 shows equal complementary percentile values, it can be understood that these are the equal 'x' percentile values desired. Note that a UR problem can be turned into a LL one (and vice versa) by finding percentile cut-off values to achieve, for example, 5% in LL and then using the complementary percentile values.

4.4. Type 4 – CE (Center)

This is common in 'adjustment' problems. For example, assume that variate A = seat height of a chair as measured from the floor

and variate B = the arm height above a reference, and that a number of test subjects have been allowed to set these to their preferred comfortable values. (Further assure that a Gaussian bivariate distributioni adequately approximates the distribution of these pairs of values and their bivariate correlation is obtained.) If it is desired in a manufactured version to make seat height and arm height separately adjustable between lower and upper values so that at least 95% of users can find a comfortable setting, this would be a typical type 5 – CE problem. In this case, again the problem can be solved by specifying equal and complementary percentile values (lower and upper values) for each variate using the correlation found between the two variates.

4.5. Type 5 – UL (Upper Left)

This is a reflection of the LL problem which again is solved using complementary percentiles. Note that a UL problem can be turned into a LR one (and vice versa (simply by switching the roles of the variates. In the following tables and figures, only values for the LL, UR, LR, and CE types will be given because LR or UL are identical by interchaning the variates 'A' and 'B'. Instead of giving percentile values, the figures and tables will provide the z equivalents of the percentile values for ease of calculating the actual variate values.

5. CONVERTING FROM A Z VALUE TO A VARIATE VALUE

Once the required z values are found from the tables and figures provided, they can be readily converted to the actual variate values by any appropriate algorithmic or table format. Analytically, a z value can be transformed back to a variate value (v) through equation (5) in which mv and sv stand for the mean and standard deviation of the variate respectively:

$$y = (z)(s_v) + m_v$$

6. EQUATIONS FOR THE GRAPHS AND TABLES

The appropriate bivariate graphs and tables for the five types of problems are provided here in the 'z' form for reasons outlined previously. Negative correlation values are limited to those greater than -0.5 for brevity and because of the lack of reported negative correlations smaller than about -0.2 in human anthropometry. Note also that because of the symmetry for the Gaussian bivariate distribution, values corresponding to negative correlation values can be omitted for the Center (CE) type of problems because they are identical to those for positive correlations. Furthermore, the Upper Left table and graph have been omitted because they are identical to those of the Lower Right with a simple interchange of variables. The graphs and tables for the four problem areas were computed by the following procedures.

6.1. Lower Left (LL): Figure 4 and Table 1.

The equal percentile cut-offs (in normalized 'z' form) given a value of and desired accommodation fraction P are found by back solving equation (6) for z_{eq}.

$$\int_{y=-\infty}^{y=z_{eq}} \int_{X=-\infty}^{X=z_{eq}} p(x,y,r)\,dx\,dy = P$$

6.2. Lower Right (LR): Figure 5 and Table 2

The complementary cut-offs are found by back solving equation (7) for z_{eq} for a desired accommodation fraction P. Note that the cut-off values are complementary in that if one is -z (x%) then the other is z (100 - x%) as indicated by the opposite signs on the same absolute value of z_{eq}.

$$\int_{y=-\infty}^{y=-z_{eq}} \int_{X=z_{eq}}^{X=\infty} p(x,y,r)\,dx\,dy = P$$

6.3. Upper Right (UR): Figure 6 and Table 3

The equal cut-offs are found by back solving equation (8) for z_{eq} for a desired accommodation fraction P.

$$\int_{y=z_{eq}}^{y=\infty} \int_{X=z_{eq}}^{X=\infty} p(x,y,r)\,dx\,dy = P$$

6.4. Center (CE): Figure 7 and Table 4

The complementary percentile cut-offs are found by back solving equation (9) for z_{eq} for the desired accommodation fraction P. Note here again that this is equivalent to both variates having the identical *percentile* cut-offs although not necessarily the same actual values.

$$\int_{y=-z_{eq}}^{y=z_{eq}} \int_{X=-z_{eq}}^{X=z_{eq}} p(x,y,r)\,dx\,dy = P$$

7. EXAMPLES

Short examples of the uses of these tables will be given for the Lower Left, Lower Right and the Center type problems.

7.1. Lower Left (LL): Figure 4 and Table 1

Assume that it is desired to accommodate 95% of the population for the problem of Figure 1 using the means, standard deviations, and correlation coefficient given previously, then, from Figure 4 or Table 1, the appropriate z value for each variate is 1.93. Substituting the appropriate pair of mean and standard deviation values for each variate into equation (3) produces the required design values of: knee space = 23.14", and head space = 38.61".

7.2. Lower right (LR): Figure 5 and Table 2

Assume here that a product must have an opening through which air is forced by a fan blade rotating behind the opening. It is desired to make the opening (D) *small enough* and to recess the fan blade a distance (L) *far enough away* from the opening and so that, for example, 99% of children's fingers will be kept out of the opening and/or away from the blades. Thus, the values (D, L) are to be chosen so as to minimize the number of *long* and *thin* fingers which would be at risk from entering the hole and

touching the blade. This identifies the problem as a Type 2 – LR in which complementary cut-off values are appropriate. Another interpretation is that the design will put only 1% "at risk" implying that the "LR" corner of a bivariate finger-length–finger-thickness plot should contain no more than 1% of the data. It is assumed for this example that the correlation between finger thickness and finger length is 0.5. From Table 2 and/or Figure 5, the appropriate z values are:

D = minimum finger thickness = the lower z = 0.81
= 79th %tile value

L = maximum finger length- = the complementary z
= -0.81 = (100 - 79) = 21st %tile value

From which the values of D and L can be computed using equation (5) once the mean and standard deviation of the variates are specified. As mentioned previously, the *upper left* problem can be viewed as a *lower right* one with the variates switched and, therefore, the lower right example as given here suffices as an example for UL as well.

7.3. Upper right (UR): Figure 6 and Table 3

Assume in this case that it is desired to set values for height and weight such that only 5% of a population will exceed both of them. This is a Type 4 – UR problem for which Figure 6 and Table 3 are appropriate. The correlation between height and weight is approximately 0.2 which from the table or figure produces the z values of 0.893 for both variates corresponding to the 81.5th percentile value of each variate (again assuming the variates are normally distributed).

7.4. Center (CE): Figure 7 and Table 4

Assume that subjects have been allowed to set their own preferred

seat height (SH) above a vehicle floor and their seat distance (SD) back from a fixed heel reference point and that the data generated can adequately be described by a Gaussian (normal) bivariate distributions with the following univariate normal statistics of mean and standard deviation where "N" indicates a normal distribution.

Seat Height = N[12", 1.2"]
Seat Distance = N[s0", 2.0"]
ρ = 0.75

It is desired to set the "tightest" upper and lower bounds on both seat height and seat distance such that at least 90% of the population will find their preferred adjustment within these bounds. This is a Type 5 problem. Using the rationale of symmetrical and complementary cut-off values, these bounds can be found from Figure 7 and Table 4. Because this is a center problem, the z values for each variate are identical and for each variable, the upper and lower z values are identical except for sign. Therefore for each variate, the lower and upper z values are:

z = (-1.86, 1.86) corresponding to the percentiles (3.12%, 100 - 3.12 = 96.88%)

From which the actual bounding values are:

Seat Height$_{lower}$ = 1.2(-1.86) + 12 = 9.76"
Seat Height$_{upper}$ = 1.2(1.86) + 12 = 14.23"

Seat Distance$_{lower}$ = 2(-1.86) + 20 = 16.28
Seat Distance$_{upper}$ = 2(1.86) + 20 = 23.72

8. TABLES AND FIGURES

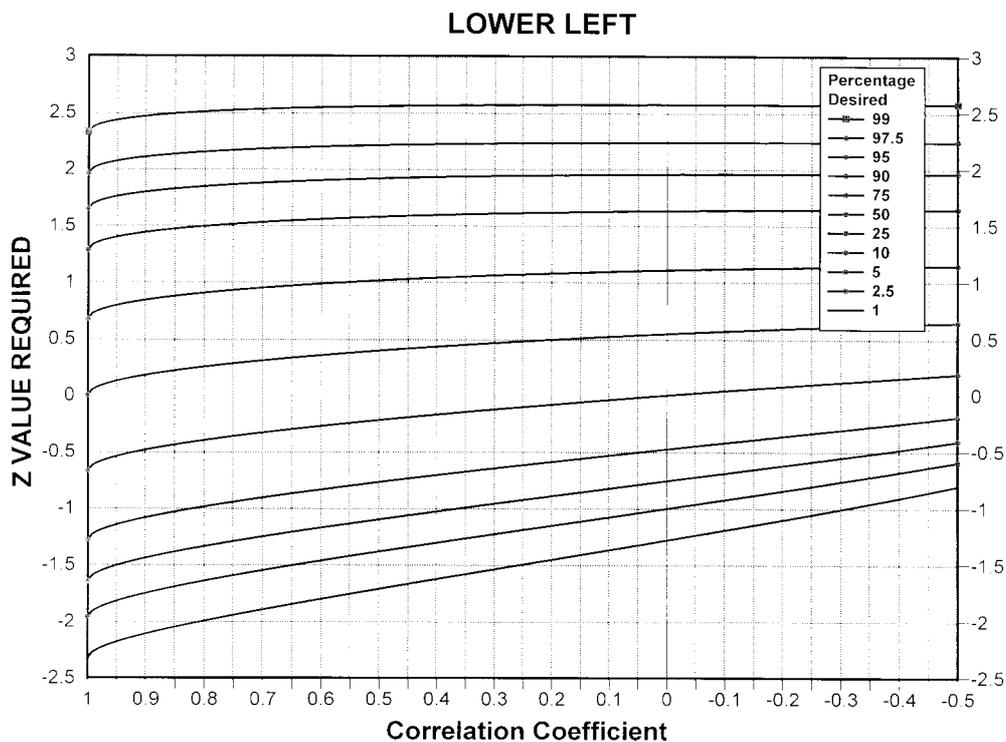
The tables and figures have been prepared in terms of the normalized variate "z" for selected correlation values and


Figure 4. Values for the Lower Left (LL) problem type.

z
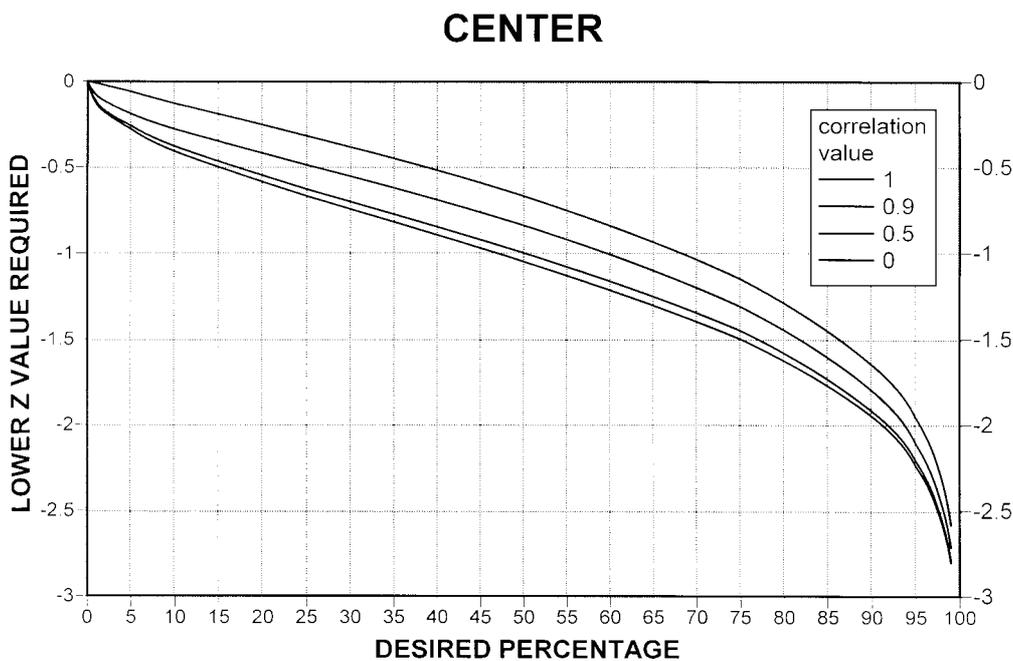

Figure 8. Data from table 4 replotted with the correlation value as the parameter in order to interpolate different percentages from the common ones used for the previous graphs and tables.

commonly desired percentage values. The tables give the z value in each cell for the indicated percentage desired with the relevant correlation coefficient between the variates.

The figures are especially helpful for determining the appropriate z value for any correlation value within the indicated range of [-0.5–1.0]. Or simple linear interpolation between neighboring correlation values in the tables should be accurate enough for most purposes. However, if it is desired to interpolate between the given percentage values, it is preferable to determine this by making a plot of z–vs–desired percentage for a selected

correlation value and then interpolating from the resulting graph. Figure 8 is such an example for four different correlation values with the data taken from Table 4. Alternatively, the appropriate equation as given previously for the problem type in question may be back solved with a suitable computer algorithm.

9. CONCLUSION

This paper has presented a series of graphs and tables suitable for bivariate design problems in which it is desired to specify

anthropometric values that together will achieve some specified accommodation percentage of the design population for five common design problem types. These values were computed by specifying the same (or complementary) percentile for each variate thereby reducing the infinite number of possible pair values to a single pair of equal percentile values. The percentile values to use are affected by the correlation between the variates. It is generally the case that the percentiles are not the same as the desired accommodation percentage. For example, if it is desired to accommodate 75% of some population in a Lower Left problem and if the correlation between the two variates is 0.4, then the percentile value to use for each variate is 85th rather than 75th percentile. Thus, approaching a bivariate design problem as two univariate ones can result in substantial errors of accommodation percentage. If, in fact, the 75th percentile values are used, the resulting accommodation percentage can be found to be equal to 61.04% rather than the desired 75%. A previous paper (Nah and Kreifeldt 1996) provides graphs and tables which illustrate the actual percentage achieved using equal percentile values for each variate for the problem types considered in this paper and for various correlation values.

Cognitive Systems Engineering

E. Hollnagel and D. D. Woods

Ohio State University, 1971 Neil Ave, Columbus, OH 43210, USA

1. INTRODUCTION

In the second half of the twentieth century, one of the major challenges to human factors engineering and industrial psychology has been to understand the complexities of human–machine systems. These systems have become indispensable in the fabric of modern society as the technical processes that sustain production, services, and communication continue to grow in complexity and interdependency. Although technological developments, especially within information technology, have made it possible to build powerful, efficient, and highly reliable machines (such as aircraft, trains, power plants, factories, hospitals, etc.), the human operator remains an essential element. The conditions when the human operator is needed may have changed, but the need of humans in complex systems has not been significantly reduced. While humans may be required to do very little when everything goes as planned, the need to act is often extreme in critical situations. Furthermore, in many daily activities, such as buying a train ticket or getting cash money, human–human interactions have been replaced by human–machine interactions.

In order to understand the complexities of human–machine systems, it is necessary to have an appropriate basis, or conceptual foundation, for description and analysis. In this respect the study of human–machine systems is no different than any other scientific discipline. Each requires a set of concepts and a corresponding set of methods. The concepts are the basic hypotheses and assumptions about the domain, which in this case comprise humans working with technology. The concepts help identify what the important phenomena are and how they can be understood, and include the hypotheses and theories that are part and parcel of the scientific discipline. The concepts are the basis for the distinctions and analyses that can be made, and provide the "intellectual glue" that keeps everything together. The methods refer to the consistent and systematic ways in which the concepts can be applied, for instance, in the form of a classification system. The application can have a practical or utilitarian purpose such as in design, or a more scientific purpose, such as improving the understanding of the set of causes that have led to a specific consequence. The methods are intrinsically linked to the data, which constitute the empirical basis for the field and thereby provide the justification for the concepts.

2. THE BROKEN CIRCLE

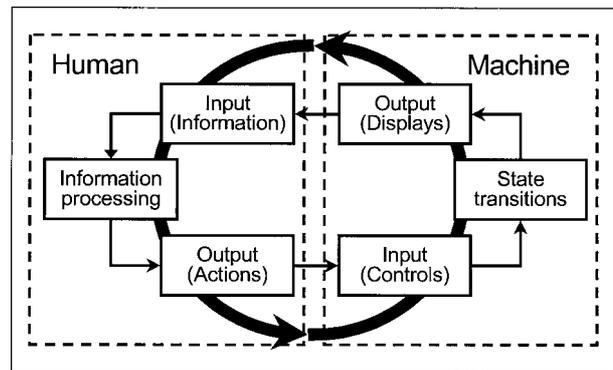
The classical view of human–machine systems depicts a human and a machine that are linked by inputs and outputs (see figure 1). The control input to the machine determines whether the machine changes state or remains in the same state. As a result of this, some output is produced — for instance a set of measurements that indicate the state of the machine and the value of specific process parameters. The measurements, or the output from the machine, become the input to the human operator. According to the classical view, this input is "processed" by the


Figure 1: The classical view of human–machine systems.

operator and results in a response or output that becomes the control input to the machine. While the engineering sciences, such as control theory, have focused on describing how the machine works, the behavioral sciences have been more concerned with describing how the operator works, i.e. what goes on between receiving the input and producing the output.

When the challenge to describe the human operator was fully accepted by the behavioral sciences in the late 1960s, the focus changed from the human-machine system as a whole to the human operator as a separate system (see figure 2). In this way the circle or coupling between human and machine was broken. The link to the process was maintained in the sense that there was both an input to and an output from the operator, but for all intents and purposes these were considered less important than the processes that were assumed to take place within the operator's mind. Typically, only the operator part of the human–machine system was developed in any detail — or considered at all. The original cyclical model that described the coupling between humans and machines was transformed into a sequential or linear information processing model that mainly tried to account for the details of the human's responding to the input.

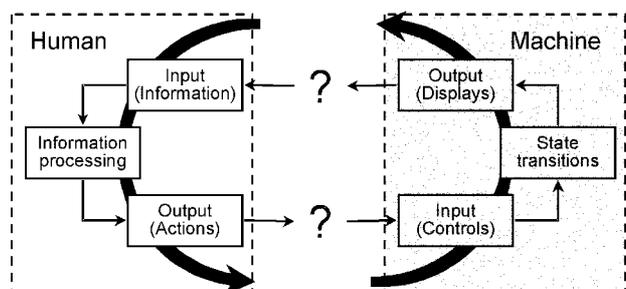
The conventional approach to the study of human–machine interaction is based on the notion of the human as an information processing system, either in the weak sense as an analogy or in the strong, metaphysical sense. This approach puts the focus on the interface or the interaction, i.e. on that which lies *between* the human and the machine, and studies the human operator as an information processing system interacting with a process or an artifact. This view is characteristic of, for instance, human factors engineering and ergonomics, human–computer interaction, cognitive science, and some versions of cognitive engineering.


Figure 2: The broken circle with the human operator as a separate system.

Although it has been very successful as a basis for models, theories, and experiments, there is a growing consensus that it includes some fundamental limitations. Foremost among them is that it unavoidably separates or differentiates between human and machine, instead of seeing them together or as a whole. Yet understanding how a human–machine system works requires the ability to describe the system as a whole, hence to see it as more than a set of interacting parts. Since the concepts and methods of the classical view have proven insufficient for this, an alternative is required.

3. COGNITIVE SYSTEMS

Cognitive Systems Engineering (CSE) was formulated in the beginning of the 1980s (Hollnagel and Woods, 1983) to provide a consistent conceptual and methodological basis for research on human–machine systems, with design and evaluation as the two major activities. In CSE the focus is not on human cognition as an internal function or as a mental process, but rather on human activity or "cognition at work", i.e. on how cognition is necessary to accomplish effectively the tasks by which specific objectives related to either work or non-work activities can be achieved. Cognition is necessary to cope with the dilemmas, double binds, and trade-offs that arise from multiple and possibly inconsistent goals, organizational pressures, and clumsy technology. Rather than being isolated in the mind of a thoughtful individual, cognition at work typically involves several people distributed in space or time, which makes cooperation and coordination at least as important as human information processing. The interacting people are embedded in larger groups, professions, organizations, and institutions, which together define the conditions for work — the constraints and demands as well as the resources. Humans at work do not passively accept the technological artifacts nor the general conditions of their work, but actively and continuously adapt their tools and activities to respond to irregularities, disturbances, and to meet new demands. Cognition is part of an interconnected stream of activity that ebbs and flows, in which extended periods of lower activity are interspersed with busy, high tempo operations where correct and timely responses may be critical.

CSE proposes that composite operational systems can be looked at as single cognitive systems. Structurally they may comprise the individual people, the organization (both formal and informal), the high level technology artifacts (AI, automation, intelligent tutoring systems, computer-based visualization) and the low level technology artifacts (displays, alarms, procedures, paper notes, training programs) that are intended to support human practitioners. But functionally they can be seen as a single system. This is reflected by the main issues of CSE:

- *Coping with complexity*. The complexity is due to the multiple sources of information and control and to the possibly conflicting goals that characterize the working situation. People usually try to cope with complexity by reducing it, for instance by structuring the information at a higher level of abstraction with less resolution and making the required decisions at that level. The development of information technology has made it possible to provide computerized tools which to some extent accommodate the operators' needs, and thereby help their coping. This kind of support

clearly involves a replication of parts of human cognition, hence the use of an artificial cognitive system.

- *The use of tools*. Tools are artifacts that are used with a specific purpose to achieve a specific goal. Tools have traditionally been used to amplify human capabilities — in terms of physical performance (reach, force, speed, and precision), and in terms of perception and discrimination. More recently, tools have been introduced which are aimed at amplifying cognition. Although some cognitive tools have existed for ages, the use of computers has made it possible to design tools for more sophisticated functions, for instance decision making and planning.

- *Joint cognitive systems*. CSE recognizes that technological systems gradually have become "cognitive", in the sense that they are goal-driven and make use of cause-based (feedforward) regulation. Technological systems can thus be seen as artificial cognitive systems that interact with natural cognitive systems (i.e. humans). It is therefore appropriate to develop a view of joint cognitive systems, i.e. of cooperating systems which are described using a common set of terms — neither as machines nor as humans, but as cognitive systems.

Any discussion of CSE must obviously refer to a definition of what a cognitive system is. To avoid the thorny issues of what cognition is, and whether it can exist in non-human systems, a cognitive system can be defined as a system that is as able to control its behavior using information about itself and the situation, where the information can be prior information (knowledge, competence), situation specific information (feedback, indicators, measurements) and constructs (hypotheses, assumptions). The control can be complete or partial and will in the main depend on the ratio between expected and unexpected information. More formally, a cognitive system can be defined as a system that can modify its pattern of behavior on the basis of past experience in order to achieve specific anti-entropic ends.

4. CONSEQUENCES OF CSE

The notion of a joint cognitive system cannot easily be accommodated within the decomposed human-machine paradigm, and CSE can be seen as an independent alternative. Current methods mainly support a decomposition of a system into its parts (and in some cases also the reverse process of aggregation), but in a manner that implies partial independence between the parts. Some attempts have been made to develop methods that focus on the interaction and dependencies between sub-systems rather than on the components-elements. An example of that is multi-level flow modeling (MFM) which supports the goals-means analysis principle (Lind and Larsen, 1995). The overall framework for analysis must, however, be extended to recognize the dependency between data and interpretation, to account for the specific role of cognition (be it natural or artificial), and to highlight the consequences for design — supported by specific guidelines and design rules whenever possible.

In accordance with the intentions of CSE, the data must be found in situations that are representative of the real world (Hutchins, 1995). Any kind of systematic study carries with it some assumptions about what is being observed. These assumptions are relatively easy to understand when cognitive

systems are studied under controlled condition, which partly explains the preponderance of such studies. Yet it is a fundamental tenet of CSE that human action always is constrained by the context and studying cognition in the "wild" therefore does not release us from the obligation of understanding the assumptions that are made, even though they may be less easy to detect.

Computer Simulation: Applications to Human Factors and Ergonomics

E.F. Fallon

Department of Industrial Engineering, National University of Ireland Galway, Galway, Ireland

1. INTRODUCTION

Simulation modeling is a powerful tool for human performance analysis in complex human–machine systems. In its broadest sense, the term simulation modeling can be applied to role playing, walk-throughs using mock-ups, aircraft training simulators, and virtual reality models of proposed systems, (Sanders 1991). However, in this chapter the emphasis is on modeling human performance or behavior in systems or as part of systems. The models referred to are abstract representations which can be coded on a computer. They are stochastic and therefore can be manipulated over time to simulate movement of the modeled system from state to state. Computer simulation of human performance in complex systems is presented as an integral part of systems design. Two categories of computer simulation models are highlighted, namely network models and microprocess models. A number of examples of software tools that implement both categories are presented.

2. COMPUTER SIMULATION

2.1. Definition

Computer simulation is the process of designing a mathematical–logical model of a real system and experimenting with this model on a computer. It encompasses the model-building process as well as the design and implementation of experiments involving the model and analysis of resultant data. Simulation modeling assumes that we can characterize a system in terms amenable to coding/computation. In this regard, a key concept is that of system–state description. If a system can be described by a set of variables with each combination of variable values representing a unique state or condition of the system, then manipulation of the variable values over time simulates movement of the system from state to state. This is precisely what computer simulation is — the representation of the dynamic behavior of the system by moving it from state to state in accordance with well-defined operating rules. Movement can be executed in a discrete manner, or a continuous manner, or a combination of these two. Experimentation with this representation allows inferences to be drawn about the real system being studied. The results obtained from running a simulation are observations of an experiment. This means that all inferences regarding the performance of the simulated system must be subject to appropriate statistical testing.

2.2. Steps in a Computer Simulation

Several stages in the development of a simulation model can be identified. At its most basic this development involves an iterative process which facilitates the evolution of an appropriate model from an initial simplified version. The main activities in the process are as follows (Chubb et al. 1987):

Problem formulation: The definition of the problem to be studied including a statement of the problem solving objective.

Model building: The abstraction of the system into mathematical–logical relationships in accordance with the problem formulation.

Data acquisition: The identification, specification and collection of data for model development and subsequent system analysis.

Model development and translation: The preparation of the model for computer processing.

Model verification: The process of establishing that the computer program executes as intended.

Model validation: The process of establishing that a desired accuracy or correspondence exists between the simulation model and the real system.

Design of experiments: The process of establishing the experimental conditions for using the model.

Experimentation: The undertaking of statistical experiments using the model.

Analysis of results: Consideration of results in the context of the objective formulated earlier.

Implementation: Implementation of the recommendations arising from the analysis of results.

The simulation modeling process may not adhere strictly to the sequence of stages outlined above as it may involve repeated evaluation and redesign of the model. Ultimately it should result in a simulation model that properly assesses the alternatives and enhances the decision-making process.

3. MODELS AND MODELING

3.1. Computer Simulation Modeling

Modeling or representing systems using abstractions is a difficult process that is made easier if the following criteria are satisfied (Pritsker and Wilson 1982):

Physical laws are available that are applicable to the system.

Pictorial or graphical representations of the system can be made. The variability of system inputs, elements and outputs is manageable.

Unfortunately these criteria are not immediately applicable to complex large systems which have been characterized as follows (Pritsker and Wilson 1982):

Few fundamental laws are available.

Many procedural elements are involved that are difficult to describe and represent.

Qualitative inputs are required that are difficult to quantify.

Random components are significant elements.

Human decision making is an integral part of such systems.

Computer simulation has been proposed as a modeling technique for tackling these problems. Complex human–machine systems can be characterized in the same manner and on this basis it would seem reasonable to propose computer simulation as a means of modeling complex human–machine systems, though the number of reported applications does not seem to support this.

3.2. Simulation of Complex Human–machine Systems

Computer simulation can provide a representation of the role of the human operator in systems. The question of interactions between tasks can be taken care of without having to resort to complex mathematical techniques. Computer simulation is

basically an expensive technique and there will necessarily be some trade-off between the complexity of the models used and the cost of the modeling effort. The simulation technique as applied to human–machine systems is usually employed in the following manner (Fallon *et al.* 1986). An underlying human performance model relevant to the current project is selected. A task analysis is then carried out and various task descriptors such as operating times, decision options, and workload requirements are determined. The model is implemented using a special purpose computer simulation package. Output requirements are determined, e.g. operator stress levels, evidence of failures, time required, and other variables that describe the human–machine system. The simulation model is then run many times in order to obtain statistically significant results.

3.3. Models

Models are representations of real or proposed systems. They are useful in describing, analyzing and designing systems and in enabling the modeler to understand the relationships between sub-systems and their interactions with other sub-systems. Models can be built to varying degrees of complexity depending on the needs of the modeler. It should be remembered that a model is a means to an end and not an end in itself, therefore, it is important to establish the purpose of the model before embarking on the study. The significance of an element of a system should be decided on the basis of the modeler's purpose. For example, if a modeler is interested in the number of units produced in a production system over a period of months, the fact that one small feature of the product can vary is unlikely to be significant. On the other hand, if the small varied feature necessitates a complex manual operation that is time-consuming and unreliable, then it may warrant further in-depth consideration. The purpose of the model will dictate the necessary action or otherwise. The ultimate success of a simulation study often depends on how well the significant elements in the model and their relationships can be defined. If the underlying relationships in models are only partly developed and understood, then the output of the simulation will reflect this.

3.4. Human Performance Models

The benefits of computer simulation can only be realized if appropriate and relevant models are applied. There are many different models of human performance and a number of different taxonomies for categorizing them, however they do not necessarily lend themselves to use in computer simulation. In the context of computer simulation, Meister (1995) identifies three relevant categories of models:

Task-network models: These models are top-down models and represent a detailed description of tasks and the relationship between them. They also require comprehensive data inputs at all subtask levels, e.g. performance time and probability of failure. They are compatible with representations of many task analysis techniques, e.g. Hierarchical Task Analysis, Decision Action Diagrams, and Functional Flow Diagrams.

Microprocess models: Meister describes this category as "bottom-up" models. Macros of human performance are synthesized from basic molecular human operations derived from research and theoretical studies, e.g. reaction times, time to move a limb, time to process x bits of information.

Control-theoretic models: These models are used to model continuous activities, e.g. tracking. Servo-control models represent interactions between the operator and the system. They are more quantitative than the other two categories of models above and address limited aspects of human behavior and performance.

Laughery (1997) only distinguishes between two categories of human performance models for computer simulation of complex human–machine systems:

Reductionist models: "Reductionist models use human–system task sequence as the primary organising structure", (Laughery 1997). This categorization is similar to the task network models referred to above.

First-principle models: "First-principle models of human behavior are structured around an organising framework that represents the underlying goals and principles of human performance", (Laughery 1997). This categorization is similar to the microprocess models of Meister.

The remainder of this article deals primarily with task network or reductionist models and to a lesser extent microprocess models used in computer simulation in human factors/ergonomics.

3.5. Network modeling

Network modeling is applied in the modeling of tasks that are mainly procedural in nature though there is no restriction on the nature of sub-tasks. A network model of a task is constructed by breaking up the overall task into a series of sub-task components, defining the sequence in which the sub-task components are performed and by specifying the selection rules for the next sub-task where a number of possibilities arise following the completion of a particular sub-task. The time to complete each sub-task must be available. Given this type of specification of the system a simulation can be performed which yields results related to system performance.

3.6. Siegel and Wolf Models

Siegel and Wolf (1968) first developed network models of human performance. These included, single and dual operator and small group models. The single operator model is time-oriented and considers operator activity as a series of discrete tasks. Parameters such as speed and accuracy (representing proficiency) and time stress threshold are used to reflect inter-operator variability. A probability of success is assigned to each task based on the goal aspiration of the operator, an accuracy factor, and time stress considerations. The goal of the Siegel and Wolf model was described as: "To allow a determination of where a man–machine system may overload or underload the operators while the system is in the early design stage", (Siegel and Wolf 1968). Essentially the state of loading of the operator is represented by time stress which is a function of the time available during the task to complete the remaining task elements.

4. NETWORK SIMULATION TOOLS

4.1. Systems Analysis Integrated Network of Tasks (SAINT)

SAINT — Systems Analysis of Integrated Network of Tasks — was a network modeling and simulation technique developed to assist in the design and analysis of complex human—machine systems. PC-based tools that contain enhanced and more comprehensive versions of its functionality have superseded it.

SAINT catered for the modeling and analysis of systems that contained procedural, risk, and random elements. It was designed to incorporate the best features of the Siegel and Wolf models and the network and symbol manipulation of the GERT simulation language. It employed a network of nodes and branches and a structured set of symbols within which it was possible to represent various task parameters. Developments of SAINT made it possible to incorporate human variability into its network models. A method was developed for building moderator functions (i.e. functions relating changes in the performance of a task to the independent variables known to affect the task) in a logical and fast manner. This was based on the premise that changes in human performance can be attributed to a number of possible factors other than simply random variation. Three classes of independent variables were identified: ability, environmental, and task variables. In addition, a set of 16 skill categories was selected in order to describe all operator task types. Quantitative relationships between performance using selected skills and the independent variables were established. Essentially this has the effect of modifying the parameters of task performance time distributions. SAINT has been applied to a broad range of problems from the military domain to evaluation of job decision aids and performance assessment of hot strip mills.

4.2. MicroSAINT

MicroSAINT is a network simulation software package for building simulation models of real-life processes. It was originally developed as a microcomputer version of SAINT and provided similar modeling capabilities without including the task moderator function facilities. MicroSAINT was initially presented as a human factors/ergonomics tool even though it differed very little from other simulation tools in terms of functionality offered. The primary difference was in the network modeling representation that was *activity on node* as opposed to the more prevalent *activity on branch*. This mapped well onto task analysis representations and possibly explains why it was more readily adopted by the human factors/ergonomics community than alternatives. MicroSAINT has found wide acceptance and is primarily used to model human service systems, training systems and human operator performance and interaction under changing conditions.

The main features of the system are: a network development tool with various routing decision types, a facility for developing mathematical expressions and functions (this can be used to implement the moderator functions described above in SAINT), a model animation facility, and automatic generation of statistics and other performance measures. MicroSAINT output can be accessed by standard statistical and analysis packages and can also be called from other software systems. MicroSAINT has been used on a wide range of applications within the manufacturing, health care and military domains.

4.3. WinCrew [1]

WinCrew is a discrete event simulation-modeling tool the development of which was sponsored by the US Army Research Laboratory's Human Research and Engineering Directorate (ARL-HRED). It combines the functionality of discrete event computer simulation from MicroSAINT with models of mental workload based on the Multiple Resource Theory (MRT) of attention. The

mission network diagram of nodes and branches is the basic building block of a WinCrew model. Task data in the form of operation times, conditions for task execution and consequences of failure are provided for each node. WinCrew also possesses a "Micro Model" feature that utilizes known human performance rules, principles and research findings to generate task mean times where test data or expert derived subject-matter data do not exist or are not available. A task allocation module that facilitates dynamic allocation while a task is being executed is also available.

The workload assessment component of WinCrew requires a number of inputs: mental resources, interfaces used, resource requirements of individual interfaces (resource/interface channels) and an assignment of resource/interface channels to tasks.

4.4. The Human Operator Simulator (HOS)

Meister (1995) classifies the Human Operator Simulator (HOS) as a microprocess model. He also describes it as a deterministic model. It is assumed that an operator's behavior is explainable and not random and that an operator's actions and the duration of these actions are determined fully by the state of the system and the operator's goals at any particular point in time. HOS works by building-up a model of human operations from a series of micro-models or fundamental human activities, e.g. reaction times, memory recall times and movement of limbs. Obviously individual micro-models can contain random components and therefore HOS is not truly deterministic. In theory, the micro-models of HOS could be combined with a stochastic network model. For example, the effect of the micro-models would be to modify the parameters of the distribution of task times. Such an approach, albeit with a restricted set of micro-models, has been implemented in SAINT and to a lesser extent in WinCrew. The Integrated Performance Modeling Environment (IPME) outlined below is a more comprehensive implementation.

The main weaknesses of HOS are that it has no mechanism for tackling error processes and only one operator can be modeled in detail. HOS was originally a research and development tool and its primary application domains were military and aerospace.

4.5. IPME (Integrated Performance Modeling Environment) [1]

IPME is a tool for analyzing human system performance in complex systems. It combines many of the capabilities of HOS with the MicroSAINT simulation engine. The key features of IPME include: facilities to model the effect of the environment, a module to model operator traits and states, a module to define user-defined performance-shaping factors, a workload measurement algorithm and simulation experimentation facilities. Unlike HOS, IPME has the capability to tackle operator task failures. It also has a novel feature that enables the definition of a physical workspace associated with a task network.

5. SUMMARY

In this article computer simulation as applied to analysis of human performance in complex systems has been defined and described. The relevance of task network and microprocess models to this activity has been established and a number of commercially available computer simulation tools that implement these types of models have been presented. It is clear that the capability to use this technology to analyze human performance in the context

of systems development exists. It is likely that further developments in the power and usability of computing systems will encourage their greater use.

Content Analysis: Hypermedia Design

N. A. Stanton
Department of Psychology, University of Southampton, SO17 1BJ, UK

1. INTRODUCTION

It has been proposed that hypermedia and hypertext systems may have much to offer the information age (Nelson 1987; Neilson 1990). The idea that access to information will determine the success, or failure, of an organization is not new. Indeed, the initial ideas behind hypermedia can be traced back to a much-quoted article printed in the *Atlantic Monthly* in July 1945 by Vannevar Bush entitled "As we may think". Bush argued that the access to, and communication of, knowledge had made a significant contribution to the outcome of the Second World War. He argued further that traditional methods of transmitting the information (e.g. scholarly journals and books) were inadequate for the task. This observation was based upon Bush's task of orchestrating some six thousand American scientists in the application of science to warfare. He found problems associated with information management that could not be resolved by available systems. This led to his rather radical (in its time) proposal for the MEMEX system:

A . . . device in which an individual stores his books, records, and communications, and which is mechanised so that it may be consulted with exceeding speed and flexibility.

Bush was able to foresee this device as tool for augmenting human activity. However, there are two main problems of information management. The first problem is one of physical management— making the information easy to handle. Piles of books, reports, and scientific articles are not easy to use in quantity. Each is designed to be used as a stand-alone source. Whilst it is very easy to read one book and one article, problems occur when the numbers increase. The second problem relates to the way in which information is accessed and retrieved. This problem is different from the first because it refers to the user getting the appropriate information from a document in a timely manner, rather than the physical management of a large number of documents. It would seem that paper-based documents are relatively easy to use, in the sense that a shelf full of books of assorted sizes and colors makes it easy to identify the one required and, once selected, the chapter, section, page and paragraph are easy to locate. However, this assumes one knows effective mechanisms for retrieving the book (e.g. books shelved according to content) and accessing the material (e.g. contents listings and indexes). These retrieval mechanisms relieve the user from knowing the entire contents and precise positions of all of the books.

The first problem has largely been solved through technological development. Bush (1945: 103) prophesied this technological development. He wrote that:

The Encyclopaedia Britannica could be reduced to the volume of a matchbox.

There are four main technologies associated with digital media and electronic publishing: storage technologies (e.g. CD-ROM), communication technologies (e.g. the information superhighway), desktop technologies (e.g. personal computers), and interface technologies (e.g. Mosaic). The second problem relates to authoring and using the material. People have problems using and authoring electronic systems. There is no clear guidance, particularly when it comes to converting existing printed material into the electronic form. Some electronic systems do no more that their paper-based counterparts, i.e. electronic page turning. Whereas other systems make anything, and indeed everything, possible. In the first implementation, users are bound to feel constrained by the system, indeed the only advantage it has over a book is the reduction in physical space requirements. In the latter implementation, users may feel that they are unable to make sense of environment: the lack of a clear structure means that everything is apparently linked to everything else. Bush (1945) proposed the notion of trails:

associative indexing, the basic idea of which is a provision whereby any item may cause at will to select immediately and automatically together. ... The process of tying two items [or more] together is the important thing.

Hammond and Allinson (1988) suggest that hypertext will lead to more efficient production of electronic material and could empower students to take full control over what they choose to view. Nelson professes that each user in the hypertext network could also become an author by structuring and changing the material in their own individual way. This is a futuristic vision of hypertext. As Nelson (1974) wrote:

the structure of ideas is not sequential. They tie in together whichway . . . In an important sense there are no subjects at all; there is only all knowledge, since the cross-connections among the myriad topics of this world simply cannot be divided up neatly.

Stanton and Baber (1994) argue that many of the hypertext systems reported in the literature have been poorly designed, and suggest that there is a single root cause of this poor design. The basic concept of hypertext, in computer science terms, is of an "n–dimensional" space, which can be traversed by moving through links. "Space" as used in this context has a well-defined meaning, as the collection of objects and activities contained within a specific domain — for example, a similar fashion to its use in that of finite state architecture. However, much current research in hypertext appears to use the term "space" in its everyday sense, i.e. as a physical relationship between objects. This has led to the use of the concept of "electronic space", which can be represented in the form of a map, and through which users navigate. The translation of the concept of "mathematical space" into "electronic space" has led to the inappropriate adoption of a spatial metaphor; this adoption may have occurred unwittingly, but the notion of hypertext as space appears to have been accepted without question by the community. The much-cited phenomenon of getting lost in hypertext documents suggests that hypertext designers do not provide information in an appropriate format for users. The fact that most of the reported incidents of getting lost occur in very small documents suggests that, unless the problem is tackled soon, as systems grow larger, "lostness" will become more prevalent (Stanton, Taylor, and Tweedie 1992). The key problems of hypertext are twofold. The

first is that designers are often unaware of the problems users have in "navigating" hypertext. Consequently, they fail to provide adequate information on the screen. Second, because hypertext is currently designed as "electronic space" designers emphasize the development of links between nodes, and users have to traverse these links. Hence, the reports of getting lost (Stanton, Taylor, and Tweedie 1992).

Stanton and Baber (1994) suggest a simple but radical shift in hypertext design: rather than using links as programmable features, they suggest that nodes should be made more sophisticated. Nodes ought to be defined in terms of specific properties that would include defined links, such as those which relate to nodes containing similar information. This concept is similar to object-oriented programming; the objects in this example are node types. The properties of the nodes would then be the links, and would exhibit such characteristics as inheritance, membership, etc. Users would allocate certain properties to nodes, and these properties would form the basis of links. In practice, Stanton and Baber propose that the form of interaction with the text would be similar to content analysis techniques.

2. CONTENT ANALYSIS

Content analysis (Kirakowski and Corbett 1989; Robson 1993) is a technique that has been around since the beginning of the century for analyzing the content of documents. The term "documents" refers to all media: newspapers, diaries, speeches, letters, reports, books, journals, notices, films, photographs, videos, radio, and television programs. Content analysis consists of five main stages as follows.

2.1. Determine Objectives

The starting point of the process is to determine the objectives for the use of the material; for example, it may be intended for use as teaching or training material, as a journal, database, or an encyclopaedia, or to support a help desk, etc. Each of these different objectives may engage the user in different types of activity and therefore require the content to be structured in a different manner. Some material may be used for more than one type of activity and therefore require structuring in more than one way. Hypermedia has a distinct advantage over traditional media by virtue of enabling different structures to be placed upon it.

2.2. Define Unit of Analysis

Based upon the objectives and the use to which the material is to be put, the next task is to define the unit of analysis. In the case of text, the unit could comprise individual words, phrases, sentences, or paragraphs, etc., whereas in the case of pictures, the unit of analysis could be an object, frame, or sequence of frames, etc. It is also necessary to consider the context within which the unit occurs as this will affect the meaning of the unit. Software tools exist for identifying keywords, keywords in context and combined criteria lists. Such tools make the task of analyzing large documents much easier.

2.3. Construct Categories for Analysis

The construction of categories will be based upon the considerations above (objectives and unit of analysis). Generic categories might be formed from subject matter, objects, authors,

countries, etc. It is desirable that the categories are exhaustive and mutually exclusive. This ensures that everything can be categorized and reduces the ambiguity of categorization. The analysis will be no better or worse than the system of categorization.

2.4. Test Coding to Assess Reliability

To determine the objectivity of the coding and categorization system, it is necessary that the scheme is tested. Typically a sample of the material is taken and coded by at least two persons who have been trained in using the coding and categorization system by the person who devised it. The categorizations made by these persons should be tested for reliability. If reliability is low (i.e. there is little agreement on which units should be assigned to the categories) then the coding scheme may need revising or more training of the persons required. If reliability is high (i.e. there is a high degree of agreement on which units should be assigned to the categories) then the scheme is ready to be used.

2.5. Conduct Analysis

The content of the documents can be analyzed according to the devised scheme. The analysis is continually open to verification and checks of reliability. Indeed content analysis should be considered as a continual process. The analyst can change the objective, unit of analysis and construct new categories, but each change should undergo some form of testing. The advantages of using content analysis to assist in the design of hypermedia systems are that it can be used on existing documents, it enables re-analysis for reliability checks, and it is relatively cost efficient compared with designing a hypermedia system from scratch. However, one must bear in mind that bias or distortion could be introduced into the analysis and that the documents have originally been produced for another purpose.

3. PROPOSAL FOR ELECTRONIC IMPLEMENTATION

To begin with, text and graphics are entered into a hypertext system, but no links have been made. The author (or user) is now faced with the task of analyzing the information on the screen. This task is analogous to content analysis as typically performed on non-electronic, open-ended information. This framework could usefully support the construction of hypertext as it allows the author to place some degree of objective structure on the information, whereas traditionally links have been almost arbitrarily assigned. To assist in this task, the system contains a hierarchy of keywords and phrases that have been entered into the database. First of all the author picks an object from the screen. Second, the object that has been selected into either text, sound, graphic or movie is classified. Third, the author is required to indicate which of the associated keywords is appropriate to the context under analysis. Fourth, the author rates the "strength of association" of this object (through the use of a slider control, the strength assigned is relative, not absolute). Keywords also need to be defined (Waterworth, Chignell, and Zhai 1993); the author may also choose alternative classifications and/or add new ones.

Users would engage in a different kind of interaction. They would not see the classification forms used by authors; rather, they would be faced with the same information and, on selecting

an object, would be presented with a box allowing them to call upon further related information. This notion is an implementation of the idea proposed by Stanton and Baber (1992), which suggested that hypertext systems should not seek to constrain users. Indeed, the user-choice screen idea could be extended to enable users to call up information that has not been entered into the author's original classification. By altering the "strength of association", users could dynamically manipulate the list of potential information sources available to them. This proposition is closer to the original formulation of hypertext than many commercial systems currently allow. This proposal might seem to incorporate the spirit of Bush's MEMEX device outlined in the introduction. However, there are two important differences: the first is that the authors of the material have analyzed the content of the information to propose a keyword classification, and the second is the idea that some documents may have stronger association with some keywords than others.

The approach proposed serves two purposes: it forces designers to shift emphasis away from links in space and on to node design, and it means that new nodes can be added relatively easily to an existing application — i.e. there will be no need to redefine all the links when a new node is added. This approach can potentially be used with current software. It is possible, for instance, on HyperCard to copy the complete contents of one card and paste it into a new card. The properties of the buttons will remain the same unless the author changes them. If there was a provision for more global structuring, such as project scripts in SuperCard, then specific properties could be attached to objects. For instance, in a database, a new piece of information could be defined as an "interface card" and given the properties of other cards in that category.

The notion of "definable nodes", as Stanton and Baber (1994) term the concept, does not mean that the basic premises of hypertext need to be altered. Rather, we feel that they will be brought to the forefront of technological development. At present, designers appear to be caught up in trivial problems posed by lack of understanding; research is being carried out into the symptoms of problems in hypertext use, rather than into their causes. Emphasis is being placed on a metaphor, i.e. navigation, which at best is misleading and at worst is wrong. Finally, there appears to be little agreement as to how hypertext ought to be used. Some applications function well as education aids, others as database inquiry tools, but there does not appear to be a consensus as to how such packages should be designed. What is applicable to education need not be applicable to database inquiry. This means that, in addition to new approaches to software design, we suggest designers should consider issues of functionality and usability as well as computational elegance and ease of design. In any hypertext package a user will require only a small amount of information at any one time. Is it more important to provide that information in a usable form, or to show what other information could be accessed? If one opts for the latter, one will arrive at a scenario similar to "channel hopping" when viewing television — there will be a wealth of "information", but little knowledge.

Design Methodology

W. W. Gasparski

Institute of Philosophy and Sociology, Polish Academy of Science, Warsaw, Poland

Methodology is nothing more than normative epistemology (Bunge 1983: 4) therefore *design methodology* is normative design epistemology. Such a characteristic needs the acceptance of a combination of the two concepts, namely: theory of cognition — i.e. epistemology, and a noncognitive but change oriented discipline — design. For some design theoreticians it would be easier to accept the combination in question if they were able to find references to the design oriented families of learned disciplines. In order to do this let us refer to Kotarbióski's praxiological inquiry and to Simon's "sciences of the artificial'. To refer to Kotarbióski is legitimized by the very fact that the *design methodology* we are talking about is of praxiological (i.e.. general methodological) origin. To refer to Simon is legitimized by the end products of any design activity which are conceptual models of manmade objects, i.e. *artifacts*.

"By creativity I understand inventiveness," says Kotarbinski, "whether in the domain of products or in the domain of methods. All efficient work leads to the rise of something what does not exist before, thus the work is creative to some extent" (Kotarbinski 1986: 42). Therefore the engineers (or engineering-like) creativity would be inventiveness in the domain of technical products and technological methods conditioned by the effective work of engineers of different specialties. Simon (1981: 129) says: "Historically and traditionally, it has been the task of the science disciplines to teach about natural things: how they are and how they work. It has been the task of engineering schools to teach about artificial things: how to make artifacts that have desired properties and how to design." Therefore design plays a twofold role: first, as a method characteristic of applied (practical) sciences oriented towards theories of particular classes of artifacts; second, a kind of activity serving the conceptual preparation of changes founded on the theories of applied (practical) sciences. Thus the subject of design methodology is about the totality of issues covered by the propositions on which the applied sciences are based, their reasoning, justification, and characteristics, and changes that have evolved from these theories.

Let us add that it is still an open question as to what degree the reasoning and justification for proposed changes are applicable only to the engineering sciences, and to what degree they are relevant to other practical sciences and design methods. These issues belong to general/generic design methodology (Warfield 1990). First, design methodology enables and simplifies the articulation of design knowledge, and, second, the conceptual apparatus elaborated by the methodology serves as a tool to do that. It is a meta-language in which a language of design is characterized and knowledge which a designer, as a reflective practitioner (Schōn 1983), produces as an additional product of his or her activity.

The language of design is one in which design solutions are formulated throughout the design process; it also includes a "language" of the particular design actions involved in that process. The first language is one of the general theory of objects (systems) adapted to the needs of particular design disciplines and to the multiple perspectives (Linstone 1995) which serve as a base for the assessment of design solutions produced by these disciplines. The second language is used to describe the inferential structure of the process of designing, actions contained within the process, and connections between them — for example, in the terms of *p-t-s* (problem-tasks-solution) networks (Gasparski 1989). This logic of the context of justification as related to design solutions is accompanied by a *sui generis* logic of discovery, or, rather, the generation of proposals from which the design solutions are selected. Zwicky's morphology, Altshuller's invention of algorithms, and so on, as well as iterative loops, may serve as examples of the second kind of design logic.

The creation of a language that is used by reflective practitioners as a means to describe design phenomenon is not, however, the main task of design methodology. The language is rather a by-product of the fundamental task of the methodology in which the primary task is to study the design process and combinations of particular design actions, in order to identify them and describe ways in which to perform them in a systematic manner — that is, to study methods of design.

Design methodology has two divisions: investigation of the design process is called the *pragmatic design methodology*, while the study of system designing is called *apragmatic design methodology*. Pragmatic methodology of design is of general character because the design process understood in terms of its inferential structure is invariant. It allows designers from one design discipline to take an advantage of the experience gained by designers involved in other design disciplines; design methodology serves as an effective intermediary to do this. The second division of design methodology is composed of several specialized subdisciplines studying design objectives of different design disciplines. General/generic apragmatic design methodology offers the subdisciplines (which are particular apragmatic methodologies) the general framework in which to investigate particular design objectives and general theses to concretize them in relation to particular cases. Among these are: (i) an outline of the general theory of change — for change is the task of design; (ii) an outline of the general theory of systems — since coping with complexity and simplifying it to manageable proportions is what design approach is about; (iii) *sui generis* ontology of practical situations, for the objects of design are collections of practical situations (from a pair of them on), the mapping of which are design problems (Æ *Design*). Design methodology, in relation to this issue, overlaps with the logic of interrogative sentences, since design problems are questions or sentences transferable to the form of interrogative sentences. The methodology of design is linked with the cognitive science, knowledge engineering, and the discipline called CAD (computer-aided design).

Design methodology of praxiological provenance is related not only to the methodology of science but also to the theories of action, practical, and applied philosophy, which study, among other things, the social context of human actions. In relation to this, we suggest that only the design which effectively prepares conceptually such impartial actions deserves the positive appraisal. "Thou shalt design — proclaims the *technological imperative -* or help implement only projects that will not endanger public welfare, and shalt alert the public against any projects that fail to satisfy this condition" (Bunge 1985: 310).

Changes conceptually prepared by design are evaluated against the criterion of their *relevancy*, and only such changes that pass the evaluation are consider *proper changes*. The relevancy concept comprises: intention, being real, rationality as well as utilitarian, ethical (moral), and aesthetical values of changes in question. This systemic assessment of design solutions needs to be guided by — among other things — the results of practical philosophy oriented toward social practice. It brings about participation of the users (of design solutions) in design processes as a method of manifestation of their values. It also brings about the so-called *technology assessment* as a method of evaluation of technical solutions from a social (resultant effects) point of view. Philosophical reflection on design pointing out design — understood in a proper way and performed in a proper manner — as a means of improving engineering, not only in a technological sense but also in a social sense, is becoming a *sui generis* designing of design. This "designological" approach is characteristic for Design Culture, the emerging stage of the Design Era (Gasparski 1993b: 156).

DIALOG: Human Reliability Assessment

H. Bubb and I. Jastrzebska–Fraczek

Technical University of Munich, Boltzmannstraße 15, 85747 Garching
Germany

1. SYSTEM ERGONOMICS AND HUMAN ERROR

Most of the conventionally applied Human-Reliability-Assessment (HRA) methods are based on an event orientated categorizing system. They provide reliable prognosis for so-called skilled-based actions, which are often enough repeated. In the case of cognitive tasks they cannot support sufficient data. The HCR (human cognitive reliability) methods classify human error as belonging only to the ratio of time available to time required. As system ergonomics deals with the information flow in a man machine system (Figure 1) as well as with the information flow between different systems, this would serve as a base to assess human reliability independent to the level of information processing.

By the information flow of a singular man–machine–system the quality of human work can be calculated as the relation of the result of a work to the task. Performance in this context is: quality per time. Limits of quality are explicitly or implicitly defined in every system. If any human doing results in a jumping over such pre-defined limits, we call that *Human Error* (HE; Rigby 1970). The probability of non-occurrence of such HE's defines the *Human Reliability* (HR). This consideration is important not only for a simple singular man–machine–system but also for any complicated combinations of different singular man–machine–systems, which describes in its totality any arbitrary system as, for example, a power plant, an assembly plant or a traffic system. Apart from technical defects, especially human errors influence the reliability and dependability of such systems. After all experience primary technical, often unimportant, failures occur and initiate inadequate human reactions. As such effects cannot be treated only by measurement in the technical area more

profound treatments of human operation in the technological context and its possibilities of deviation are necessary. System ergonomics can be used as a base.

2. THE IDEA OF SYSTEM ERGONOMICS

System ergonomics starts with a general description of properties of every task and assigns experimental experience, and, from that, ergonomic recommendations to the partial aspects of the task can be made. The fundamental idea is that by the knowledge of the information transfer by the subsystems man and machine, the tasks to be performed by the operator may be designed. For this designing of the task that results from the system mission and from the specifically chosen layout of the system and the system components (e.g. the machine), the following fundamental rules are to be considered, formulated as questions:

1. Function: "What has the operator in view and how far is he assisted by the technical system?"
2. Feed back: "Is the operator allowed to recognize it, if he has effected something and what was the success of it?"
3. Compatibility: "How much effort has the operator to make in order to convert the code system between the different technical information channels?"

The *function* may be separated into the intrinsic task-contents and the influenceable task-design. Under this aspect the *task-contents* is essentially defined by the *temporal and spatial order* of the activities which are to be carried out to perform the total task. It may be described by the terms operation (= *temporal* organization), dimensionality (= *spatial order* of the task) and manner of control (= the *time and location window* within which the task must be finished (Bubb 1988). The *task-design* refers to the system structure that may be chosen to a large extent by the system planner. In this area the degree of difficulty may be influenced by the specifically designed layout. It can be distinguished between the manner of presenting task and result to the operator — the so-called *display (compensatory* respectively *pursuit task)*, and the manner of involving the operator in the total system — the so-called *manner of task (active* respectively *monitive task)*.

Feed back calls for a certain kind of redundancy, which asks for the *number of sensory organs*. A further aspect is the *time* that occurs between the input of information on the control element and the reaction of the system on the output side. Considering

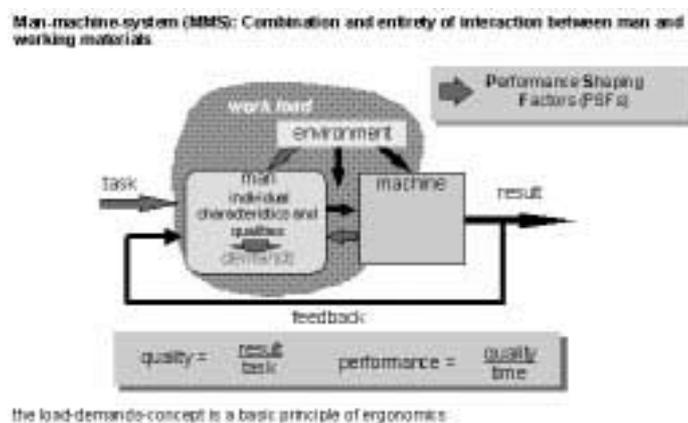
Man-machine-system (MMS): Combination and entirety of interaction between man and working materials


Figure 1.

the relevant recommendations a well-designed feed back allows the operator always to answer the question:

- "What have I done?"
- "In what a state is the system?"

Compatibility describes the facility that enables the operator to convert the code system between the different information channels that he has to handle. It characterizes the obvious between different areas of information, as reality indication by instruments, control elements, and internal models of the operator. Neglecting the rules of compatibility decreases the human reliability immensely (Spanner 1993).

3. HE SOFTWARE–TOOL DIALOG

As Sträter (1997) has shown, by the system ergonomic aspect an important number of human errors observed in the reality can be categorized and explained. Although he found some human error probability data from real live observations using a system ergonomic categorizing scheme, these results should be substituted by experimental investigations under controlled working conditions. For this reason the software DIALOG was developed. It allows to investigate to a far extent the different aspects of the system ergonomics described above. The task for the subject is to re-write a combination of several numbers between 1 and 20. This is an example for *sequential operation* of different degree of difficulty. Simultaneously further tasks can be displayed in form of traffic lights (with the color sequence "green," "yellow," "red"), which are to be switched off by a mouse click before the appearance of the color "red," up to nine traffic lights can be presented. That is an example for *simultaneous task* of different degree of difficulty. By an additional indicated circle different time windows can be investigated. This circle is originally "green." During the task a "red" segment appears increasing with time. That is a representation of a *static task* ("manner of control"). Figure 2 shows an example of the video screen, as it is presented to the subject during the experimental run.

Experiments were carried out using the described equipment. Thirty-two subjects had to accomplish different tasks presented by DIALOG during a session of ~1.5 h. All reactions of the subjects were recorded by DIALOG. In the following only a part of the possible analysis is reported.

4. RESULTS

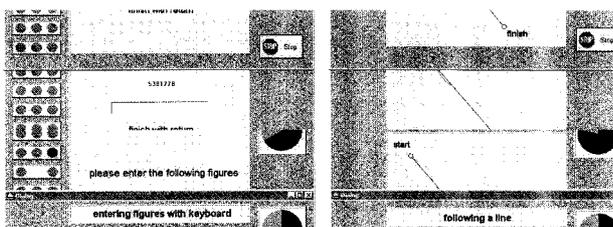
In a first investigation the areas "operation" (sequential task of the difficulty "5 numbers" and "7 numbers" in combination "with" and "without simultaneous switching off of traffic lights") and "manner of control" ("with" and "without a temporal window of 4 s respectively 8 s," within which the tasks had to be accomplished) have been the objective in view.


Figure 2.

It was found out that time pressure results in a more increased error probability than additional simultaneous tasks: In the case of recording five numbers the average error probability was ~0.03. This value increased with the factor 14 to 0.43 under the condition of time pressure. The simultaneous task of switching off traffic lights had no additional effect to the error probability, with a time window of 8 s. Without time pressure the increase of the difficulty of a sequential task of five to seven numbers had an effect of the factor 2.5. Under the condition of time pressure of 4 s the same increase had only an effect of the factor 1.3. A more difficult task seems to stimulate the attention. This suggestion is substituted by a more detailed investigation of errors, so one could separate the following kinds of error (Swain and Guttmann 1983):

- error of quality, z_1 (writing a wrong number, e.g. 123 instead 124);
- error of part omission, z_2 (omitting one number, e.g. 12 instead 124);
- error of omission, respectively negligence, z_3 (the task is totally neglected); and
- error of addition, z_4 (writing an additional number, not being asked for, e.g. 1234 instead 124).

In the case of time pressure all the types of error can occur in combination with a time error, i.e. the task is not finished within the time window, t (Figure 4).

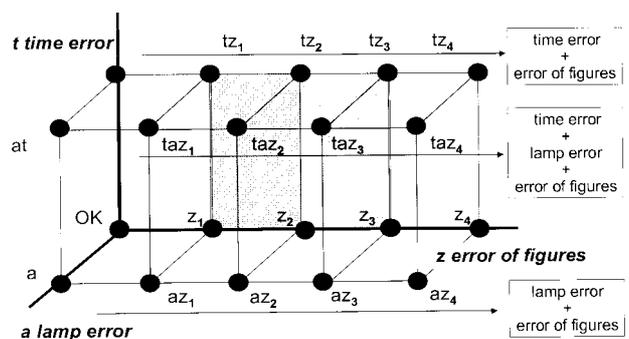
Whereas the error of negligence does not appear without time pressure, this type crops up with time pressure and has a value of 0.076. Under the condition of time pressure the time error appears with a probability independent of the difficulty of the task of 0.07–0.09. Of course, all types of error are increasing with time pressure (see above). There is one exception: The error of quality disappears under this condition. The probability of all kinds of error becomes smaller when these appear in combination with time error. There is again one exception: the error of omission


Figure 3.
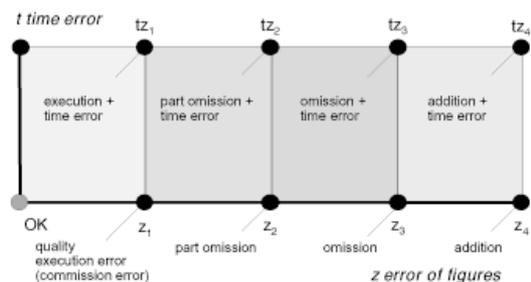

Figure 4.
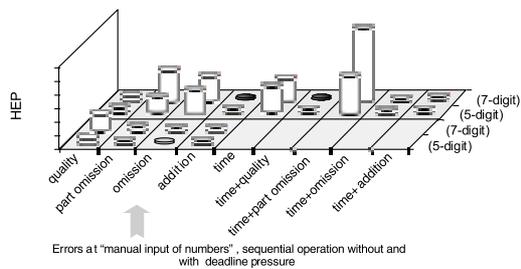

Figure 5.

Figure 6.

increases in connection with time error with the factor 16 for five numbers and 12 for seven numbers.

The observation shows that a more difficult (sequential) task under the condition of time pressure has an under-proportional ascent of error probability in relation to the behavior of more easier tasks (Figure 6).

Digital Human Models for Ergonomics

J. C. Woldstad

Texas Tech University, Lubbock, TX 79409-3061, USA

1. INTRODUCTION

Digital human models in the context of this section are computer-generated representations of human beings used in computer-aided design (CAD) or similar programs. These models are increasingly being used by ergonomists and other engineers to design both equipment and work environments to meet the needs of human operators. They have the advantage of allowing the designer to explore the potential advantages and disadvantages of different design configurations without requiring the construction of expensive physical mock-ups used in the past.

Using a digital human model, design engineers can position and manipulate operators of varying anthropometry within the simulated work environment. A variety of different analyses can be performed depending on the sophistication of the computer package. Currently available analysis modules include: reach and clearances, field of vision and visual obstructions, work posture and biomechanics, metabolic energy expenditure, time and motion, and others. In addition, the ability of these models to dynamically simulate human operators within proposed engineering projects has become a popular presentation and sales tools.

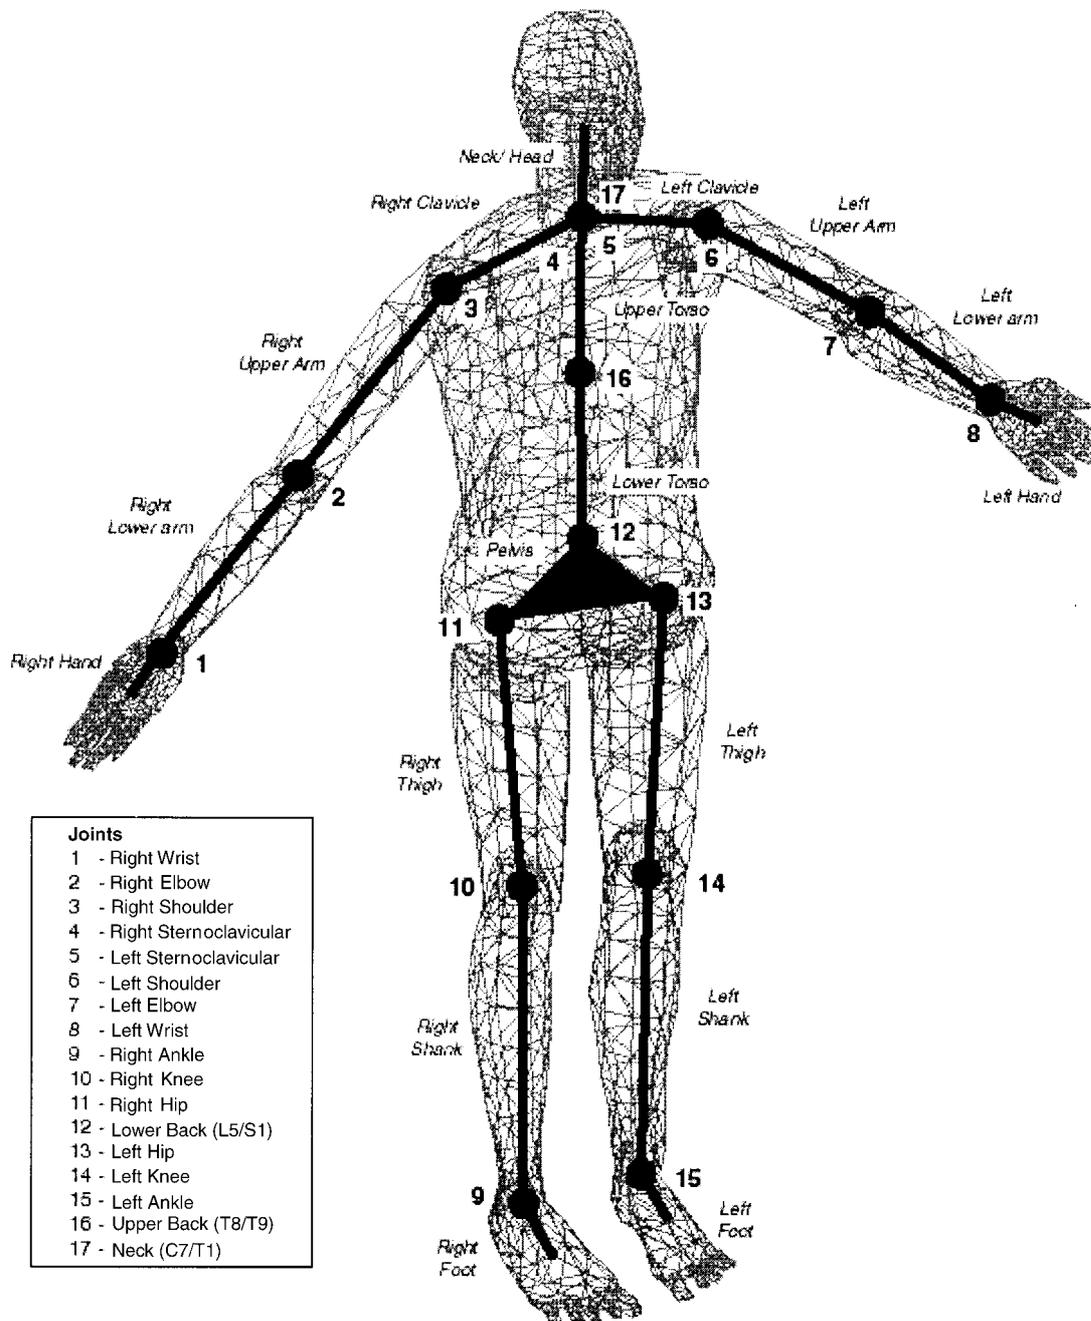

Figure 1. Typical simple three-dimensional link system for the human body.

2. MODEL STRUCTURE AND FORM

Most digital human models are composed of an underlying rigid-link framework similar to that used in many biomechanical models of the human body. This framework assumes that the body can be represented as a series of straight mechanical links connected at pin joints that roughly corresponds to the human skeleton. The sophistication of this framework will vary considerably from a relatively simple representation (Figure 1) to models that include more than 90 different links and 140 degrees of freedom. In addition, more sophisticated geometric models of the skeleton have been developed for joints that cannot be easily modeled using a rigid link structure. Most notably, a spherical model of the shoulder joint has been developed in an attempt to model the complexities of the shoulder complex (Badler *et al.* 1993).

The underlying skeletal structure of digital human models is almost always covered with solid geometric constructs used to represent the surface of the human body. Initially, these constructs or geometric primitives consisted of articulated polygons that would leave noticeable gaps between the segments when the model was positioned in extended postures. More recently, complex geometric models and smoothing algorithms have been developed that virtually eliminate the robot-like appearance of some of these models. In addition to surface geometry to represent the human body, most models come with a variety of different clothing options that can be applied to the model. Clothing options often interact with range-of-motion and collision detection components of the model to increase the realism.

3. ANTHROPOMETRY, POSTURE, AND MOTION

Anthropometric dimensions for most models can either be inputted directly or extracted from a number of existing databases. A fundamental limitation of digital human models is their inability to capture the large variation in human size and shape. Designers often desire models or manikins representative of various percentiles of the population (usually the 5th percentile female, 95th percentile male). Unfortunately, manikins of this type cannot be accurately constructed due to the inherent co-variance between human dimensions. The designers of digital human models have derived a number of different solutions to overcome this limitation. One approach has been to statistically model the relationships between different dimensions and then to select multiple dimensions that represent the boundary of a combined or joint confidence interval. Another has been to construct a family of representative anthropometries for the population under study. This group of manikins is either selected using Monte Carlo techniques or using data for whole-body surface scans of actual individuals.

To be effectively used, manikins not only need to be dimensioned, but they must be accurately positioned in the work environment. Similar to the anthropometric modules, most models allow the user to manipulate the posture of the manikin directly or use postures generated by the computer program. Postures generated by the program can be from a library of predefined "typical" human postures for the desired activity or generated using an inverse kinematics algorithm. Postures in most programs are limited by the known range-of-motion for the joint being positioned. Range-of-motion data is based on several

anthropometric surveys that have collected this information in addition to body dimensions. Accurately reproducing human body postures in a simulated environment has proven to be one of the more difficult tasks in constructing digital human models. As noted above, many human models have a large number of link segments and joints requiring the specification of many different parameters to fully specify the posture (some models have more than 140 degrees of freedom). Human body postures in general are also highly indeterminate or redundant, meaning that when the position of the hands and feet are fully specified, the rest of the body can still be positioned in many different ways. Research to understand how the human body selects from the many different potential postures available is currently ongoing at several universities and has not yet produced definitive results.

Human body motion algorithms are also included with many computer packages. These can produce typical reach, lift, and grasp motions for a stationary model, or walking and carrying motions for a model moving through the environment. Problems accurately predicting human motion are analogous to those associated with predicting postures, with even a higher level complexity involved. Similarly, our current understanding of human motion is not sufficient to allow truly accurate representation in a virtual environment. However, the algorithms employed often produce visually compelling animations of work activities and environments.

4. REACHES AND CLEARANCES

The principle use of digital human models by designers has been the comparison of the dimensions and limitations of the human body to the geometry of the proposed device or work area. Work envelopes can be easily calculated using these models to indicate the portion of the environment that can easily be reached by a worker in the simulated environment. Similarly, collision detection components to most models can be used to determine when and how a worker's body will come in contact with a component of the environment so that clearances can be determined. The determination of reaches and clearances depend upon the anthropometry of the individual manikin employed and the use of many different anthropometries that are representative of the population of interest (as discussed above) is usually necessary for accurate estimates. In addition, the posture and motion components to a model can play a key role in obtaining accurate estimates. Figure 2 below shows a typical use of a digital human model to determine both a reach and a clearance. In Figure 2, the operator must insert her arm into a limiting enclosure to manipulate a tool or device. The model is able to show how the enclosure limits the reach, and to some extent the motion of the operator.

5. VISION

Several models also allow the user to view the virtual environment from the perspective of the human manikin within the environment. This view allows the designer to explore the environment for potential visual obstructions. The view generated depends on the anthropometry, posture, and motion of the manikin, as well as, assumptions regarding the useful field of human vision. Figure 3 shows a typical scene from the point of view of a manikin within a virtual work environment. In this case the position of displays and controls for the seated operator are of concern in the design.

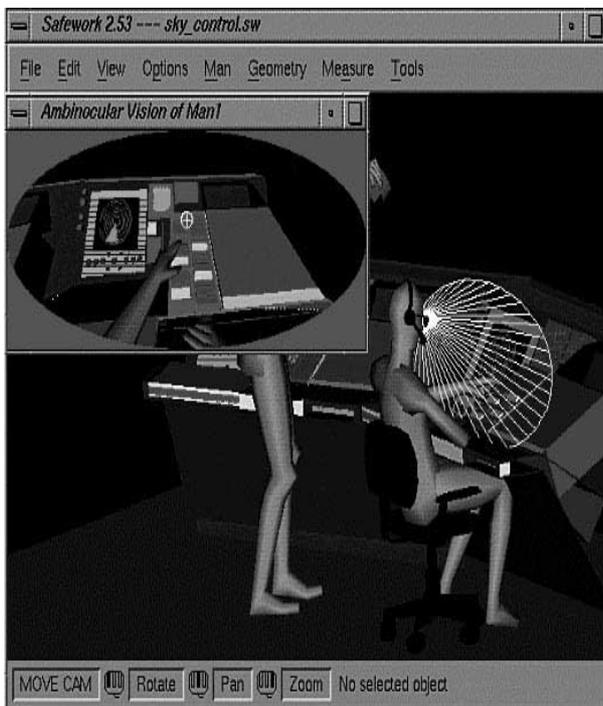

Figure 3. Field-of-view evaluation. (reprinted with permission from Safework, Inc., 1999)

6. BIOMECHANICS

Biomechanical models are often incorporated into modeling packages to allow the designer to estimate the mechanical stresses placed upon the internal structures of body during different activities. The objective is to estimate how work activities stress the bones, muscles and connective tissues of the body and to predict when these stresses will lead to damage of these structures. This approach is very popular in ergonomics because it closely corresponds with most expert views of the etiology of injury during manual materials handling (NIOSH 1981). Simple biomechanical models estimate the torque placed upon the joints of the body related to a work activity. More complex models will estimate parameters such as joint strength capabilities, internal muscle forces, and lower back intervertebral disc compressive force. A majority of models currently used are either based on or are similar to the 3D Static Strength Prediction Program produced by the University of Michigan (Chaffin *et al.* 1999). A typical output from this program is shown in Figure 4.

Biomechanical models are either two- or three-dimensional and either static or dynamic. For static models, the calculations require information on the orientation of the links in the model (subject posture), the length of each segment, the mass of each segment, and the location of the center-of-mass or each segment. Dynamic models require this same information plus the angular joint accelerations, linear acceleration of each segment at the center-of-mass, and the moment-of-inertia of each link through the center of mass.

7. OTHER MODEL FEATURES

A variety of other model analysis tools and features in addition to those described above are available for digital human modeling software, depending on the manufacturer and the intended use of the software. Some currently available features on different models include:

- Predetermined time study analysis based on the Methods Time Measurement (MTM) system.
- Work posture analysis based on the Ovako Working Posture Analysis System (OWAS) to analyze the relative discomfort of the back, arms, and legs in working postures.
- Metabolic energy expenditure rates based on the models of Garg *et al.* (1978).
- Analysis of manual materials handling tasks based on the National Institute of Occupational Safety and Health's (NIOSH 1994) lifting equation and the psychophysical limits recommended by Snook and Ciriello (1991).
- Upper limb analysis based on the Rapid Upper Limb Assessment (RULA) tool.

8. LIMITATIONS OF CURRENT MODEL

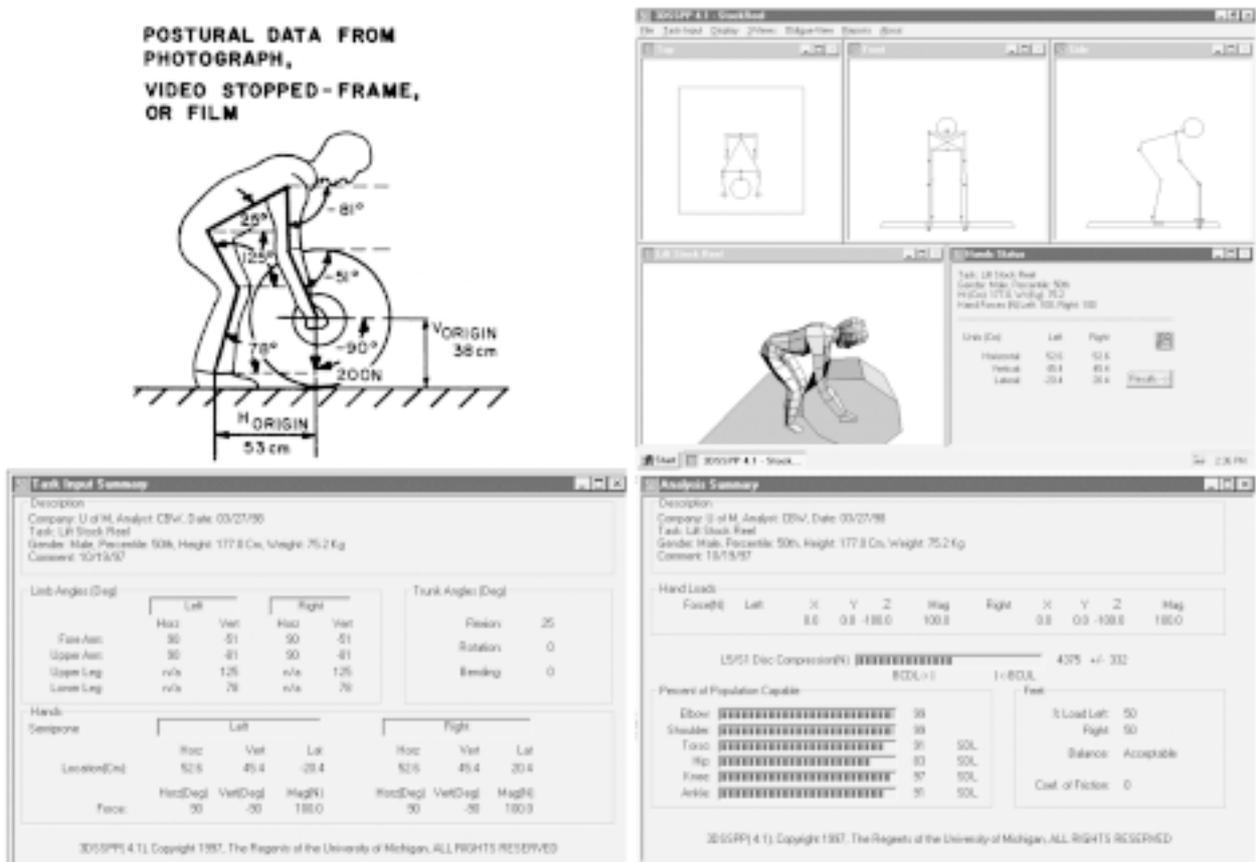
Current digital human models appear to be limited much more by our understanding of ergonomics and human behavior than by computer technology. Deficiencies in currently available data on three-dimensional human anthropometry and strength limit model accuracy. In addition, we do not have a clear understanding of the basic principles behind human posture and motion, as noted previously. In many cases, the methodology used by models is not clearly specified so that qualified users can judge the accuracy of the prediction due to the proprietary nature of many programs.


Figure 4. Work task and main output screens for the University of Michigan 3D Static Strength Prediction Program™ (reprinted with permission from the University of Michigan, 1999).

Standardization of language, computer file format and program structure is also clear needed in this technology. Undoubtedly, computer models will become more accurate as ergonomic tools advance, but in the interim, designers and ergonomics should attempt fully to understand the tools being employed in these models and use appropriate professional judgment.

9. RECOMMENDATIONS

- Digital human models are a useful tool for ergonomics analysis and will become increasingly more popular in the future.
- Models are currently available to assist designers in analyzing reaches and clearances, visual limitation, biomechanics, and a variety of other task functions.
- Limitations exist in our current anthropometric and strength databases, as well as, our current understanding of human posture and motion. Professional judgment should be exercised in interpreting model results that rely on this information.
- Additional information on human digital modeling can be obtained from the Society of Automotive Engineers (SAE),

Technical Subcommittee G-13 on Human Modeling Technology.

Ecological Ergonomics: Theory in Context

N. Stanton
Department of Design, Brunel University, UK

1. INTRODUCTION

Ergonomics abounds with comparative studies that exhort the merits of one particular design over another, one particular environment over another, one particular training regime over another, and so on. While these are undoubtedly useful studies in their own right in that they answer questions to matters of current short-term concern, it is questionable whether they offer long-term advancements for ergonomics. Is the discipline to be chained to a cycle of testing?

Dowell and Long (1989) identified four deficiencies in the current status of the discipline, namely: poor integration, suspect efficacy, inefficient practices, and lack of systematic progress. These problems do not bode well for advancement. By way of softening the blow, Dowell and Long suggest that the trial and error approach, characterized by the conception of ergonomics as a craft, may be attributable to the relative youth of the discipline: its genesis being dated as 12 July 1949 (Oborne 1982).

The title "Ecological Ergonomics" might strike the reader as a little odd: surely all ergonomics studies are inherently ecological? This is not the case. Generalizing findings from one context to other contexts misses the essence of ecology: context has a direct bearing upon the phenomena being observed. In a different context, behavior may be very different. Intuitively we know this to be true, and this has led to calls for "user-centered design" and "field trials" in the development and evaluation of products.

2. THE ROLE OF THEORY

From the arguments raised by Dowell and Long (1989), it might be reasonable to suppose that the discipline would benefit from more theory building by its disciples. Certainly, this would tackle some of the deficiencies they have identified. The role of theory is to provide explanations that show causal linkages at work in the phenomenon we observe. In practice, theories are derived through the passage of time and considerable research effort. A life cycle of a theory might start with a conceptual framework. Conceptual schemes offer aid to theoretical advancement, for example, as a mechanism for classifying data and organizing ideas. Analyses of this information may lead to prototheories, which are typically loosely formulated, but offer claims regarding causal sequences. As data is gathered and organized, the theory can be modified reiteratively in the light of new evidence. The process of generating hypotheses based upon the theory, and testing these hypotheses and modifying the theory could go on *ad infinitum*. However, there are two points of exit. First, the evidence could become unequivocal, turning the theory into a law. Second, the theory could be overthrown by a paradigm shift within the discipline which makes the theory untenable. However, in most cases, theories tend to exist on balance scales: the weight of evidence presented either tips in favor of, or against, the argument.

3. MODELS OF HUMAN ACTION

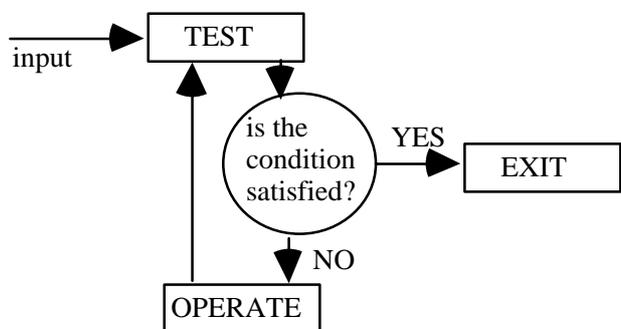
In an attempt to predict human behavior with technological artifacts, theorists have tended to opt either for parsimony or for over-inclusiveness. An example of a parsimonious account is TOTE (Miller *et al.* 1960). Each TOTE unit contains four elements: Test–Operate–Test–Exit (see Figure 1). TOTE offers a functional, goal-oriented explanation of human behavior. For example, consider the goal for an operator of maintaining a target state for a process variable. To ensure that the variable is kept at its target level (e.g. level of a liquid in a vat) the operator is required to conduct a TEST (e.g. compare the value of the variable against its target). If the variable is above or below the target state, the operator might OPERATE a valve to return the variable to its target state. After operating the valve the operator would be required to conduct another TEST, to check that the desired state had been reached. If the variable had been returned to the target value, the operator could EXIT that task. The original conception of TOTE appears to suggest a fractal-like relationship between a multiplicity of units.


Figure 1.
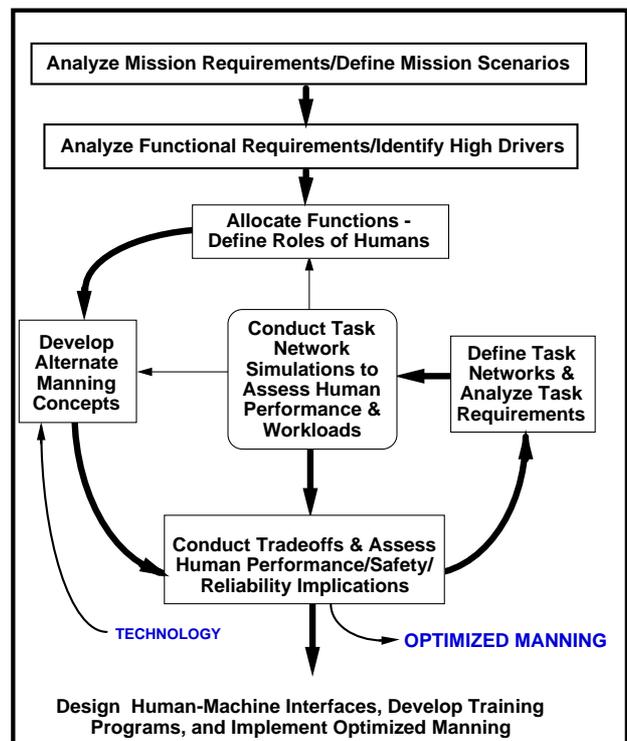

Figure 2.

An example of over-inclusiveness is the model of Performance Shaping Factors (PSFs: Miller and Swain 1987) where anything, and indeed everything, is thought to influence human behavior. PSFs include human–machine interface characteristics, task demands, task characteristics, instructions and procedures, stresses, environment, sociotechnical aspects, and individual factors. Literally hundreds of factors can be implicated as having an effect on human behavior.

In the comparison of these two approaches, the oversimplification of the first and the over-complexity of the second are striking. If we are to explain behavior, however, we must look to the simplest description that accounts for the phenomenon observed. Recent research on PSFs suggests that most of the variance in behavior can be accounted for by relatively few factors. In a study by Fujita (1993), 20% of the variation in operator performance was accounted for by training and experience. Similarly, in a study reported by Glendon *et al.* (1994), 30% of the variance was accounted for by work pressure. These data suggest that a small pool of factors could be identified to account for most of the influence on human behavior.

Carroll (1990) proposed the notion of a task-artifact cycle in order to explain the link between human activity, the design of artifacts, and the situation in which the artifacts were used. Carroll suggests that these elements are interrelated: the task sets the requirement for the artifacts and the artifact, in situations of use, defines the task. He argues that the artifacts cannot be fully understood outside the situations within which they are used. These propositions lead me to believe that context plays a central role in the task–artifact cycle, see Figure 2.

Norman (1988) illustrates a cycle of human action that makes implicit reference to the context in which the activities are performed. He describes a seven-stage model of action comprising: perception, interpretation, evaluation, goal formation, intention, sequencing actions, and execution of actions. Norman also draws the distinction between knowledge in the world and knowledge in the head. This is an important point; it suggests two types of context: external context and internal context.

4. THE IMPORTANCE OF CONTEXT

At present there appears to be a rather lively debate between cognitive scientists and ecological psychologists regarding the explanation of human action. Norman (1993) offers a caricature of these two approaches. The symbolic cognition stance taken by cognitive science focuses exclusively upon the symbolic representations of the mind and the processing structures of the brain, whereas the situated action stance taken by ecological psychology focuses almost exclusively upon the way in which structures of the world guide and constrain human behavior. At either extreme end of these viewpoints, something is missing from the explanation.

Human *action* occurs as an *event* within a *context*. By understanding the relationship between these three entities (i.e. the relationships between human action, device states, and context of the interaction), one might begin to propose a contextual theory of human action. In explaining behavior, we often point to the context in which certain decisions are made, but there are two types of context: internal and external. Internal context (cf. knowledge in the head) refers to the knowledge,

beliefs, experiences, and motivations of the individual concerned. External context (cf. knowledge in the world) refers to the situational, temporal, informational design and environmental characteristics present. To ignore either will result in an incomplete account.

5. AN ANALYSIS OF SITUATED ACTION

Gaver (1991) argues that information regarding the affordance of a device (i.e. the potential for action) is supplied not only by direct perception but also by exploration. Information about the operation of a device becomes apparent through interaction with that device. As the interaction progresses, new (previously unapparent) affordances are made available. Gaver calls these *sequential* affordances, when one action leads to a new affordance, and so on. For example, a door handle has the affordance of grabbing, the grabbing leads to the affordance of turning, and the turning leads to the affordance of pulling. Each action in turn leads to a new possibility that ultimately satisfies the goal of opening the door. Suchman (1987) refers to this type of activity as "situated" planning. Errors may occur when there is an incompatibility between the affordance offered by a device and its actual properties in two main ways. The first type of incompatibility occurs when a device does not allow an action that it appears to afford. The second type of incompatibility occurs when a device allows a certain action but it does not result in the desired goal.

In a recent paper, Baber and Stanton (1994) proposed a methodology for analyzing the situational component of human–artifact interaction. This approach suggested that by mapping a description of human activity onto a description of product states one could begin to identify situations where the product would allow erroneous activity. The methodology makes the relationship between product design, situational use, and errors explicit.

6. CONTEXTUAL ACTION THEORY

The value of an action performed, or a choice made, at one point in time often depends upon its relationship to the context within which it occurs. The coping model used in health psychology provides an analogous framework for a theory of contextual action. I am suggesting that it is necessary to consider how people cope with the operation of a device within a given context. This understanding will enable us to organize the existing research data to take the discipline beyond the last study to be published. Contextual Action Theory (CAT) would explain human action in terms of coping with technology within a context. To understand the theory, it is necessary to understand what enables people to cope, or fail to cope, with tasks.

In essence there are five main phases associated with contextual action. In the first phase, the actual demands and actual resources are presented to the actor. The actual demands are made up of the design of the device, the tasks to be performed on the device, environmental constraints (e.g. time), and so on. Factors relating to external context have impact here. Actual resources are represented by the training, knowledge, and experience of the actor with the device, and so on. Factors relating to internal context have impact here. The second phase consists of an appraisal of those demands and resources by the actor. It is noteworthy that actual demand and resources may differ from perceived demand and resources. A comparison of perceived

demand and perceived resources occurs at the third phase. It is proposed that an imbalance at this stage would lead to some form of degradation. Possible pathways that the degradation might take would occur in the fourth phase; these include emotional and behavioral responses or abandonment. Examples of emotional responses include decreases in user satisfaction and motivation. Examples of behavioral responses include increases in errors, increases in reaction time, increases in inefficient or inappropriate activities. The ultimate pathway would be for the user to abandon the interaction altogether. The effects of these responses on the interaction with the device are appraised in the fifth phase and fed back to the internal and external contexts.

It is possible to identify imbalance between actual (A) and perceived (P) demand (d) and actual (A) and perceived (P) resources (r). Hypothetically, imbalance would lead to some form of degradation in performance, as indicated by the use of pathways. Examples of the forms of imbalance are as follows:

Ad>Pd or Ad<Pd
Ar>Pr or Ar<Pr
Pd>Pr or Pd<Pr

In addition to the above framework, CAT incorporates the *coping hypothesis*: people cope with technology. A basic premise of the notion of comparing demands with resources is that, if demands cannot be met by existing resources, one way of compensating is to change the demands. Thus, a novice device user may interact in a different, less efficient manner than an expert. The novice reduces the demands by making the device less demanding. An obvious example is the use of icons and menus in preference to function keys and commands in computing tasks. If this pathway is not sought we may indeed observe some form of degradation in performance. One might propose that a well-designed interface helps novice users cope with a device, whereas experience helps expert users cope with a poorly designed interface.

Ecological Interface Design: Applications

S. Chery and K. J. Vicente

Cognitive Engineering Laboratory, Department of Mechanical and Industrial Engineering, University of Toronto, 5 King's College Road, Toronto, Ontario Canada M5S 3G8

1. INTRODUCTION

Ecological interface design (EID) is a theoretical framework for human-computer interface design in complex work domains (see the article "Ecological Interface Design: Theory" by Torenvliet and Vicente) that is based on the ecological approach to human factors (see the article "An Ecological Approach to Human Factors" by Hajdukiewicz and Vicente). This article surveys the application domains that EID has been applied to so far. In addition, three particular applications of EID (conventional power plants, neonatal intensive care units, and hypertext information retrieval) are described in more detail. Given the insights obtained from the research conducted to date, the contributions of the EID framework are also summarized.

2. SURVEY OF APPLICATION DOMAINS

The EID framework was originally developed in the context of process control applications (Vicente and Rasmussen 1992). However, as the rest of this section will show, more recent research has considerably expanded the scope of the EID framework to a diverse set of application domains. Table 1 provides a representative list of references on EID, organized by application domain. Several conclusions can be derived from this brief survey. Most of the research is still in the area of process control. The most thoroughly investigated test bed is the process control microworld that has been the subject of a number of experiments conducted by Vicente and colleagues; see Vicente (1996) for a review.

There is some evidence of technology transfer from academe to industry. The most ambitious application has been implemented by Toshiba in Japan – an advanced control room for a future nuclear power plant (Itoh *et al.* 1993, 1995). This implementation is particularly noteworthy because it has been constructed on a very large scale; it is a fully functional, prototype control room connected to a full-scope plant simulator.

Also notable is the work of Pejtersen (1992), who designed an innovative full-scope document retrieval system that has been made available as a commercially available product and is currently being used in several public libraries in Scandinavia. It has been recognized by one international design award and one national design award, and it has been nominated for several others. These examples of technology transfer show that the EID framework is addressing problems relevant to the needs of industry.

The applications in table 1 span a relatively broad and diverse set of domains, including physical work domains that are primarily driven by causal constraints (e.g., process control) as well as social work domains that are primarily driven by intentional constraints (e.g., public library information retrieval). This diversity shows that the EID framework is fairly generalizable in terms of its applicability.

3. THREE EID APPLICATIONS

Section 2 was a broad survey of the work conducted on the EID framework. This section gives a deeper description of how EID can be applied in practice by describing examples from three different work domains (conventional power plants, neonatal intensive care units, and hypertext information retrieval). Each example begins with a brief description of the work then summarizes the abstraction hierarchy analysis, the interface design, and the empirical evaluation.

3.1. Ecological Display Design for a Conventional Power Plant

Computer displays are used for monitoring and control activities of large power plants with hundreds or even thousands of variables. Because of the need to navigate across many displays, operators may become disoriented and experience difficulty in remaining informationally coupled to the plant state and structure. Burns (1999) has investigated how an EID display may be implemented so as to support goal-directed problem solving while avoiding the problems typically associated with interface navigation in a large-scale system.

3.1.1 Abstraction hierarchy analysis

Burns (2000) applied the EID principles to a fossil-fuel power plant simulation obtained from industry. The simulation was of intermediate fidelity, containing 402 variables. An abstraction hierarchy representation was developed for the plant using five levels of constraint:

Table 1. Representative survey of EID applications

Application domain	Sectors	Sources

- *Functional purpose*: electrical energy production
- *Abstract function*: mass and energy flows
- *General processes*: volumetric flows and heat transfers
- *Physical function*: physical connection of the components of the plant
- *Physical form*: spatial arrangement and appearance of the plant components

3.1.2 Design

Display elements were designed for the top four levels of the abstraction hierarchy. The functional purpose view displayed the status of the plant relevant to its intended purpose. The abstract function view conveyed the mass and energy transformations throughout the plant. The generalized function view displayed the various flow rates and heat transfer rates. Finally, the physical function view showed the various components involved in the work domain operations, their settings and their physical connections. Three display suites were then constructed using the display elements just described. Each display suite contained all the display elements at the various levels of the abstraction hierarchy, but these elements were integrated in three different ways with varying implications for interface navigation.

In one display, only one window was visible at a time, allowing participants to view each level of abstraction serially. As a result, participants had to integrate information across displays by physically switching from one window to another. In a second display suite, four windows were visible at a time, allowing participants to view all levels of abstraction in parallel. However,

each level was displayed on a different window, so participants had to integrate information across displays mentally. Finally, in the third display suite, information at all four levels of abstraction was displayed at the same time and in the same location by superimposing display elements on top of each other. This configuration resulted in a seemingly very cluttered arrangement (figure 1).

3.1.3 Evaluation

An experiment was conducted to evaluate these three display suites with undergraduate engineering students as participants. Each participant performed search tasks, fault detection, and diagnostic tasks with one of the three display suite conditions. Surprisingly, the results revealed that performance was best in the seemingly cluttered, superimposed display. Despite slower fault detection times, participants in this highly integrated condition exhibited more accurate fault detection, as well as faster and more accurate diagnosis results. Thus, participants were able to overcome the visual complexity of the display and obtain a superior level of performance. These results have important practical implications for how to implement EID in large industry-scale work domains.

3.2. Ecological Display Design for a Neonatal Intensive Care Unit

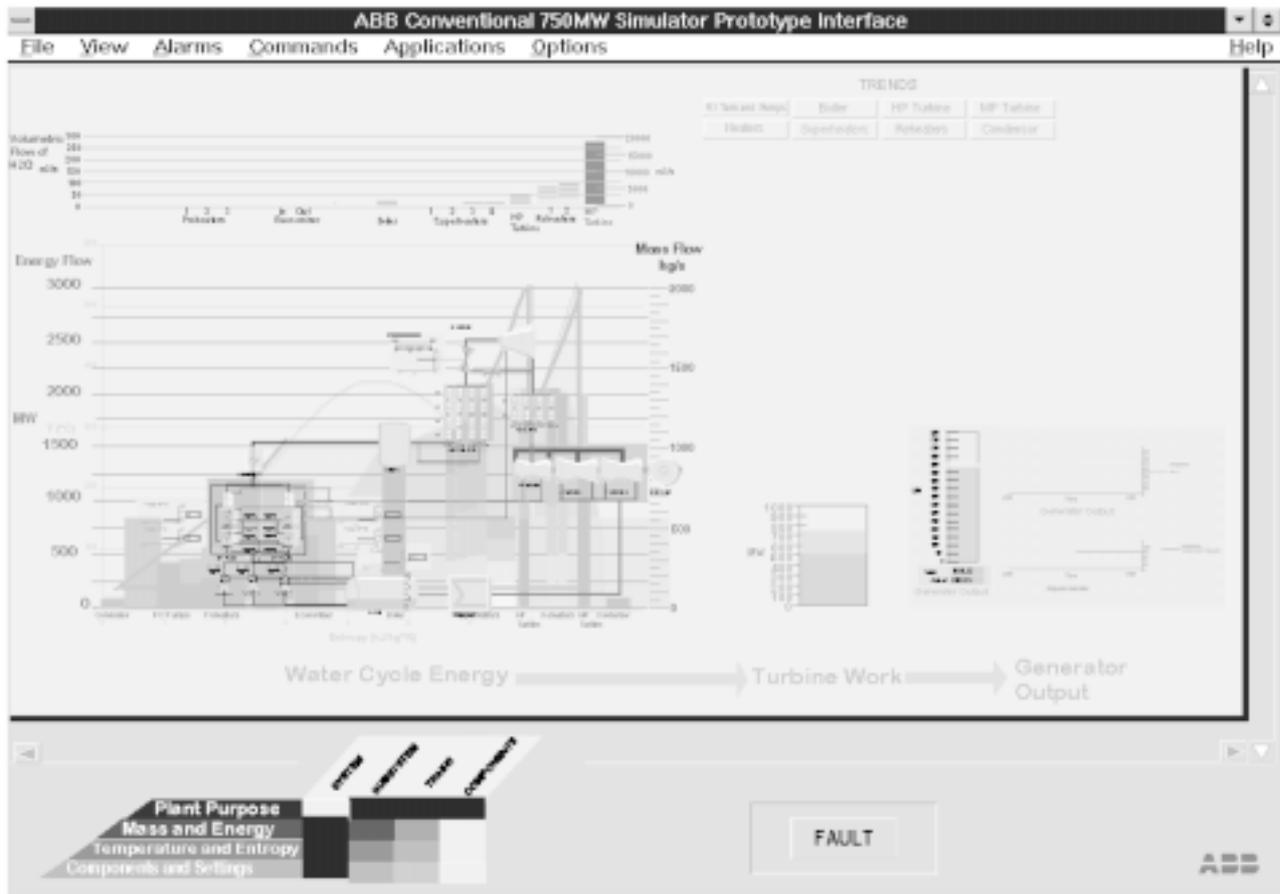
Sharp and Helmicki (1998) applied the principles of EID to the development of an interface for the representation of infant tissue oxygenation processes in a neonatal intensive care unit. The


Figure 1. The highly integrated EID display designed and evaluated by Burns (1999).

purpose of their work was to assess the applicability of EID to medicine, a new domain with properties that are different from those of industrial process control.

3.2.1 Abstraction hierarchy analysis

Their first step was to develop an abstraction hierarchy representation of the physiological processes involved in tissue oxygenation. The levels of abstraction that had been developed for process control were not as relevant for medicine. As a result, Sharp and Helmicki (1998) identified a new set of levels of abstraction by identifying the nomenclature used by experts in this application domain. New domain-specific labels (purpose, balance, processes, transport/storage/control, and physical form) were used for the completion of an abstraction hierarchy by modeling tissue oxygenation at each level of abstraction.

3.2.2 Design

The second part of the project was to map the work domain constraints onto an interface. A significant obstacle was identified at this stage. Not all the variables that were identified by the abstraction hierarchy analysis could be sensed directly. As a result, these variables could not be directly mapped on the display, as the principles of EID require. In some cases it was possible to overcome this problem by deriving the required variables analytically or heuristically from sensed data; in others the required variables simply could not be displayed. The resulting EID display is shown in figure 2.

3.2.3 Evaluation

A comparative evaluation was performed using the EID display just described and the display currently used by physicians in this work domain. The accuracy of the diagnostic capabilities of

participants at three levels of experience (attendees, medical residents, and fellows) was assessed on both interfaces. The results showed that the attendees and residents performed better using the EID display. There was no significant difference between displays for the fellows, presumably because their greater level of experience allowed them to overcome the deficiencies of the existing display.

Sharp and Helmickis (1998) research is important because it shows that several significant obstacles may be encountered in applying the EID framework to new application domains. In this particular case, the obstacles were overcome by identifying a new set of domain-specific levels of abstraction and by analytically and heuristically deriving variables that could not be sensed directly. Despite the fact that some variables identified by the abstraction hierarchy analysis could not be displayed, the EID display produced a significant improvement in performance for the two less experienced groups of participants.

3.3. Ecological Interface Design for Hypertext Information Retrieval

Xu *et al*. (2000) applied EID to the domain of hypertext information retrieval. Like Sharp and Helmicki (1998), they too were interested in determining whether the EID framework could be applied to another domain besides process control. The domain chosen by Xu *et al*. was HyperErgo, a hypertext database consisting of ergonomic guidelines for computer workstation design. This domain differs substantially from process control in that it does not involve control of a dynamic system governed by physical laws. Instead it involves searching through a static database of information. Thus, the work of Xu *et al*. represents a strong challenge to the generalizability of EID.

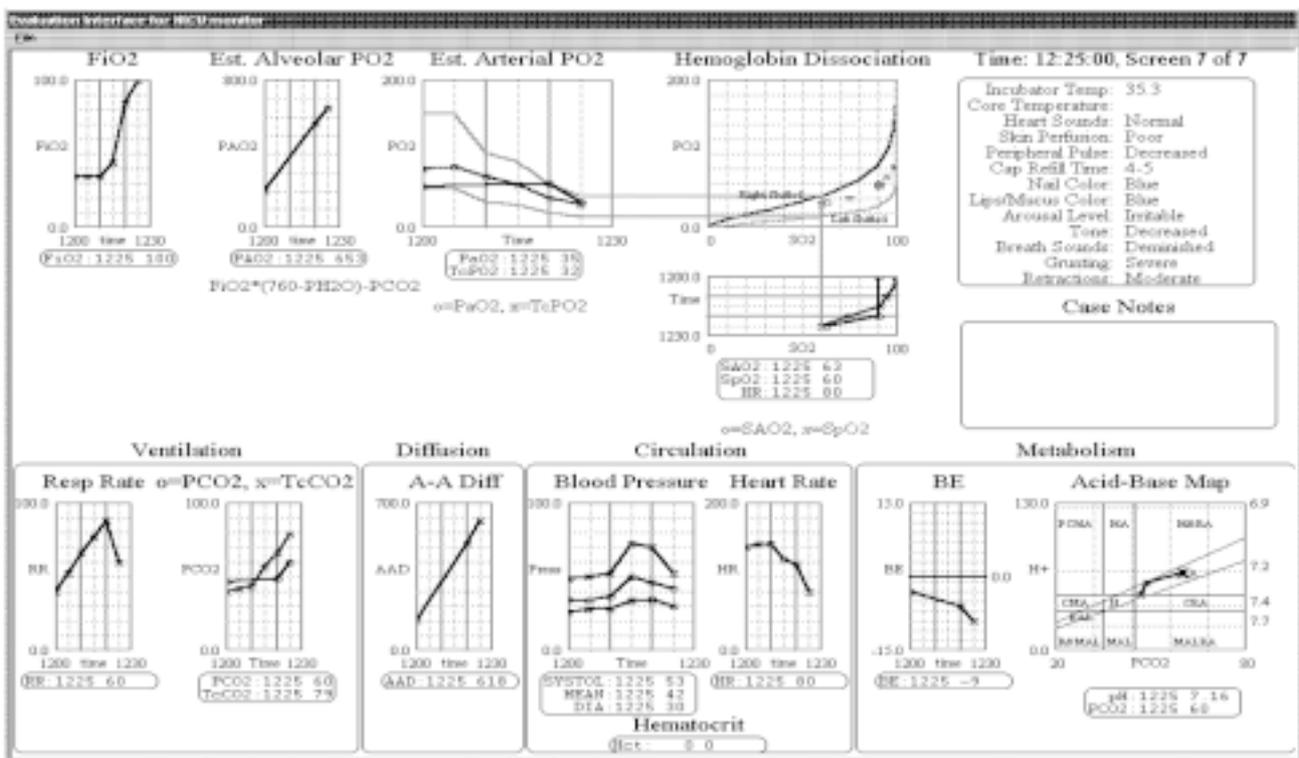
The existing interface for HyperErgo served as the baseline


Figure 2. The EID display designed and evaluated by Sharp and Helmicki (1998).

control condition. That interface organized nodes in the hypertext database hierarchically according to a part-whole relationship that Xu *et al.* called a classification hierarchy. This type of relation is different from the means-ends relation defined by the EID-advocated abstraction hierarchy representation. Three levels of part-whole resolution were identified in this structure. Participants navigated in the structure by clicking on certain icons in the hypertext interface to search for information.

3.3.1 Abstraction hierarchy analysis

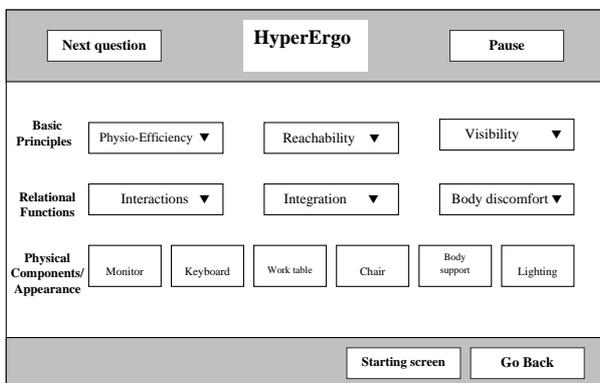
Xu *et al.* (2000) conducted an abstraction hierarchy analysis of the HyperErgo database. They identified five levels of abstraction with the following content:

- *Functional purpose*: to assure productivity, safety, health, and comfort
- *Abstract function*: first principles based on criteria of physiological efficiency, visibility, and reachability
- *Generalized function*: physical component interaction, physical component-body zone Interaction, and physical component-body area interaction
- *Physical function*: the components of the computer workstation
- *Physical form*: the appearance and spatial connectivity of those components

3.3.2 Design

An interface was then designed to convey information at four levels of abstraction (the functional purpose was deliberately omitted in the design). Note that the nodes in the database remained unchanged. The only difference was that they were connected according to the means-ends relations defined by the abstraction hierarchy analysis. In addition, the form in which information was presented was also kept constant. Figure 3 shows an example display from the redesigned interface for HyperErgo.

3.3.3 Evaluation

An evaluation was conducted to compare the classification hierarchy and abstraction hierarchy interfaces for HyperErgo. University students performed three types of search tasks (simple, complex, and problem solving) on both interfaces. A number of different performance measures were collected (search time, search accuracy, subjective ratings of preference, and disorientation measures). The results revealed no statistically


significant difference on the simple search task. However, as the complexity of the search task increased, there was a corresponding increase in the performance advantage of the EID interface (based on means-ends relations) over the classification hierarchy interface. For the complex and problem-solving tasks, a clear and statistically significant demarcation could be seen between conditions in favor of the EID interface. These empirical results show that the benefits of the EID framework generalize to domains whose characteristics are very different from those of process control or medicine.

4. CONTRIBUTIONS OF EID

Empirical evidence up to now indicates that an interface using EID can consistently outperform interfaces based on more traditional approaches. Perhaps just as importantly, this result has been obtained across a relatively diverse set of application domains, from physical work to social work. Thus, EID appears to represent a step forward in research on human-computer interface design for complex systems.

Despite these positive achievements, there are still comparatively few applications of EID to commercial products in industry. In part, this may be due to the fact that the EID framework is a relatively new approach to interface design. Regardless of the reason, much applied research still needs to be conducted to determine whether the benefits obtained in the research laboratory can also be obtained in operational settings. The empirical evidence gathered so far suggests this is a fruitful path to follow.

Electromyography: Fundamentals

G. S. Rash[†] and P. M. Quesada[‡]

[†]BIO/MED Research & Consulting, Louisville, KY 40241, USA

[‡]University of Louisville Speed and Scientific School, Louisville, KY 40292, USA

1. INTRODUCTION

The study of muscle function through analysis of the electrical signals emanated during muscular contractions is termed electromyography (EMG). EMG is often misused and abused by many clinicians and researchers. Even experienced electromyographers fail to provide enough information and detail on the protocols, recording equipment and procedures used to allow other researchers consistently to replicate their studies. Hopefully, this chapter will clarify some of these problems and give the reader a basis for being able to conduct electromyography studies as part of their on-going research and practice.

2. WHAT ARE WE MEASURING?

Electromyography is measuring the electrical signal associated with the activation of the muscle. This may be voluntary or involuntary muscle contraction. The EMG activity of voluntary muscle contractions is related to tension. The functional unit of the muscle contraction is a motor unit, which is comprised of a single alpha motor neuron and all the fibers it enervates. This muscle fiber contracts when the action potentials (impulse) of the motor nerve which supplies it reaches a depolarization threshold. The depolarization generates an electromagnetic field and the potential is measured as a voltage. The depolarization, which spreads along the membrane of the muscle, is a muscle action potential. The motor unit action potential is the spatio- and temporal summation of the individual muscle action potentials for all the fibers of a single motor unit. Therefore, the EMG signal is the algebraic summation of the motor unit action potentials within the pick-up area of the electrode being used. The pick-up area of an electrode will almost always include more than one motor unit because muscle fibers of different motor units are intermingled throughout the entire muscle. Any portion of the muscle may contain fibers belonging to as many as 20–50 motor units.

2.1. Motor Unit

A single motor unit can have three to 2000 muscle fibers. Muscles controlling fine movements have smaller numbers of muscle fibers per motor units (usually less than 10 fibers per motor unit) than muscles controlling large gross movements (100–1000 fibers per motor unit). There is a hierarchy arrangement during a muscle contraction as motor units with fewer muscle fibers are typically recruited first, followed by the motor units with larger muscle fibers. The number of motor units per muscle is variable throughout the body.

2.2. Types of EMG

For the purpose of this chapter there are two main types of electromyography: clinical (sometimes called diagnostic EMG) and kinesiological. Diagnostic EMG, typically done by physiatrists and neurologists, are studies of the characteristics of the motor unit action potential for duration and amplitude. These are typically done to help diagnostic neuromuscular pathology. They also evaluate the spontaneous discharges of relaxed muscles and are able to isolate single motor unit activity. Kinesiological EMG is the type most found in the literature regarding movement analysis. This type of EMG studies the relationship of muscular function to movement of the body segments and evaluates timing of muscle activity with regard to the movements. Additionally, many of these studies attempt to examine the strength and force production of the muscles themselves.

3. RELATIONSHIP OF EMG TO BIOMECHANICAL FACTORS

There is a relationship of EMG to many biomechanical variables. With respect to isometric contractions, there is a positive relationship in the increase of tension within the muscle with regards to the amplitude of the EMG signal recorded. There is a lag time, however, as the EMG amplitude does not directly match the build-up of isometric tension. One must be careful when trying to estimate force production from the EMG signal, as there is questionable validity of the relationship of force to amplitude when many muscles are crossing the same joint, or when muscles cross multiple joints. When looking at muscle activity, with regards to concentric and eccentric contractions, one finds that eccentric contractions produce less muscle activity than concentric contraction when working against equal force. As the muscle fatigues, one sees a decreased tension despite constant or even larger amplitude of the muscle activity. There is a loss of the high-frequency component of the signal as one fatigues, which can be seen by a decrease in the median frequency of the muscle signal. During movement, there tends to be a relationship with EMG and velocity of the movement. There is an inverse relationship of strength production with concentric contractions and the speed of movement, while there is a positive relationship of strength production with eccentric contractions and the speed of movement. This means one can handle a larger load with eccentric contractions at higher speeds. For example, if a weight was very large and you lowered it to the ground in a fast but controlled manner, one handled a large weight at a high speed via eccentric contractions. One could not raise the weight (concentric contraction) at the speed it could be lowered. The forced production by the fibers are not necessarily any greater, but you were able to handle a larger amount of weight and the EMG activity of the muscles handling that weight would be smaller. Thus, one has an inverse relationship for concentric contractions and positive relationship for eccentric contractions with respect to speed of movement.

4. CHOOSING AN ELECTRODE AND AMPLIFIER

With regards to recording the EMG signal, the amplitude of the motor unit action potential depends on many factors which include: diameter of the muscle fiber, distance between active muscle fiber and the detection site (adipose tissue thickness), and filtering properties of the electrodes themselves. The objective is to obtain a signal free of noise (i.e. movement artifact, 60 Hz artifact, etc.). Therefore, the electrode type and amplifier characteristics play a crucial role in obtaining a noise-free signal.

4.1. Electrode

For kinesiological EMG there are two main types of electrodes: surface and fine-wire. The surface electrodes are also divided into two groups. The first is active electrodes, which have built-in amplifiers at the electrode site to improve the impedance (no gel is required for these and they decrease movement artifacts and increase the signal-to-noise ratio). The other is a passive electrode, which detects the EMG signal without a built-in amplifier, making it important to reduce all possible skin resistance as much as possible (requires conducting gels and extensive skin preparation). With passive electrodes, signal-to-noise ratio decreases and many movement artifacts are amplified along with the actual signal once amplification occurs. The advantages of surface electrodes are that there is minimal pain with application, they are more reproducible, are easy to apply and are very good for movement applications. The disadvantages of surface electrodes are that they have a large pick-up area and, therefore, have more potential for cross talk from adjacent muscles. Additionally, these electrodes can only be used for surface muscles.

Fine-wire electrodes require a needle for insertion into the belly of the muscle. The advantages of fine-wire electrodes are an increased band width, a more specific pick-up area, an ability to test deep muscles, isolation of specific muscle parts of large muscles, and an ability to test small muscles that would be impossible to detect with a surface electrode due to cross-talk. The disadvantages are that the needle insertion causes discomfort, the uncomfortableness can increase the tightness or spasticity in the muscles, cramping sometimes occurs, the electrodes are less repeatable as it is very difficult to place the needle/fine-wires in the same area of the muscle each time. One should stimulate the fine-wires to be able to determine their location, which increased the uncomfortableness of using this type of electrode. For certain muscles, fine-wires are the only possibility for obtaining their information.

Differences between the recording of surface and fine-wire electrodes, in part, are related to the differences in the bandwidths. Fine-wire electrodes have a higher frequency and can pick-up single motor unit activity as the fine-wire electrode band width ranges from ~2 to 1000 Hz. The surface electrode band width ranges from ~10 to 600 Hz.

4.2. Amplifier

Whether using surface or fine-wire electrodes, there are some electrode configurations that can also aide in decreasing unwanted noise. A monopolar arrangement is the easiest as it is a single electrode and a ground. However, this arrangement picks up more unwanted signals than any of the other potential configurations. Bipolar arrangements are widely used in movement analysis. In this arrangement, there are two active electrodes and a ground. The process is to look at what is common with the two active electrodes and to determine that this is noise and throw it away, keeping what is different in the two electrodes as the signal of interest. This is termed a differentially amplified system and is less prone to interference from adjacent and deeper muscles. A third arrangement is that of a double differentiated system. This is a system that has three active electrodes and one ground, therefore, possessing the ability to have two pairs of bipolar signals which are then again differentially amplified. This gives a smaller pick-up area, therefore, even less noise than the bipolar electrode

by itself. These electrode arrangements are unique to the amplified system purchased and much thought should be given when purchasing a system so that at minimum a bipolar system is acquired.

There are many other amplifier characteristics that should be noted. The first of which is the signal-to-noise ratio. This is the ratio of the wanted signal to the unwanted signal and is a measure of the quality of the amplified signal. The higher the ratio, the greater the noise reduction. Electrodes with on-site pre-amps (miniaturized and at the site of the electrode) are some of the best at providing a very large signal-to-noise ratio. The gain of the amplifier is also important. This is the amount of amplification applied to the signal and it should be sufficient enough to have output amplitude at 1.0 V. Another important characteristic of the amplifier is the bandwidth. This is simply the range of the collectable frequencies of the amplifier, and one wants this high enough to reject the low frequency movement artifacts and low enough to attenuate the signal as little as feasible. This means in general, one should be collecting in a range from 0 to 600 Hz for surface electrodes and 0 to 1000 Hz for fine-wire electrodes. Using the Nyquest Theorem, this means that one must sample at a minimum of 1200 Hz for surface electrodes and 2000 Hz for fine-wire electrodes to ensure capturing the entire signal. Once the signals have been recorded, then one could use a 10–15 Hz high-pass filter to eliminate the movement artifacts (some prefer to use an analog filter on the front end, but we prefer to filter movement artifacts after collection). One must make sure all applied filters have zero phase shifts. The measure of the ability of the differential amplifier to eliminate the common mode signal is termed the common mode rejection ratio. The higher the common mode rejection ratio, the better the cancellation of common signals (noise). A value of 10 000 (80 dB) is desirable. The input and impedance of the system should be $> 10^{12}$ ohms and have a low input bias current of the order of 50 pica-amps or less. A high input impedance allows for as much of the signal available for amplification to be amplified. Any signal input below the input bias current is not amplified. With these characteristics in mind, one should be able to purchase an amplifier that is sufficient for collecting electromyography signals.

There is also the potential for error introduced by the analog to digital board chosen. Most boards are only 10–12 bit boards and if the system does not allow full use of the collected range, one introduces error. This means if your collection is set-up for ± 10 V and you are collecting EMG, which is in the ± 1 V range after amplification, you are not optimizing your system and you will have quantization and sampling error. Therefore, one must be sure that the software and hardware arrangement purchased allows for optimization of the collected voltage range within the A-D range.

5. PLACING THE ELECTRODE

The electromyographer must have a very good understanding of the anatomy of the human body as electrode location and placement is very important. The first task is to clean the skin over the site where the electrode will be placed in order to reduce any skin resistance. This simple task can reduce the resistance of the skin by 200%. For many clinical applications of EMG, the belly of the muscle is used as a site for placing the electrodes. However, to assure repeatability of finding the specific site the

electrode was placed, the use of bony landmarks as a reference is a must. There are numerous books and publications describing the exact locations of placement of the electrodes for this purpose. Another widely accepted method of placing the electrodes or surface electrodes is to use the motor point. As with placing the electrodes over the belly of the muscle, there are numerous publications that give the general motor point locations as a starting location, then you can find the exact position by using the motor point finder or ohmmeter. Another specific issue that must be addressed is the interelectrode distance. Many electrodes have a constant interelectrode distance, but several have a variable interelectrode distance. This creates a potential problem in that one must be sure that this distance is kept constant throughout all subjects and trials to assure that the electrodes are over the same muscle fibers.

6. REDUCING NOISE

There are many sources of noise (any unwanted signal collected along side the wanted signal) and some of these sources are: electrostatic field (skin), electromagnetic fields (power lines), motion artifact due to loose electrodes at the skin interface or loose leads on the wires, involuntary reflex activity (clonus), and any other electrical devise that might be in the room when the studies are occurring. The majority of these artifacts can be removed from the system by a few simple means. Proper cleaning of the skin is one such measure. If site pre-amplified electrodes are not used, this becomes a more crucial task. Using bipolar differentially amplified or double differentially amplified systems also help dramatically in the removal of artifacts from the system. Attaching all loose electrode leads and making sure that there is some slack in these leads is important as well. If your system has the possibility to use the battery supply as opposed to line feed for the power source, this is a great advantage and should be utilized. Before beginning the collection of data, one should check that the electrodes is making proper contact and that there is no tension on the wires and that all of the wires are plugged into all connectors sufficiently. Once the electrodes are in position the subject should have manual muscle tests applied for the specific muscles being tested to make sure that the electrodes are picking up muscle activity appropriately. If certain electrodes seem to be working inappropriately, one can try switching the leads if possible with their system, or just switching electrode channels to see if this particular electrode works in another channel. If the signal is still bad after switching channels, one can switch electrodes to see if the electrode itself is malfunctioning. One must remember that there is a degradation of the signal as the amount of adipose tissue over the muscle being examined increases. Therefore, it may be difficult to pick-up any usable signal when dealing with obese individuals when using surface electrodes.

7. THE SIGNAL
7.1. Filtering the Signal

One disadvantage of using the newer computerized collection systems is that many do not afford one the ability to see a raw EMG signal in real time (like an oscilloscope). It is imperative that one somehow view the raw signal prior to any processing (except an analog anti-aliasing filter) as it is often difficult to differentiate between signal and noise in a raw EMG signal and usually impossible to differentiate if any processing has been done

to the EMG signal. Once the investigator looks at the raw signal, they need to determine if there is any filtering which needs to be done. The novice electromyographer may have trouble determining problems in the raw EMG signal. However, there are several items that can be looked at to help in this determination. Wavering base line is seen many times with low frequency movement artifacts. Large spikes can be indicative of abrupt movements of the electrode. Other things to look for are common signals across all channels and an underlying 60 Hz signal superimposed on the signal. If the signal does not look clean, the investigator may want to filter the data (some investigators say to always filter the data). There are three main types of filters applied to EMG data: high-pass, low-pass and notch filters. There are many types of filters that can be applied such as: Butterworth, Chebyshev, etc. These investigator's routinely use a fourth-order Butterworth high-pass digital filter with a 10–15 Hz cut-off, depending on the activity being analyzed (10 Hz for walking and 15 Hz for rapid movements) to remove movement artifacts. On the other end of the spectrum, we use an analog low-pass filter with a cut-off of 600 Hz for surface EMG and 1,000 Hz for fine-wire EMG as an anti-aliasing filter. If it was determined that 60 Hz signals were superimpose within the signals, we would use a digital notch filter to remove the signals within a 55–65 Hz range.

7.2. Processing the Signal

Now that we have a clean EMG signal, we can begin to look at the signal to gain information about the muscles. The primary information to be gained is on and off information. In most movement analysis situations, only the raw EMG is used. No processing other than that which is used for cleaning up the raw signal (high- and low-pass filters) is used. There are many common forms of processing that are done with EMG signals. The most common are: half-wave rectification (deletion of all negative aspects of the signal), full-wave rectification (absolute value of the entire signal), linear envelope (low-pass filtering of the full-wave rectified signal), root-mean-square (basically square the signal, take the mean of a timed determinant window ~100–200 ms, then take the square root), integrated EMG (area under the rectified curve can be determined for the entire activity or for preset time or amplitude values), and frequency analysis (typically determined via fast Fourier analysis and looking at the power density spectrum). Depending on your application, each of these processing techniques may have merit but each have disadvantages as well, since with any processing done to the data, information is lost.

8. NORMALIZING THE SIGNAL
8.1. Time Domain

For comparisons of EMG data from task to task or person to person, data needs to be presented in a common format. Thus, several means of normalization of the signal have been developed for both the time and amplitude domains. Probably the two most widely used time-base normalization techniques are to either normalize to a task/cycle or to phases within the task/cycle. As an example lets assume we want to look at the EMG of the back muscles with an individual who continually lifts items from the floor and places it in a bin. We can define a cycle as being from the initial movement of the object off the floor until the initial

movement of the object off the floor for the successive lift. One would then just simply divide the time-base by the total amount of time it took to perform the task and then all movements would be with respect to the percent of the cycle. This works well for many cyclic tasks, but has disadvantages if the task contains more than one phase. Dividing up the time-base to the percent of a phase works well for task with multiple phases. Using the same lifting task, lets now define the lifting phase as being from the point that the object begins to move from the floor until the subject obtains a fully erect standing position. The second phase would then be from the point at which the subject reached the standing position until the item is placed in the bin and a third phase would begin at the point when the object was placed in the bin until the subject is back in position to lift another object. Each one of these phases is handled as a separate event. Thus, the time it took to lift from the floor to the standing position would be used as the divisor to make a percent phase for the lifting phase, the time it took from the point when the body reached an erect standing position until the item was in the bin would be used as the divisor for the second phase, and so on for the third phase. This type of time-based standardization is very useful when the task has clear phases that can be determined. For the sake of this example, lets say that the maximum EMG activity occurred just prior to setting the item down in the bin. It is much more meaningful to be able to say that the maximum amount of the EMG was found at 95% of the second phase than to say the maximum EMG was found at 55% of the task. From this point you would have to go back and figure out what movement was going on at 55% of the task. Additionally, the intra and inter subject variability of setting the object in the bin at the same point in a multiphase cycle is typically large. For this reason, our lab prefers to use percents of phases when possible.

8.2. Amplitude Domain

Many times the amplitude of the signal is normalized as well. Probably the most widely used is to standardize to the maximum voluntary isometric contraction (MVIC) for the specific muscle being used. Based upon published references for manual muscle testing, the examiner then applies a force to the body part in sufficient magnitude that the subject is unable to maintain a static position while exerting against the examiner with a maximum muscle contraction. It is debatable if one can really ever obtain a true MVIC. Therefore, several other techniques have been devised. One of those is to use the maximum level of the signal across the entire task. In the lifting task previously described this would mean to take the maximum EMG level from each specific muscle during the entire task then normalize to this value. Many people prefer to use several peaks (4–5) and average these as the maximum so as to avoid the potential of using an erroneous high-spike as the maximum value. Another means of normalization is to use the mean level of the signal across the entire task. However, this is much less sensitive to any rapid peaks that were obtained during the task and would heavily skew the data if the majority of the signal contained times when the muscle was not active. A problem that exists when using the maximum or mean level across the entire task is that the EMG signal will vary based upon the velocity of the joints during the contractions. Therefore, unless one standardizes the velocity of the task, this method may not allow for comparisons across tasks. Another technique very

similar to the MVIC is to use a know level of force (e.g. divide by the amplitude of the EMG when lifting 20 lb at the specific velocity that the task will be performed). Another variation of this is to use the amplitude of the EMG signal when exerting a known force against an immovable object, therefore, eliminating velocity from the equation. All of these methods have positive and negative attributes and they are means of trying to compare amplitudes between muscles and individuals. Additionally, if the subjects being examined have any pathological conditions that involve the muscles you are testing (e.g. they have low back pain and you are measuring lifting), it will be virtually impossible to get a true MVIC and questionable whether the other normalization techniques are of any value as well. Regardless of the normalization technique used, whether it is time-based and/or amplitude based, one must remember that absolute information will be lost.

9. INTERPRETING THE SIGNAL

Now that we have cleaned up the data and completed any normalization that we may want to do, it is time to look at the signal and try to interpret its meaning. One must understand that there is a large variability of the EMG signal itself. Whether this is task-to-task variability within the same person or person-to-person variability within the same task, many combinations of muscle activity can produce the same movements because of the redundancy present in the neuromuscular system. EMG can be variable from task to task because of this normal redundancy, velocity or cadence changes, or slightly different movement patterns even though under observation they look the same. A normal range of EMG phasing will exist for a task but one must be very cautious of trying to define discreet points in the tasks where these patterns begin and end. This must be kept in mind when interpreting the EMG signals. Other factors enter into the equation with interpreting the EMG of individuals with pathological conditions that influence the task-to-task variability. The changes in velocity or cadence, the onset of fatigue, and the presence of pain can all effect the EMG patterns. Cross talk also makes interpretation of the signal difficult. Cross talk is interference of the EMG signals from adjacent muscles or deeper muscles that are within the pick-up area of the electrode. There are no fixed solutions available at this point and the size of the patient and size of the electrode lead does play a major role in the ability to decrease or increase cross talk. For example, if your system has electrodes with fixed active electrode distances which are large and you are working with a pediatric population you can be assured that your data will have large amounts of muscle information from adjacent and underlying muscles that is not wanted with your data. Many examiners utilize fine-wire electrodes in order to try to remedy this problem.

Now that we spent much time filtering and normalizing our data, it is time to discuss what the EMG signal can actually tell us. The muscle on and off timing patterns and relative increases and decreases in muscle activity are the two main parameters gained from the electromyography data. EMG data cannot tell us how strong the muscle is, if one muscle is stronger than another muscle, if the contraction is a concentric or eccentric contraction, or if the activity is under voluntary control by the individual. The strength of the muscle or determining one muscle to be stronger than another is one of the main areas that researchers

want to use EMG data for. The normalizing to the MVIC, the average, or max during the cycle are all attempts to allow us to compare from muscle to muscle within the same person and from muscle to muscle between individuals. This is routinely done but one must be cautious of the results due to the problems inherent with the collection techniques and variability among muscles, individuals, and tasks. Besides using EMG for determining the EMG patterns (times of activation and times of rest) many researchers use electromyography for evaluating the changes in the signals as the muscles fatigue. All of these are valuable uses of electromyography in occupational biomechanics.

With this overview of electromyography fundamentals in movement analysis, the reader should have a good idea of what the general process entails. By no means does this chapter give the investigator all the knowledge needed with becoming a proficient electromyographer. However, it gives a good overview and when augmented with other readings and material the reader should be able to utilize electromyography as a tool in their research and practice.

10. SUMMARY

10.1. Surface EMG

- Skin preparation
- Alcohol removal of dirt, oil, and dead skin.
- Shave excess hair if necessary. (Under ideal conditions this should always be done. However, it is not feasible in many cases.)
- If the skin is dry, some electrode gel rubbed into the skin can help.
- If the person is going to be sweating, spray an antiperspirant on the skin after cleaning with alcohol.
- Placement of electrodes
- There are specific references for different ways to measure for placement (Norris 1963, Johnson 1988, Goldgood 1984).
- General guidelines for large muscle groups:
- Best if over the largest mass of the muscle and align electrodes with muscle fibers.
- Use motor point and motor point finder to locate (general location charts are available).
- Cross talk
- Not a real problem with large muscle groups.
- Can sometimes be avoided my adjusting the electrode size, interelectrode distance (if an option on your brand of electrode), or by use of fine-wires.
- Application
- Skin placement.
- Avoid movement of electrodes by using straps or tape to firmly secure electrode in place.
- Avoid bending of leads, place leads pointing in the direction that you want the wire to continue in. (e.g. for electrodes placed on an extremity, have the lead pointing towards the proximal end of the extremity so that the wire will not have to be bent in order to go in the proximal direction).
- Avoid any stress on the wires by making sure that the wires are loose underneath the tape or wrap that is holding them in place. Be sure to check when the wires cross the joint that once the joint is fully extended the wires are not drawn taunt.
- Avoid placing electrodes over scars.
- Testing
- Do manual muscle tests to assure that you are getting a signal and that you are over the intended muscle.

- Do trial session to check signal and to get subject used to the setup and how instrumented.

10.2. Fine Wire EMG

- Indications
- For small muscles.
- For deep muscles not accessible by surface electrodes.
- To isolate specific muscles from a muscle group or adjacent muscles.
- Preparation
- Skin same as with surface electrodes.
- Electrode: fine-wires made as described by Basmajian and Stecko (1961) (wires typically connect to either the site pre-amplified electrode or fine-wire connectors and some type of ground is used).
- Can use topical agents: ethyl chloride, floromethane or EMLA patch or cream if desired (EMLA is a controlled substance in many countries).
- Assistant: needed to help in preparation, stabilize subject's extremity, or distract if needed. Having the subject blow out forcefully as the needle is inserted works well.
- It is usually easier to have the person in a laying position for insertion of the fine-wire electrodes.
- Inserter: needless to say, washing of hands and universal precautions are in order.
- Placement
- Use of a cross sectional anatomy book or EMG guide to locate insertion point and the direction of application is advised. We prefer Aldo Perotto, *Anatomical Guide for Electromyography: The limbs and Trunk*, 3rd ed. (Springfield: Charles C. Thomas).
- Can check placement of the fine-wires with electrical stimulation or my manual muscle testing if adjacent muscles would not be activated by the same movement needed for testing the selected muscle.
- Can use fine sandpaper on the wire ends to improve the quality of signal. (Only the end which is to be attached to the electrode, as the other end must be sterile.)
- After securing the wire to the electrode, tape the wire in place to the skin with small loop of wire to allow for movement.
- It is a good idea to recheck the placement of the wires via electrical stimulation or manual muscle testing if questions arise during the collection process.
- Removal of the wire
- To remove the wires, gently pull the wires out and check the ends of the wire to assure that no wire broke off inside the body.
- Special *Sharps* canisters are required for disposal of the needles. For disposal of the wire and gloves, you should check with your infection control or OSHA office to determine what needs to be done at your facility. At our facility, unless the gloves and wires have dripping blood, which could easily get on some one, they can be disposed of in a standard trash can. If the blood could drip off, therefore being a biohazard, then a biohazard container must be used.
- Processing of the fine wire electrodes — easiest means of obtaining fine-wire electrodes is directly from a vendor. We have used Nicolet Instrument Corporation (tel.: + 00 1 608 271 3333) for purchasing fine-wire electrodes. These

electrodes come in packs of 10 (using 27-gauge _ 33-mm needles) and can come in single or paired-hooked wires. One disadvantage to purchasing these needles already prepared is the limited number of size choices of needles. For example, in many individuals these needles are not long enough to reach the deep muscle being studied nor are the wires long enough once inserted to reach the electrode. In this case you can make your own electrodes as described by Basmajian and Stecko (1961) and then having them sterilized at your local hospital facility.

10.3. Data Collection for Surface and Fine Wire Electrodes

- It is preferred to do no processing on the original data during collection (except an analog anti-aliasing filter) as it is difficult or impossible to know if noise has corrupted your data.
- Collect surface EMG at a minimum of 1200 Hz.
- Collect fine-wire EMG at a minimum of 2000 Hz.
- A high-pass filter with a cut-off of 10–15 Hz works well for removing movement artifact.
- A front-end analog low-pass filter at 600 Hz for surface EMG and 1200 Hz for fine-wire EMG works well as an anti-aliasing filter.
- It is common to normalize the time-base to either a percent of the task involved or to percents of individual phases within the overall task.
- There are several means of normalizing the amplitude of the signal:
  - Percent MVIC.
  - Maximum level of signal across the task.
  - Mean level of signal across the task.
  - A known level of force.
  - Common types of processing are:
  - Half-wave rectification.
  - Full-wave rectification.
  - Linear envelope (also known as mean absolute value or mean rectified value).
  - Integrated EMG.
  - Frequency content analysis.

10.4. Additional Comments

When using EMG for research purposes:
- Care should be taken to use the appropriate units when reporting EMG data.

- When referring to the amplifier gain, the units should be in a ratio or dB.
- The input impedance should be expressed in ohms.
- The common mode rejection ratio should be as a ratio or in dB.
- When referring to filter bandwidths cut-off, the units should be in Hz.
- EMG, when a raw, average or rectified signal, should be referred to in millivolts.
- If the EMG has been integrated, then it should be expressed in terms of millivolt seconds with the specific period of analysis. If the integrated EMG was time reset or voltage reset, then the specific time or voltage should be indicated. Otherwise, individuals would not be able to reproduce the study that you have conducted.

Electromyography: Methods and Techniques

H. Strasser

Ergonomics Division/University of Siegen, Paul-Bonatz-Str. 9–11, 57068 Siegen, Germany

1. INTRODUCTION

Electromyography means the graphic representation of electric potential changes in the musculature (*myo* = muscle), i.e. biopotentials which can be picked up on the surface of the skin over a muscle, most favorably in a bipolar electrode configuration. These biopotentials can, in general, be interpreted as the spatial and timely summation of action potentials (e.g. Zipp 1982, Strasser *et al.* 1992). A burst of positive and negative peaks in the electromyogram (EMG) includes information in the frequency range between just a few Hz and ~1.5 kHz. However, spectrum analysis of raw EMG shows that the main energy is in an area under ~70 Hz. For details, see Kumar and Mital (1996). Fatigue of a muscle does lead to an increase of the lower frequencies and to a decrease of the higher frequencies in the spectrum. Changes in the frequency domain of the electromyogram are, however, not pronounced enough to reliably correlate them with definable degrees of fatigue of a muscle. Therefore, for occupational health and ergonomics purposes, usually amplitude and not frequency measures of the bioelectric activities are of interest. A fundamental understanding of the electromyographic activity patterns is provided by the work of Laurig (1970) or Tichauer (1978).

2. ELECTROMYOGRAPHIC ACTIVITY (EA) AS AN AMPLITUDE MEASURE

EA as the envelope of the rectified and low-pass filtered raw EMG (Figure 1) correlates with the exerted muscle force under static conditions.

Fatigue leads to an increase in excess of the corresponding characteristic line of the EA force course. EA can be used as a parameter for the "physiological cost" of manual work, i.e. for the quantification of the muscle activation which the human organism must exert to carry out a task under given working conditions. The "physiological cost" resulting from more or less favorably designed working tools which are operated by hand or also from more or less favorable manipulative work during motion-technical work design varies distinctly (Strasser and Ernst 1992, Strasser and Müller 1999).

3. STANDARDIZATION AND SPLITTING-UP OF EA TIME SERIES ASSOCIATED WITH REPETITIVE MANUAL MOVEMENTS INTO STATIC AND DYNAMIC COMPONENTS OF MUSCLE STRAIN

A careful processing of the raw EMG and calculation of standardized (normalized) electromyographic activity (sEA) is necessary for the evaluation of electromyographic time series (see tracings in the lower left part of Figure 2). To correlate EA time series with repetitive movements, smoothing procedures are first required. This can be done using computer software by taking the sliding average of actual digitalized values and immediately preceding and succeeding values. A sampling rate of, e.g., 16.66 Hz (1000 values/min in the analog–digital converter) suffices. Considerably more interpretable information than in an arithmetic mean can be found in the maxima and minima of EA time series, which then become much clearer and are the correlate of cyclical activation of a muscle. Minima represent the activity in the relaxation phase; maxima represent the contraction of a muscle. The mean difference between maxima and minima can therefore be attributed to the movements. It represents the dynamic part of the muscle strain. The mean minima are associated with the quasi-static base activation. To avoid artifacts, the extreme values should be determined by first averaging over a single cycle and then averaging over several cycles; this results in a physiological representation of repetitive movements. For example, if the extremes are determined from a range of 5%, then the thus calculated maxima and minima can be interpreted as the 95th and 5th percentiles (Hagberg and Sundelin 1986). An averaging over a longer period results in reliable extreme values. For the electromyographic evaluation of static work the above-described procedures of splitting-up EA into static and dynamic components, of course, are not to be applied.

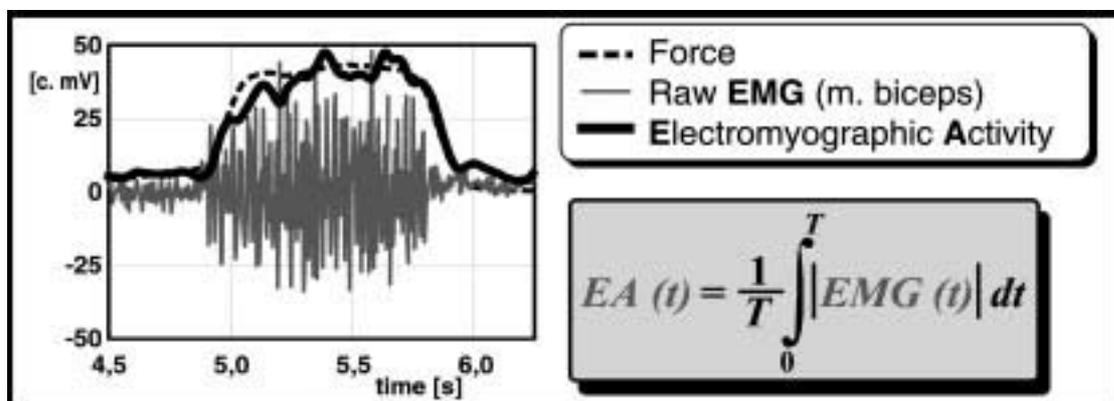
EA values result as an amplitude measure from many uncontrollable influences (varying distances between the two active electrodes, the kind of electrode gel and the time needed


Figure 1. Burst of myoelectric signals (raw electromyogram) associated with the activation of the biceps, exerted force and electromyographic activity EA(t).

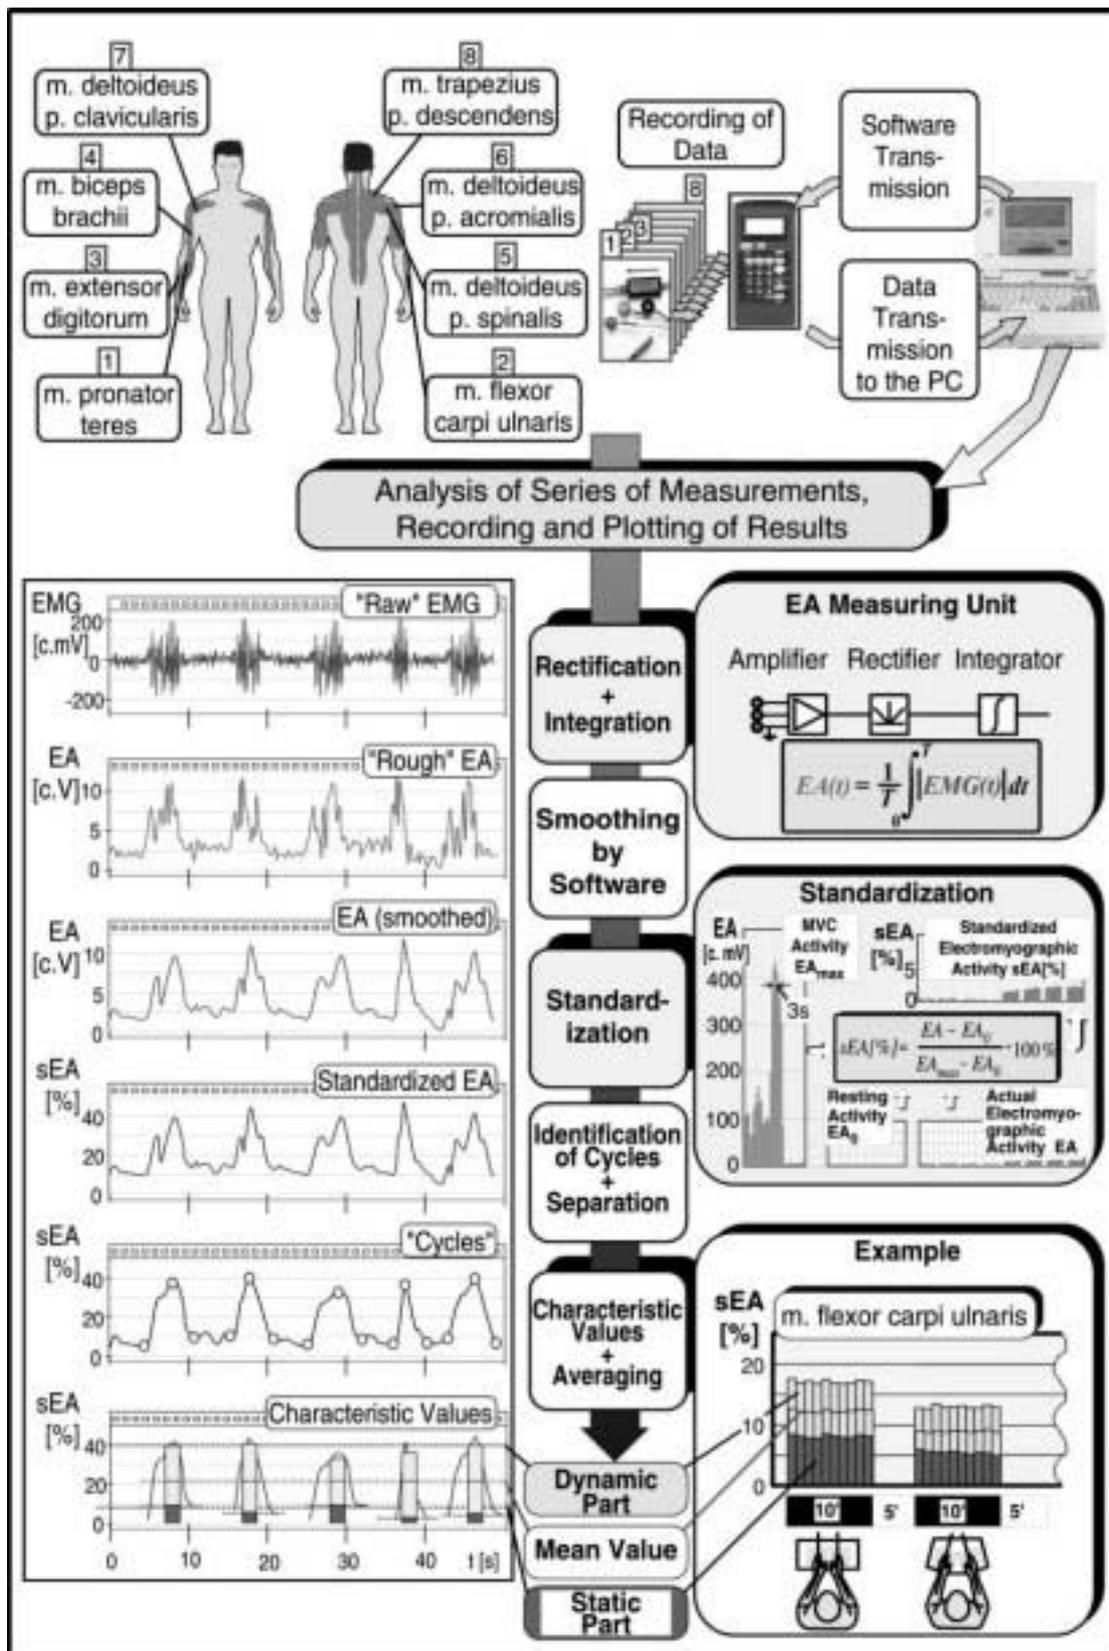
$$EA\,(t) = \frac{1}{T} \int_{0}^{T} \left| EMG\,(t) \right| dt$$


Figure 2. Outline of procedures for the evaluation of the electromyographic time series, starting with picking up myoelectric signals from muscles involved in work, recording time series of electromyographic activity EA(t) by a portable data recorder, and standardization of the A-D-converted EA.

for it to take effect, the impedance of the amplifier, the thickness of the subcutaneous skin layer over a muscle, etc.). The amplitude measures of the electromyographic data are therefore not directly interpretable. They vary greatly in repeat measurements under identical conditions even with the same test subject and even more when the measurements result from different tests after the electrodes have been reapplied even under the same operating conditions. Intermuscular comparisons are also not possible using electromyographic activity. Therefore a standardization of the EA values is necessary.

There are several possibilities for the standardization of EA data (Mathiassen *et al.* 1995, *passim*). For example, the measured values of a test series can be related to the globally highest or lowest measured value. These maxima or minima as reference values must, however, be the same for each test subject to ensure comparability of the data between the test subjects. Further, all individual EA values from predetermined test sections, e.g. 1 or 5 min mean values, can be related to the average value of a complete test series with several repeat measurements and several parameter variations. Depending on the amount of effort, these attempts at standardization allow at least interindividual comparisons of the measured data; however, they do not make intermuscular comparisons possible. In other words, the data are at most interpretable as stress data; they are not, however, interpretable as characteristic values of strain, i.e. they cannot be used to evaluate the degree to which a physical capacity is occupied by an imposed workload.

4. INTERPRETATION OF STANDARDIZED EA VALUES AS STRAIN PARAMETERS

Strain differs from stress in that stress (in this case the muscle force required) causes an individually differing degree of strain, depending on the muscle's capacity. If EA data is to be interpreted

as characteristic values of strain, then the actual EA values measured in certain stress situations must be related to the highest possible EA of a muscle resulting from maximum voluntary contraction (MVC). Even without external force demand, a muscle produces biopotentials that can be measured on the skin's surface as EA_0, which may differ from muscle to muscle. Thus, similar to the determination of the working heart rates as indicators for the total (whole body) strain during dynamic muscle work, it is advisable to "calculate" the resting value 'out' of the actual EA values and use the differences $EA_{max} — EA_0$ and $EA_{actual} — EA_0$ for the standardization. EA_0 — which are determined by the quality of the electrical amplifiers — should only be a few percent of the maximum activity EA_{max}. The resulting standardization approach that allows the interpretation of EA as strain data is shown in Figure 2. The respective maximum activity EA_{max} must be determined for each individual muscle for such standardizations.

5. NECESSITY OF MULTICHANNEL ELECTROMYOGRAPHY

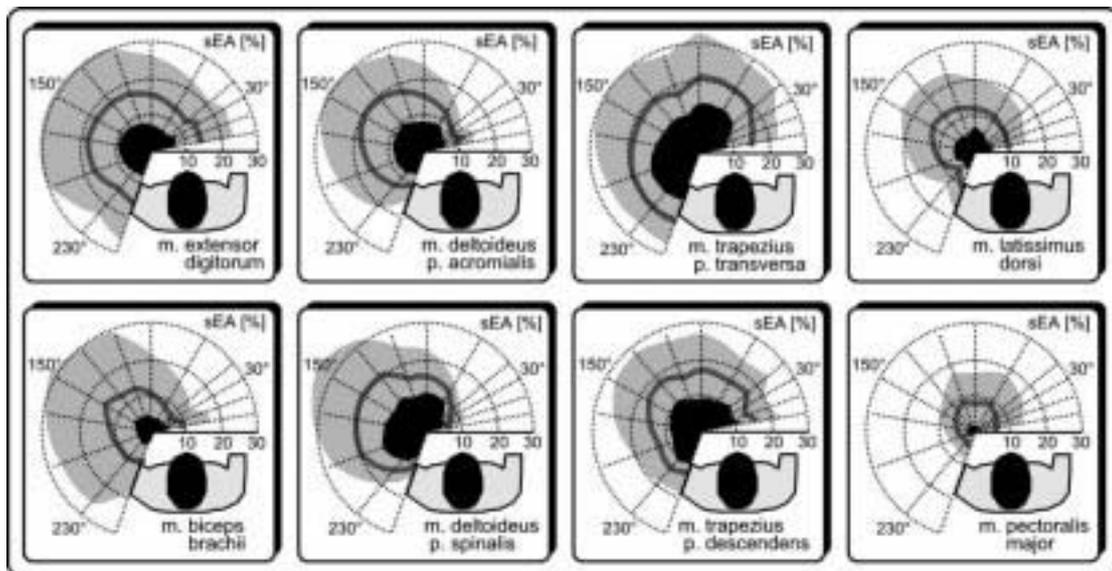
Manipulating objects in a three-dimensional space requires, e.g., forces for the vertical lifting of an object against gravity, the moving of the object toward or away from the body (horizontally), and possibly inward or outward rotation forces of the lower arm during pronation and supination. Therefore, the specific maxima for the muscles involved in such activities must be determined individually for correct standardization. Thus, the muscle groups involved in working must be carefully selected already before the beginning of an electromyographic study. The same is true for the determination of the data for the standardization process. As an example Figure 3 shows EA of eight muscle groups of the hand–arm–shoulder system responsible for elementary arm movements during manual material handling. It becomes clear


Figure 3. Static and dynamic components of the electromyographic activity (black and gray areas respectively of the circle diagrams; bold line indicates the mean EA) of eight muscle groups acting on the forearm, upper arm, shoulder and upper parts of the torso during manual materials handling in different directions between 10 and 250° (means from 11 Ss during manipulation of an external load of 1 kg over a distance of 38 cm at a working speed of 24 cycles min⁻¹) (from Strasser and Müller 1999).

that multichannel electromyographic registrations are necessary even for simple tasks.

The measuring of one or another muscle may lead to clear results and their interpretation may seem plausible. It is usually, however, inadequate for the complexity of the interactive "muscle play" of agonists and antagonists as well as synergists. It is usually not possible correctly to represent this via just a few electromyographic derivatives, i.e. singular electromyographic studies are often insufficient or invalid.

6. EXPERIENCE WITH ELECTROMYOGRAPHY AS A METHOD TO ASSESS THE ERGONOMIC QUALITY OF WORKPLACES AND WORKING TOOLS

In the past years a great deal of experience has been gained with computer-aided electromyography. Advanced methods as described above enable the measurement of the intensity of muscle exertions that are demanded when working with hand-held tools and controls. The same is true when repetitive manual movements during material-handling tasks have to be performed. Utilizing multichannel recording devices, physiological responses of those muscles involved in work can be quantified in figures and numbers, whereby more or less ergonomically designed tools, like masons' trowels, file handles, screwdrivers, wrist rests, and keyboards, lead to different physiological costs associated with work (e.g. Kluth *et al.* 1997, Strasser *et al.* 1996, 1998). So, after the pioneering feat of Tichauer (1978) electromyography meanwhile became a powerful ergonomic method all over the world (e.g. Eklund and Freivalds 1993, Kilbom *et al.* 1993, Marras 1990).

Ergograms

V. F. Venda†

†University of Manitoba, 75 Allendale Drive, Winnipeg R3T 5B6, Canada

1. INTRODUCTION

Theoretical and applied ergonomics studies need highly developed models of dynamic work processes and of interactions in complex human–machine–environment systems (Karwowski 1991). Verbal descriptions of human work provide not much assistance to ergonomists in prediction of work efficiency in different work environment, during training processes or when different work skills and technologies are being implemented (Karwowski and Mital 1986).

To study dynamics of work ergonomics and particularly its work dynamics oriented part called ergodynamics (Venda and Venda 1991) need special models, or ergograms. Ergograms are graphic models presenting work efficiency, Q, as functions of environment parameters, E, work factors, F, work strategies (skills, methods, technologies), S_i, and time, T.

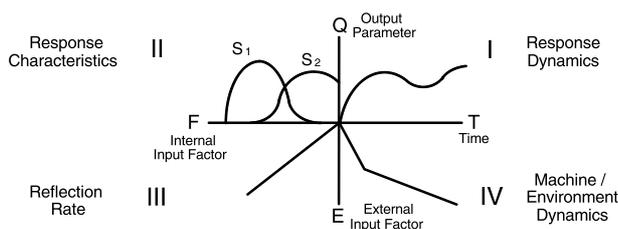
A *single ergogram* has only two axes, F and Q. It shows work efficiency static characteristic curves, $Q_i(F)$. A double ergogram presents side by side work statics, $Q_i(F)$, and work dynamics, $Q_i(T)$. Usually ergonomist shows at the left side the characteristic curves of the work strategies (functional structures), $Q_i(F)$, and dynamics of work efficiency in time, $Q_i(T)$ at the right side of the double ergogram. The next type of ergograms is a triple ergogram, or a triogram. It has three axes, F, Q and T, and three quadrants presenting three interconnected diagrams: $F(T)$, $Q_i(F)$ and $Q_i(T)$.

The most advanced ergogram has four different axes, parameters (F, Q, E, T) and quadrants. We call this ergogram the quadrigram.

2. SINGLE AND DOUBLE ERGOGRAMS

We start description of all ergograms with the quadrigram. This the most advanced and complicated type of ergograms includes the single, double and triple ergograms as its parts which will be explained in a due course.

The quadrigram ("quadri" in Greek means four), as the name suggests, is ergogram which has four quadrants and four different axes; Q, T, F and E (Figure 1).

The T-axis measures the time of interaction; or simply the time allotted for a task or series of tasks. The Q-axis measures the work *output parameter*. This is the efficiency (safety, productivity, quality) of human work. This axis is usually normalized against some desired or recognized level of efficiency. The E-axis measures the *environmental parameter, which is an*


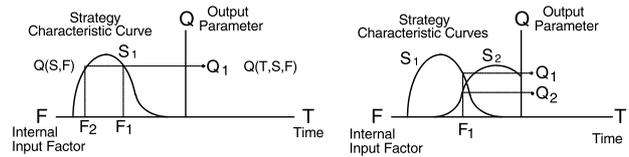


Figure 2. Characteristic curves for a single work strategy S_1 (a) and for two different work strategies S_1 and S_2 (b). Work efficiency is a function of S and F in statics (a) and of S, F and T in dynamics (b). Two different factor F, F_1 and F_2, may lead to the same efficiency (a); one F may lead to different efficiencies (b).

external input factor for the human. This factor is an objective measure of the task, such as size of the information input as a number of elements on the computer screen presenting the task.

The F-axis measures the *internal input factor, or work factor*. It is connected to the external input factor but presents internal, psychological reflection of the external parameter E. The E- and F-axes are related. They use the same units of measurement, but depending on the subject's psychological and physiological state (whether stressed or relaxed, for example) the value of the internal input factor may differ very significantly from that of the external input factor. We call F a work factor because its value is close correlated with value of work efficiency, Q. Correlation between E and Q may be very low.

Each quadrant is an individual plot showing the relationship between the two parameters on its axes. Each pair of adjacent quadrants shares an axis, thus they are functionally, and visually, related. The overall result is a diagram where the four parameters (on the axes) are displayed in four different graphs, and one can observe the relationships between them, both direct and indirect.

The transformation dynamics theory and ergodynamics (Venda and Venda, 1995) are the fundamental basis of the quadrigrams and other types of ergograms.

Figure 2 shows the top half of the quadrigram. It is the double ergogram, or a *transformation ergogram*. The left side of the upper diagram shows a strategy characteristic curve (S_1), which describes the relationship between the output parameter (work efficiency) and the internal input factor, F, for a given functional structure (or cognitive strategy). A functional structure (strategy) is the human's method or algorithm used for completing the task. In accordance with the first law of ergodynamics, $Q(F)$ is a bell-shaped curve if the full range of F was studied.

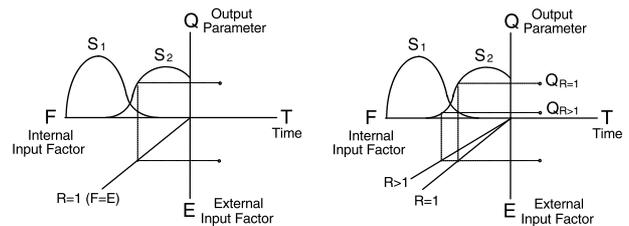
Figure 3 shows the complementary situation, where we have two different outputs for a single input. Here we have two different strategy curves (S_1 and S_2). These represent two strategies that one could use to complete a task. Given an input factor, the output


Figure 3. Different types of reflection: (a) a single normo-reflection; (b) two different reflection vectors.

Figure 1. Components of the quadrigram.

parameter may be very different, depending on which strategy is used.

Consider a simple task such as the alphabetical sorting of a set of cards with names on them. Sorting is a well-known and well-understood task. Although simple sorting is now in the domain of routine software design, it has more complicated analogies in human interaction systems. For example, an operator processing priorities of emergency signals at a power plant or similar facility is doing a type of sorting.

There are numerous documented strategies for sorting. One strategy might be to go through all the cards and find the lowest alphabetic name and then find for the next lowest and so forth until all the cards are in order. Another strategy might be to put each card into some subpile containing a smaller range such as A–E, F–H, etc., and then sort these subpiles. For a large set of cards the latter strategy would be much more efficient, but for a very small number of cards the former would probably be faster.

In accordance with the Second Law of ergodynamics, every work task can be done using a number of different strategies. Each strategy is presented with a certain bell-shaped characteristic curve $Q_i(F)$. Often there is no single best strategy for all situations. Certain strategies may suit a given range of information input volume better. Different strategies also play a role in learning situations, where a trainee may 'graduate' from a simple strategy to a more complex, more efficient one or may learn specialized strategies for specific situations.

3. THE QUADRIGRAMS

The quadrigrams demonstrate how complex the relationship can be between the external input and the human output of a task in human–machine–environment interaction. The quadrigrams help to further explain and predict this relationship.

Let us discuss several examples. Each example in this section describes a different feature of the quadrigram. We start with a simple example and add new concepts as we progress.

Consider the alphabetical sorting task described above. If we plot the information from this example on a quadrigram, then we measure the time taken to complete the task on the time axis. The external input factor of the task is a measure of the size of the task. It could be measured as the number of cards to sort or the number of characters in each name. This measure of the task is an external input, X. It gives a value on the E-axis (Figure 3). This allows us to plot a point in the fourth quadrant $E(T)$.

The internal input factor F is related to the external input factor E by the reflection rate R. Under normal reflection we have $R = 1$ and thus $F = E$. This means that normally the subject's response will be directly related to the external input of the task E. We call such case a normo-reflection (R_N).

Very often we start from the external signal E. If it was perceived as is (R_N), then we analyze the direct human–environment interaction: $F = E$. Thus instead of axis F, we may have a second axis E.

But sometimes (and very often) human performance may be initiated without any visible changes in the environment. The performance may be based on reminiscence of some prior information, new task, forecasting of future needs, etc. Here we have $E = $ constant ($DE = 0$) and $F > 0$. That means that measurement of the environment parameter E does not help to understand and model the performance. In this case we may

have two axes F and no axis E. This use of the triagram should be of special interest for psychological studies of human activity that do not depend directly on the dynamics of the environment.

Strictly speaking, when we talk about the environment's influence on human performance, we usually consider the influence of the environmental dynamics: changes (deviations) of environmental parameters from the level that human beings were adapted to. We all know from experience that a stable environment does not bring any new information. One no longer senses touch, sound, light, or other stimuli if s/he has adapted to them. That means that after enough time for adaptation, a stable E leads to $F = 0$. Therefore we may measure and draw the deviation of E from some constant, adapted level the ergograms.

The second quadrant $Q(F,S)$ in Figure 3 contains characteristic curves of the functional strategies (for example, of cognitive strategies) and gives us the output parameter Q as a function of F and the strategy S. For the sorting example the output factor would be a measure of efficiency or productivity. It could be measured in units.

Given the output parameter, we can plot a point in the first quadrant $Q(S,F,T)$. This quadrant gives us the final results of output versus time. It is labeled the response dynamics of the system.

So, to summarize the process: first we plot the task as a point in the $E(T)$ coordinates (fourth quadrant). Then we use a reflection vector R (in the third quadrant) to relate the external E and internal F input factors. When we find the actual value of internal input factor F and, if we know the human functional strategies and which concrete one is being used, S_i, then the F–S_i–Q analysis (second quadrant) yields the output parameter Q. We can then plot the task's response dynamics, solving for $Q(T)$ in the first quadrant.

This example describes the 'base case' for using the quadrigram. The other examples described below present applications of the quadrigram to explain more complex phenomena, but they all use the same approach in plotting the information.

4. REFLECTION VECTOR

The quadrigram is very convenient to model different stress levels. The second example deals with a situation where the psychological state of the subject changes. Instead of having a stable situation, consider a case where the subject is under great stress. Here the *reflection rate* ($R = F/E$), plotted in the third quadrant as a respective reflection vector, is no longer unity (Figure 3b). Instead of using a reflection rate $R = 1$ where the external input factor corresponds exactly to the internal input factor, the reflection rate is increased. When $R > 1$ the subject reacts as if the task was of greater complexity than is the case for the concrete strategy used. This is typical for the stress situations, for example in emergencies.

On the quadrigram, this is reflected as a high level of the internal input factor F. Here, the external input factor E, which is an objective measure of the volume of information, is much lower.

This example demonstrates the function of the reflection rate F/E in the third quadrant. The performance of the same subject doing the same task may vary substantially if the state of stress is different. Under high stress levels (performance anxiety, emergencies) the subject will be in a state of over perception.

S/he will react as if the volume of information is very high. The subject will try to internalize more information than need be considered. In extreme cases the subject may 'overload' and reach a very low state of efficiency. On the other hand, if an operator is sick, tired or inattentive ($R << 1$), s/he may process the problem using less information than is given. The subject here lacks some required inputs to the problem, and as a result cannot perform as effectively as possible.

Vector R in the third quadrant is a very universal element as well as the quadrigram itself. The vector may reflect the processing of information by an expert or a display system. The expert or display system may add some details to the initial environmental signal E, so information displayed F would be larger than the environmental information: $F > E$ and $R > 1$.

The information display may restrict the initial signal to large information chunks that the human operator could perceive simultaneously. Here the total number of information chunks would be smaller. Thus, $F < E$.

In practice vector R might be non-linear. Indeed, the operator could ignore small deviations of the control parameters ($F/E = 0$). Here the RE angle could equal 0. Middle size deviations could be taken objectively ($F/E = 1$). Very big, emergency deviations could be subjectively enlarged ($F/E >> 1$). This effect could be also reflected by rotating R in time according to the actual E and human operator psychological state dynamics that was analyzed earlier.

The quadrigrams are especially effective for dynamic modeling of human–machine–environment systems. A situation of great interest is when we want to model a dynamic system; i.e., a system with some degree of feedback. As a crude example, consider the task of memorizing the names of a group of people. The group is introduced and the subject must repeat the names. Initially the guesses will be mostly wrong. However, if the task is repeated, the subject will now be familiar with some names, and will likely do better on the second attempt. The success of the first attempt will have a definite bearing on the volume of information of the second attempt.

Suppose we use the E-axis to measure the number of unknown names (Figure 4).

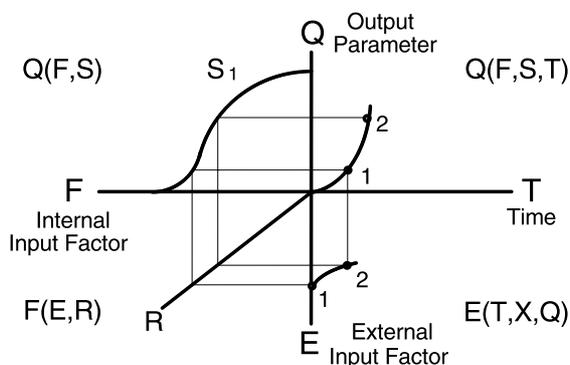
Initially this will be the entire group. The people are introduced and the subject is asked to repeat the names. The subject will probably guess some fraction correctly. The second time the subject tries the task, it will be easier. Some information


Figure 4. Modeling a dynamic human–machine–environment interaction using quadrigram.

would now be internalized. The volume of information input for subsequent attempts will thus be lower.

We could repeat the process a few more times until all the names were remembered and the system is in steady-state. In this example, the output parameter would be measured as the number of names remembered. The external input factor E would be a function of the time, the success of the previous try, and the size of the group $E(T,Q,X)$. This simple example can be considered to be a rudimentary dynamic system. In a dynamic system, the four quadrants contain the four curves $Q(T,S,F)$, $Q(F,S)$, $F(E,R)$ and $E(T,Q,X)$, and the output parameter Q of one cycle affects the external input factor E of the next cycle.

To conclude this short explanation of the idea and practical possibilities of the Ergograms, we recommend its use in the design, analysis and improvement of dynamic human–machine–environment systems. The most general and universal type of Ergogram is the quadrigram. With this versatile model, one can describe a wide variety of human interaction situations. With the graphical structure of the quadrigram one can visually relate input factors to the system reflection rate and see their influence on output through different strategies. All these parameters affect performance in human–computer interaction.

The use of the quadrigram is not limited to situations where hard quantitative data is available. It is also useful for visualizing the relationships between factors in theoretical problems. Even for case studies and single incidents, the quadrigram provides a framework from which to evaluate results and illuminate complicated causal relationships.

While the complete quadrigram may seem complex, the amount of information it contains more than justifies the effort required to understand it. Most potential users would already be familiar with portions of the model, such as output versus time. The quadrigram provides the opportunity to supplement familiar knowledge with a model that gives insight into both causes and effects of changes in the system components.

5. ERGOGRAMS IN MODELING COMMUNICATION DYNAMICS

In accordance with the Third Law of ergodynamics (the law of transformations and interactions), interactions and transformations between two work strategies S_1 and S_2 goes through the intersect point of the bell-shaped characteristic curves of S_1 and S_2 which reflects equal and common state for the two strategies. Efficiency of every functional strategy S_i is being characterized with the values of efficiency Q_i as function of the internal input factor F. F is often called also a parameter of human–environment mutual adaptation, or efficiency-complexity factor. If the efficiency of the two strategies is equal ($Q_1 = Q_2$) and the factor value is the same $F = F_{1,2}$ that means the strategies have an equal and common state. The experiments have shown that this common state is the best for the total productivity of the individuals using the two different functional strategies.

Thus, the most productive interaction between two different functional strategies goes through an environment state common for the interacting strategies. This is when the factor F and efficiency Q are equal for the strategies: $F = F_{1,2}$; $Q_1 = Q_2$.

Studies of interaction and transformation processes in communication between a teacher (professor) and students are very important for improvement of education process.

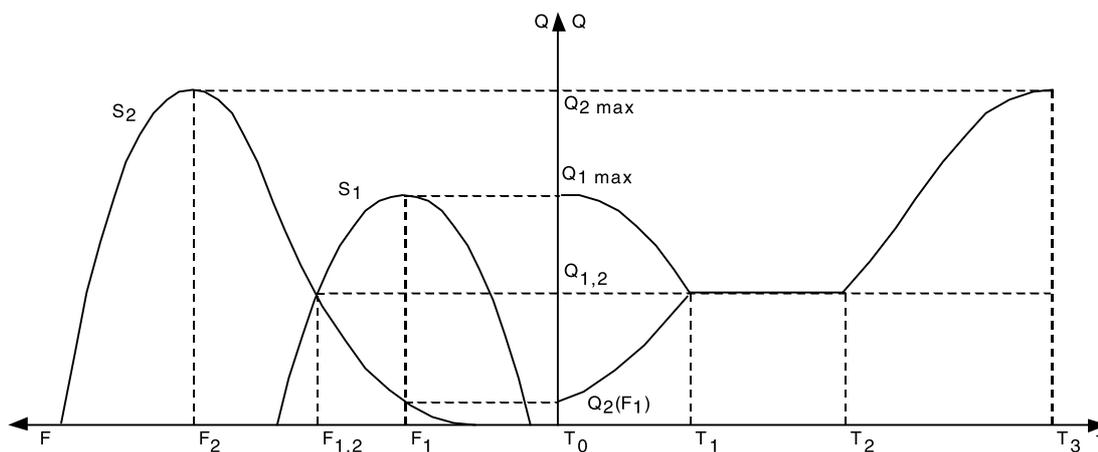
The central problem is a mutual adaptation between the


Figure 5. Process of professor–student mutual adaptation: the professor decreases the information presenting speed F from $F_{2\,opt}$ to $F_{1\,opt}$ and then leads students to the transformation S_1 into S_2 when $F = F_{1,2}$ and then to the maximal comprehension speed $Q_{2\,max}$. Q, Speed of knowledge transmitting (by professor) and comprehension (by students).

professor's speed of information presenting at the lectures and the students' perception and comprehension of the information.

In our experiments speed of presenting information was measured as the number of test questions (topics included into current tests and the final exam) explained by the professor during one lecture. The speed of the students' comprehension was measured as the number of questions they answered immediately after the lecture. Data were collected and given us by 27 professors from 15 Russian universities that took part in our program in 1986–90.

The functional strategy of students' managing of the course S_1 has a low optimal information perception speed $F_{1\,opt}$. At this perception speed, they reach the maximal comprehension $Q_{1\,max}$ (Figure 5).

The professor has some optimal information volume $F_{2\,opt}$. At this volume, s/he can manage the course with maximal efficiency $Q_{2\,opt}$.

A goal of the professor–student interaction is for the students to obtain strategy S_2, with a high information comprehension speed, equal to $F_{2\,opt}$. The student's starting functional strategy of understanding, based on the previous knowledge strategy, is S_1. If the professor presents information at his or her optimal speed $F = F_{2\,opt}$, the student's efficiency level of comprehension will be very low: $Q_1(F_{2\,opt}) \ll Q_{1\,max} = Q_1(F_{1\,opt})$. That means that the professor presents new knowledge too fast and students understand almost nothing. The efficiency of the education process in this type of registered and analyzed cases was close to zero: $Q_1(F_{2\,opt})$.

We measured F as the professor's information presenting speed in our experiments simply as the number of words the professor said, calculated with recorded audio tape. We measured F as the student's information perception speed as the number of words and symbols written during the lecture.

We measured Q as knowledge volume the professor presented as the number of topics (test questions) covered in the lecture. Q as knowledge volume comprehended by the students was the number of test questions the students correctly answered immediately after the lecture.

Please note that the scale of F at Figure 5 is reversed: the values of F increase from right to left. The ergograms give

ergonomists wide freedom in research, design and modeling human–machine–environment systems. One may change the axes, or their directions, to adapt the ergogram to the concrete needs.

Educational experiments have shown that if someone's comprehension efficiency decreases very much, then very strong negative emotional reactions and psychological resistance often appears. Lower efficiency means higher complexity. So, not only does low lecture time efficiency result for the students, but they also become hostile toward the professor. This resulted in obstacles for the professor–student interaction.

We decreased the complexity of the interaction and learning process by special organizing of the mutual adaptation between the professor and the students.

To improve students' comprehension at the start of the course, the professors decreased the volume of information presented at the lecture F from $F_{2\,opt}$ toward the F acceptable for the students. They started from a very simple short introduction, with minimal complexity and maximal efficiency of student comprehension: $F = F_{1\,opt}$, $Q_1(F_{1\,opt}) = Q_{1\,max}$. In fact we recommended that professors start from slow dictating of basic terms and definitions, and introduction into disciplines. By analyzing huge data on university educational processes, we found two main disadvantages: (1) the knowledge transmitted by professors and comprehended by the students did not equate; and (2) lecture information is not associated with concrete images of work processes (in ergonomics), technologies (in industrial engineering), or experiments (in psychology).

6. RECOMMENDATIONS

Here is how to use of ergograms to increase interaction efficiency. Even though we are talking about professor–student communication, this is only an example of many cases where ergograms may be used to improve communications in worker team, training center, in human–machine and human–computer interaction.

To reach mutual professor–student adaptation, we recommended that the professors who participated in the experiments should reach (in the beginning of the course by slowing down the teaching tempo) and maintain mutual

adaptation between the tempo of knowledge presented and its comprehension. After that, the professors gradually increased the volume of information presented from $F_{1\,opt}$ to $F_{1,2}$. Even with this very essential decrease of information presenting speed (if compared with usual $F_{2\,opt}$) in the interval of changing F from $F_{1\,opt}$ to $F_{1,2}$, the students' comprehension efficiency decreased from $Q_{1\,max}$ to $Q_1(F_{1,2})$. Not all students were motivated enough to make some extra effort to perceive the larger volume of information and overcome the added complexity of learning performance. We found that to be a crucial period of the professor–student mutual adaptation process. At the crossing point for both functional structures $F_{1,2}$; $Q_{1,2}$, the optimal conditions to transform S_1 into S_2 occurred. We recommended that the professors' speed of information presenting, F, should stay constant for the time the students need to change their previous functional structure from S_1 to S_2. This time was spent especially to help students to replace their previous cognitive strategy S_1, based on separate perception of different short topics, by the cognitive strategy S_2, based on understanding of general fundamentals of the discipline taught. Perception of it proceeded by big information chunks using associations between the topics.

After that time, when the new (for the students) structure S_2 (old for the professor) has been already formed by transformation of S_1 into S_2, increasing the information presentation tempo F led to fast increases in student comprehension efficiency, using the new structure S_2. Figure 6 shows this transformation, using a dynamic ergogram with an added F-axis. This axis helps to display both the dynamics of factor F and work efficiency Q.

The ergogram at Figure 6 has three axes F (two times, as $E = F$ and F), Q and T. This ergogram is called a triagram. It shows the dynamics of a factor in time $F(T)$, so one can evaluate not only the values of efficiency when different structures are used, but also times when those levels of efficiency would be reached according to the values of F at respective moments.

We should note an assumption is being used in building the "triagrams": human work structure is indeed inertial, so when F reaches some value F_1 the respective efficiency value $Q(F_1)$ will be reached, not at the same time, but later. This time delay could be easily assessed in the experiment as a reaction time. In using the quadrigram this assumption is not necessary. The time delay in human–machine mutual adaptation is easily displayed there. But in comparison with our ordinary ergogram (Figure 2) the triagram has unquestionable advantage and could be widely used.

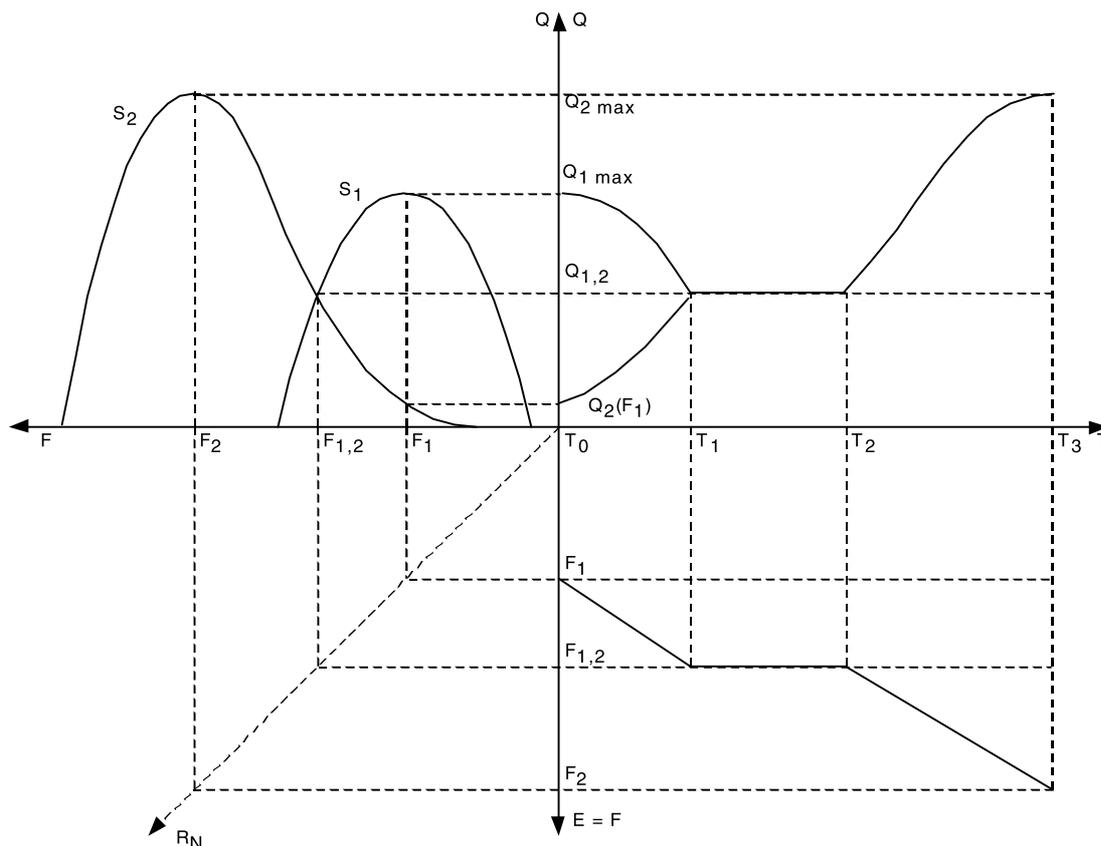
A group of professors who participated in the experiments increased F monotonically as usually. The students did not have the time and conditions to transform S_1 into S_2. They continued to use the initial cognitive structure S_1. Then, when the professor's information presenting tempo became higher than $F_{1,2}$, the professor's performance efficiency, speed of presenting knowledge Q_2 increased, but ~40% of the students decreased their


Figure 6. Triagram showing successful dynamics of professor–students interaction if there is a temporary stabilization of information volume presented F during time $T_1 - T_2$ to allow students to transform structure S_1 into S_2 and then increase performance efficiency Q. Figure 7. Ergogram showing unsuccessful dynamics of teacher–student interaction if the teacher presents information monotonously increasing a tempo of information presenting even starting from a tempo optimal for students' perception $F_{1\,opt}$ but without fixation of $F = F_{1,2} =$ constant to give students time for transformation S_1 into S_2.
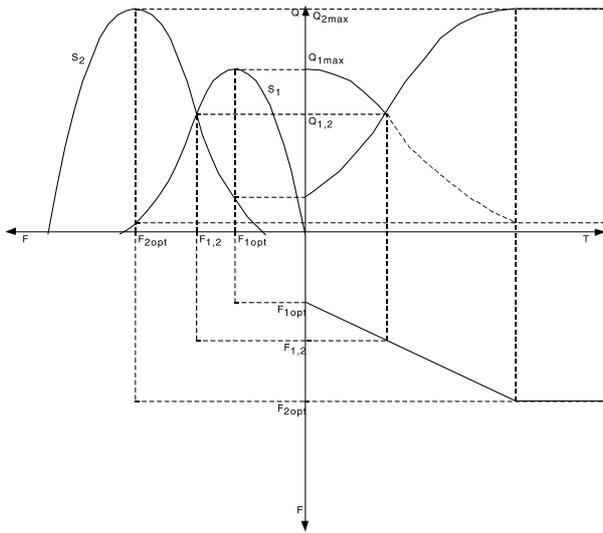

Figure 7.

comprehension efficiency Q_1 very quickly. This process is shown using quadrigram in Figure 7.

This analysis revealed that the current educational method typical for the universities and vocational training centers, based on monotonic increasing of the volume of knowledge presented to students, at a certain stage leads to almost zero lecture efficiency for a big part of the students. In our experiments the part was ~40%.

Ergonomic Data for the Design and Evaluation of Technical Systems

H. Schmidtke and I. Jastrzebska-Fraczek

Department of Ergonomics, Technical University of Munich, Boltzmannstraße 15, 85747 Garching Germany

1. INTRODUCTION

Even a considerable amount of ergonomic data and recommendations and their didactical presentation in various educational publications, e.g. Schmidtke (1993), Luczak (1993), Bullinger (1994), or data collections (van Cott and Kinkade 1972, Woodson 1981) is available today. And experts frequently note that some work places and tools partly display decisive ergonomic deficiencies. One clear cause is that the dissemination of ergonomic knowledge is not as widespread as would be beneficial for the employee or system user. The designer of work places and tools often has not as much experience in this field as necessary and is guided by his intuition only in ergonomic issues. However, in many cases, even the ergonomic expert finds it rather difficult to compress the available know-how into tables in a way that renders it adequate for each individual application. This leads to an performance or health protection, where a consequent application of ergonomic experience in this field would result in considerable improvements. This is the indication where marked benefits can be gained from an appropriate application of a computer.

2. THE ERGONOMIC DATABASE (EDS) AS AN EXAMPLE FOR AN ELECTRONIC DATABASE FOR THE ERGONOMIC DESIGN OF MAN-MACHINE-SYSTEMS

2.1. Modules and Targets of the Ergonomic Database

As early as during the planning and developing phase, and subsequently during the designing and blueprint phase, the ergonomic database (EDS) confronts the designer of equipment and work places with the most important ergonomic demands posed on the components he works on and their interaction in the work tasks. In contrast to CAD systems, EDS is a pure database system. Figure 1 depicts the main menu mask of EDS.

EDS consists of two different modules:

- basic — contains the ergonomic data compiled for technical components, environmental factors and work tasks; and
- individual — contains data on body measures, human forces, sizes of movement and methods for strain/stress analysis (man module), ergonomic requirements for specific types of work place (consulting module) and a module for ergonomic examination and evaluation. Finally a checklist for task and product analysis is included.

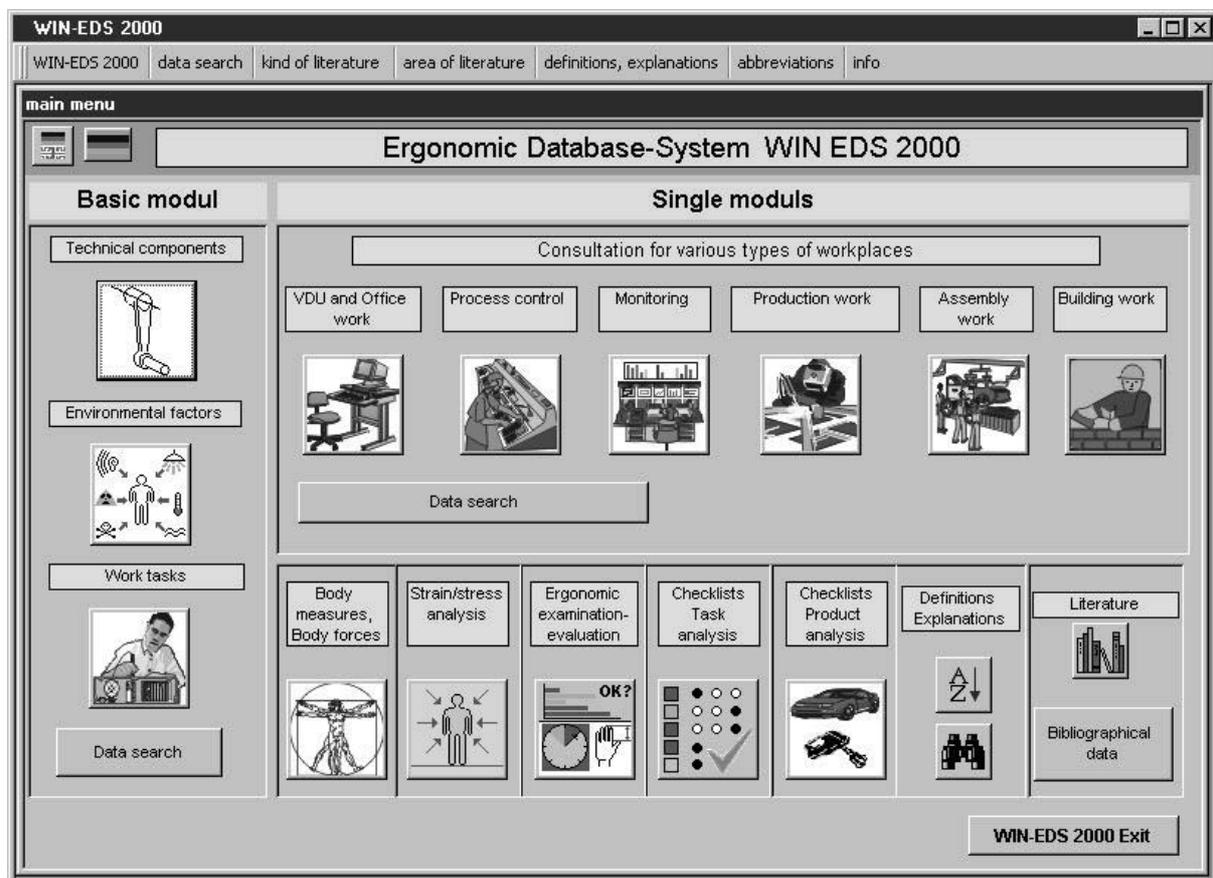
In addition to the data base system, each menu mask shows a direct access to literature search and a definition of ergonomic


Figure 1: Main menu EDS

terminology. The access to the database, literature search, and explanation of ergonomic terminology is guided by menu support. EDS is self-explanatory to an extent that the user can work with standard commands.

The data compiled in EDS comprises requirements on man–machine systems classified according to the following categories:

- Technical components — 15 submenus, 107 data sheets, 1080 single positions.
- Environmental factors — five submenus, 18 data sheets, 142 single positions.
- Work tasks — six submenus, 23 data sheets, 198 single positions.
- Additional data on:
- body measures — 11 data sheets, 108 single measurements;
- human forces — eight data sheets, 46 examples for force activities;
- size of movements — six data sheets, 31 individual measurements;
- strain/stress analysis — three methods for analysis;
- consulting on task — six submenus, 180 data sheets, 1871 single positions) categories;
- checklist for task analysis — six types of work, 520 questions; and
- checklist for product analysis — four types of products, 490 questions.
- The literary search is classified according to fields (e.g. technical components) and types (e.g. books, standards).
- The collection of definitions for ergonomic terminology presently contains > 450 alphabetically listed definitions.

The majority of databases available so far are oriented upon checklists, similar to those already used in various areas of technology. The database concept presented differs from the checklist concept. It compares defined positions to specified values. Even if not all ergonomic requirements can be translated into numbers, verbally formulated demands can be useful and important for the designer of work or tools However, practical application has proved it to be useful to integrate a module "Checklist for task analysis" and "Checklist for product analysis" into the EDS besides the pure data collection. By means of this modules, it is possible to compile a specific checklist for a testing task without much effort.

2.2. Technical Components

The term "Technical components" covers a very wide scope. It can be used to describe a single key in a keyboard as well as a large switchboard. This means for the understanding of this database system, all components at the interface to the human user are included. Consequently, technical components not representing an interface to the user, as a rule, are not an object of ergonomic observation. The following classification for technical components has been applied:

- Access to workplace.
- Work tables.
- Consoles.
- Seats.
- Body support.
- Equipment for optical and acoustic information.
- Displays.
- Control devices, general requirements.

- Control devices for rotary motion.
- Control devices for linear motion.
- Pedals.
- Transport, lifting, conveying and storage equipment.
- Lifesaving and protection equipment.
- Facilities for test and maintenance.
- Workplaces and means for production.

The subsequent lower level — as an example from transport, lifting, conveying and storage equipment — contains the relevant characteristics:

- Design of lifting equipment.
- Safety devices on lifting equipment.
- Handcarts, forklift trucks.
- Elevators for persons and loads, ladder shaft.
- Design of trailers.
- Transport containers and packing materials.
- Mass of goods manually transported.
- Angular speed of goods to be inspected.
- Handles on packing materials, equipment and drawers.
- Shelves.
- Deposit shelves for office materials, records and regulations.

2.3. Environmental Factors

The group of ergonomic requirements for environmental factors lists demands and permissible limits basing on laws and regulations, as well as provisions and definitions in standards and regulations, as long as they do not contradict generally accepted ergonomic know-how. The following environmental factors contained in EDS at the present:

- Illumination.
- Noise effects.
- Climate, ventilation.
- Vibration.
- Toxic substances and radiation.

2.4. Work Tasks

In the third group of the database system, from the wide scope of work categories those with a high degree of general applicability were selected. The positions contained in the individual characteristics mark technical and organizational pre-requisites for an optimum execution of the tasks. A consideration of the ergonomic specification may avoid particular obstacles in the tasks, however, on its own it does not guarantee that the entire work content in a task does neither poses too much or too little demand on the worker. The following structure of the work tasks in EDS has been applied:

- Putting into and placing out of operation for technical equipment.
- Visual supervision.
- System control.
- Disturbance and emergency treatment.
- Material handling and maintenance.
- Requirements on staff.

All issues listed in above are contained in individual data sheets. Each sheet provides detailed information on the screen (figure 2). In principle, each data sheet is designed in a way that the ergonomic specifications are described qualitatively or with measures and numbers in a list of varying length.

Figure 2: Excerpt from data sheet for room illumination

2.5. Structure of Single Modules in EDS

2.5.1. Consulting module

The consulting module contains data on specific work places as it can be seen in figure 1. The structures correspond to those of the basic module.

2.5.2. Data on body measures, human forces and size of movements

The data on body measures and human forces have an additive character with respect to the previous categories. They provide further information that may be important for the design of technical components. Yet for the application of the data on forces, it is important to note that the values given are isometric maximum forces in all cases. Maximum forces can only be performed for very few seconds.

The tables containing body measures are structured as follows:

- The first and the second column give the number and term for the relevant body measure.
- The subsequent six columns contain the body measures for men and women (mm) each for the 5th, 50th and 95th percentile.
- The last column provides notes on the source in literature.

The material compiled comprises a total of 108 individual measures.

Structure of data sets for body measures (mm):

- Body measures: standing — height.
- Body measures: standing — width.
- Body measures: standing — reach and depth.
- Body measures: standing — circumference.
- Body measures: sitting — height.
- Body measures: sitting — width.
- Body measures: sitting — depth.
- Body measures: head.
- Body measures: hand.
- Body measures: finger.
- Body measures: foot.

The data on body forces give maximum isometric human position forces for occasional activity. They were taken from Rühmann and Schmidtke (1992).

The material compiled contains 46 cases of exerted force. In contrast to the characteristics for body measures, only values for the 5th, 10th and 50th percentile are given, since for the design of work or tools, only information on the lower percentile classes is of importance.

2.5.3. Methods for strain/stress analysis

On the sector of strain/stress analysis three analysis methods are available at the present, this is for prevailing holding tasks (the procedure for the determination of permissible muscle strain in alignment to VDI (German Association of Engineers) and the comparatively restrictive method according to NIOSH) and the procedure presented by Spitzer, Hettinger and Kaminsky for the analysis of energetic stress during dynamic muscle work.

The section strain/stress analysis contains thee different methods:

- Inquiry of muscular strain according to VDI.

Figure 3: Excerpt from data sheet for body measures

- Inquiry of muscular strain according to NIOSH.
- Inquiry of muscular stress according to Spitzer *et al.*

The analysis procedure based on the work of Burand and published by VDI is primarily suitable for activities involving the lifting or lowering of material, tools or parts. Although the algorithms for calculation provide recommendations for pure shifting operations on almost identical level, there is no information at the present to which extent these recommendations are scientifically founded.

Similar to the VDI procedure, the NIOSH procedure currently discussed in International Standardisation (draft 1992) is mainly suitable for activities, where material, tools or parts have to be lifted or lowered. As already mentioned, the NIOSH procedure is highly restrictive and provides comparatively low permissible loads.

In contrast, the analysis method according to Spitzer *et al.* is based on experiments and refers to the so-called group evaluation tables published by the authors. In this case two parameters are considered:
- the body position or movement; and
- the type of work.

The analysis method according to Spitzer *et al.* is only applicable for the determination of the energy expenditure during the strain of larger muscle groups of the body. It is not suitable for holding tasks or one-sided strain of smaller muscle groups. Therefore, it has to be emphasised that reliable data on the work dependent energetic stress can only be gained for measurements of the energy expenditure at the work place.

Since, as a rule, a work task is set-up from various elements of activity, requiring different body positions or movements and consequently strain the individual muscle groups to a varying extent, the analysis has to be done separately for each individual element of activity. The computer-aided analysis method summarizes the values of energy transfer determined according to a temporal evaluation to a work transfer value for the entire task.

2.5.4. Module "Computer-aided ergonomic evaluation"

Whereas all modules discussed so far contain ergonomically relevant data, the module "Computer-aided ergonomic evaluation" serves the purpose of creating a defined evaluation task for the evaluation protocol. For this purpose, a decision has to be made, whether test positions have to be taken from the basic or the consulting module (figure 4). For instance, if it is intended to evaluate safety parts on lifting devices from the module "Technical components," by a mouse click on the dialogue button "Technical components," a list of the sections it contains is opened. It includes the section "Equipment for transport, lifting, feeding and storing." A mouse click on the relevant button opens a list of the data sheets included in this field.

According to the evaluation task, the button "safety parts on lifting equipment" has to be clicked. This calls all 17 evaluation positions from this data sheet. The user has to decide by clicking onto the relevant buttons, which individual positions he wants to include in the evaluation protocol.

With the dialogue button "Survey test record" the test protocol thus created is opened. Now the actual values determined on the test object can be entered into the protocol. In addition, it contains

Figure 4. Mask for ergonomic evaluation

information on the type of test method suitable for the analysis and whether the individual positions for health, work safety, performance, comfort, functionality/technical reliability are decisive. The user can set his own priorities in the evaluation.

When the analysis is terminated, a graphical survey of the test result can be called via the button "graphic profile." In addition it is possible to print a list giving all test requirements that are not accomplished. Finally, a conclusive evaluation report can be printed including a graphic depiction of the evaluation, statistics, and individual results.

2.5.5. Module checklist for task analysis and product analysis

If it is intended to do ergonomic tests using the basic or consulting module, this may require modern measurement equipment. If this is not available or if it is sufficient to do a more qualitative task analysis, the module "Checklist" can be selected.

The module Checklist for task analysis is based on the six types of work place contained in the consulting module (figure 1). For each type of work place, a series of areas for analysis have been defined (e.g. environmental impact, tools, controls, physiological strain, etc.). The user then has to decide, which section is important for the test or is insignificant. By clicking onto the relevant buttons, he opens a list of questions. An example using the environmental factor "illumination" may be: "Is the illumination of the work place or room sufficient for all visual tasks?" The user can then answer this question with "yes," "no" or "not applicable" using his own experience or questioning the staff concerned (figure 5).

When all questions have been answered, the user receives an information that he now can proceed to the test result. For this

purpose, he can choose between several depictions. They can print a list of all questions posed sorted according to fields or criteria (e.g. health, performance, comfort, etc.) or only those questions answered with "no" during the test, i.e. where ergonomic requirements have not been accomplished. Here again a sorting according to fields or criteria is possible. Finally, the entire test result can be printed as a test report containing a graphical depiction of the evaluation.

The checklist for product analysis is build up in the same manner and contains up to now the following types of products:

- Motor car.
- Omnibus.
- Truck.
- Earth-moving machinery.

2.5.6. Literary search and definitions of ergonomic terminology

As already mentioned in Section 1 the EDS is completed by a literature compilation, which can be called according to the type of literature and field of application. Naturally, the limited content means that not all relevant information is included. Here a courageous selection and omission had to be done.

Experience has shown that the users wish to obtain more detailed information on some terminology from the field of ergonomics. This need was catered for by offering slightly more than 450 terms around this field alphabetically for selection. When terms have already been defined in standards or regulations these definitions were used.

Figure 5: Cut out from the checklist of process control (areas) and from questions according to 'enviromental factors' on the checklist of process control

3. CONCLUSION

As the description of EDS shows, the system comprises a large amount of ergonomic information that plays a decisive role during the development phase of the product (or work place) as well as its acceptance test.

To meet this demand on an international level, decisions have to be made on the questions, which are the ergonomic core data, which are the differences to the published standards (frequently only covering minimum requirements) and to which extent the core data correspond to international Standardisation and literature.

1. INTRODUCTION

The idea of a *usability evaluation* is gaining momentum, and the term *usability* is becoming common parlance in product design. This is a welcome shift in emphasis towards "ease-of-use" in product development. In many respects, the fundamental tenet of usability is that a product should be easy to use. This heightening of interest does not mean that usability (AKA user friendly, ergonomically designed, user-centered design, consumer-oriented product development) is a new concept. Ergonomists have been beating this particular drum for the past fifty years or so. Just over twenty years ago, Ivergard (1976) pointed out that very little research had been published on consumer ergonomics. While that picture has changed somewhat (there is a growing literature on physical aspects of product use), there is still little published on cognitive aspects of product use (Baber and Stanton 1994).

Although one can point to the consequences of not considering usability, there is much debate as to what the term actually means. One of the main problems with the term "usability" is that it means different things to different people. Some may suggest that usability is simply another attempt to introduce "user friendliness" back into product design jargon: usability is simply new wine in old bottles. Others argue that the issues surrounding usability have already been dealt with in "user-centered design". Baber (1993) points out, using the analogy of the soupstone, that the term usability takes on individual meaning to each person involved in evaluation to describe whatever they are doing: the individual adds his or her own ingredients. The trouble with this approach is how can we determine if one product is better than another, or indeed if the product has achieved some acceptable benchmark? Clearly this matter needs to be resolved as a matter of urgency, particularly in the light of recent legislation which makes usability a legal requirement in some products! This is a rather ridiculous situation given the debate and controversy surrounding the concept of usability (Stanton and Baber 1992).

2. WHAT IS USABILITY?

While it is possible to indicate the necessity for usability in product development, as a concept it has proved remarkably resilient to definition; we all know what it is, but have difficulty reaching an agreed, coherent definition (it is our own personal soupstone) which will allow recommendations to be made concerning how best to make something more "usable". This is the first, and perhaps most important, stumbling block in determining methods appropriate to evaluation. If we cannot agree on what usability is, how can we hope to measure it? It is likely that different definitions of the concept will lead people to measure different aspects of product use. This suggests that a usability evaluation may not have a common standard between individuals. If usability

is to be more than an ephemeral concept, we must agree on its constituent ingredients. Stanton and Baber (1992) draw upon a decade of work represented by Shackel (1981), Eason (1984), and Booth (1989) to suggest the factors above serve to shape the concept of usability and define its scope. These are as follows.

1. Learnability: a system should allow users to reach acceptable performance levels within a specified time.
2. Effectiveness: acceptable performance should be achieved by a defined proportion of the user population over a specified range of tasks and in a specified range of environments.
3. Attitude: acceptable performance should be achieved within acceptable human costs in terms of fatigue, stress, frustration, discomfort, and satisfaction.
4. Flexibility: the product should be able to deal with a range of tasks beyond those first specified.
5. The perceived usefulness or utility of the product: Eason (1984) has argued that "the major indicator of usability is whether a ... [product] ... is used". As Booth (1989) points out, it may be possible to design a product which rates high on the LEAF precepts set out above, but which is simply not used.
6. Task match: in addition to the LEAF precepts, a "usable" product should exhibit an acceptable match between the functions provided by the system and the needs and requirements of the user.
7. Task characteristics: these include the frequency with which a task can be performed and the degree to which the ask can be modified, such as in terms of variability of information requirements.
8. User characteristics: another section that should be included in a definition of usability concerns the knowledge, skills, and motivation of the user population.

Whilst we may argue over the relative merits of different ingredients and the labels we give them, this rarely becomes more than a exercise in semantics. ISO 9241 goes some way toward incorporating the above factors, but we feel that it falls short of a comprehensive definition in an important way. From reading ISO 9241 (at the time of writing this was still unreleased), we feel that usability has been defined by what can be measured: usability is what usability evaluations do. This appears to concentrate largely on the LEAF precepts mentioned above (Learnability, Effectiveness, Attitude, and Flexibility). We believe that haste in producing *the definition* of usability should be tempered by rather more circumspect consideration about what is meant by usability.

3. TECHNIQUES FOR EXAMINING USABILITY

The reader will not be surprised to learn that each of the various factors that make up usability has spawned particular approaches to usability evaluation. In this section we present approaches related to aspects of product development. We are particularly concerned that reliance upon one approach exclusively, or a very narrow definition of usability, could lead an individual to perform a limited usability evaluation. This concern should become obvious when we map evaluation methods onto the ingredients of usability.

3.1. Usability in the Design Process

Traditionally, usability assessments have been performed at the end of the design cycle, when a finished product can be evaluated.

However, it has been noted that the resulting changes proposed may be substantial and costly. This has led to a call for usability considerations to be introduced in earlier aspects of the design cycle. The most obvious way in which to collect information about how people perform a task is by watching them do it, or asking them how they go about it.

Observation of human activities may afford the collection of data about the real interaction between the human and the machine. Yet what is observable might not, for example, tell you about the decisions being made, or the alternatives not selected.

Interviews, on the other hand, may enable a quick way to get to the unobservable decision-making process, particularly if the interviewee is describing a recent event and how they dealt with it. However, it has been found that post-event descriptions can vary from what was in fact being done at the time. A solution to this is to get people to "think aloud" (concurrent verbal protocol) as they are dealing with an event — although this may result in them actually changing the way they do things in order to make the process of description easier!

This information can then be analyzed by a variety of means — for example, task analysis, link analysis, time-line analysis and layout analysis. These are described below.

Task analysis has many derivatives: British ergonomists use Hierarchical Task Analysis (HTA), which allows them to describe human behavior in units from a hierarchical presentation, describing behavior in terms of goals, plans and actions. However, HTA often presents only ideal behavior, or an agreed consensus of ideal behavior; the task analysis may then feed into user requirements and system specification. This mapping assumes that existing task practices are ideal, and it may be necessary to abstract further task goals at a general level before proposing desired human activity and specifying system requirements.

Link analysis allows examination of the way in which humans use displays, and the cataloguing of the frequency with which they switch between displays and the time spent at each display. Together with an expert rating of the importance of each display, this enables the presentation of an optimum layout of the displays.

Time-line analysis enables the study of the task sequence and the operations performed. System bottlenecks may become apparent, thus prompting the need for redesign. A new design can then be rerun and reanalyzed to discover if the bottleneck in the system has been cleared.

Layout analysis is a means of examining display and control layouts by four criteria. These are: functional classification, importance of item, sequence of use, and frequency of use. Based on this analysis, the layout may then be subjected to improvement and redesign.

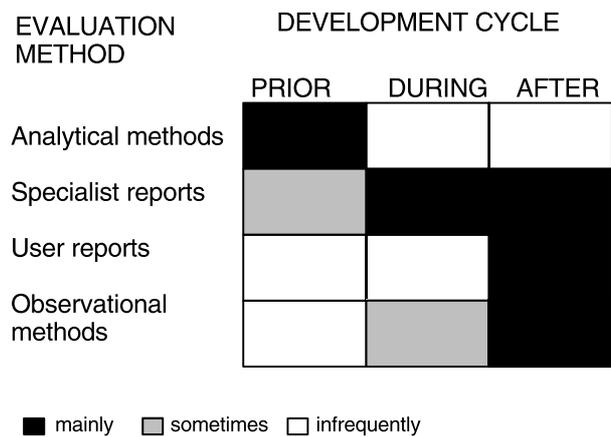
The criteria for acceptance of methods will include the time limit of the project, resources available, skills of the practitioners, and the stage of design. For example, a technique such as link analysis is relatively easy to perform and does not require knowledge of


Figure 1.

ergonomics in its use. Hierarchical Task Analysis, however, requires considerable experience if it is to be used effectively.

Usability evaluation and assessment may enter all stages of the design process, from a requirement analysis, through initial design specification and prototyping, up to and including the working product. If we consider the four classes of evaluation method proposed by Whitefield, Wilson, and Dowell (1991) — namely, analytical methods (e.g. Keystroke Level Model: KLM; Task Analysis for Error Identification: TAFEI), specialist reports (e.g. layout analysis), user reports (e.g. interviews) and observational methods (e.g. HTA and link analysis) — each method is appropriate to certain stages of the product development cycle.

As Figure 1 suggests, analytical methods are mainly appropriate prior to product development. At this point, there is a good opportunity to iron out many potential problems at relatively little cost. During product design, specialist reports provide the main input; after product development most of the methods appear to be used. However, this is the most costly point in the design process at which to make changes and therefore underlines the impetus to include usability considerations earlier on. In this way, we may view usability input as a coarse-to-fine design approach. Early on in the design process it is able to offer a range of alternatives, which are successively refined until the product is implemented. This refinement goes hand in hand with the prototyping and evaluation process. Although Figure 1 may represent our notion of current practice, this does not necessarily mean that it is a desirable position. We are particularly keen to involve user evaluations earlier on in the design process.

Rapid prototyping is one means of achieving this. Developing prototypes enables the users to make a contribution toward the design process. In this way identified problems may be reduced well before the final implementation of the product. The contributions of the user do not only take the form of expressed likes and dislikes, but may be more objective in terms of performance testing. This participation may also provide the designers with a greater insight into the needs of the users. This can be particularly important when the users may not be able to express clearly what features they desire of the system, since they are unlikely to be aware of all the possibilities that could be made available. However, participants involved in prototyping should be either "real" end-users or, at least, representative users. Organizations often employ "product specialists" to act as users,

but these specialists will develop expertise which differs from that of "real" users. It would make more sense to use an ad hoc panel of users in the absence of access to "real" users.

In the rapid prototyping process, successive generations of the product are evaluated and the requirement specification finely tuned until the final product emerges. Rapid prototyping is a means of introducing the typically "late" evaluation techniques (illustrated in the "after" section of figure 1 — i.e. human factors methods used after the developmental cycle is complete) earlier on in the development cycle. Thus changes are likely to be more acceptable in terms of cost and therefore more likely to be implemented. Rapid prototyping recognizes that product development should be incremental, and allows usability to be incorporated into a succession of stages. As such, it manages to infiltrate the design process in a subliminal way rather than being a cumbersome add-on. Some organizations conduct prototyping trials in "usability labs". This formalizes the evaluation and provides the opportunity to capture behavior from a variety of sources simultaneously — for example, keystroke, eye movements, verbal protocols, and physical activity. This data is recorded by computer, eye cameras, audio tape recorders, and video recorders, thus enabling the analysis to be conducted at the analyst's leisure, and allowing the users' behavior to be scrutinized in fine detail. However, the mass of data generated will not take into account the fact that much of it is likely to be meaningless in the absence of performance criteria.

3.2. Evaluating Existing Products

Many writers have developed checklists for the evaluation of products in terms of their usability, one of the most detailed and helpful of which was developed by Ravden and Johnson (1989). Of the factors listed above, checklists will be most useful for 2, 3, 6, and 7 (effectiveness, attitude, task match, and task characteristics), and can be used to elicit users' attitudes, or to evaluate the relationship between task performance and computer. However, checklists are not the best way to assess items 1, 4, 5, and 8 (learnability, flexibility, perceived usefulness, and user characteristics). These could be considered either through experimentation (for 1 and 2, learnability and effectiveness) and observation (for 1 and 5, learnability and perceived usefulness), or through detailed specification of performance objectives (4, flexibility), or through development and testing of scientific theories (8, user characteristics). It is these latter approaches which are currently proving difficult to use. The main problem lies in the question of how to define performance criteria and experimental measures, which is mainly due to the fact that performance will be highly context dependent. It will hinge upon the nature of the task being performed and the knowledge that users bring with them to the interaction. In the absence of a coherent theory, one cannot model user characteristics. We are left, therefore, with an engineering, rather than scientific, approach. This means that the most promising way to measure usability effectively is by using real users of the computer system in question — for example when prototyping in system development. Many of the methodologies are similarly heuristic in nature and are not proven nor validated. This means that they should be used with caution. Other approaches available to researchers are verbal protocol, experimentation, task analysis, and simulation; these can be very useful in product evaluation,

but need to be performed after training in order to yield meaningful data.

3.3. Evaluating Early Concepts

While existing products can be evaluated quite simply by asking people to use them and then using a range of techniques to observe and analyze this usage, it is a harder proposition to evaluate conceptual products, i.e. paper-based designs. Yet, it is while the product is in its conceptual stage that the designer will have the best opportunity to incorporate usability into the design. A problem with usability is that, while it is possible to base specifications on products with which the designers are familiar, these products may not in themselves be "usable". As these familiar products are altered through redesign, then the usability specifications will necessarily alter — change the product and the nature of the product's use is changed.

A number of packages exist that allow designers to prototype proposed mock-ups of products. While such prototypes can be used to apply specific guidelines of product design, they cannot be used in an evaluation of usability unless they form part of a rapid prototyping schedule. Furthermore, it is only possible to prototype products when the task has been adequately described. This point is illustrated by Carroll and Rosson's (1991) notion of a task—artifact cycle. Basically, the design of a product will influence its use, which will influence users' goals, which will influence the design of a product. They suggest that scenario analysis or storyboarding as a means of capturing this cycle. This allows designers to maintain a flexible attitude to what and for whom they are designing. The designer's conception of how a task is performed is very different from that of a user, and this means that a gulf may well exist between design and user requirements. Capture techniques for user requirements have been developed, and a number of these which exist in ergonomics, such as task analysis, can be used successfully for this purpose. These can then provide objective information concerning real task requirements, which, in turn, can form the basis of specifications. However, such specifications will only provide "static" product data — i.e. information concerning how the product ought to look, not necessarily how it ought to be used "in anger". Baber and Stanton (1994) present a technique (TAFEI) which they claim can be used to analyze human interaction with products while development is still at the conceptual stage. This technique is potentially very useful to product designers.

4. SELECTION OF METHODS AND TECHNIQUES

To assist in the process of selecting methods and techniques to be employed in the usability evaluation we have devised the following heuristic chart (Figure 2) which could enable product designers to determine which method(s) is/are appropriate for their usability evaluations. This list is not intended to be exhaustive, and we invite readers to add their own. We have tried to highlight the need to consider those demands and constraints being placed on the project that are likely to affect the appropriateness of evaluation methods.

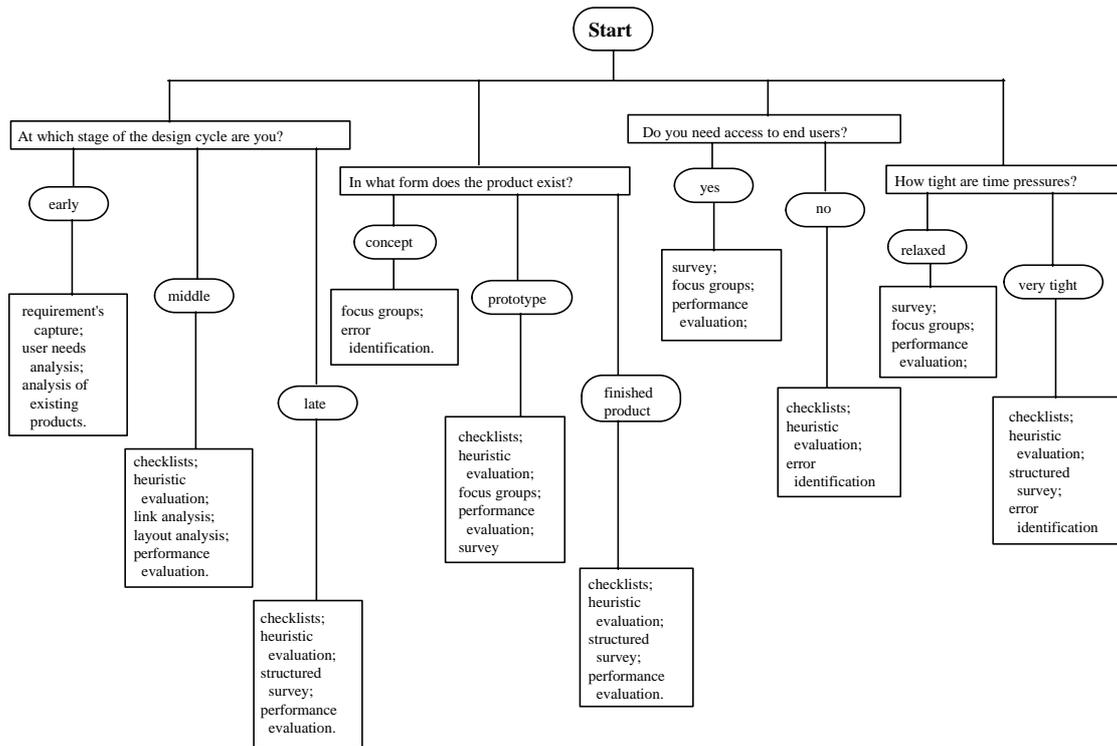
We have reduced the number of questions that the designer needs to ask about the end-user and project. The purpose of these questions is to enable the decision on choice of method to be based upon a considered judgement, rather than an ad hoc selection. We are not necessarily proposing that the procedure


Figure 2.

should be rigidly adhered to, but rather that considerable thought should be given to the choice of any one method in preference to another. We feel that the selection process should be the subject of further research and that the process should be as objective as is possible.

In brief, our approach makes explicit the questions that designers would ask before opting for an evaluation method. The factors to be considered are:

- the stage of the design cycle
- the form of the product
- access to end users
- time pressures

First, the stage that the design cycle is in needs to be ascertained: i.e. early (whilst the product is still in the conceptual stage), middle (when a prototype of the product has been produced) or late (when the final version of product has been produced). Different methods are appropriate at different points in the design process, as we have indicated. The second question asks if the product (or a similar product) needs to be in existence before the method can be used; some methods do not rely upon product existence. The third question relates to the availability of end-users. Again, some methods can be used independent of access to end-users. The forth question determines the time window of the project, as some methods can be performed relatively quickly. At present the checklist method appears to be the most popular in current practice; consideration of Figure 2 makes it clear why this is the case. The use of a checklist in the hands of an experienced designer and ergonomist can make it a very cost-effective evaluation method. Examples of other methods will be found throughout this volume.

CONCLUSIONS

In order to be used, and used effectively, any product should be "usable". This is not simply a truism (although at first glance it may appear so). Products should be designed to conform to basic principles of usability. This article has sought to outline some of these principles, and relate them to methods for usability evaluations. We would caution sole reliance upon outcome measures in usability evaluations, as they do not necessarily guide redesign of products. In usability evaluations we believe that product *use* is of greatest importance, and feel therefore that process measures are of most benefit. This observation is made on the premise that an understanding of how the product is being used will ultimately provide more useful information to the designer than telling them that the product was not usable. Usability can facilitate the design of human-centered products which are not only "user friendly" but also useful. Our interpretation of the concept of usability suggests that it is important to ensure a good task match between products and users. This task-oriented approach — rather than a technological one — is indicated by the methods we propose.

Goals Operators Methods and Selection Rules (GOMS)

P. Timmer

Ergonomics and HCI Unit, Department of Psychology, University College London, England

1. INTRODUCTION

One area of growing importance to ergonomists, and an area of specialism, is that of human–computer interaction (HCI). While the commercial trend is toward increasing the role of computing technologies in the workplace, accompanying this trend is an increase in design problems that concern the specification and evaluation of software applications. GOMS, or the Goals Operators Methods and Selection rules method (Card, Moran and Newell 1983), was developed at an early stage in the history of HCI research, and is a method with enduring appeal. When considering ergonomic contributions to the system development process, contributions may be considered along two dimensions; the stage at which the contribution is made, and the nature of the contribution. System development may be characterized in terms of a set of stages: requirements capture; design specification (conceptual and detailed); implementation; and evaluation (including testing and maintenance). The nature of a contribution, at any stage, may be either analytic or empirical. Therefore, when considering the stage of requirements capture, an ergonomist may either survey users to empirically elicit expressed requirements; or generate requirements analytically, following reflection on the domain, tasks, and so forth. Using this scheme of characterization, GOMS may be described as a method for analytic evaluation. To understand the enduring appeal of GOMS, one needs to adopt a slightly more complex view of the stages of system development. While the product under development will necessarily be evaluated, or at the least tested to ensure it works once implemented, specifications (for that product) at earlier stages of development may themselves be evaluated. For example, an ergonomist may generate two interface design specifications and wish to evaluate them both, to know which will be more effective, before the time-consuming and expensive stage of implementation is undertaken. Only by adopting a suitable method for early evaluation can such a design decision be made reliably. Given that at early stages of development device specifications alone exist (the process of implementation comes later), historically analytic methods have been required for early ergonomic contributions. (The recent rise of early prototype construction however, increasingly enables empirical contributions to be made at early stages of development.) GOMS was one of the first methods to support the early evaluation of design specifications, this being possible because GOMS supports the "prediction" of human–computer performance, rather than the "description" of empirically observed interactions. There are few methods in HCI which are predictive, fairly accurate, and which can be carried out quickly on the metaphorical "back of

an envelope". Hence the resilience of the GOMS method within HCI.

2. GOMS OVERVIEW

Models are frequently constructed in HCI design to reason about design decisions. Such models may be of the domain, user behavior, device behavior, user and device (work system) behavior, work system performance, and so forth (Whitefield 1990). The GOMS method outlines a set of components that, when combined, constitute a GOMS model. Such a model is largely of user behavior (both physical and mental). The GOMS method may be considered less a single method and more a family of methods, as models may be constructed at different levels of description, depending upon the purpose behind construction. The starting point for a GOMS model is to construct a hierarchical task description of the sub-tasks that a user must necessarily undertake to complete a task. This "Unit-Task" level of description may then undergo progressive decomposition, to "Functional", "Argument" and finally "Keystroke" levels of description (Card et al. 1983). A GOMS model at the keystroke level of analysis is at once: (1) the most detailed level of description (of the interaction); and (2) the level at which the greatest predictive accuracy and differentiation (from one design to another) are obtained. Before examining the assumptions that underlie the GOMS method, and providing an illustration of model construction, some consideration needs to be given to the scope of the method.

2.1. Scope

Construction of a GOMS model, from a design specification, is appropriate when the task to be modeled is well learned by the user. Card et al. (1983) focused upon the domain of text editing, a domain where a task such as correcting a spelling mistake requires little conscious thought beyond identifying the word to be corrected. An important consequence of scoping models to well-learned tasks is that it is possible to assume that the user does not undertake any complex cognitive behaviors. Instances where a user must reason about their next action, solve a problem prior to action selection, learn something during interaction (that has a bearing on later parts of the interaction), and so forth, do not fall within the scope of an accurate GOMS model. In addition to this "well-learned task" assumption is a further assumption that tasks are performed without error. Predictions of, for example, the time it will take a user to correct a spelling mistake will be accurate (within limits) provided the user makes no slips or mistakes in carrying out the correction task. Finally, when considering a GOMS model's contribution to design, greatest utility is attained when: (a) two interface specifications need early evaluation; and (b) criteria for deciding between specifications largely rest on speed or time to complete different tasks. As will be illustrated, a GOMS model that describes interaction at the level of individual keystrokes can be used to generate predictions of the time to be taken when completing different tasks. The design specification that leads to the fastest time to complete a given task may then be considered the superior design, i.e. the design that should be chosen for implementation. GOMS is therefore a time/speed-oriented method for early evaluation. It offers little assistance to the process of diagnosing, for example, why a dialogue's syntax leads to repeated user failure. The dialogue

should have been well learned by the user prior to modeling, and thereby lead to error-less performance.

2.2. Assumptions

The GOMS method is suitable for modeling user cognition (mental behavior) for well-learned tasks. As for any cognitive task analysis method, a set of assumptions about user cognition are utilized in model construction, assumptions that may be termed a "cognitive architecture" (Anderson 1983). Card et al. (1983) outline the "Model Human Processor" (MHP) architecture as a basis for the GOMS method.

The MHP describes the user in terms of a set of interconnected processors and memories. A single "Perceptual" processor accounts for how the user becomes aware of visual and auditory signals. Drawing upon knowledge from experimental psychology, a uniform time to process a perceptual signal is suggested (100 msec). Processed signals, from each modality, are then transferred to image stores within working memory, visual, and auditory stores respectively. Associated with each image store (and memory) is an assumed time for a signal to decay (if it has not been transferred to Long-Term Memory (LTM)), and a limit on the quantity of information that can be stored (a limit of 5 letters may be stored in the auditory image store for 1500 msec, after which time decay will take place if those letters have not been transferred to LTM). A second "Cognitive" processor is then proposed to operate on all the contents of working memory. Accounting for all cognition in terms of a single cognitive processor is possible because of the well-learned task assumption, separate processors for problem-solving, reasoning, learning, and so forth, are unnecessary as such cognitive behaviors fall outside of the scope of the method. The cognitive processor is assumed to link incoming perceptual information with memories for actions, what is called the "Recognize–Act Cycle". Once a specified action has been established, the third and final "Motor" processor is assumed to convert a mental representation (for an action) into physical behavior itself. These assumptions, embodied within the MHP, inform the structure of particular GOMS models, and are operationalized largely at the Keystroke level of modeling, the level at which times are associated with discrete keystrokes.

3. THE GOMS METHOD

The method itself shall now be considered. Four basic components are assumed: goals; operators; methods and selection rules. A goal is defined as a specification for a desirable state of affairs to be achieved during interaction, and may be decomposed into sub-goals. In text editing, for example, a goal may be to correct spelling mistakes within a document. Here, the top level goal is expressed as "GOAL: EDIT-MANUSCRIPT", and may be decomposed into instances (or "units") of correcting individual spelling mistakes. Each instance of a correction may be expressed as "GOAL: EDIT-UNIT-TASK". Within the MHP, it is assumed that information enters the architecture via the perceptual processor, is processed and action thereby arises. Each unit task is therefore decomposed into "acquisition" and "execution" sub-goals: "GOAL: ACQUIRE-UNIT-TASK"; "GOAL: EXECUTE-UNIT-TASK". The goal structure may thus be represented:

GOAL: EDIT-MANUSCRIPT

- • GOAL: EDIT-UNIT-TASK
- • • GOAL: ACQUIRE-UNIT-TASK
- • • GOAL: EXECUTE-UNIT-TASK

Goals are attained by sequences of operators, which are elementary perceptual, motor or cognitive acts (following the MHP's assumptions). With a goal such as "GOAL: ACQUIRE-UNIT-TASK", a perceptual operator "GET-NEXT TASK" may be employed, which describes the search for the next spelling mistake. Once the mistake has been identified, the execution goal "GOAL: EXECUTE-UNIT-TASK" may be attained by further sub-goals of "HIGHLIGHT-WORD", "MODIFY-WORD", and the mental operator VERIFY-EDIT". Building upon the goal description above, integration of reference to operators takes the following form:

GOAL: EDIT-MANUSCRIPT
- • GOAL: EDIT-UNIT-TASK
- • • GOAL: ACQUIRE-UNIT-TASK
- • • • • GET-NEXT TASK
- • • GOAL: EXECUTE-UNIT-TASK
- • • • GOAL: HIGHLIGHT-WORD
- • • • GOAL: MODIFY-WORD
- • • • • VERIFY-EDIT

Goals may be attained by more than one sequence of operators, each sequence may be described as a method. The goal "HIGHLIGHT-WORD" may be realized using a "MOUSE-METHOD" or a "KEYBOARD-METHOD". The MOUSE-METHOD may be decomposed into: move mouse to word; double click on word. The KEYBOARD-METHOD may likewise be decomposed into: move cursor to word; hold down shift key; use arrow keys to move cursor over word; release shift key. These alternative methods for attaining the goal are then embedded within the expanding task description as follows:

- •••GOAL: EXECUTE-UNIT-TASK
- ••• GOAL: HIGHLIGHT-WORD
- ••• • [select GOAL: USE-MOUSE-METHOD
- ••• • • • MOUSE-TO-WORD
- ••• • • • CLICK ON WORD
- ••• • • GOAL:USE-KEYBOARD-METHOD
- ••• • • • CURSOR-TO-WORD
- ••• • • • HOLD-SHIFT-KEY
- ••• • • • ARROW-OVER-WORD
- ••• • • • RELEASE-SHIFT-KEY

Where more than one method exists for attaining a goal, rules of selection are needed to determine under which circumstances each method is employed. Given that the task is well learned, it is likewise assumed that such rules are well learned and reliably implemented without conscious thought of selection. In the case of the goal "GOAL: HIGHLIGHT-WORD", rules may be:

Rule 1: "USE-MOUSE-METHOD" is the default method
Rule 2: If the cursor is already next to the word to be highlighted, and your hands are on the keyboard, "USE-KEYBOARD-METHOD" should be employed.

Having considered the basic components of the GOMS method, let us now illustrate its use with a simple example.

4. GOMS ILLUSTRATION TO THE KEYSTROKE LEVEL

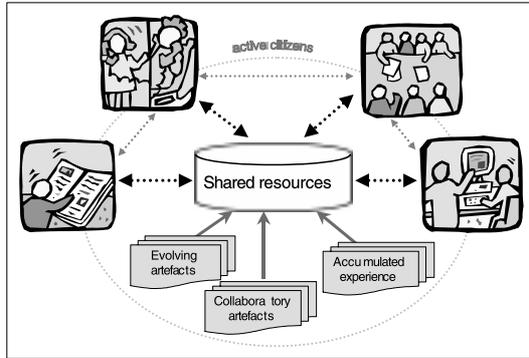
Let us consider the case of an ergonomist who has designed two competing dialogue specifications for a hardware firm's stock control application. Users of the application are to be well-trained employees of the firm, and the representative task to be considered here is that of specifying the details of a product as a means of querying stock details. Here we shall only be concerned with the


Figure 1. Text-box and command-line interface design specifications

dialogue for specifying the product, thus ignoring how the application presents the results of the query. In particular, we shall consider the dialogue for querying whether or not a 12-inch Stillson wrench is in stock (Newman & Lamming 1995).

Figure 1 shows the two competing dialogue specifications. For the text-box design, two generic data entry fields are presented for the input of details concerning a device and its size. In addition, an acknowledgment button is shown. For the command-line design, the command "cat" specifies that the query refers to a search of the catalogue, "still/d" specifies the first five letters of the name of the device being queried, with the switch "/d" indicating that the preceding letters refer to a device. Finally "12/s" specifies the attribute 12-inches, with the switch "/s" indicating that reference is being made to the size attribute of the device. Using the GOMS method, the following models may be constructed.

GOMS model for text-box specification:

    GOAL: QUERY-DETAILS-STILLSON-12
    •   GOAL: SPECIFY-CATALOGUE-DEVICE
    •   •   ACQUIRE-DEVICE-LABEL
    •   •   HOME-TO-MOUSE
    •   •   MOVE-MOUSE-TO-TEXT-BOX
    •   •   ACTIVATE-TEXT-BOX
    •   •   HOME-TO-KEYBOARD
    •   •   SPECIFY Stillson
    •   GOAL: SPECIFY-CATALOGUE-DEVICE-SIZE
    •   •   ACQUIRE-DEVICE-LABEL
    •   •   PRESS Tab
    •   •   SPECIFY 12
    •   GOAL: TERMINATE-QUERY

    •   •   ACQUIRE OK BUTTON
    •   •   HOME TO MOUSE
    •   •   MOVE-MOUSE-TO-OK-BUTTON
    •   •   PRESS-OK

GOMS model for Command-line specification:
    GOAL: QUERY-DETAILS-STILLSON-12
    •   GOAL: ENTER-CATALOGUE-MODE
    •   •   HOME-TO-KEYBOARD
    •   •   SPECIFY-CATALOGUE-COMMAND
    •   GOAL: SPECIFY-CATALOGUE-DEVICE
    •   •   SPECIFY Still
    •   •   SPECIFY-DEVICE-SWITCH /d
    •   GOAL: SPECIFY-CATALOGUE-DEVICE-SIZE
    •   •   SPECIFY 12
    •   •   SPECIFY-DEVICE-SIZE-SWITCH /s
    •   GOAL: TERMINATE-QUERY
    •   •   PRESS carriage return

Once such models have been constructed, the method provides a set of values for the time it should take a user to execute a range of different low level physical actions with the computer. The basic operators considered are:

time to make a keystroke (K);	
best typist (135 wpm)	0.08s
average skilled typist (55 wpm)	0.20s
average non-secretary typist (40 wpm)	0.28s
worst typist (unfamiliar with keyboard)	1.20s
time to point (P) with a mouse at a target	1.10s
time to home-in (H) on an input device	0.40s
time to mentally (M) prepare to specify an input	1.35s
time for device to respond (Rt) to an input	

(depends on device)

Given these tabulated values, and models that capture the frequency of each basic action with each dialogue specification, prediction of the times to carry out the query task with each design may be calculated. Generating such a prediction involves calculating the total number of each basic operation and multiplying by the time value provided for that operation. Therefore, for the text-box specification, the following prediction is generated (assuming the user is an average non-secretarial typist and system response is instantaneous).

GOAL: QUERY-DETAILS-STILLSON-12	
GOAL: SPECIFY-CATALOGUE-DEVICE	
ACQUIRE-DEVICE-LABEL	
HOME-TO-MOUSE	1H
MOVE-MOUSE-TO-TEXT-BOX	1P
ACTIVATE-TEXT-BOX	1K
HOME-TO-KEYBOARD	1H
SPECIFY Stillson	1M + 8K
GOAL: SPECIFY-CATALOGUE-DEVICE-SIZE	
ACQUIRE-DEVICE-LABEL	
PRESS Tab	1K
SPECIFY 12	1M + 2K
GOAL: TERMINATE-QUERY	
ACQUIRE OK BUTTON	
HOME TO MOUSE	1H

MOVE-MOUSE-TO-OK-BUTTON   1P
PRESS-OK   1M + 1K
Predicted time (Pt) = 3H + 2P + 3M + 13K
        Pt = (3*0.4) + (2*1.1) + (3*1.35) + (13*0.28)
        Pt = 11.09s

For the command-line specification, the following prediction is generated.

GOAL: QUERY-DETAILS-STILLSON-12
GOAL: ENTER-CATALOGUE-MODE
HOME-TO-KEYBOARD   1H
SPECIFY-CATALOGUE-COMMAND   1M + 3K
GOAL: SPECIFY-CATALOGUE-DEVICE
SPECIFY Still   1M + 6K   (a)
SPECIFY-DEVICE-SWITCH /d   2K   (b)
GOAL: SPECIFY-CATALOGUE-DEVICE-SIZE
SPECIFY 12   1M + 3K   (c)
SPECIFY-DEVICE-SIZE-SWITCH /s   2K
 GOAL: TERMINATE-QUERY
 PRESS carriage return   1M + 1K

   Predicted time (Pt) = 1H + 4M + 17K
         Pt = (1*0.4) + (4*1.35) + (17*0.28)
         Pt = 10.56s

In this command-line specification, the keystroke-level model assumes a single mental operator (at (a)) incorporates the specification of both device and switch (at (b)). The same is true at (c). Six keystrokes are shown at (a) to incorporate the space bar keystroke between "cat" and "still/d". It can therefore be seen that the keystroke level model predicts a half-second time saving when interacting with the command-line specification, as compared to the text-box specification. Such a time saving may well constitute the basis for a design decision in favor of the command line interface. An example of one such case, project "Ernestine" (Gray, John, Stuart, Lawrence and Atwood 1995) demonstrates how, when time is an important criteria, and the task is well learned (command language lexicon and syntax), GOMS accurately predicts that it may well be misleading to consider graphical user interface design specifications as a panacea for improved HCI usability.

Heart Rate as Strain Index

B. Kapitaniak

Maître de conferences à l'université Pierre et Marie Curie, faculté de
médecine Pitié-Salpêtrière, Paris, France

1. INTRODUCTION

The simplicity and the facility of receiving and constantly
monitoring the ECG signal, without any inconvenience for the
subject and with a low rate of interference, make it very popular
for the studies on work stations. Most often, the ECG is used for
calculating the average heart rate, which is one of the parameters
determining the index figures of the arduousness caused by the
work loads.

The advantages of the heart rate (HR) as a biological parameter
are numerous and undeniable. As far as methodology is
concerned, this parameter may be recorded without any
inconvenience for the subject, and continuously practically
without any time limit.

The heart rate is generated by the autonomous cardiac system
and then modified by an inhibiting action of the parasympathetic
vegetative nervous system or by an activating action of the
sympathetic system. This implies that any action of the vegetative
system has an effect on the heart rate: physical load, emotions,
noise, heat, general mobilization of the organism. All this makes
the heart rate a very interesting parameter for an ergonomist.

2. VALUES OF HEART RATE

In a subject, the instantaneous heart rate (calculated by taking
the inverse of the interval of each successive cardiac cycle)
fluctuates around an average counted over a minute. These
variations correspond to continuous adjustments that follow
breath rate, vessel tonus, thermoregulation, the control of blood
pressure, and, in all likelihood, other function of the vegetative
system. The spectrum of the heart rate includes the frequencies
of several corresponding oscillatory phenomena whose variations
result in this physiological arrhythmia called sinus arrhythmia.

The first records on the sinus arrhythmia (Krough) date back
to the beginning of the twentieth century and refer to the influence
of the breath rate on the heart rate. In 1938 Djourno worked out
a method of measuring the instantaneous heart rate.

The term "sinus arrhythmia" was introduced in the 1950s
to emphasize the physiological nature of that phenomenon. It
describes the arrhythmia occurring without any disturbances
of conductivity, i.e. recorded on perfectly healthy people. The
arrhythmia is noticeable only when observing the
instantaneous heart rate and at rest it can reach up to a 25%
deviation from the average heart rate, which is a relatively
constant value for a given functional state of the body. There
is a good correlation between the acceleration of the heart
rate and the reduction of the arrhythmia. In other words, the
stronger the impact of the adrenergic system on the heart, the
smaller the arrhythmia.

The average heart rate follows a circadian rhythm. It decreases
during sleep by 10 to 15 bpm (beats per min) in the first four
hours, but remains higher in day sleep than in night sleep.

2.1. Value at Rest

The inter-individual differences of heart rate at rest are very wide.
Average values contained between 40 and 100 bpm are considered as
normal, whereas in most cases these values range from 60 to 90 bpm.

The heart rate at rest rises by approximately 5 bpm between
the age of 25 and 60. In pregnant women the heart rate at rest
gradually rises until in the ninth month it reaches values higher
by 30% of the normal rate.

The heart rate may rise by 10 to 12 bpm in the two hours
following a meal. Coffee or tea increase the heart rate even more.

2.1.1. Posture influence

The heart rate is linked to the posture and its variations. The
heart rate is 10% higher when sitting than when lying, and 5 to
15% higher when standing. The shifting of position, both in work
and at rest, is marked by a transitory acceleration or slowing
down determined by the acceleration of the body mass
respectively from head to feet (quick shifting from crouching to
standing) or the opposite.

2.1.2. Environment influence

The environment changes the level of the heart rate at rest. Thus
the exposition to heat leads to an increase of the heart rate in
relation to the increase of the cutaneous blood flow necessary for
thermoregulation.

Exposure to an unknown noise of an intensity over 90 dB
provokes a progressive acceleration of the heart rate reaching 6
to 8 bpm in a few hours. In addition, a rapid transfer to high
altitude provokes an acceleration of the heart rate at rest due to
the decrease of oxygen content in the air. This persists for only a
few days if the altitude does not exceed 2 000 meters, and
disappears after a period of acclimation of about 10 days. For
higher altitudes it persists continuously.

2.2. Values during Physical Work

During physical work the heart rate increases systematically
whatever the task. However the mechanisms of the increase are
different according to the type of effort put in.

2.2.1. Dynamic work

During dynamic work an increase of the cardiac output
proportional to the power of the exercise and to the oxygen
consumption may be observed. It is accompanied by a decrease
of peripheral resistance making blood flow easier and limiting
the increase of blood pressure, which is insignificant during a
moderate dynamic effort and which concerns only systolic blood
pressure during an intense effort.

The increase of the cardiac output first results from a fast
increase of stroke volume at the beginning of the exercise, and
then essentially from cardiac acceleration. For moderate exercises,
therefore, there is an almost linear relation between the heart
rate and the power of the exercise, which allows deduction of
this power from the heart rate and knowledge of the subject's
physical capacity.

Since the heart rate increases more for arm work than leg
work with the same energy consumption, one must be quite
prudent when trying to assess the energy cost of a task
according to the heart rate. This can only be done with a
sufficient degree of certainty if an individual calibration was

realized during a simultaneous recording of the two physiological magnitudes, and moreover during an exercise which involves the same muscle groups as those prompted during the studied task.

2.2.2. Static work
During continuous static work involving a force higher than 20% of the maximal force (maximal voluntary contraction — MVC), the peripheral resistance increases because of the compression of the vessels by the contracted muscles. This increase leads to a significant reduction of the venous return and a defect in cardiac filling. At the same time, the muscles working in hypoxia trigger an adrenergic reflex which results in cardiac stimulation; this, in turn, increases the heart rate and blood pressure. This increase depends on the relative load supported by the muscle in terms of MVC percentage. These reactions are almost independent of the muscular mass involved in the contraction, which bears out their reflex origin.

2.2.2.1. Postural load
The professional work executed in uncomfortable postures generates an increase of the heart rate — standing, leaning forward, standing on tiptoe, kneeling or lying on one's back in restricted spaces, or work carried out with arms outstretched.

A postural constraint which involves levels of force lower than 15% MVC provokes cardiac accelerations between 100 and 120 bpm.

2.2.2.2. Static load
The motionless holding of an external load by muscles in isometric contraction is a very frequent situation in industrial work. At the end of the time limit of static holding, forces between 50% and 60% MVC, values of the heart rate between 120 and 130 bpm, and blood pressure between 150/100 and 170/120 are observed. For higher percentage of the MVC (> 70%) the values recorded at the end of the time limit are even higher.

2.3. Values Involving Emotive Stress
Among the physiological mechanisms involved in emotional reactions, the secretion of suprarenal catecholamines is systematically evoked. One of the consequences that may be easily observed is an acceleration of the heart rate without any relationship to oxygen consumption or even to the increase of cardiac output.

All stress situations lead to a cardiac acceleration: work under time constraint, the subject's anxiety, the occurring of an accident or a danger, increased responsibility, fear or physical pain. Cardiac accelerations up to 115 bpm were observed in dental patients during painful operations.

Conversely, when the cognitive work load is moderate and the work has become monotonous, the heart rate often slows down.

3. HEART RATE MEASUREMENT
3.1. Historical Methods
The first instrumental measurements, confined to laboratory studies, were recorded by Boas as early as 1928. They were based on electrocardiographic detection (ECG) of the cardiac rhythm. But it was Brouha who, in the 1940s, introduced measurements

of heart rate into industry. His field methodology was based on taking the pulse (cardiac pulsation perceptible in the wrist) with no instrument other than the chronometer, and on drawing a cardiac recovery curve established during a three-minute pause, thus constituting only a minimal inconvenience in the operator's work. The Brouha method still remains useful when no modern equipment is available.

In the 1960s and '70s, measurements in the field were carried out thanks to telerecording or the Holter system. Cardiac telerecording consists of a radio carried by the subject transmitting the ECG to a receiver. The result may be recorded on paper, onto a magnetic band and processed later, or on-line.

The "Holter" is a magnetic or hardware recorder which enables long recordings of an ECG signal of up to 48 hours, which can later be processed using various programs. The device is used in cardiology for clinical purposes, but may also be used on work stations. Its main drawback in ergonomics is the cost of the equipment and the training required for the processing of data.

3.2. Current Methods
Today, the heart rate is most often measured with monitors that allow automatic counting, displaying, and recording of the heart rate. The different appliances use either electrodes attached to the skin and connected with cables, or contact electrodes fixed with a chest belt on the thorax.

As the ECG signal picked up by the electrodes is recognized, the device counts the number of heart beats in a predetermined period of time or, depending on the appliance, the time elapsed for a specific number of beats. The choice of the counting time (integration constant) is adjustable between instantaneous heart rate and average rate in 1 minute. The appliance records only the calculated values. It therefore disposes of an autonomy which depends on the choice of the integration constant — the longer it is (for example, 1 minute) the longer the autonomy (24 to 48 hours), whereas for the instantaneous heart rate it seldom exceeds 3 hours.

The advantages of the system are numerous: continuous recording on long duration, simplicity of use, reduced dimensions, insignificant weight, low cost. The main drawback is the lack of control of the quality of the recording (detection of artifacts and parasites), since the original signal is not recorded. The technology of heart rate monitors is evolving rapidly, tending towards miniaturization, increase of recording autonomy, larger choice of time constants.

Currently, there are a dozen heart rate monitors available on the world market. The choice of an appliance must be based on its reliability, its range of choice of the integration constant (minimum required for instantaneous HR: 5 or 15 s and 1 min), its autonomy (minimum required for instantaneous HR: 4 hours and 24 hours with a constant of 15 s), and its cost. The cost of the electrodes must also be included in the running costs when the appliance uses disposable electrodes. This additional cost does not exist in appliances that use permanent contact electrodes.

3.3. Practical Technique of Measurement
The fact that heart rate varies according to numerous psycho-physiological factors makes it compulsory to watch the subject's activity directly during the recording. It is almost impossible to distinguish a cardiac acceleration of metabolic origin from one

of reflex origin using the recorded pattern. A precise description of the subject's activity is therefore necessary in order to interpret the results of his or her heart rate.

For each recording of the heart rate during professional activity one must choose the recording parameters which best correspond to the studied activity. Among these, the choice must consider above all the integration constant and the recording time.

3.3.1. Integration constant

Generally the longer the integration constant, the fewer rapid fluctuations appear. The time constant should be chosen according to the character of the constraint. To study the strain due to the execution of short time rapid gestures (for example, feeding a welding robot with a 24 s cycle), an instantaneous heart rate or a constant of 5 s must be chosen.

When the physical task includes important elements of static load, which lead to cardiac accelerations of reflex origin, the time constant must also be the shortest possible.

For studies concerning a strain due to mental load or stress situations, it is better to record the instantaneous heart rate whereby it is possible later to relate the beginning of an acceleration to a precise event and even to analyze the sinus arrhythmia.

The choice of a time constant implies the choice of a method of observation during the recording of the heart rate. The precision level of the task analysis depends on the task itself. If the content of the task is dynamic, general, and prolonged (for example, manual handling in loading a truck), it is sufficient to observe the physical characteristics of the work accomplished (tonnage, unitary weight of the carried load, walking speed, distance, height of lifting, other events). In such cases, the method best adopted is the recording of the average heart rate for 1 minute.

3.3.2. Recording time

The choice of the recording time depends on the constraint to be studied. The execution of dynamic, general, prolonged and repetitive work with short cycles could be studied with a recording limited to approximately 1–2 hours. The more heterogeneous and complex the task, the longer the recording time must be. The latter must always encompass the time corresponding to the whole set of various operations representing an entire productive set.

4. TREATMENT OF RESULTS

4.1. Absolute Values

The relevant values of the HR are, on the one hand, the average values of the period of work considered, which give an idea of the average workload imposed on the heart, and, on the other hand, the acceleration peaks which reveal the occasional risk sustained by the heart.

The average values may be calculated on complete work cycles provided that the same cycle is repeated continuously and that the profile of the HR in the cycle is not a slope. If, during a cycle or shift, the HR constantly increases, the average value will give an imprecise idea of the workload, in which case the final value is more relevant.

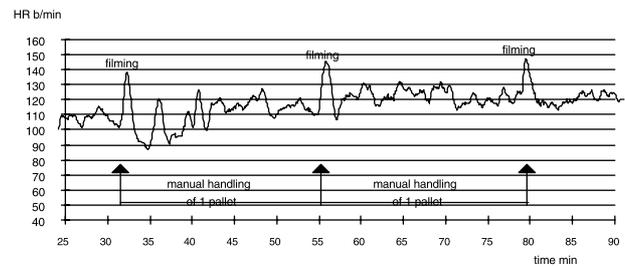
The occasional peak values allow the risk that a workload presents to the operator's health to be measured. Even if such


Figure 1. Heart rate during manual handling of small parcels (5 to 10 kg)

peaks are followed by adequate rest periods, they must be limited in value and duration as violent acceleration may be dangerous for the integrity of the cardiovascular system.

Figure 1 illustrates the changes in heart rate during the manual handling of small parcels in the building of pallets for supermarkets. The peaks correspond to the task of filming the pallet with the roll for stabilization.

4.2. Cardiac Cost

Brouha (1963) has introduced in work physiology the concept of *cardiac cost* by analogy with the energy cost of a task. The cardiac cost (CC) is defined as the difference between the HR value during a task and at rest.

4.2.1. Rest reference

The value at rest may be taken in different ways:
- in sitting position in the same condition as those at work, recorded over a period of approximately 15 minutes (Brouha 1963);
- for the study of work stations with recordings of long duration (> 8 h), Malchaire has suggested that the lowest value observed during the recording should be taken as a reference;
- for recordings of 24 h duration, Chamoux has proposed that the value of the fifth centile should be taken as a reference.

Despite all its drawbacks, Brouha's classic reference seems to be the most relevant for calculating the cardiac cost, even if during the shift day it is possible to note negative costs. It takes into account the subject's state at the beginning of the work and allows a better assessment of the effect of the task on the cardiac acceleration. The other references are difficult to obtain for they require recordings over very long periods and their use does not exclude the influence of the variability of the measured magnitude.

4.2.2. Relative cardiac cost

In order to limit the influence of differences in the physical capacities of subjects the relative cardiac cost (Ccr) may be calculated. The Ccr is a cardiac cost expressed in percentage of the maximal theoretical cardiac cost (CCmax) calculated from the maximal theoretical heart rate (HRmax). The proposed equation to calculate HRmax is the simplest and no more imprecise than other more complicated equations.

HRmax = 220 – age
CCmax = HRmax – HRrest
CCr = CC/CCmax * 100%

4.3. Sinus Arrhythmia

Many authors have expressed the opinion that the sinus arrhythmia is a good indicator of stress. A number of ergonomic studies performed on occupations as diverse as air traffic controllers, highway truck drivers, and surgeons confirm the practical usefulness of this parameter as far as the measure of the stress is concerned.

The methods of assessing the sinus arrhythmia applied so far have been mainly designed to test its behavior under the emotional loads during which the average heart rate does not change substantially. A simultaneous analysis of the deviations of the instantaneous heart rate from its average, and the beat-to-beat deviations are usually applied. Using Fourrier's analysis of the heart rate, the following parameters are considered: the frequency of maximal and minimal instantaneous values of the heart rate, the standard deviations from the average values, the values of the differences between two consecutive heart beats, the values of the positive and the negative differences between the consecutive impulses, and their distribution.

5. INTERPRETATION OF RESULTS

The interpretation of the results of recording the heart rate as an index of strain is all the more difficult as the constraints likely to have an effect on the vegetative nervous system are numerous. These difficulties even increase if the intensity of each constraint is moderate. This means that it will be impossible to distinguish the part of the cardiac response which is due to slight physical effort from that due to passing emotion, brief exposure to a noise or moderate heat, with all of them acting simultaneously.

Figure 2 shows the heart rate reached during an exercise on a circus trapeze by an artist revolving on his head. The same physical exercises are executed on a trapeze at 0.5 m and 5 m above the ground during a rehearsal, and at 5 m above the ground during a show. The only explanation for the differences observed during the same physical exercise is the emotional reaction.

When a heart rate occurring in conditions where a subject is exposed to multiple constraints is 40 b/min higher than the value observed at rest, the only observation that can be made is that the strain is excessive, but it is impossible to determine a dominating factor responsible for this excess.

5.1. Basis of Reference Values

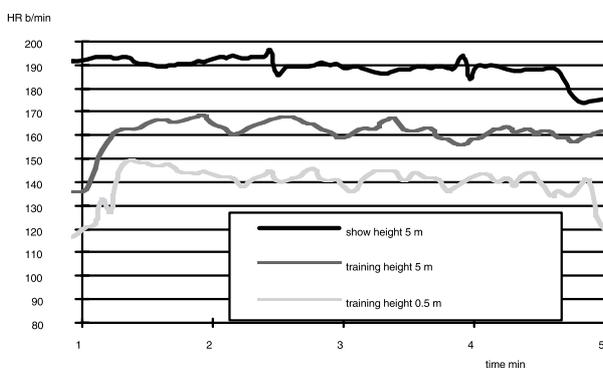
The thresholds proposed in the norms or recommendations are first given by way of example and are likely to be modulated. They


Figure 2. Heart rate during trapeze exercises

must not be considered by the ergonomist, or by those responsible for the production, as thresholds which can be "reached", but rather as limits from which one must try to keep as far as possible.

These thresholds can only be indicated according to the dominating constraint, given the different mechanisms involved by the different constraints. In the case where the constraints are multiple, only a competent ergonomist can interpret the result correctly. This implies of course that all HR recording is accompanied by a direct observation of the activity.

For the cardiac costs observed during the general dynamic exercise, the choice of the reference at rest determines the interpretation of the results. If Brouha's method is used, the average cardiac cost of the shift day thus calculated should not be higher than 30 to 35 bpm. For short periods of work, it is better not to go beyond a cost of 45 to 50 bpm. This is a consensus based on numerous experiences in the field, but with no rigorous experimental demonstration. If the reference of the fifth centile is adopted as the HR of rest, these values must be revised up. The average CCr observed during a shift day should not be higher than 30%, whereas with very short efforts it could go up to 50% provided the period of intense work is followed by an adequate recovery period.

The definition of a "short period" is as much a matter of consensus as the threshold values. In principle, the threshold values proposed for the workshift are normally fixed at 8 hours, and the values for "occasional" work do not exceed 30 minutes per shift (< 6% of work time).

5.2. Reference tables

Table I. Grid for assessing the general dynamic workload from the heart rate for occasional tasks (performed during 8 hours of work) and punctual tasks (performed for less than 30 minutes out of 8 hours of work).

	Classification of cardiac strain					
	Continuous (8 h)			Occasional (< 30 min)		
Class	HR	CC	CCr	HR	CC	CCr
Rest	80	0	0	80	0	0
Slight	100	20	20%	110	30	30%
Moderate	115	35	30%	130	50	50%
High	130	50	45%	150	70	65%
Very high	150	70	60%	170	90	75%

Table II. Limit values of cardiac costs not to be exceeded according to the principal work constraint, either in average values, or in peak values.

Principal constraint	Limit Values			
	Continous		peak	
	CC	CCr	CC	CCr
Dynamic	35	30	50	50
Static	Inapplicable		25	20
Stress	20	15	40	35

Human Body Positioning Analysis

S. A. Lavender and G. B. J. Andersson

Department of Orthopedic Surgery, Rush-Presbyterian-St Luke's Medical Center, 1653 West Congress Parkway, Chicago, IL 60612, USA

1. INTRODUCTION

Positioning analysis refers to the evaluation of the body's posture that occurs during a work task. The analysis of work postures is a fundamental concept in the study of industrial and office ergonomics. Working in "awkward" postures is considered one of the classical risk factors associated with upper extremity cumulative trauma disorders (Putz-Anderson 1988, Sommerich *et al.* 1993). Although it must be remembered that posture is a time-dependent quantity and changes with movement. At some point as movements become faster it makes little sense to talk in terms of limb or body part's (segment) posture or a joint's position and instead focus on the dynamic characteristics of the motions involved as these potentially relate more to the risks inherent in the activity. With slower or even static work activities the posture to a large degree impacts the mechanical loads experienced by the muscles and joints within the body.

The objectives of this chapter are threefold. First, to review why position (body's posture) is important. Second, to review the various ways postures and or joint positions can be described and quantified. And third, to discuss in general terms how postures can be controlled through workplace interventions.

2. WHY IS POSITION (BODY POSTURE) IMPORTANT?

In a biomechanical sense, position data are used to describe the orientation of each individual body part being studied within a two- or three-dimensional space. Operationally, these data may be obtained qualitatively through categorizing observed postures (checklist), or quantitatively using goniometers, or by using video-based, sonic-based or electromagnetic-based motion measurement systems. Qualitative observations and goniometers are used to assess postures directly but in doing so fail to provide information about the body's orientation relative to a world coordinate system. More advanced motion measurement systems provide the orientation of a body part relative to a known global coordinate system. The difference in orientation between a body part and an adjoining body part can be determined, and it is this difference that defines the posture referred to in the orthopedic and ergonomics literature.

2.1. Importance of Global Orientation

In addition to representing the posture, the global orientation becomes important if one wishes to study the load placed on a connecting joint between two adjacent body segments due to gravitational loading. Gravity, depending on the mass of the body part being studied, can be a major contributor to the moment acting on an articulation within the body during a work activity. When an individual is performing a work task in a posture that does not change over time (or changes very slowly) the mechanical loading of the affected joints is in large part due to the 'external' moments created by each body segment's orientation in space relative to gravitational and other applied external forces. The latter might include the weight of a tool in the hands or forces due to acceleration of the body ('G' forces). In order for the posture to be maintained, the net external moment must be neutralized by the combined internal moments stemming from muscles and other passive tissues (ligaments, disc fibers, inactive muscle, etc.). Because of the short lever arm over which muscle forces act, the muscle forces needed to stabilize the body are quite large relative to the applied external forces and therefore are the primary contributors to the mechanical loads placed on the body's joints. Thus, by analyzing the position of body segments relative to the world coordinate system, the external moments due to gravity can be determined. And it is these external moments that are determinants of joint loading.

2.2. How Posture Affects the Muscle Physiology and Biomechanical Relationships

Posture defines many of the biomechanical relationships within the body including the muscle length and the length of a muscle's lever arm. Muscle length determines the overlap that exists in the actin and myosin fibers within the sarcomeres. There is an optimal amount of overlap in these fibers when it comes to developing force within the muscle tissue, thereby making strength a quantity that is dependent upon posture. This variation in muscle strength as a function of muscle length is known as the "length–strength" relationship within muscle. In addition, strength is dependent upon posture because the length of the lever arms over which muscles exert force change with the orientation of one body segment relative to another. For example, the erector spinae muscles have been shown to have a longer lever arm (greater mechanical advantage) when the spine is maintained in a lordotic posture (Tveit *et al.* 1994). Thus, both the muscle length and its mechanical advantage change as a function of body posture.

To some degree this is simplistic in that the length of single joint muscles, for example, the brachiallis can easily be inferred based on a single postural measurement. For muscles that cross multiple joints the relationship is the same in general terms, however, the length is dependent obviously on the orientation of all joints involved. The length of the Biceps is dependent upon forearm rotation, elbow flexion, and shoulder motion (glenohumeral rotation). The lengths of the flexor digitorum profundus muscles are dependent upon the wrist posture and the interphalangeal joints. Each of the joints serves as a pulley for the long tendons extending out to the fingertips. When the pulley system is altered, for example, through carpal tunnel surgery in which the transverse carpal ligament is severed, the relationship between muscle length and joint posture changes such that a worker may be forced to use muscles that are nowhere near their optimal length.

As muscles approach their maximal length more and more of the internal forces are developed through the passive tissues. For example as the trunk is fully flexed Floyd and Silver (1951) reported that the erector spinae muscles became electrically silent. This means that the passive tissues developed the stabilizing internal moment, namely ligaments, passive muscle and tendon stretch, and disc fibers. If repeated often this loading of the passive

tissues may leads to laxity within the structures responsible for stabilizing the vertebral column. Where the passive tissues are not capable of producing the necessary internal moment to stabilize the body part, muscles still must be recruited. Given that the muscles are operating from a weak position due to their stretched position, the risk of overexertion injury is increased near the end range of motion.

2.3. Interplay between Posture and Motion

When motion is involved, the contribution of body segment orientation to the net external moment changes over time. Now the external moment is composed of the forces due to the body segment's linear acceleration ($F = m.a$) and the inertial properties of the body segment as it is being rotated, in addition to the static moments discussed above. Hence, with motion, body positioning while still a contributing factor contributes less to the net moment and the overall anticipated joint loading. The faster the motions the more important the dynamic terms become in terms of mechanical loading and tissue injury (Marras *et al.* 1993, 1995). Alternatively, when motions are very slow the inertial and acceleration components may be negligible, and hence the posture takes precedence in determining the resulting joint loads and the potential injury risk, particularly near the end range of normal motion for an articulation.

3. WHAT ARE "AWKWARD" POSTURES?

Ergonomic texts often refer to "awkward" postures as being risk factors for cumulative trauma disorders. This is distinctly different from awkward motions. For in the latter the posture is a time varying quantity and only held for an instant in time. Therefore, concern regarding awkward postures applies primarily to static work tasks. But what makes a posture "awkward"? Clearly, it takes more than being static for a posture to be awkward. Someone working with no shoulder flexion or abduction can be working in a static (non-changing) posture. However, few would contend that having the arms hanging by the side is an indicator of an ergonomic problem. Conditions often associated with awkward postures are:

1. Joint rotations near the end range of motion.
2. Those that require compound rotations of a joint.
3. Those that require muscle force to maintain.

By themselves each of these factors can be shown to contribute to the awkwardness, however, none define the condition exclusively. For example, we think of extreme wrist flexion or extension as being awkward. However, for the knee or elbow the 'neutral' posture is very near one end of the range of motion. Moreover, we would consider 90° of shoulder abduction as awkward, yet this is not near the end range of motion. Compound rotations, as the name implies, refers to rotations in two or three planes of motion. For example, wrist flexion combined with ulnar deviation while not at the end range of motion would be considered an awkward posture. Postures that result in substantial gravitational loading, as with 90° of shoulder flexion, require muscle force to maintain. Over time the muscles can be expected to fatigue thus leading to discomfort on the part of the worker. Again, however, this condition is not necessary or sufficient by itself to define awkward. The elbow can be flexed 90° while holding a tool or working at a keyboard. Even though there is gravitational loading, and hence, muscle recruitment, this posture

would not be considered awkward. In essence, awkward postures can best be defined as static postures in which one or more of the listed conditions exist.

Awkward postures are cause for concern as these are frequently cited as precursors to injury development in occupational settings. Work postures that require neck flexion, trunk flexion, trunk lateral flexion and twisting, shoulder flexion, shoulder abduction, wrist flexion, ulnar deviation, have all been associated with discomfort or injury reporting in the workplace (Tanzer 1959, Maeda 1977, Armstrong *et al.* 1982, Hagberg 1984, Masear *et al.* 1986, De Krom *et al.* 1990, Punnett *et al.* 1991, Winkel and Westgaard 1992, Armstrong and Lackey 1994). Figure 1 shows a simple model illustrating that the physical characteristics of the work site, the individual employee's characteristics, and the psychosocial work environment all contribute to the work posture attained while performing a particular work task. Thus, ergonomic evaluations of the work tasks need to document the postures observed, preferably in a quantitative fashion, and investigate the workplace, individual and psychosocial factors that may be responsible for the observed work postures.

3.1. How Long are Awkward Postures Held?

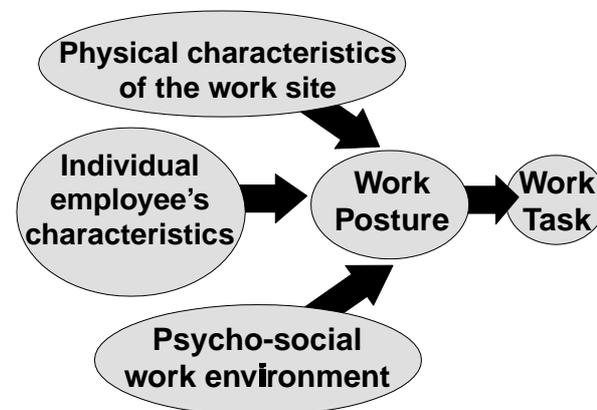
Two key parameters of the work posture that affect an employee's ability to perform the work task(s) are the duration of the posture and the rest or recovery time between the work postures. Figure 2 shows the hypothetical interaction between the rate of fatigue, the degree of postural deviation, the duration of a work task, and the recovery time between work tasks. The longer a posture must be held (duration) the faster and individual will fatigue. The rate of fatigue is also dependent upon the degree of postural deviation, with greater deviation from a neutral relaxed posture leading to an increased onset rate of fatigue. This is primarily due to the increased muscle force that is most often associated with greater postural deviation. The time between work tasks allows muscles responsible for maintaining the body posture to rest and recover. The greater the recovery time between work tasks the slower the onset of fatigue. Therefore, any analysis of postures observed in the workplace is not complete unless these two parameters are also recorded. While the link between muscular fatigue and injury is not necessarily known at this time, the link between muscular fatigue and discomfort is pretty


Figure 1. Potential factors accounting for the body postures observed in task performance.
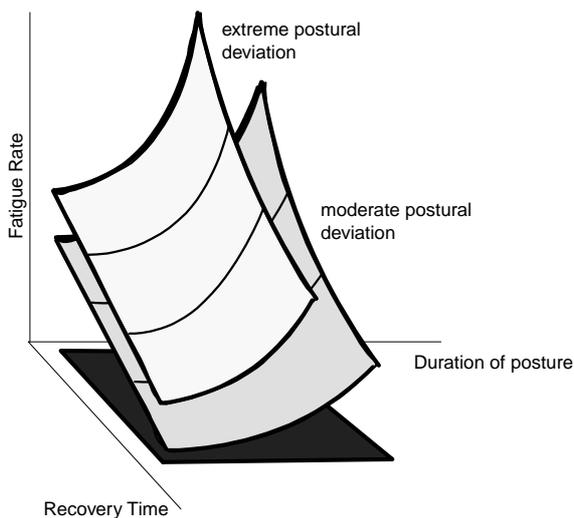

Figure 2. A conceptual model showing the theorized interaction between postural deviation, posture duration and recovery time.

straightforward. Fatigue has generally been associated with reduced productivity, work quality, and attentiveness, in addition to an increased accident potential.

4. DESCRIBING AND QUANTIFYING POSTURES AND OR JOINT POSITIONS

Postural descriptions usually form the basis of an ergonomic analysis. Often work postures, or ranges of motion in dynamic activities, serve as the flag that captures the ergonomist's eye. This is because, in general, the more a posture deviates from that of a relaxed standing posture with the arms at the side, the more loading experienced by the joints, tissue compression, and or force required in the muscles. Thus, when an ergonomist tours a facility and sees individuals working with the hands above shoulder level, the back bent or twisted, or the wrist extremely flexed, immediately there is cause for concern. This is especially true if the postures are held for any duration. If the postures are transitory as part of an overall motion, then it is the end range of the motion that will capture the ergonomist's eye. Once observed, the work postures need to be described so that risk assessments can be made and the observations communicated to others.

Several techniques are available for describing and quantifying postures. They range from simple gross descriptions, for example pinching or pressing (Armstrong *et al.* 1979), to categorical descriptions joint angles (Armstrong *et al.* 1982, McAtamney and Corlett 1993), to full quantitative measurement of three-dimensional angles. If measuring angles, even coarsely, the first and foremost requirement is the selection of a measurement system. In ergonomics, postures are most often described in terms of the orthopedic angles as defined by the American Academy of Orthopedic Surgeons (1965). This system defines each joint's posture by evaluating the angle between adjacent body parts. Other systems quantify postures by determining each body segment's orientation relative to a global coordinate system. This type of postural description is required to use the 2D and 3D Static Strength Prediction Models developed by the University of Michigan (Chaffin 1970, Chaffin *et al.* 1977).

The second major issue is the degree of accuracy that is required. In an ideal world we would always collect extremely accurate postural data. However, in reality increased accuracy comes with an increased price. The cost of measurement equipment, data collection and processing time, and training on the part of the individuals assessing the workplace may make that added accuracy gained by more precise measures not cost effective. In general, however, the better you can describe the problem that exists the better chance that your will solve the problem. Thus, the more quantitative the description the better the reading of the true problem.

In deciding on the appropriate workplace assessment method the evaluator should keep in mind how the assessment will be used. Qualitative descriptions of postures may be adequate when the assessments do not have to be communicated to others, and budgets for workplace interventions do not have to be justified. But in most cases one's observations need to be summarized and communicated to management in a form that allows all to understand the seriousness of the problem. Reporting that a task needs to be modified because the operator "works in a posture with flexed wrists" may not adequately communicate the problem and the need to invest the money in correcting the problem. By quantifying, the same report could have communicated that the operators, on average, exhibited 50° of wrist flexion. Not only does this accurately describe the nature of the problem, but it also provides a benchmark by which future intervention efforts can be compared. Goals can be developed for the intervention process, for example, that the average wrist flexion be reduced to < 15°. Mock-up workstations can be created before the resources are invested to ascertain whether the postures were controlled by the proposed intervention by comparing pre and post measurements.

When measuring orthopedic angles a goniometer can be used to quantify postures. However, it is imperative that the measurements be obtained without interfering with the work process. Therefore, most of the time postural measurements are made from videotapes rather than from the observed individuals directly. This introduces a number of errors into the process however. Ideally the video camera is oriented in a plane orthogonal to the plane of measurement and adjusted such that the center of the image corresponds to the articulation of interest. With two-dimensional motions, for example lifting tasks within the mid-sagittal plane, locating the camera in an orthogonal plane is a possibility. High contrast adhesive markers attached to the limbs and the torso facilitate the extraction of measurements from videotape by providing consistent reference marks on the limbs and joint center locations. In reality most studies need to quantify the posture of multiple body parts at the same time thereby leading to wider camera angles and increased error in measuring postures further from the center of the video-camera lens. One of the challenges facing the ergonomist is where to position the camera such that all the articulations of interest are visible at the same time and are not blocked by machinery or other equipment in the workplace.

With tasks that create postural deviations in three dimensions it becomes very difficult to accurately measure postures from the screen directly. Because we can extract the necessary information from a two-dimensional image on the video monitor to simulate the observed posture. The ergonomist is then better off measuring the simulated posture than attempting to measure from the video

monitor directly. The use of multiple video cameras increases the accuracy of three-dimensional postural descriptions. Wherever possible a synchronization signal is used to insure that video data are describing the same motion or posture. In a laboratory setting when an individual performs a task within a calibrated region of space, the data from two or more video cameras can be obtained and integrated to resolve the three-dimensional coordinates of the body segments. But these systems are very difficult to use in normal work environments. More recently magnetic based systems have become available that allow three-dimensional posture and motion measurement of multiple body segments without relying on video data. Unfortunately, because these systems are susceptible to interference introduced by metallic objects in the work environment, they are of limited use outside the laboratory.

When the study is limited to specific body parts, for example the spine or the wrist, electrical goniometers or inclinometer may be used. The simplest version of an electrogoniometer consists of two rigid tangs that can be affixed to the adjacent body segments

Figure 3. Electrical goniometers used to quantify postures and motions of the wrist (a) when performing a keyboarding task (photo courtesy Richard Marklin) and on the spine (b) when performing a beverage delivery job.

hinged by a potentiometer. These devices are usually strapped or taped to the skin such that the axis of rotation aligns with the joint's axis of rotation (Figure 3a). For the elbow an electrical goniometer designed to measure flexion should be should be positioned such that it is on the lateral side of the upper and lower arm with the potentiometer centered over the joint between the humerus and the radius. A single axis potentiometer works well if the joint can be conceptualized as a hinge joint. With the knee, for example, this assumption may not be valid as there can be three-dimensional motion in addition to a shifting center of rotation as the femur tibial contact point changes with knee flexion. Thus, for extremely accurate measurements a more complex set of goniometers may be needed (Chao 1976).

Trunk postures and motions have been measured using various types of instrumentation. Nordin *et al.* (1984) reported a flexion analyzer that was essentially an inclinometer strapped on the back. This device provides data indicating the duration of the working time that was spent in five flexed postures consisting of 18° intervals between 0 and 90°. This device is useful for obtaining an overall picture of the trunk postures required in a job across many tasks and work cycles. The device clearly distinguished the difference between dentists, who flexed forward only moderately, and warehouse workers who worked in deeply flexed postures. The same device was later used by Magnusson *et al.* (1990) to study the trunk postures in assembly line workers performing highly repetitive work. Snijders *et al.* (1987) reported on the development of a device that can be worn beneath the clothing and can collect three-dimensional trunk postural data throughout a workshift of eight hours or more. The data are stored on a multichannel tape recorder and can be analyzed later. Marras *et al.* (1992) have developed the Lumbar Motion Monitor, which in addition to measuring the instantaneous posture of the lumbar and lower thoracic spine in three dimensions, provides the angular velocities and accelerations associated with the movements. The LMM gives very precise information regarding the postures and motions from each individual activity sampled. If one is looking at primarily static task then the postural data are the primary focus of the analysis. If one is looking at a dynamic material handling task then the motion parameters such as range of motion, velocities, and accelerations become the focus of the analysis. This device is now commercially available (Figure 3b) as are other devices that perform a similar function. The key to these devices is the software used to collect and analyze the workplace data. It needs to allow the observations to be grouped according to the tasks and subtasks observed and allow the user to enter relevant workplace data, for example reach distances, weights handled, and working heights, with each observation recorded. This insures that the motions and the workplace parameters responsible for those postures or motions are linked within the database. This is essential when analyzing the data to determine the best type of workplace interventions.

5. SUMMARY

Analysis of work postures, whether qualitatively or quantitatively performed, is a crucial step in the identification of ergonomic problems. The work postures define the strength demands and the degree of muscular loading experienced by the affected articulations and are frequently associated with discomfort or injury in the workplace. Various means are available for

performing postural analysis. The more quantitative the description and the more employees studied the better the chance that the physical characteristics of the work site responsible for the posture will be identified. Once work posture problems are identified several options are available to control work postures, or at least, the total duration of an employee's work experience in the identified postures.

1. INTRODUCTION

In most of production systems, such as assembly lines of a semiconductor plant, manufacturing processes of a chemical factory or process controls in power plants, the human operators follow the standard operation procedure (SOP) to perform their tasks. However, some errors many occur and result in product deficiency or system breakdown. Comparing the equipment errors and human errors, the former is more obvious whereas most of the human errors except few significant ones that cause an accident are hidden in the operating process. Such latent human errors have to be clarified by some special techniques, otherwise the exist in the process and may gradually damage the system.

Each human task may involve several potential error modes, but only some of the error modes have high occurrence probability that cause severe consequence. If a task contains human error modes with high error probability or severe effects, this task is called the critical human task. From a quality control point of view, the more efficient strategy to improve product quality or system reliability is by identifying the potentially critical human tasks so that the corresponding errors can be reduced.

Here, a newly developed method on human error analysis, so-called the "Human Error Criticality Analysis (HECA)" is introduced. HECA is a practical method to identify the potentially human tasks and their associated error modes, as well as showing the relationships among these error modes.

2. BACKGROUND OF THE HECA

Methods have been developed for criticality analysis. The most popular method used in the military is Failure Modes, Effects and Criticality Analysis (FMECA), which identifies all possibilities of catastrophic and critical failure so that they can be eliminated or minimized through re-design at the earliest life cycle time. The FMECA method has many advantages since it is easy to understand, well accepted, a standardized approach, non-mathematical, etc. Nevertheless, FMECA is a hardware-oriented method and it analyzes hardware reliability while assuming the software and human to be perfect, which may lead the analyzers to neglect the risk caused by human error. The fundamental of FMECA, such as basing on SOP, has been applied to the development of HECA, which is used systematically to evaluate the human-related failures.

Another widely used method from the human perspective is human reliability analysis (HRA) methods used to identify human error path by event or fault trees. The HRA methods have some databases of human error to support the technique, but they have some limitations on evaluating the critical human tasks. The most noticeable deficiency is that the probability of error occurrence is calculated based on the event tree, and thus the degree to which the error affects the risk cannot be fully determined until the outcome is integrated into another consequence analysis technique. One of the steps in HECA is estimating human error probability (HEP) such as that in the HRA method, but for some improvement the risk assessment and human reliability can be analyzed simultaneously by HECA.

3. IMPLEMENT OF THE HECA

3.1. Main Steps

The analysis process of HECA is based on the SOP. Using the criticality matrix and HECA event tree, the HECA report can be completed to produce outputs such as critical human tasks list, critical human error mode list, reliability information and HECA event tree. Thus, HECA consists of four main steps: task analysis, HECA event tree construction, HEP estimation and HECA worksheet analysis.

Step 1: Determining SOP and performing task analysis:
- Coding and describing each human task in HECA worksheet.
- Identifying human error modes of each human task in HECA worksheet.
- Predicting the error effect of the error mode in HECA worksheet.
- Classifying the severity of error effect in HECA worksheet.

Step 2: Constructing the draft HECA event tree.

Step 3: Estimating the HEP of human error modes (λ_{ij}), probability of hardware failure (γ_{ij}) and error–effect probability (β_{ij}):
- Filling the HEP of human error modes (λ_{ij}) in HECA worksheet.
- Filling the probability of hardware failure (γ_{ij}) in HECA worksheet.
- Filling the error–effect probability (β_{ij}) in HECA worksheet.
- Calculating the human tasks (λ_{ij}) via HECA event tree.
- Calculating the human reliability of tasks (R_i) and the human reliability of mission (R_m).

Step 4: Completing HECA worksheet:
- Calculating the criticality index of error modes (CI_{ij}).
- Calculating the criticality index of tasks (CI_i).
- Drawing and analyzing criticality matrix.
- Listing the critical human tasks, critical human error modes, reliability information and showing the HECA event tree.

3.2. HECA Worksheet

The HECA worksheet has to be completed through deep interviews with managers or specialist of the operating system. The HECA worksheet (Table 1) is composed of 13 items, defined as follows:
- Human task identification number: number of human task.
- Human tasks: describe all the tasks operated by person(s) in a selected mission.
- Human error modes: state of error committed by person(s). This mode may either be an omission or commission. All human error modes should be listed and analyzed whether they may cause immediate or latent failures of the system.
- Probability of hardware or software failure (γ_{ij}) includes the failure probability of material, equipment, tool and even software. The failure rate of hardware can be generated from the database, e.g. MIL-HDBK-217F (1992) or by the judgment of an experienced engineer.

Table 1   Human Error Criticality Analysis (HECA) worksheet (a sample)

human task identification number (ID)	human task	human error modes	probability of hardware failure(γ_{ij})	HEP of human error mode(λ_{ij})	HEP of human task (λ_i)	error effect	severity classification	error-effect probability (β_{ij})	criticality index of human error modes(CI$_{ij}$)	criticality index of human task (CI$_i$)	human reliability (R$_i$,R$_m$)	remarks
1...	Inspecting before assembly Recording part #

:	:	1.1.2 wrong record	☐	0.005		part's quality	C4		1			
:	:					:						

- HEP of human error mode (λ_{ij}): probability that ith human task is performed and jth human error mode happened. This mode may just be a simple error (i.e. human error only) or a compound error (i.e. human error leading to hardware failure has occurred or simply a prior human error has occurred). If the human error mode is a compound error, this HEP of human error mode is called CHEP (conditional human error probability). The joint HEP of jth human error mode (λ_{ij}) multiplied by the failure probability of the hardware (γ_{ij}) (assume the human error and hardware failure are independent), i.e. joint HEP = $\lambda_{ij} \times \gamma_{ij}$. There are many ways to estimate the HEP of human error mode (λ_{ij}); some are statistical, and some are judgmental. But it is important to differentiate whether the HEP is a simple HEP or a CHEP to avoid misinterpretation.
- HEP of human task (λ_{ij}): probability when ith human task is performed and an error mode occur. Table 2 shows the levels and description of different λ_i. This is calculated by:

$\lambda_i = 1 - \Pi_j(1 - \lambda_{ij} \times \gamma_{ij})$, if all of the human error modes are simple errors and each of them are independent.

$\lambda_i = 1 - \Pi_j(1 - \lambda_{ij} \times \gamma_{ij})$, if all of the human error modes are compound errors and not only is each of them are independent, but also the human error and hardware failure are independent; or

$\lambda_i = 1 - [(1 - \lambda_{i1}) \times (1 - \lambda_{i2}) \times \dots (1 - \lambda_{ij} \times \gamma_{ij}) \times (1 - \lambda_{in} \times \gamma_{in})]$, if some of the human error modes are compound errors and the others are simple errors.

- Error effect: include the error impacts to hardware system, system function, mission objectives, personnel safety, etc.
- Severity classification: impact of the human error mode on the system level. Can be considered from the standpoint of safety, reliability, maintainability, quality, cost, etc. Table 3 is an example of severity classification of cost.
- Error–effect probability (β_{ij}): conditional probability that the error effect will result in the identified severity classification given that the jth human error mode of ith human task has occurred. Table 4 describes the failure effect of β_{ij} in a case.
- Criticality index of error modes (CL$_{ij}$): a criticality number standing for the occurrence probability of ith human task attributable to jth human error mode which results in the identified severity classification. Criticality is equal to the HEP of human error mode (λ_{ij}) multiplied by the probability of error effect (β_{ij}), i.e. CI$_{ij}$ = $\lambda_{ij} \times \beta_{ij}$ (simple errors) or CI$_{ij}$ = $\lambda_{ij} \times \gamma_{ij} \times \beta_{ij}$ (compound errors).
- Criticality index of human task (CI$_i$): occurrence probability

of ith human error that results from one or more human error modes that will induce the identified severity classification. Can be calculated using CI$_i = 1 - \Pi_j(1 - \lambda_{ij} \times \beta_{ij})$ (simple errors) or CI$_i = 1 - \Pi_j(1 - \lambda_{ij} \times \gamma_{ij} \times \beta_{ij})$ (compound errors).

- Human reliability (R_i or R_m) is the probability that a person correctly performs ith human task in a required period and in a specified environment. Human reliability of mission (R_m) is the probability of successfully performing all the tasks of the mission. Based on the data of HEP of human error mode (λ_{ij}), HEP of human task (λ_i) and HECA event tree, one can calculate for human reliability (R_i or R_m). If all the sequential human tasks are independent of each other, the human reliability of ith task and human reliability of mission can be calculated by:

$R_i = 1 - F_i = 1 - CI_i = 1 - \Pi_j(1 - \lambda_{ij} \times \beta_{ij})$ (if all the errors are simple error), where F_i is the failure probability of ith task, $R_m = \Pi_i R_i$ (series system) or $R_m = 1 - \Pi_i(1 - R_i)$ (parallel system); or

$R_i = 1 - F_i = 1 - CI_i = 1 - \Pi_j(1 - \lambda_{ij} \times \gamma_{ij} \times \beta_{ij})$ (if all the errors are compound error).

According to the HECA worksheet data, we can construct the criticality matrix. Then, the final HECA event tree can be presented subsequently. Figure 1 shows a partial HECA event tree in a case.

Figure1. A partial HECA event tree.

Table 2. HEP of human error modes χ_{ij}) of a case study.

Level	Description	λ_i vlaue		Average
A	Frequent	1.0	0.1	0.5
B	Probable	0.1	0.01	0.05
C	Occasional	0.001	0.0001	0.005
D	Remote	0.001	0.0001	0.0005
E	Improbable	0.0001	0.0	0.00005

Table 3. Severity classification of cost.

Level	cost loss percentage	description
C1	100	hardware system will result in 100 cost loss given the error effect happen
C2	75	hardware system will result in 75 cost loss given the error effect happen
C3	50	hardware system will result in 50 cost loss given the error effect happen
C4	25	hardware system will result in 25 cost loss given the error effect happen
C5	0	hardware system will result in 0 cost loss given the error effect happen

3.3. Criticality Matrix

The criticality matrix provides a method of identifying and comparing the error occurrence probability among human tasks (or among human error modes) with respect to the error effects which consider safety, cost, and reliability of the system. The matrix is constructed by plotting human tasks (or human error mode) identification numbers against the severity classification category which can be represented by either the error occurrence probability level or the criticality index of human tasks CI_i (or the criticality index of human error modes CI_{ij}). Figure 2 is an example of criticality matrix in a case study.

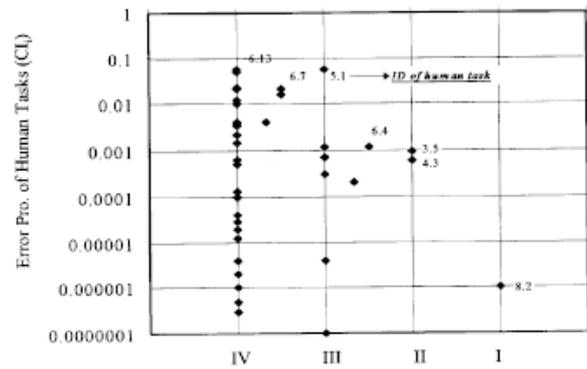
The completed matrix shows the distribution of criticality of human tasks relevant to severity classification, and provides a criticality order for assigning correction priorities. The further away the diagonal appears from the origin, the greater is the


Figure 2. An example of Criticality Matrix.

criticality of the related human task, and the more urgent it is to implement a correction action or design change. For instance, task 8.2 in figure 2 is the critical one.

4. CONCLUSIONS

HECA has been applied to some real cases. For instance, the igniter operating tasks (Yu *et al.* 1997) and the initiator assembly tasks of the missile system (Yu *et al.* 1998). Based on the results of analysis in initiator assembly tasks and the constraints of cost and time factors, some corrective actions are taken and their effectiveness of improvement have been evaluated. It reveals that not only the human assembly reliability has been enhanced by 9%, but also that the risk occurrence probability and safety severity decrease significantly.

The current limitation of HECA method is that the processes are getting complex as applying to a very large system, and this may be solved by computerization of HECA in the future.

Human Factors Design Tools for Consumer– Product Interfaces

J. V.H. Bonner

Teeside University, Institute of Design, School of Law Arts and Humanities, Middlesbrough, UK

1. INTRODUCTION

As the use of computer-embedded technology in consumer products increases and advances are made in novel display and control devices, so the design considerations of consumer–product interfaces draw closer to the design of computer interfaces. Conventional consumer products such as video cassette recorders (VCR), microwave ovens, pagers and heating control systems, along with more state-of-the-art products, such as personal digital assistants (PDA) and digital television, now adopt many interface characteristics similar to desk-top computers including touch sensitive displays, cursor controls, icons and menus. It is unwise, however, to assume that computer interface design knowledge can easily migrate to consumer–product interfaces.

There are distinct differences between the two types of products particularly within the context that they are used. Unlike computers, consumer products usually have very specific purposes or functions. Many products have been a part of domestic life for longer and therefore have a much deeper historical and cultural role in the environments in which they are used. The functions of an oven, for example, have been established over many years, leading to deep-rooted expectations about its purpose in the home. Interaction activity between a user and a consumer product is usually less time consuming than computing tasks and more intermittent. Furthermore, users generally lack willingness to understand or use new features. Commonality between different product interfaces is rare and users often do not expect similar controls and displays between one product and another. It is also far more common for a user to also be the purchaser of a consumer product than is the case with commercial computer users. This can affect user attitudes towards usability. Many consumer products are used by more than one individual, creating collective responsibility to care for and maintain consumer products. The challenge for product interface designers is to understand this complex web of user–product interaction.

Over the years, the computing industry has embraced and accommodated interface design issues with the development of new disciplines such as software design (Winograd 1996) and human computer interaction (HCI) (Laurel 1990, Preece *et al.* 1994). In contrast, most consumer products still rely upon the skills of manufacturing and production engineers along with design engineers and industrial designers. There has been little need for a strong emphasis on interface design issues beyond conventional "knobs and dials" human factors knowledge, although this is changing. Jordan *et al.* (1996), for example, offer a useful range of informal usability methods which can be applied to consumer products. However, with the onset of "convergence technology" (the merging of telecommunication, computer and consumer products), new consumer products are beginning to emerge that have few design precedents. The design of product interfaces is becoming less defined by hardware constraints and more defined by the imagination of designers and the needs of potential users.

This has created a demand for designers and design tools capable of creating, building and testing speculative and conceptual proposals in which the interaction between the user and the product is as important as the product itself. Many consumer product manufacturers now employ interaction designers whose specific role is to address the interaction aspects of the "softer," less defined and often more complex product interfaces. Interaction design is not, however, entirely synonymous with human factors. The heart of interaction design is fundamentally a creative process where pragmatic consideration of good product interfaces must be balanced with marketing and aesthetic demands as well as usability issues.

This chapter briefly describes a human factors-based design toolset which begins to fulfil these requirements by allowing human factors issues to be addressed very early in the design process but also allowing creative, incomplete and speculative interface design solutions to be proposed.

2. RATIONALE FOR THE DESIGN TOOLS

Many traditional human factors methods require the formalization or visualization of an interface before any serious usability study can take place. Even with an iterative, software-based rapid prototyping approach, design solutions need to be quite "mature" before evaluation studies can occur. With this in mind, these design tools were developed to support the interface design process prior to the use of software-based prototypes.

In developing the design tools, much of the theoretical underpinning has been drawn from the field of HCI, reflecting the recent shift from a cognitive engineering paradigm to theories considering the importance of context such as activity theory (Nardi 1996). The design tools described here are still in their infancy and many of the techniques adopted should be familiar to practicing HCI specialists. In summary, the design tools are based on the following criteria.

They should support the interface design process at very early conceptual stages especially where few "role models" exist or where novel display and control devices are being considered:

- users and designers should be involved in both the design and evaluation of interfaces;
- the context in which the product interface could be used should be considered;
- the use of "transitional objects" (concepts, ideas and suggestions placed in real world situations) to allow users and designers to discuss and suggest design proposals; and
- design methods already familiar to designers should be used.

3. OVERVIEW OF THE DESIGN TOOLS FOR NOVEL CONSUMER–PRODUCT INTERFACES

The toolset comprises of four related and inter-linked design tools where iterations can occur between and within the design tools. They are:

- contextual enquiry;
- card sorting;

- scenario design; and
- inspection methods.

All these occur before the building of software-based prototypes.

3.1. Contextual Enquiry

The first design tool is used to understand the context within which the product will be used. This requires conventional observational and data gathering exercises such as interviews, video, focus groups and so on. Designers are solution rather than problem focused and in many cases the tendency is to observe until a potential solution is found. For many designers the approach used in this tool is unconventional because broader, more "peripheral" data is gathered. The key to this design tool is to encourage designers to move the focus of their observation work so that more than the product in question is observed. It is also important that designers suspend their natural "solution generating" process as long as possible and allow the complexity and subtlety of the contextual frame to unfold. From the contextual enquiry work, designers propose two "outputs" for the next design tool.

First, a typical event or scenario that they feel will capture important interaction events that will test the usability and acceptance of an interface, for example preparing a new meal from a cookbook using a microwave and conventional oven.

Second, a range of possible existing and proposed control and display solutions that support existing or new product functions which are appropriate for the chosen scenario. These can be incomplete or even ambiguous proposals. An example could be a new recipe planner for a microwave interface.

Complete or well-defined solutions are not a necessary prerequisite to progressing to the next design tool.

3.2. User Requirements Capture through Card Sorting

The purpose of this design tool is two fold: first, to describe elements of the task or scenario and to design product functions using cards; second, to allow designers and potential users to discuss, arrange and sort these cards allowing a set of user requirements to be produced. The cards are composed by the designers and can describe concepts, design features or control and display proposals both in text or images. Cards should appear "rough and ready" to suggest to the participants that they represent tentative solutions and are amendable. The scenario cards should reflect not just tasks but also other events that may affect the use or non-use of the product. The function cards describe different interface features, for example alternative methods of selecting and altering the power level of a microwave.

Once the cards are completed by the designers, workshops are set up where representative users can discuss, place and sort the cards. Participants' first sort and place the scenario cards that best describes, by consensus, the structure and order of the scenario (Figure 1). It is important that the group plan by consensus to allow users to articulate differences in approach and understanding of the tasks within the scenario. These differences in approach provide useful contextual information.

Once this stage of the card sorting is complete, the designers have a physical representation of the scenario. The card "map" should be photographed to allow further analysis of the participants' placement and inclusion of cards. These "maps" can also

Figure 1. Participants sorting and placing cards

Figure 2. Making notes on consensus statements

be compared with results of other workshops. The next stage requires the participants to go through each function card and agree on its importance to the scenario. The cards are sorted by placing them into labeled bins such as "really useful" and "really useful but not for this scenario." Again this has to done by consensus to promote discussion.

The favored cards are then placed into the scenario plan providing important indicators to the designers of where and how proposed ideas would be adopted within the scenario. Participants should be actively encouraged to introduce new cards or change existing cards. During the card sorting activities one of the designers should record significant events (Figure 2) that have implications for interface design. Within the design tools, guidance is provided for the designer on how to do this.

Analysis takes place through debriefing exercises with designers and participants and also between the design team, through video analysis and reviews of the scenario maps and selection strategies. By setting different scenarios through workshops and exercises, designers normally get a very good feel for what type of innovative proposals can be implemented.

3.3. Interface Design Development through Scenario Design

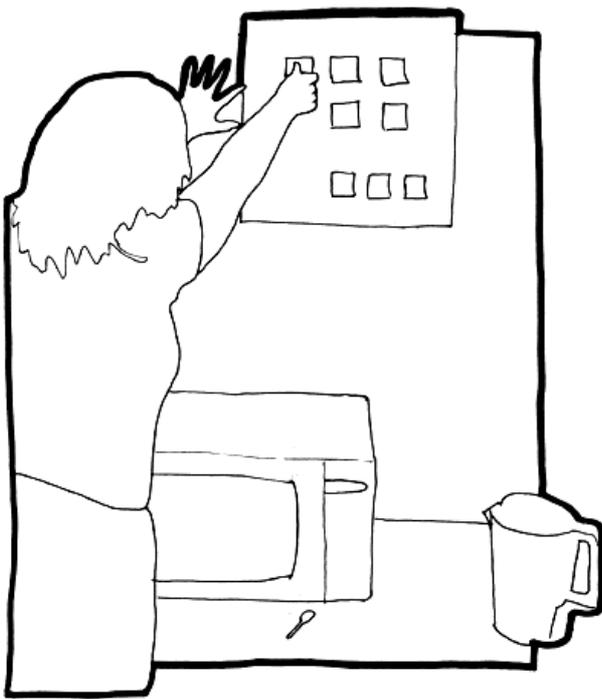
The next design tool refines and details the interface elements into a storyboard and produces a list of all the proposed inter-


Figure 3. Taking tabs off the board before placing on a mock-up product
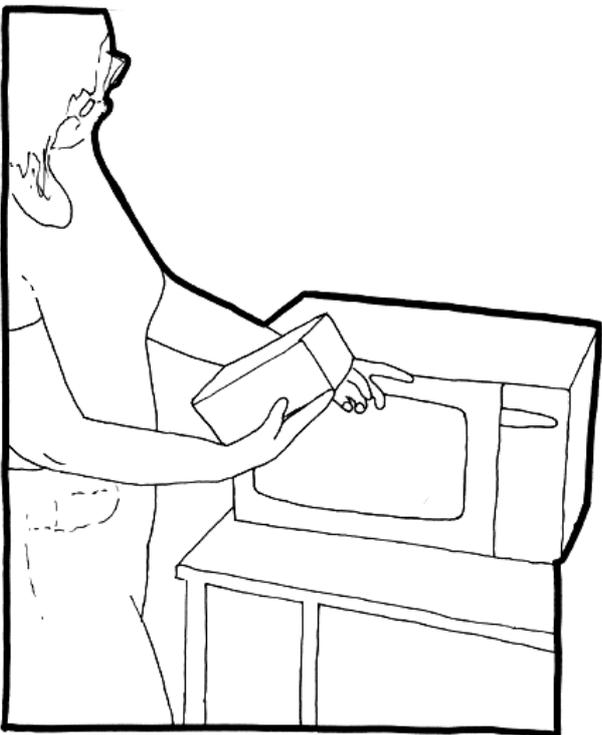

Figure 4. Use of a mock-up in the scenario design tool

face control and display function descriptions. These function controls and displays should then be converted into "tabs" (Figure 3). These will be more detailed and coherent descriptors based on the function cards used in the card-sorting tool. It is important that fundamental concepts and ideas are still perceived as being open to critical judgement and alteration.

The scenario for this design tool should be as realistic as pos-sible. For example, if one of the scenarios proposed was to cook a meal for four, this should be done in practice with real food and cooking implements. During the task, participants take off each tab from a board when they are required in the task and place them on a mock product. The mock-up does not have to be par-ticularly realistic apart from dimensional requirements. The mock-up becomes a very important vehicle and point of discussion between the participants and the designers (Figure 4).

For example:

Participant: "at this stage I want to tell the microwave that I want this pie to be defrosted for 5 minutes." Selects a preferred "defrost" tab from the board."[N]ow I need a way of telling it that I want this done for 5 minutes." Looks a tab board for possible options.

Designer: "from the different ways of doing this on the board, which do you think would be the best way at this stage?"

If the tasks involve the use of a working product (such as a microwave to actually cook the meal) then, as far as possible, the mock-up and tab board should be referred to before using a working product. This prevents the existing interface from driving the flow of interaction activity. The results from the design tool emerge through video analysis, user statements and opinions and mock-up designs.

3.4. Inspection Methods for Designers

The final design tool is an inspection method approach that does not require involvement with participants. It provides a systematic way of considering many of the high-level human factors issues that affect the usability of product interfaces. One of the advan-tages of using this design tool is that it can be used with concep-tual ideas that have little low-level detail and include novel interaction styles. Other types of inspection methods exist but require the interface design to be more complete or assume more common computer-based controls and displays.

The inspection methods include design heuristics and check-lists that deal mainly with issues related to the anticipated con-text in which the product will be used and places broader attention on users, tasks and the environment beyond the scenarios that have been selected in the previous design tools. They also deal more specifically with interaction design issues and how users typically process information. The intention of this design tool is to re-examine the proposed interface design and take a more objective and broader critical review of usability issues. In going through the inspection methods, it should be possible to examine interaction issues more methodically.

Where possible, solutions are provided when a usability prob-lem is identified. Revised solutions should be evaluated by using more focused scenario design exercises. Some problems are, how-ever, best resolved by moving forward to the next design phase, prototyping, particularly where "time-based" interaction activi-ties are concerned. Software-based prototypes can now be developed using more traditional evaluation methods that have been successfully applied in the development of many computer and consumer-based products.

4. CONCLUSIONS

A substantial number of design tools and methods have been developed in the past, but few have been adopted by designers.

Designers complain that they do not offer sufficient benefits to justify the implementation costs. The design tools outlined here, which have been based on HCI principles and theories have been adapted, developed and refined by involving designers (the end users) in the development process and have been through many iterations. The tools have to fit the requirements of designers, meaning that they have to be easy to learn, quick to implement, require little formal training and integrate into existing design cultures.

The key to the success of the design tools has been the use of "transitional objects" (cards, scenarios, foam models being used as points of discussion) overcoming many of the communication problems that can occur between users and designers. None of these concepts or approaches are radical or new to designers but traditionally have not been used so explicitly in this way and so early on in the design process. A further benefit is that designers do not have to resort to lengthy user studies or users having to be heavily briefed before being effective.

Improvements to the design tools are still being made and further evaluation studies are planned. Nevertheless they appear to satisfy two often-conflicting demands: appropriateness within a product design culture supported with sound theoretical underpinning.

Human Sensory Measurement Application Technology (HSMAT)

K. Suzuki

Research Institute of Human Engineering for Quality Life, Osaka, Japan

1. INTRODUCTION

New technologies became widespread at the same time as the rapid economic growth that started in Japan in the mid-1970s, making our lifestyles very convenient and comfortable. Technological advances in manufacturing and information sciences have made it possible to create customized products and environments in response to various human needs. However, these new technologies or products often failed to provide true satisfaction for their users. More and more people are now experiencing technology-related stress and fatigue, and the number of illnesses caused by these problems is increasing.

At the end of the 1980s when this phenomenon emerged, industry started paying more attention to human well-being. Technologies, products and environments needed to be designed to satisfy human psycho-physiological (including sensory) needs in order to reduce problems related to the human factor at home as well as the workplace, and to improve the overall quality of life. Aiming to create a sense of well-being in fields such as health, safety, convenience and comfort, human-oriented manufacturing forms the basis of achieving a more comfortable and rewarding lifestyle. Human-oriented manufacturing requires objective comprehension of the physiological and psychological state of humans, and also the influence of products and environments.

On this basis, "Human Sensory Measurement Application Technology" (HSMAT) was established in 1990 as a national 9-year research project to compile physiological and psychological data to form the core of the analysis, and to develop standard technologies for measuring human senses. This chapter describes the objectives and major results of the HSMAT project.

2. PROJECT OVERVIEW

The HSMAT project has a total budget of ~$140 million and is part of the Industrial Science and Technology Frontier Program overseen by the Agency of Industrial Science and Technology of the Ministry of International Trade and Industry (MITI). The project was commissioned through the New Energy and Industrial Technology Development Organization (NEDO). The Research Institute of Human Engineering for Quality Life (HQL) based in Osaka, Japan, undertook this project in cooperation with six national research institutes, the laboratories of 25 major corporations and six universities. The main objectives of the HSMAT project were to establish technologies that quantitatively measured and evaluated human sensations, and apply these technologies to the design of user-friendly products and reduced-stress living and working environments meeting various individual needs.

The HSMAT project consisted of two stages: I (1990–94) and II (1995–98). During Stage I, individual and basic research was conducted to establish human sensory measurement technologies.

During Stage II, the focus of the research was shifted to the integration and application of these technologies, especially toward developing human sensory indices that reflected human sensations.

2.1. Stage I (1990–94): Fundamental Research

Stage I of the project included the development of technologies for generating and controlling the external stimuli that influence human senses, and simple, non-invasive, quantitative determination of physiological values resulting from external stimuli. These technologies have made it possible to estimate sensory measures based on physiological measures. Particular developments included non-invasive devices that made it easier to make objective and practical measurements of variations in human senses and in bodily conditions caused by external stimuli. These measurement technologies involve measuring metabolic functions, the central nervous system, the autonomic nervous system, and the ocular function.

Quantitative physiological data was recorded using physiological measurement devices, and the relationship between physiological responses and external stimuli was studied. This has allowed an evaluation of human senses, i.e. the levels of fatigue, stress, alertness, and comfort with regard to the human-friendliness of products and environments.

The systems also created synthetic environments by controlling different external stimuli including heat, noise, vibration, lighting and composition, and were able to make assessments under different conditions without using human subjects.

2.2. Stage II (1995–98): Development of Indices and their Applications

The primary objectives of Stage II were to adopt the human sensory measurement technologies developed during the first stage in order to establish technologies for developing human sensory indices and to develop application technologies that incorporated human sensory indices into the design of industrial products or environments. These technologies evaluate the human-friendliness of products, and also of living and working environments.

2.2.1. Human sensory indices

Human sensory indices are technologies for measuring and evaluating stress, fatigue and alertness induced by physical environments or products, and for evaluating the compatibility of environments and products to humans in terms of comfort, familiarity and ease of operation. These technologies were developed by refining and systematizing the human sensory measurement technologies developed during Stage I.

2.2.2. Human sensory indices application technologies – applied case studies and the development of evaluation simulators

The validity of human sensory indices was demonstrated in close to real-life conditions, and statistical data were collected during the demonstration to fine-tune the indices. A series of applied case studies was conducted in newly constructed laboratories to confirm the robustness of each human sensory index, and to integrate the related indices. Each laboratory was equipped with a simulated environment presentation system that created desired

working or living conditions by adjusting environmental factors, such as lighting, room temperature, noise, air flow, humidity, and color temperature.

Evaluation simulators that evaluated products and environments in place of human subjects were also developed.

3. OUTCOMES

Subsequent sections describe the results of the research undertaken in the HSMAT project. These sections are based on a written report published by the Human Sensory Measurement Application Technology Evaluation Committee and the Evaluation Group of the Industrial Technology Council.

3.1. Human Sensory Indices

3.1.1. Indices for measuring stress, fatigue and alertness

These indices estimate the mental conditions (stress levels) of humans by quantitatively measuring physiological conditions such as blood pressure, heart rate and skin temperature. Other indices evaluate work adaptability by humans by estimating the level of physical activity (from sleep to active) determined by physiological factors such as EEG, blood pressure and core temperature. The indices can be applied to evaluate the adaptability of monitoring work required at plants and airport control towers to prevent serious accidents.

3.1.1.1. Development of technology and a method for measuring, analyzing and evaluating stress

A high-performance stress hormone evaluation system was developed on the basis of evaluating human stress levels by monitoring changes in the volume of stress hormones found in saliva (and urine). The device makes it possible for companies to improve employee health care without professional medical help. If worker stress levels are examined on a regular basis using the device, stress-related diseases caused by overwork can be prevented.

3.1.1.2. Telemeter-style non-restrained physiological measurement devices

These three portable devices measure human physiological conditions such as systolic blood pressure, electrodermal activity and blinking. The net weight of the device for measuring systolic blood pressure is 200 g, the wrist-watch style electrodermal activity measurement device only 60 g and the headband-like device for measuring blinking is 70 g. These newly developed devices are much smaller and lighter than other devices with similar functions. They are superior because they are also very easy-to-use, less restrained, and are suitable for practical use. Stress levels can be evaluated by using these three devices together.

3.1.1.3. Non-contact skin temperature measurement system

This system is a world-first for automatic and non-invasive measurement of facial skin temperatures using infrared and color images. Stress levels are estimated from the images, and expressed numerically.

This system can be also applied to workplace stress management and to evaluating the development process for stress-reducing products.

3.1.1.4. Visual sensory fatigue measurement device

This is a portable and lightweight measurement device for simultaneously measuring three major visual functions (focusing, pupil diameter and eye movements). It weighs 350 g, one-fifth of the weight of conventional models.

3.1.1.5. Monitoring system for estimating alertness levels

This monitoring system is a device that estimates human alertness levels by measuring heart rate and core (eardrum) temperature. By monitoring the alertness of workers who monitor work at plants and airport control towers, the system can prevent accidents caused by human error or declines in work efficiency.

3.1.2. Indices for measuring and evaluating environmental adaptability

Using physical environmental quantities as parameters, these indices measure and evaluate the adaptability of environments to humans to design comfortable work and living environments in tune with human sensory perceptions. The indices are determined from major environmental factors, namely vision, sound and oscillation, and heat.

3.1.2.1. Technology for designing the visual environment of offices

This model evaluates the spatial impressions of offices and other spaces, including perceived comfort levels and the sense of openness. It evaluates any given space based on its dimensions, coloring and lighting. A visual environment adaptability evaluation index was created to provide guidelines for designing working and living environments.

3.1.2.2. Color presentation technology

This technology quantitatively evaluates chromatic adaptation in actual situations and accurately predicts corresponding color images in various states of illumination.

After the validity of the method for predicting corresponding color images was confirmed, a newly developed chromatic adaptation transform received international recognition after being presented to the International Commission on Illumination (CIE). In 1994, the proposal was published as a CIE technical report entitled, "A Method of Predicting Corresponding Colors under Different Chromatic and Illuminance Adaptation."

3.1.2.3. Sensitivity to vibration while sitting

This research resulted in vibration stimuli presentation technology based on waveform control, and an evaluation method for sensitivity to vibrations. Differences in the curvature of the spine are considered, and the degree of discomfort estimated when the whole body is subjected to vertical vibrations while sitting.

It will be possible to standardize the sensitivity level for different postures or for when different parts of the body are subjected to vibrations. This novel method considers changes in posture responding to actual situations.

3.1.2.4. Human thermal model and thermal sensation prediction model

Physique and other individual differences were considered when constructing the human thermal model, which estimates the skin temperature and perspiration of different parts of the human body.

The thermal sensation prediction model accurately estimates skin temperature and thermal sensation, even in dynamic and uneven thermal environments (errors within ± 0.5%). The effects of thermal environments in real-life settings can be evaluated using the latter model, which predicts the changes in thermal sensation when a person moves from one room to another or leaves a house. The model is a potential new thermal comfort index.

3.1.3. Indices for evaluating product adaptability

Actual consumer products such as clothes, a chair and a bed were used to develop practical indices for evaluating product adaptability in terms of human body size, shape and movement. Other indices measuring product usability via human–product interaction have been developed to evaluate equipment operability in specific working conditions, including monitoring cranes and plants.

3.1.3.1. *Practical postural measurement and evaluation system*

This system evaluates the adaptability of chairs based on the posture of a worker sitting and performing a task over a long period. It evaluates the shape of the sitting surface and the distribution of body pressure. The system can be used as a design support tool, easily evaluating design ideas and creating chair models in the product development process, and also for data acquisition and data processing when necessary. Companies can use the system to collect basic information when establishing design or evaluation criteria.

3.1.3.2. *Platform system for supporting the design process*

This is a prototype design support system to allow designers to easily find data relevant to human life engineering. An advanced system has been developed on the basis of the prototype. The platform system allows designers to create high-quality product designs using common data and evaluation criteria in a relatively short time. A variety of products can be designed and evaluated by running computerized human models (computer manikins) on this system.

3.2. Human Sensory Indices Application Technology

3.2.1. Applied case studies

The combined effects of multiple environmental factors have been clarified using experiments in various conditions created with a simulated environment presentation system that adjusts different environmental factors, including lighting, room temperature, noise, air flow, humidity and color temperature. Careful investigation of the effectiveness and limitations of human sensory indices in use should facilitate the development of systems or devices, which can measure and evaluate products and environment comfort in real-life settings.

A database containing various types of human data obtained through the HSMAT project, and a handbook providing information on advanced technologies for gauging biological, behavioral and subjective measures will be produced after refining the indices and other resulting technologies. In the near future, comprehensive guidelines indicating proper application of human sensory indices will be constructed by integrating and systematizing the results of the HSMAT project.

3.2.2. Evaluation simulators

3.2.2.1. *Thermal sweating manikin*

This thermal sweating manikin simulates human skin temperatures and perspiration. Unlike conventional thermal manikins, it can simulate skin temperature and perspiration changes over time, and can also be made to perspire profusely. Micro-climates (humidity) within clothing can also be simulated. The manikin can make different poses including, standing, sitting and lying down, and can be used to design and evaluate products such as bedclothes, chairs, and comfortable clothing.

3.2.2.2. *Human comfort meter*

This is a small manikin with movable joints and adjustable height that is equipped with 12 thermal comfort sensors. The manikin allows accurate evaluation of the adaptability of products to humans, and expresses thermal sensations as numerical values.

4. CONCLUSION

The HSMAT project was the first national research project to systematically study humans in order to develop technologies directly related to our lifestyles. Although this project has only outlined some human characteristics, the results are expected to contribute greatly to improving product design and working and living environments. Some of the results will be applied to develop technologies for scientific analysis of human behavior for a new national project starting in 1999. The HSMAT project results and the new developments will further accelerate technological development in human life engineering.

1. INTRODUCTION

Traditionally, human factors engineering issues are not well integrated within system design efforts. Where human factors engineers *are* called upon, it is usually late in the design process or even post-design. Therefore, human factors engineering solutions are often not implemented due to the increased cost of late design changes. System design deficiencies become operations problems and require highly skilled users to overcome these deficiencies. These skill requirements drive increased training demands and potential user availability problems. Exacerbating this problem is the rate of technological change that levies significant constraints on system development time. Program managers are pressured to demonstrate development progress frequently resulting in premature allocation of system functions when the requirements are not yet defined. These factors substantially reduce or eliminate time for late changes.

Systems engineers are not always familiar with the issues of human–system integration. Further, human factors engineers and systems engineers speak different technical languages. To address both issues, a human systems engineering process has been defined using systems engineering terminology. For this chapter, 'Human Systems Engineering is defined as the activities involved throughout the system life cycle that address the human element of system design' (IEEE 1220-1994, 1998). These activities include the definition and synthesis of manpower, personnel, training, health hazards, safety issues, human factors and any other issues addressing human activity within the system. This concept of the human systems engineering process while consistent with traditional definitions of human factors and human systems integration, fully imbeds human engineering into the systems engineering process and employs common terminology. The concepts and process presented in this chapter influenced and are integrated into IEEE 1220-1998, *Standard for the Application and Management of the Systems Engineering Process* (1998), a commercial systems engineering standard.

This chapter will describe the human systems engineering process, identify examples of methods that support the process and provide examples of design efforts that applied this process.

2. SYSTEMS ENGINEERING

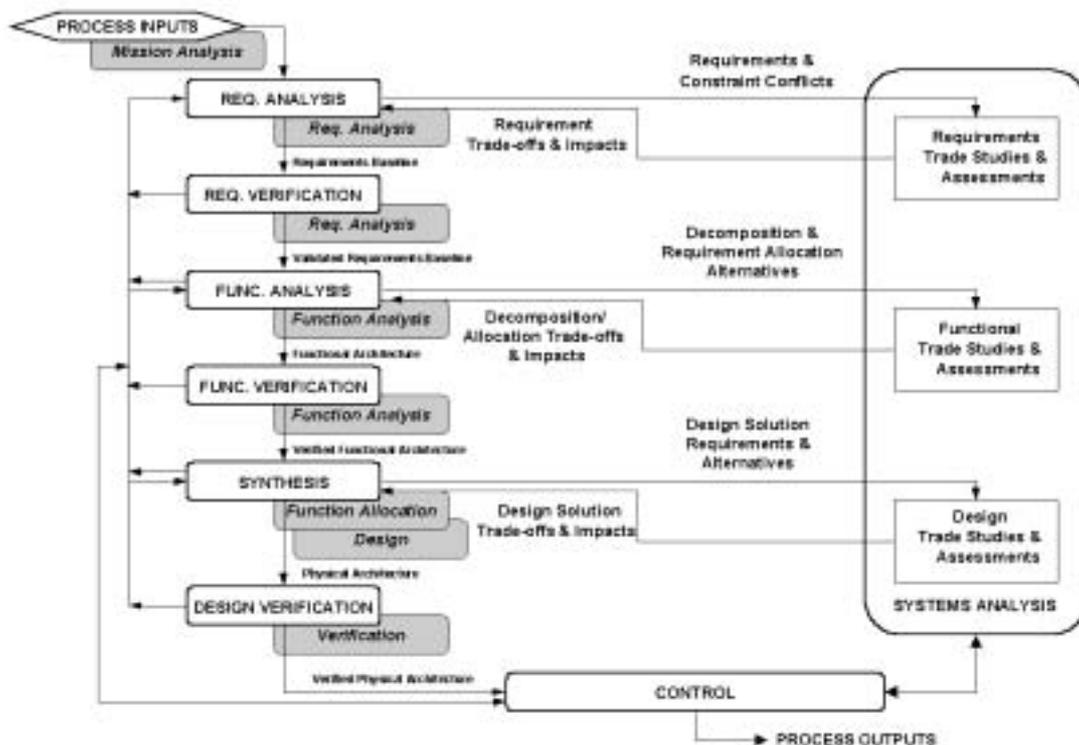
Systems engineering is an iterative and interdisciplinary process through which system requirements are transformed into a system solution. Systems engineering addresses not only the physical design of the system, but also all phases of the system lifecycle. The process begins with definition and analysis of the requirements, translates those requirements into a functional definition of the system and creates from those functions a detailed design. Systems engineering is iterative and begins with concept-level requirements; develops and decomposes more detailed requirements, functions and designs; and integrates system components to form a coherent definition of the system. Solutions


Figure 1. Human systems engineering process and systems engineering process of IEEE 1220–1994 (1994)

are continually revised, improved, updated or modified until system design factors are optimized. Systems engineering is also interdisciplinary, addressing hardware, software and human issues in addition to cost, manufacturing processes, logistics and lifecycle issues. To have a measurable impact on the final system solution, human engineers must use the terminology of systems engineers and operate within the framework of the systems engineering process.

3. HUMAN SYSTEMS ENGINEERING

To achieve the desired impact, human systems engineering must be fully integrated with systems engineering. Human systems engineering products must be the result of a disciplined engineering effort that is conducive to overall system analysis. To meet these needs, the human systems engineering framework was modeled after the systems engineering framework developed for the evolving IEEE 1220 specification. Figure 1 depicts how human systems engineering (shaded blocks) integrates with the systems engineering process.

In addition to consistency with the systems engineering process, the human systems engineering process must be consistent with its heritage in human factors engineering. To meet this goal, multiple sources of human factors process descriptions were evaluated. Key documents included the ShipSHAPE process (Malone 1997), the NATO panel research group's report on *Analysis Techniques for Man–Machine System Design* (Beevis *et al.* 1994), *Human Factors in Systems Engineering* (Chapanis 1996) and an HFES Conference Workshop on human factors methods (Chapanis and Shafer 1995). Leveraging process descriptions of human factors engineers ensured that the process defined in the systems engineering framework would be true to the problems and issues it is intended to solve.

As depicted in Figure 1, the human systems engineering process follows the basic top-down systems engineering framework. The six major steps of the human systems engineering process are mission analysis, requirements analysis, function analysis, function allocation, design and verification. The following sections define and describe the major steps of this human systems engineering process and provide examples of methods that are applicable to that design step.

3.1. Mission Analysis

The start of a system engineering effort is mission analysis, where the overall system purposes, objectives, capabilities, operational environments and basic functions are determined. Mission scenarios are identified or created. The focus in this step is on the definition of the system boundaries, treating the system as a 'black box' and defining inputs, outputs, environments and other constraints.

To articulate the mission, narrative mission descriptions and graphic mission profiles can be employed. Narrative mission descriptions detail the mission in terms of the characteristics, sequences and times of mission events, mission constraints and environmental conditions. Details of the description facilitate identification of top-level functions required of the system. Graphic mission profiles illustrate the sequence of events that will determine the performance requirements of the system.

3.2. Requirements Analysis

Requirements analysis is performed to identify the characteristics of the system necessary to meet mission requirements. Intended users and maintainers of the system and activity-related needs of users are determined. The feasibility and internal compatibility of the system requirements are assessed. Measures of effectiveness and measures of performance of the mission, human and job/task requirements are defined. In this step, the role of the human, and manning, training and cost guidelines are also developed.

3.3. Function Analysis

Function analysis output supports development of the system's functional architecture — the sequence of operations or events that turn inputs into desired outputs — and compares design alternatives. Although the system may be broken into functions, tasks and subtasks to be performed, they are not allocated to any particular system component. This step and the three following steps are initially performed at a high system level with little function decomposition, but are iterated to greater levels of detail.

Function flow diagrams and behavior graphs are methods to analyze system functions. Function flow diagrams depict the sequential relationship of the system functions. This method logically inventories the system functions and structure. Behavior diagrams describe system behavior of control and information flow and scenario modeling, providing a complete behavioral model of the system.

3.4. Function Allocation

A critical step of the human systems engineering process is determining what functions are to be performed by humans. Function allocation distributes the defined functions among available resources (humans, hardware, software or combinations). The allocation of some functions will be mandatory and predetermined by constraints established in the Mission Analysis or Requirements Analysis steps of design. Allocation decisions are determined by a comparison of performance among humans, hardware, and software; cost factors; anticipated operator workload; and cognitive support for the operators. Allocation decisions should be made to maximize total system performance and effectiveness. Allocation of a function may require redefinition of its component subfunctions. Function allocation will be guided by information requirements and decisions required to initiate, sustain and otherwise support mission functions. How these allocation decisions impact total system performance is determined and adherence to defined requirements assessed.

Function allocation has been aided with guidelines to assess human capabilities and function requirements, such as 'Fitts' lists' and evaluation matrices and while these guidelines are helpful, they can be dated and must be used judiciously. Today's technology affords us far more automation potential than in the past, but it comes with a cost. With automation comes a certain degree of cognitive distancing between the operator and the task; therefore, this automation must be applied carefully. Methods to support this step rely heavily on the engineer and designer and are not well automated themselves. This is an area ripe for more research and development of standardized methods.

3.5. Design

This step is where the bulk of human factors and ergonomics methods have traditionally focused and where the majority of human system issues are resolved. A time-based description of the allocated system architecture must now be defined, and interactions between tasks, and between humans and equipment examined. The flow of information and objects between components of the system is defined. The architecture is analyzed and functions and tasks are redefined as necessary. Determination is made as to whether the specified levels of activity (physical, cognitive, temporal) for humans and equipment can be met with projected or currently available resources. Once the functional architecture meets mission and system requirements, operator interfaces may be specified and designed. Changes made to the functional architecture at this step will require a return to earlier steps to ensure that all system/mission requirements will be met. The following substeps support the design step.

3.5.1. Task design and analysis

Human tasks required to ensure successful completion of the function are developed in terms of cues required to alert the human that a decision/action needs to be taken, the decision/action to be made, the information required to support the decision and mechanisms to implement the results of the decision/action. The critical characteristics and interactions are also articulated. In addition to supporting other steps of the human systems engineering process, Operational Sequence Diagrams (OSD) and Critical Task Analysis (CTA) methods are excellent tools for task definition and analysis.

3.5.2. Human interface design

Interfaces between humans and hardware, software and other humans are designed such that physical and procedural interfaces are considered. Link analysis and design option decision trees facilitate this substep of design.

3.5.3. Performance, workload and manning level estimation

Physical (perceptual, psychomotor, physiological, etc.) and cognitive workload levels for individuals and teams are estimated to provide approximate system performance. Workload stressors and their effects on human performance, operator coping strategies and the effects of task neglect/delay are defined. Workload and the resultant manning and training requirements should be optimized to meet required performance levels. Task network models and simulation provide mechanisms for early assessment of system performance with the defined human role. Subjective workload ratings during prototype testing also facilitate performance evaluation.

3.6. Verification

The potential performance of the system with respect to its ability to achieve required levels of operation is assessed. Verification may be carried out either during conceptual stages using analytical or executable system models or after a physical prototype or mock-up has been constructed using human-in-the-loop simulations. Verification of some system components may be concurrent with design of other components. If the system under design is unable to achieve the required levels of performance

and operation, then either the requirements must be altered or the design must be improved through re-allocation of functions or selection of an alternate design. Storyboarding with subject-matter experts, followed by prototype usability testing, will help verify the system meets its requirements. Early in system design, modeling can be employed to assess the design; however, it is critical to conduct human-in-the-loop testing of the system to fully verify the design.

4. APPLICATIONS

Human systems engineering has been effectively applied to system design efforts. The following are examples of projects that have employed the steps described in this chapter and supported the evolution of the human systems engineering process.

The NATO Seasparrow Surface Missile System (NSSMS) used this approach in the development of the graphical user interface (GUI) of the system (Wallace *et al.* 1995). In this program, mission and operational requirements were identified and OSD developed. The OSD articulated tasks that supported required functions and were used to define information requirements, displays and critical system events which impact decisions. This task information was then used for system design and assessment. Models of the design and simulations of human performance measuring workload were run. This design data was then used to develop prototypes, which were analyzed with human-in-the-loop testing. By applying this top-down approach, the human systems engineering team worked with the systems engineering team to define an optimized NSSMS GUI display.

A top-down approach facilitates design of all systems, not just GUI designs. A similar approach was applied in the redesign of the Naval Space Operations Center at the Naval Space Command (Bohan and Wallace 1997). This project focused on the re-design of a collaborative work environment where team interaction was critical. At project commencement, missions were defined and required functions identified. Tasks were then articulated with OSD, providing the framework for link analysis. A rapid prototyping tool modeled the layout and simulated communication. Based on this analysis, optimal layouts were prototyped for human-in-the-loop evaluations. This evaluation method provided two benefits to the project. First, the users provided insight about the design that engineers alone do not have; and second, the users fully supported the design as they were part of its development from cradle to grave. The newly designed center was unveiled in May 1997 and since proven successful.

Once the human systems engineering process was defined and documented for the Navy's SC-21 Science and Technology Manning Affordability Initiative and was instantiated within IEEE 1220-1998, the process was used to develop the web site (www.manningaffordability.com/hes) which provides a mechanism to 'teach' systems designers about human systems issues. Greater levels of detail of the human systems engineering process are included here.

5. CONCLUSIONS

The rapid and continual advancement of technology makes the human more likely to be the limiting factor in system design and performance, making it increasingly important that the human factors and ergonomics communities work together with

systems engineers. Communication and integration are central to *successful* design development and there are many mechanisms that facilitate both across systems design teams. Involvement in the professional groups and societies of the designers and specialty engineers with which we interact is an excellent mechanism for understanding the systems design process more fully and becoming familiar with specialized terminology. Advanced systems engineering environments that support the full systems engineering process can facilitate communication and integration while reducing design costs and errors by removing the need to translate system design data between disciplines, automatically flagging design changes and notifying the appropriate personnel.

Great gains in improved design will be realized by the use of a systems engineering terminology to articulate a human systems engineering process which feeds the systems engineering process directly. The human systems engineering process is built on the foundation laid by ergonomics and human factors communities over past decades. It is differentiated from more traditional approaches in that it is fully imbedded into the systems engineering process in practice and terminology. Use of a rigorous process, such as that defined here, is critical to ensuring enhanced system and human performance.

Job Analysis and Ergonomic Assessment after Injury

L. S. Strickland† and G. S. Rash‡

†Spalding University, Louisville, KY 40203, USA

‡BIO/MED Research & Consulting, Louisville, KY 40241, USA

1. INTRODUCTION

Returning an injured worker to the work environment at the highest possible level of independent functioning is the ultimate goal of any rehabilitation effort. Assuring the long-term success of the individual within the worker role will require a well-stated problem encompassing the individual's "design" and the design of the workplace. For the ultimate goal of returning a worker to the workforce, the job site evaluator must assess the worker, the work site and the actual work being performed.

2. JOB SITE ANALYSIS

2.1. Need for Job Site Analysis

When working with an injured worker there is need to perform a job site analysis to:

- focus the rehabilitation effort and determine the specific end goals that are meaningful, relevant and measurable;
- determine work site modification needs if the individual will not be able to attain his/her prior level of physical or cognitive functioning;
- ensure an appropriate match between the injured worker and his/her previous job to reduce potential future injuries; and
- assist the employer in making the job easier, safer and less tiring.

2.2. Physical Demands

Job analysis is a process of obtaining an accurate description of all job requirements. This evaluation is used in conjunction with other industrial therapy services in the effort to return an injured worker to the job. Detailed information in all the following job demands should be included as part of the job analysis:

- Walking.
- Standing.
- Sitting.
- Climbing.
- Crouching.
- Bending.
- Lifting.
- Carrying.
- Pushing/pulling.
- Reaching.
- Handling and fingering.

Other job demands such as sensory, and cognitive and psychological stress must also be taken into consideration to return successfully an injured worker to the job. The job site analysis incorporates the worker and their abilities along with assumptions of potential or future exposure to unsafe or harmful work practices.

2.3. Recommendations

After conducting the analysis, recommendations should be made about environmental modifications, tool and equipment modifications, individual work practices and the workers health maintenance. Environmental modifications, such as changes in the work station so that the worker has a sit/stand option, or changes in the lighting may be appropriate. Incorporating the use of shock-absorbing gloves, cutting or remove ledges under tables, etc. may be recommended as tool or equipment modifications. Additionally, modifications to the individual's work practices and techniques such as reducing reaching above shoulder level or reducing forward bending may be included. Last, the worker's health maintenance and general wellness may need addressing. These recommendations may consist of programs involving ongoing exercise programs to reinforce good body mechanics and posture, or simple 1–2-minute neck and upper back exercise breaks every 2 h.

3. TRAINING

To make extensive ergonomic recommendations of the work site, the practitioner should have received specific training in ergonomic studies and be recognized as a qualified ergonomics practitioner (BCPE 1995). Several government publications can be used as references in the development of the practitioner's knowledge of job analysis and include *Dictionary of Occupational Titles*, 4th edn (1991), *Handbook for Analyzing Jobs* and *A Guide to Job Analysis* (Superintendent of Documents). To assure a well-stated problem that includes recommendations, practitioners working in industrial rehabilitation and ergonomics must have education in, and be familiar with, the following areas:

- Workplace design.
- Anatomy and physiology.
- Kinesiology.
- Biomechanics.
- Anthropometry (the science of the variation in body size among individual, genders and races).
- Sensory nervous system.
- Musculoskeletal system.
- Normal and abnormal psychology.

4. TOOLS OF THE TRADE

In preparing for a job site analysis, the practitioner must gather the appropriate tools to be used in the assessment process. These items may include (but are not limited to) a written job description provided by the employer, tape measure, stopwatch, scale, push–pull gauge, chalk, goniometer, plumb line, Polaroid (or digital) camera, photo release forms, laptop computer and a video camera. The employer should provide prior approval of any pictures and/or videotaping of a work site and/or work production practices. Sample job site analysis forms are given in Tables 1 and 2.

The exact form a practitioner uses within their practice will be based on many factors. The type of work environment and jobs being evaluated, the needs of the worker, employer, and other interested parties such as insurance case managers. The format should be developed in response to feedback from referral sources. Many employers and case managers may want recommendations and concise summaries on the front page of the evaluation with the detailed analysis after the summary. The analysis forms provided do not take into account reasonable

accommodations that need to considered when determining if an individual can return to a particular job. These accommodations will be unique to the situation based on the employer's resources and the abilities of the worker. If appropriate, the reasonable accommodations can be included under the "other comments" section of the evaluation.

4.1. Accounting for Demographics

Workforce demographics have been changing over the past two decades. The face of the workforce is more female and older in age than the workers in the past. Large increases in female and older workers have an impact on workplace safety and injury management. Age and gender have been correlated with dynamic balance skills, ability to climb and the ability to lift. Older workers, female workers and older female workers may be at high risk for injury and, once injured, may face more challenges in returning to work. These individuals may also be more susceptible to re-injury. The 1991 revised National Institute of Occupational Safety and Health (NIOSH) lifting equation defines lifting capacity of young, healthy workers; therefore, the job site evaluator must

The Person

Relevance & Meaningfulness of job:

Values & Interests:

For each performance component, determine the level of challenge required to perform job	Level of Performance			Comments
	Min	Mod	Max	
Physical Components • Sensation/ Sensory Integration

The essential functions of a job are those duties that must be performed unaided or with responsible accommodations

Min= is needed for job, but not for essential job functions, occasional, required< $1/3^{rd}$ of the time

Mod= is needed to carry out essential job functions, but is not the major component(s) for essential function Frequently, required > $1/3^{rd}$ < $2/3^{rd}$ of the time

Max= is needed to carry out essential job duties -- is the major component(s) needed for essential job function, constant, required > $2/3^{rd}$ of the time

consider the context of the work as it relates to the individual worker's abilities to assure success.

4.2. Workers Physical Conditioning

An individual's physical conditioning may have a profound effect on work capacity. Poor conditioning and unhealthy lifestyles can lead to an increase in risk of injury. Post-injury, the worker should be involved in a structured health and fitness program after formal medical interventions are completed to progress cardiovascular conditioning, heighten flexibility and strength to help control

fatigue and improve body posture and positioning during work tasks.

5. CASE EXAMPLE

A previous case will be used to illustrate the process. A 42-year-old female warehouse employee who had worked for the company for 4 years sustained an acute lumbar strain 1 week before while working the first shift in a snack food warehouse. The employee is a union employee. Soon after the onset of pain, 3 h into an 8-hour shift, the employee informed her supervisor of the injury.

_____   _____
Consultant   Date

(Adapted from Burt & Smith, 1996 Watson 1997)

The employee has received a muscloskeletal assessment from a physical therapist and has received therapeutic modalities to modulate symptoms and promote soft tissue relaxation and healing. Exercises for mobilization and spinal restriction correction were performed for 5 days after the incident.

5.1. Injured Worker's Job Site Analysis

Job analysis is the foundation for providing information to assist in returning the injured person to the workforce. The analysis should include information pertaining to job tasks and/or specific services for an injured employee. Identification of stressful postures and positions, ergonomic recommendations and reasonable accommodations to return the worker quickly to the same or alternate work tasks are the goal. Table 2 shows the job site analysis forms completed for the worker in question.

From the job site analysis, it can be seen that the significant items are that the worker is on her feet for the entire work shift. She lifts items weighing 10–12 lb throughout the majority of her work day and she has routinely to stoop and bend many times a minute continuously for durations of ~2 h. Additionally, she must routinely reach overhead, which extends her trunk.

5.2. Injured Worker's Job Analysis Recommendations

Most return-to-work recommendations typically include generic suggestions, which would be applicable to any worker doing the

Table 2.

JOB SITE ANALYSIS

Job Title: _Warehouse loader_____ Employee: _____Jane Worker_____
Location: _____Warehouse area C_____
Work Hours: __7:00AM_ to _____4:30PM_ Days ___5/wk___ Overtime Per Wk. _≈ 2 hrs./day 3-5
days/wk_mandatory 12 hrs. per week during part of year, often volunteers for overtime__

The Job

General Job Description:
1. Picking of products from warehouse shelves to supply orders.
2. Placing items in 24"X 32" box cases.
3. Tapping cases closed with strapping
4. Loading 10-12.5 # cases of snack food products into trailer at a loading dock.
5. Checking off orders and signing out

Equipment, Tools, Work aids:
6 foot Ladder to reach snack food products on overhead shelves which are 8 and10 feet off ground

Essential Job Functions:
Loading 10 –12.5 pound cases of snack food product into trailers, Picking items off shelves, placing into cases.

Time Spent:
Standing _8-10_hrs. Sitting ____-0-_ hrs.   Inside Bld. ___8-10___ hrs.   Out of door ____-0-_ hrs.

Activity	Yes	No	Repetitive (Frequency)	Continuous (# Hours)	Comments
Stoop/Bending	X		5-8 times/min.	1-1 ½ hrs	Performs this task when picking products off shelves. Performs this task for 2 hours, then switches to loading. Bends over box while strapping box
Squat/Crouch	x		1-2 times/min		When loading trucks, squats to lift 24"x32" boxes
Kneeling		x			
Climbing	X		3X/5min		Climbs ladders to retrieve some items needed for loading. Most items are located from waist to 5" overhead height
Reaching Overhead	X		7-8/min		To pick products off shelves, last 4 cases loaded on truck require overhead lifting of cases
Manipulate/Finger	X		20/min		Tripod pinch & release light weight 8-12 oz bags of snack food product
Grasping/holding	x				Holds bags of product for ≈ 3 seconds Holds boxes of orders for 1 minute while loading trucks

Lift/Carry	Hrs/Reps/Position	Lift/Carry	Hrs/Reps/Position
0 – 10 lbs.	6 hrs./8 hrs shift 140 times per hr.	11- 20 lbs.	8-10 times per hour
21 – 50 lbs.	Rarely	Over 50 lbs.	Never

Environmental Conditions:
Cold ___unheated warehouse_____ Heat_____unaircond. warehouse_____
Lighting:__45 foot candles_____ Vibration: _____--_____
Dampness _____--_____Dust/Fumes _____--_____ Noise _____--_____
Other:
Concrete floors – standing throughout the day

---

specific job. This is because more times than not the first job analysis performed by a professional is after a worker has been injured. This was the case in the present example. Simple items like anti-stress mats in front of the product shelves for reducing muscle fatigue, using a picking tool for the lightweight 8–12 oz bags of snack foods to reduce the hyperextension of the trunk, and lifestyle changes to incorporate exercising would be helpful for most all workers.

Specific to the present worker is the use of the picking tool for the lightweight snack food bags. This would reduce the number of times the worker flexes the trunk and goes into extreme extension. Additionally, she needs to stretch her neck and upper back a minimum of once an hour and she needs more alternating of job task. She should not remain in one position for > 10 min and should alternate between task more routinely. With respect to lifting, she needs to avoid frequent lifts of > 10 lb and restrict repeated trunk bending and rotating. This worker will also need an exercise program designed by a rehabilitation therapist to address her specific needs and a lifestyle change, which includes routine exercise.

The Person

Relevance & Meaningfulness of job: Worker is a single mother. Position at warehouse provides sole income for family of four. Worker reports satisfaction in her role within the organization.
Injury: Acute Lumbar strain at L3-5.

For each performance component, determine the level of challenge required to perform job	Level of Performance			Comments Worker has been using a lumbar support belt periodically during loading tasks.
	Min	Mod	Max	
Physical Components • Sensation/ Sensory Integration		X		
• Visual Perception		X		
• Range of Motion			X	**Movement in trunk extension, R sidebend is restricted. Job requires overhead reaching. Worker does no routine fitness program outside of work.**
• Strength & Muscle Tone			X	**Job requires lifting, bending and carrying throughout day. 10 –12.5 # lifted No routine conditioning program**
• Coordination		X		**Tripod pinch used during picking of product from shelves**
• Balance & Posture			X	**Tasks of climbing, reaching overhead and carrying. Worker has rounded shoulders, no routine stretching program. Poor body mechanics demonstrated during lift & carry**
• Endurance			X	**Job requires lifting carrying and climbing through out shift.**
Mental ▪ **Cognitive:**		X		
▪ **Decision making:** ▪ **Concentration requirements:**	X			
• **Multiple tasking/Shifting attention:**	X			
• Mood & Affect	X			
• **Behavior**	X			
• **Thought content**	X			
• **Emotions**	X			
• **Body Image**	X			
• **Volition**	X			
Sociocultural • Cultural values, beliefs, language	x			
• Interpersonal skills	X			
• Management of social roles	X			

The essential functions of a job are those duties that must be performed unaided or with responsible accommodations
Min= is needed for job, but not for essential job functions, occasional, required< 1/3rd of the time
Mod= is needed to carry out essential job functions, but is not the major component(s) for essential function Frequently, required > 1/3rd < 2/3rd of the time
Max= is needed to carry out essential job duties – is the major component(s) needed for essential job function, constant, required > 2/3rd of the time

6. CONCLUSION

From the example given, one can see that except for the added task of accounting for the workers specific injury limitations, a post-injury job site assessment is really no different than any other job site assessment. However, this is a significant exception. As stated in the training section, the knowledge of workplace design, anatomy and physiology, kinesiology, biomechanics, anthropometry, the nervous system, the musculoskeletal system and normal/abnormal psychology are needed. Many of us lack the knowledge of how the pathology of the condition affects the other components. This can be learned over time, or one can solicit the aid of a medical/rehabilitation specialist to deliver a team approach. The later approach being the preference for these authors.

Recommendations:

Environmental Modifications:

Flooring: Anti-stress mats located in front of the product shelves would reduce muscle fatigue

Tool/Equipment Modifications
Reaching overhead & bending: The weight of the product being "picked" off shelves weights 8-12 oz. Worker could use a lightweight reacher when obtaining product off high and low shelves in warehouse to avoid extreme truck extension and flexion.

Modification of Work Techniques/Approach
Breaks: Provide two, 1-2 minute neck and upper back exercise breaks every two hours

Alternate job tasks: Frequent alternation between sit, stand and walking should be performed. The worker should not remain in one position for longer than 10 minutes and should alternate between tasks every two hours.
Lifting: Avoid frequent lifts above 10#, restrict repeated trunk bend and trunk twist

Health Maintenance/Wellness Recommendations:

Stretching and Flexibility program as designed by rehabilitative therapist. Lifestyle modifications to incorporate flexibility, strength and endurance activities into daily activity configuration.

Job Load and Hazard Analysis

M.K. Mattila

Occupational Safety Engineering, Tampere University of Technology, PO Box 541, FIN-33101 Tampere, Finland

1. INTRODUCTION

Job Load and Hazard Analysis (JLHA) is a simple and standardized method for workplace investigations for occupational healthcare and for occupational safety management. The method is best suited for screening of the risks at jobs, preventing health and safety hazards at the workplace, and for determining the contents of the occupational healthcare program and the safety prevention program.

The method was developed in Finland after the Finnish Occupational Health Care Act came into force in 1983. The Occupational Health Care Act requires workplace investigations for the analysis of hazards inherent in the work and working conditions. Workplace investigations as the basis of occupational healthcare is a new concept first defined in the Act. It soon became evident that workplace inspections were a central problem hindering enforcement of the Act (Mattila 1985). The aims of the method are:

- identification of the health hazards to which workers are exposed in their work and by their working conditions;
- to help determine the contents of the occupational safety and health program according to the real needs that arise from jobs and working conditions; and
- to support the prevention of hazards and to facilitate the selection of appropriate preventive measures.

2. BASIS OF JOB LOAD AND HAZARD ANALYSIS

The JLHA comprises the identification of health hazards, their assessment, conclusions and proposals concerning measures to be taken, and follow up. The method is based on the principles of job analysis, self-evaluation, participatory ergonomics, risk assessment and group work. At the same time the conduct of the analysis result is based on the expertise of safety and health professionals.

Information is collected during the visit to the workplace using forms of analysis where the number of items is kept as small as possible. Different types of loads and hazards are considered:

- chemical hazards;
- physical hazards;
- physical workload;
- mental stress factors; and
- injury (accident) risk.

Each item is assessed on a three-point ordinal scale according to occurrence and relevance to workers' health. Written guidelines for assessment are provided (Mattila 1989).

The information is gathered, and the assessment is made in two ways: (1) the occupational healthcare and safety personnel interviews workers and makes observations at the workplace during an inspection tour, whereafter they make their assessments;

and (2) the workers complete a questionnaire form (in which five items are illustrated with several typical examples). It is suggested that a group carries out the analysis at the workplace where, for example, the physician, the nurse, the safety supervisor and worker representatives take part.

3. SAFETY AND HEALTH IMPROVEMENT PROGRAM BY COOPERATION

The cooperation team formed for group problem-solving discusses the findings. The team can comprise, for example, the safety specialists who participated in the safety inspection and, whenever possible, a member of line management. Working together, the team comes up with a comprehensive assessment of risks of jobs and makes ideas for preventive measures.

Next, the occupational health professionals independently evaluate the jobs on the basis of all data. These conclusions, together with proposals for correction or prevention, are then presented to the management of the company. As a result the occupational health professionals present a proposal for the occupational health program.

In this way the JLHA method organizes the cooperation between different levels of the company and yields information about job safety. The following connections and effects are considered particularly important:

- The occupational health program is based on the results of the risk assessment of the workplace.
- The occupational safety personnel receive information about hazards at work while they are involved surveying the workplace.
- Occupational health professionals have access to the occupational safety personnel's information pertinent to workplace hazards, e.g. accident data or the result of industrial hygiene measurements.
- Management obtains the information it needs about operational disturbances, hazards and workers' experiences, and the hazard survey of the workplace can lead to improvements in the production system and to planning for preventive measures.
- The risk assessment of the workplace becomes part of the company's safety information system and constitutes a database on work conditions.

4. RECOMMENDATIONS

The JLHA method has the following characteristics:

1. Job analysis makes it possible to analyze all working conditions. This approach has proved practical in linking information about hazards and stress to the contents of occupational healthcare.
2. The cooperative approach is realized through a cooperation team that evaluates the gathered information. The cooperation team contributes the advantages of group problem-solving. The results become more comprehensive, different personnel groups are concerned in the process and have the change to express themselves, the necessary cooperation takes place, and the acceptability of and confidence in the assessment improves.
3. Workers' active role in hazard screening guarantees that all the problems recognized at the workplace come up for closer

consideration. Workers have proved themselves ready to play an essential part in identifying hazards.

4. The independent role of occupational healthcare personnel is further strengthened when they make assessments independently, and when their conclusions and proposals are reflected in the contents of the occupational healthcare program.

5. The JLHA has numerous indirect, special advantages: proposals for measures to eliminate unsatisfactory working conditions are more numerous and of better quality, cooperation between occupational healthcare and occupational safety receive an efficient forum, workers' confidence in the analysis increase, and the analysis has an invigorating effect on all occupational safety activities at the site and obviously have a positive effect on its safety climate.

6. The method offers numerous possibilities for the utilization of information. Most of the utilization occurs in occupational healthcare, where the information is useful in the initial medical examinations of new workers, in advising workers about safe performance, and in studies on the relations between working conditions and workers' health status. But the information has also other users, e.g. in preventing hazards during planning, in production design and in management.

7. Systematic workplace investigations may be one part of the information system of organization and may help the management in guiding the system, thereby contributing to the realization of safety objectives.

Medical Equipment Usability Testing: An Introduction

V. J. Rice

Ammed Center & School, Ft Sam Houston, TX 78234–6131, USA

1. USABILITY TESTING INTRODUCTION

The proof of the pudding is in the eating.

Usability testing is conducted in order to develop a product that, when placed in the hands of users, will perform as intended. Conducted iteratively throughout the product development process, usability professionals seek to prevent production of a poorly designed product that will compromise the safety and productivity of the individuals who use it.

McClelland has stated that usability testing is the systematic evaluation of the "interaction between people and the products, equipment, environments, and services they use" and "is the fundamental principle that underpins all ergonomics" (McClelland 1990, p. 218). However, what is included in the "systematic evaluation" of the "interaction" often depends on the training of the individual conducting the usability testing. Usability testing is not merely establishing user preference regarding what users like or dislike about a product, nor is it concerned with merely handing out equipment to physicians or other healthcare workers and asking for their open-ended, informal feedback. Stanton and Baber (1996) suggest usability testing consists of the eight factors seen in table 1, while Booher (1990) suggests five ingredients to evaluate equipment including manpower, personnel, training, human factors, system safety, and health hazards (table 2). Combining the efforts of these two authors with personal experience reveals the authors' expectations of usability testing (table 3). Usability testing is a comprehensive, structured approach intended to answer questions about whether the end users of equipment can use it easily, safely, effectively, and efficiently.

Table 1. Components of Usability Testing (Stanton and Baber, 1996).

Components	Definition
Attitude	Acceptable performance within acceptable human costs (fatigue, stress, frustration, discomfort, satisfaction).
Effectiveness	Acceptable performance should be achieved by a defined proportion of the user population over a specified range of tasks and enviroments
Learnability	Allow users to reach acceptable performance within specified time frame.
Flexibility	The product should be able to deal with a range of tasks, beyond those first specified
Task match	The needs and requirements of the user should match the functions provided by the system
Task characteristics	The frequency with which a task can be performed and the degree of modification according to variability of information requirements
Product utility	How frequently the product is used
User characteristics	Knowledge, skills, and motivation of the users

Table 2. Components of MANPRINT (Booher, 1990).

Domain	Description
Manpower	Number of human resources required and available to operate and maintain equipment/system
Personnel	Aptitudes, experience, and other characteristics necessary to achieve optimal system performance
Training	Requisite knowledge, skills, and abilities needed by personnel to operate and maintain equipment/system
Human factors Engineering	Comprehensive integration of human characteristics into system development, design, and evaluation to optimize human-machine interface and performance
System safety	Ability of the system to be used, operated, and maintained without accidental injury to personnel
Health hazards	Inherent conditions in the use of the equipment /system that can cause death, injury, illness, disability, or reduce job performance of personnel

1.1. Process/Procedure

To be most effective, both in terms of ensuring a quality product and keeping costs low, usability testing should be incorporated throughout the design process. The process typically incorporates the nine steps shown in figure 1, which are reiterated during each phase of product development: prototype/initial development, laboratory-based efficacy testing (static, mock-up, simulator), and field-testing. (For a detailed description of the steps involved in usability testing, see Rice 1995.) During the first steps of the process, the human factors professional meets with product developers, management, purchasers, salespersons, subject matter experts, and users (in medical applications, the user may be the medical technician or care provider, while the "purchaser" may be the patient who is "purchasing" the service or treatment). Using a variety of techniques (interview, questionnaire, focus groups, observation, task/function analysis, etc.), the design objectives for each group are identified according to their desires for the final outcome features of the product. Usability evaluations should identify both positive and negative aspects of a product, from the points of view of all interested parties. By identifying what constitutes a successful product for all, the results of user testing can help to generate a product that is desired by and does not harm the end user, and creates financial gain for the manufacturer. The critical success factors for each group are then incorporated into measurable performance criteria for experimental testing. The success factors are prioritized, to determine which are critical and which may used as tradeoffs between groups, should that become necessary.

After the nine steps in the usability assessment are completed (table 3), the results are used to reassess the product design, and the process is started again, in a consequent stage of the development process (product development, laboratory testing, field testing). Although usability testing is most effective when conducted in an iterative fashion throughout the design process, other procedures are used. For example, instead of repeating the entire nine steps, one or two steps may be repeated, if the desired changes so warrant.

Table 3. Components of Usability Testing (Rice, 1999).

Component	Description
Task match/ Effectiveness	1) Establishment of critical success factors for all interested parties (manufacturer, developer, purchaser, user) and assessment of the products in terms of meeting those factors. 2) Flexibility to meet changing needs.
Human factors	1) Match between known human characteristics (abilities and limitations of physical, cognitive, and emotional domains) and requirements to operate equipment. Educational level required. 2) Detailed description of the user populations, along with match or mismatch with equipment requirements 3) Selection criteria, if necessary: aptitude, experience and other characteristics necessary to safely operate equipment.
User performance	1) physical 2) cognitive (decision making, etc.)
User attitudes	Users subjective ratings including ease of use, preference, perception of safety, comfort, etc.
Training	Amount of training, type of training (written, oral, performance, training for stressful enviroments), depth of training, user knowledge and skills necessary to benefit from training, need for over-riding previous learning, and efficacy of training.
Manpower	Number of personnel to operate and maintain equipment and/or system.
System safety	1) Ability of the system to be used, operated, and maintained without accidental injury to personnel, and within acceptable human costs (fatigue, stress, frustration, discomfort, satisfaction). 2) Comprehension of and efficacy of warnings.
Human error	Evaluation of potential human error and establishment of failsafe designs or error tolerant systems.
Health hazards	Inherent conditions in the use of the equipment/ system that can cause death, injury, illness, disability, or reduce job performance of personnel.
Integration	Integration of the equipment or operational system within the existing procedures and organizational enviroment.
Cost	Costs listed in other categories (manpower, training) are combined with other costs (production, supplies) to achieve and estimated cost comparison or cost/ benefit ratio.

1.2. Fidelity

If the field testing of the equipment is accomplished in a simulated environment, such as in an integrated anesthesia training environment, then a final assessment conducted during or immediately following actual use is suggested to ensure ecological validity (Bogner 1998). Difficulties with using the equipment may be identified during or immediately following actual use that would not be identified during simulations. This was the case in research on decision-making under stress in which Mackenzie and his colleagues (1996) videotaped actual emergency room cases in which difficulty of package removal and inaccessible data via a video display terminal were revealed.

The proof of the pudding is in the eating. This means the product can only be determined as being safe, effective, efficient, and acceptable when it is put to use by the user population. This is the basis of usability testing. However, information should also

1 SME / USER / INVESTIGATOR

3 ESTABLISH DESIGN OBJECTIVES

5 DEVELOP PERFORMANCE CRITERIA

6 ESTABLISH MEASUREMENT TECHNIQUES

7 WALK-THROUGH / TRAINING

8 ASSESSMENT (conduct testing, evaluate data, identify results)

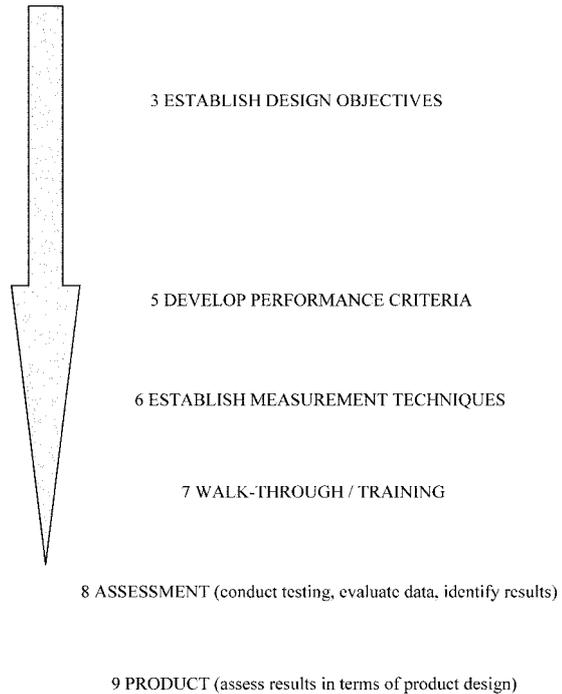
9 PRODUCT (assess results in terms of product design)


Figure 1. Usability Testing Process., SME = subject matter expert)

be gathered immediately after new products go on the market. If this is not done, direct evidence of success may be missed as people tend to complain about a product that is difficult to use or causes pain immediately after its use; but rarely voice their pleasure. Immediate follow-up with new users results in quick retrieval information on the product.

To reiterate, usability testing of medical equipment should yield a design, which achieves the critical goals of all persons who develop, manufacture, sell, purchase, prescribe, and use the equipment.

2. UNIQUE CONSIDERATIONS FOR MEDICAL EQUIPMENT USABILITY TESTING

The unique considerations for usability testing of medical equipment include the user population (aptitude, capabilities, and limitations), the context in which the equipment will be used, the complexity of the equipment, and the integration of the equipment into medical or rehabilitation based practice.

2.1. User Population

The *user population* includes medical personnel (physicians, nurses, technicians, therapists), patients, and non-professional healthcare providers, such as friends and family members. Therefore, the patient's disease process, the residual capabilities of the patient, and the skills and limitations of each user group must be carefully considered during the design process. Obviously, the educational background, experience, and personal characteristics of these groups are diverse.

The healthcare system is increasingly moving toward the use of technical level personnel. The physician may not be the sole user of complicated medical equipment. Instead, physicians

assistants, nurses, and a variety of specialty technicians may share in the responsibility. A physician typically has seven to ten years of education post bacheloreate degree, while many medical technicians attend a two-year trade school following high school. The design of all aspects of the equipment and/or system should be aimed at the lowest educational level of potential users.

Increased longevity of the normal aging population, of rehabilitation patients (for example, persons experiencing spinal cord injuries), and of those with newly identified diseases (such as autoimmune disorders) has increased the population requiring home-based rehabilitation equipment. The individuals needing care may be providing it themselves and the symptoms of their disease or disability may interfere with their ability to correctly use the equipment. Care may be furnished by lay providers, who may be retired or infirm themselves. For example, lay providers may be of high school or college age and need to furnish care before their working parents return home. Increased longevity and the increase in home-based care has created even greater diversity in the capabilities of user groups (Bogner 1998). The strengths and capabilities of these individuals (users) are not within the typical human factors' database used to match task requirements with human capabilities. The need for identification of user characteristics and evaluation of user groups are therefore even more important to prevent human error in the operation of home-based equipment.

The aptitude, skills and knowledge necessary for operating the equipment, as well as for understanding training and warning labels of the users, must be known. Equipment use, instructions, training programs, and warnings should be specifically designed for the user populations. However, this is not always the case, as shown in research conducted on readability of patient education literature. Merrit, Gates, and Skiba (1993) found that pamphlets designed for use by persons experiencing hypercholesterolemia required college-level reading skills according to three different methods for analyzing literacy levels. Thus, most of the individuals in the United States who could benefit from these pamphlets would be unable to comprehend and utilize information important to their health and well-being. Techniques such as editorial reviews and readability scoring should be part of usability testing for training, instructions, and warnings.

Systems designers and managers sometimes use training to make up for design limitations; however, this can result in unexpected and excessive costs for training courses, facilities, and devices, while not necessarily assuring an appropriate level of performance. An even worse prospect, poorly designed training, can induce unanticipated error which can potentially harm care-givers or their patients. Training which is specifically designed to accomplish learning within a particular context must be carefully designed. For example, if the individual receiving training will be functioning in a highly stressful environment, then specific training strategies designed to ensure fidelity of training should be used. Although the manufacturer cannot always follow their product to ascertain whether training has been conducted, it can (and perhaps should) become part of the sales package. In a study focused on the evaluation of mechanical aids for moving patients, trained nurses were used as subjects. Although the nurses were responsible for moving patients using mechanical devices as part of their job, 61% had received only informal on-the-job training. The researchers suggested specific,

practical training in assessing situations, selecting the correct sling, and correctly using mechanical aids for nursing personnel (McGuire, Moody, and Hanson 1996). In the introduction of new equipment and/or training, it is important to remember that the new learning may be superseded/interrupted by prior knowledge. By considering training during the equipment development process, it can be carefully developed as part of the total equipment package, rather than as a backup for poor design.

2.2. Context

The *context* in which the item is to be used is of particular consequence. As pointed out by Bogner (1998), without consideration of the context of use, it is impossible to identify factors (including equipment design) that may contribute to human error. Some of the contextual factors within medical-based facilities include high stress, time pressures, substantial workload, sleep deprivation, and staffing shortages. It is well known that decision-making and cognition are altered by stress levels, sleep deprivation, and fatigue. These potential contributors to human error should be considered and evaluated as part of usability testing, either through use of known information (databases) or real-time research.

One method of attaining ecological validity is through "naturalistic" research. This may involve computer controlled simulations or real-world video taping to delve into the medical contextual environment. This method is suggested for evaluating the medical environment, which is highly dynamic and uncertain, having ill-defined and/or changing goals, and entailing considerable time.

Other aspects of the medical arena, tasks, and cognitive processes of users must also be assessed and utilized in the design process. Cognitive research using a concurrent verbal ("think aloud") protocol has proved successful for assessing physician's informational needs in medical computing, and for use in iterative system development. Using this technique yields information that appears unattainable through interview, questionnaires, and simple observation. According to the authors, this technique helps the designer to comprehend the context, thought processes, and decision-making in healthcare operations so that medical information systems and decision support systems can be designed accordingly.

The context for rehabilitation or assistive devices differs from that of hospital-based equipment. Home-based products can potentially be used in the patient's home, at the beach, in a car, at work, or on a sports field. Context also can include users being relaxed and undistracted or panicked, frenzied, and sleep deprived. The weather could be sunny and bright, foggy, windy or rainy. Fail-safe designs, with several safety features may seem like "over-kill"; but such designs may ultimately prove themselves cost effective both in terms of safety and user preference. At the very least, tolerant designs should be implemented for cases in which dire consequences could result.

At times, usability testing is either not included, or it is not accomplished during the development process or in the environment in which the product will be used. Although not optimal, evaluations of already existing products can be completed in order to recommend design changes to the manufacturer or to give recommendations to those who purchase or prescribe equipment. Most patients and family members do not select their

own equipment without input from healthcare personnel, and many pieces of equipment are prescribed by healthcare personnel. One example of post-production usability testing is that conducted on the effectiveness of mechanical aids for moving patients from their beds to chairs, from their chairs to the bath and shower, and vice versa. McGuire and colleagues (1996) evaluated operator and patient safety, subjective evaluation (confidence, comfort, effort), performance, and advice needed during testing. Although areas for potential improvement of the equipment were noted, the crux of the article centered on the general guidelines delineating selection criteria for those purchasing and prescribing mechanical aids for their patients.

As noted in the opening section of this chapter, evaluating equipment during or immediately following actual use can be helpful and can address contextual issues. Questions can be answered as to whether people are using the product, its effectiveness, and their level of satisfaction with the product. Survey techniques can be used. In one such study, persons with spinal cord injuries were surveyed about the use of bowel care/shower chairs at home. Over 66% of those who regularly used these chairs felt their safety was compromised during their use and less than 54% were satisfied with the design and usability of the chairs. Caregivers also reported being dissatisfied with the chairs. Reports of patient falls (35%) and pressure ulcers (24%) stated they were specifically related to chair use. Other issues raised were lack of hand access to perianal area for digital stimulation, difficulty rolling and turning the chair, difficulty keeping the chair clean, and lack of durability of the seat and brakes on the chair (Nelson, Malassigne, Amerson, Saltzstein, and Binard 1993).

Without assessing the equipment in the environment in which it will be used, the information gained will be incomplete, the equipment may or may not be as effective as it could be, and potential harm to users may be missed. Usability testing of medical equipment should be part of a good quality assurance and safety program for any manufacturer.

2.3. Complexity of Medical Equipment

For *complex medical equipment*, the design considerations go beyond those for simple pieces of equipment. Considerations include physical and cognitive requirements, the human–computer interface, hardware and software, monitoring and input devices, as well as visual/auditory/written instructions, training and warnings. The contained knowledge-base and access to that data can also be part of the total assessment (such as information on diagnostic flow charts). The physical and cognitive requirements demanded by the equipment may involve relatively conventional information regarding human characteristics, as well as storage of detailed anatomical, physiological, or medical information. For example, traditional human factors information includes anthropometric dimensions such as reach and body size. An evaluation could involve keyboards used with medical equipment. Reduced size keyboards have been integrated into some designs, however the reduction cannot go below 16.7 mm center-to-center key space (standard is 19.05 mm) without performance degradation. Medical information might be provided by virtue of written guidance, available on an expert system. Usability testing could involve testing of the use of an expert system and whether the system guided the practitioner quickly

and easily to the correct information. The former involves retrieving data from known sources, while the latter requires evaluation of patient-oriented thought processes by healthcare personnel, in order to design an effective system. Another item of conventional knowledge is the rule of thumb for discrimination of auditory or visual information ($\pm$ 7). The warning signals for monitoring anesthesia during an operation exceed that capability. In a typical operating room, an alarm sounds every 4.5 minutes, with 75% of the alarms being false (they do not signal a change in patient status requiring intervention). Also, alarms may require a corrective response, alert the anesthetist to an abnormal, but intended state, signal an artifact that requires no action, or be a reminder for other behaviors. The point being that the complexity of the equipment and the situation yields unique situations to be evaluated.

2.4. Product Integration

A product will not be used if it is not *integrated* into the system into which it is introduced. Knowledge of the current system and methods of that systems use, how and why information is gathered by healthcare professionals, and how tasks are conducted are essential to encouraging integration of a product. For example, in conducting a pilot study of a medical imaging system for data management, objective cognitive-based performance was added to the usual subjective preference testing. After introduction of the new system, it was found improvement was masked by users' previous strategies and their consequently incorrect interactions with the new technology (Wu, Smith, and Swan 1996). A lack of education, training, practice, and delineating the differences in the two systems, and the strategies needed for each, almost prevented the adoption of a superior system. Users' attitudes and motivation can also prevent acceptance of a new product or system.

Using quality management techniques, such as continuous assessment protocols, can help to ensure the product achieves what it is designed to achieve, and that it is integrated into the daily operations of the healthcare system. This process is initiated at the start of the project and at each successive stage to re-evaluate whether the prototype conforms to the expectations of the developers, designers, and various user groups. Traditional approaches of modeling behavioral and cognitive aspects based on a users' requirements analysis and use of an observational task analysis have not been found to reveal the true picture, and have resulted in the failure of the integration of new information management tools. For example, the missing ingredient in one such system was information on how the recorded data was to be used. Once that was known and understood by the designers, it was possible to redesign the system for more than simply recording of information.

Physicians and other healthcare professionals often do several things at once, such as asking questions of their patients while they are conducting a physical or functional evaluation. Therefore, computer-based data recording and retrieval may not be the best solution in healthcare, as it interrupts the patient care process. Speech recognition has been investigated, as it gives users freedom of movement and the ability to carry on concurrent tasks, while simultaneously entering or retrieving data. Since healthcare workers tend to record a brief description of what may be a lengthy evaluation, use of pen technology also provides greater

mobility compared with being tied to the computer keyboard and terminal. It also makes use of their already learned responses and methods of providing patient treatment. Both speech recognition and pen technology have the propensity to improve the interaction between the physician and the patient by increasing eye contact, and improving the relationship between the patient and the care provider.

Each of these examples illustrates the point: integration of a new product within the cultural and contextual system in which it is to be used vastly improves chances of success.

3. RATIONALE FOR CONDUCTING USABILITY TESTING OF MEDICAL EQUIPMENT

Who bears the cost of poorly designed medical equipment? The patient who may receive less than optimal treatment, or be injured or killed; the healthcare provider who struggles with appropriate use of the equipment, thus wasting time and energy; the purchaser and prescriber of equipment who must conduct informal usability tests and/or closely study equipment-based publications to determine the best equipment for their use; the manufacturer whose product does not sell, and neither the sales personnel or management understand why; the manufacturers, insurance companies, and patients who must pay extra costs to cover lawsuits, which have resulted from wrongful injury or death lawsuits. All of us pay, in one way or another. Some pay with their lives or quality of life, and some pay financially; but we all pay.

Usability tests should include cost estimates for informed decision-making regarding production and/or purchase. It has been suggested that adding human factors results in an increase of total design costs from 0% to 8%, with 8% being high unless it includes costs associated with integrated logistics support (Booher 1990). This is perhaps a small price to pay for the safety and productivity improvements which are generated through usability testing.

Criticisms of usability testing state that too many people must be included in assessments (with such a variety of users), they take too much time, and they are too expensive. However, research conducted by Lewis (1994) demonstrated that observing five participants allowed discovery of 80% of a product's usability problems (as long as the average likelihood of problem detection ranges between 0.32 and 0.42) , and that observing additional participants revealed fewer and fewer new usability problems.

Managers use systematic methods for product evaluation including demonstrations, clinical scenario simulations, and conceptual models with an interdisciplinary team and tape-recording the joint sessions for later analysis. In essence, managers have devised informal usability testing strategies, with an emphasis on application integration. It is not known how much time this takes of vendors, or if potential purchases turn down equipment should vendors not comply with the informal testing, continue to provide unsolicited material, or insist on using their own marketing strategies. However, if independent usability research has been conducted, this information could be provided early in the process and should be an integral part of any marketing strategy.

Investment on the front end will yield both immediate and long-term productivity and cost avoidance advantages. Costs of retrofitting expensive equipment or re-developing equipment based on human factors deficiencies is extremely costly, but, it seems, industries rediscover this fact continuously.

Unfortunately, unless legal action is taken or a report is filed with the Food and Drug Administration, the manufacturer may bear no "visible" consequence of their poor design. However, they still pay financially with loss of consumer confidence.

All interested parties want safe, usable, and affordable products. What will influence manufacturers to institute testing to help deliver such a product? Top management, who design and structure the reward system for their employees can influence the organizational structure that will ensure total quality management of their products. The key to their hearts may be assuring them of a competitive edge in a global market, cost savings, their experiencing a loved one whose suffering is perceived as having been avoidable, or legally mandated compliance. Will such a mandate occur? At this point, the answer to that question is unknown. What is known is that usability testing can reduce waste, unnecessary operations, and maintenance costs, while increasing productivity and avoiding injury.

The MUSE Method for Usability Engineering

K. Y. Lim

Nanyang, Technological University, School of Mechanical and Production
Engineering, Singapore 639798

1. INTRODUCTION

MUSE (M̲ethod for US̲ability E̲ngineering), a human factors
structured analysis and design method, was developed between
1987 and 1992 to advance the methodological foundation of
human factors design. The method has evolved through a number
of versions since its early conception in 1988 (see Walsh, Lim,
Long and Carver 1988, Lim, Long and Silcock 1992). MUSE is
the first and arguably the most complete structured human factors
method to be developed.

MUSE is the result of a project commissioned specifically to
solve the "too-little-too-late" problem of human factors input to
interactive systems development. Human factors inputs may be
"too little" since frequently only advice is offered. Inputs may be
"too late" because evaluation is often the main (or worse the only)!
human factors contribution to interactive systems development.

As a structured analysis and design method, MUSE addresses
the problem by specifying explicitly the human factors design
inputs and processes required at each stage of the design cycle.
By making the scope, format and timing of its design contributions
explicit, MUSE enables a more timely and effective intersection
of human factors and other system design inputs. In this way,
MUSE facilitates cross-disciplinary integration of methods, such
as with structured software engineering methods like the Jackson
System Development (JSD) method, Structured Systems Analysis
& Design Method (SSADM), etc. Thus, an efficient system
development process is ensured, which in turn enables a more
effective uptake of human factors design contributions.

MUSE provides design support throughout the system
development life-cycle, including explicit stages and procedures
for user requirements analysis, task analysis and u!ser interface
design. Thus, the method advances human factors design
specification (as opposed to the traditional focus of human factors
on design evaluation only), by taking system development from
the description, analysis and synthesis of user tasks to a user
interface design specification. It should be noted that MUSE
advocates iterative design, and facilitates prototyping by specifying
explicitly the design descriptions to be derived at each stage of
system development. The MUSE method also exploits the
potential of a common notation for cross disciplinary design
communication, by recruiting the well developed structured
diagram notations offered by the Jackson System Development
(JSD) method, a software engineering structured analysis and
design method. The notations exploited by MUSE include basic
constructs such as sequence, selection, iteration and hierarchy;
as well as more powerful constructs to describe concurrent,
interleaved and uncertain events. These constructs enable a
human factors designer to provide a more specific description of

user tasks and a concise way of specifying dynamic aspects of a
user interface design. Examples of the latter human factors
specification may include relating and timing software functional
supports and screen actuations to user tasks, and the definition
of contexts for triggering particular error and dialogue message
displays.

It can not be over-emphasized that the MUSE method need
not be applied in its entirety. Although the method includes very
detailed products and procedures, a human factors designer may
choose to apply MUSE at its top level only; that is to use its
stage-wise design framework to guide human factors input to
system development and to identity cross disciplinary contact
points to facilitate design collaboration. In this respect, MUSE
can be configured for integration with any explicit system
development method, since its conception of the human factors
design process is generic. In another scenario of method
application, a human factors designer may choose to apply only
the early stages of MUSE to support requirements and task
analysis, followed later by task synthesis. In this case, the designer
may also wish to exploit its structured diagram notations to enable
more explicit and specific user task description (see Lim 1996).
Naturally, the MUSE method may be applied in its entirety, for
instance in large systems development projects or for long life
systems, both of which would require comprehensive design
process and documentation to support systematic specification
and later system maintenance. Case-studies of all of these
scenarios of application of MUSE exist.

A brief account of the MUSE method follows. For a detailed
description, the reader is referred to Lim and Long (1994).

2. MUSE: A STRUCTURED HUMAN FACTORS M̲ETHOD FOR US̲ABILITY E̲NGINEERING

MUSE involves a number of design stages grouped into three
phases as follows:

i   Information Elicitation and Analysis Phase. Background
    information to support design is derived and processed at
    this phase including human factors analyses (see Figure 1).
ii Design Synthesis Phase. This phase is concerned with the
    initial definition of the system and its sub-systems. One or
    more conceptual designs of the target/new system is then
    synthesised.
iii Design Specification Phase. The three stages in this phase
    address the detailed design of a new system, including human
    factors specifications of a user interface design.

A brief de!scription of the design stages of MUSE follows.

2.1. Extant Systems Analysis Stage

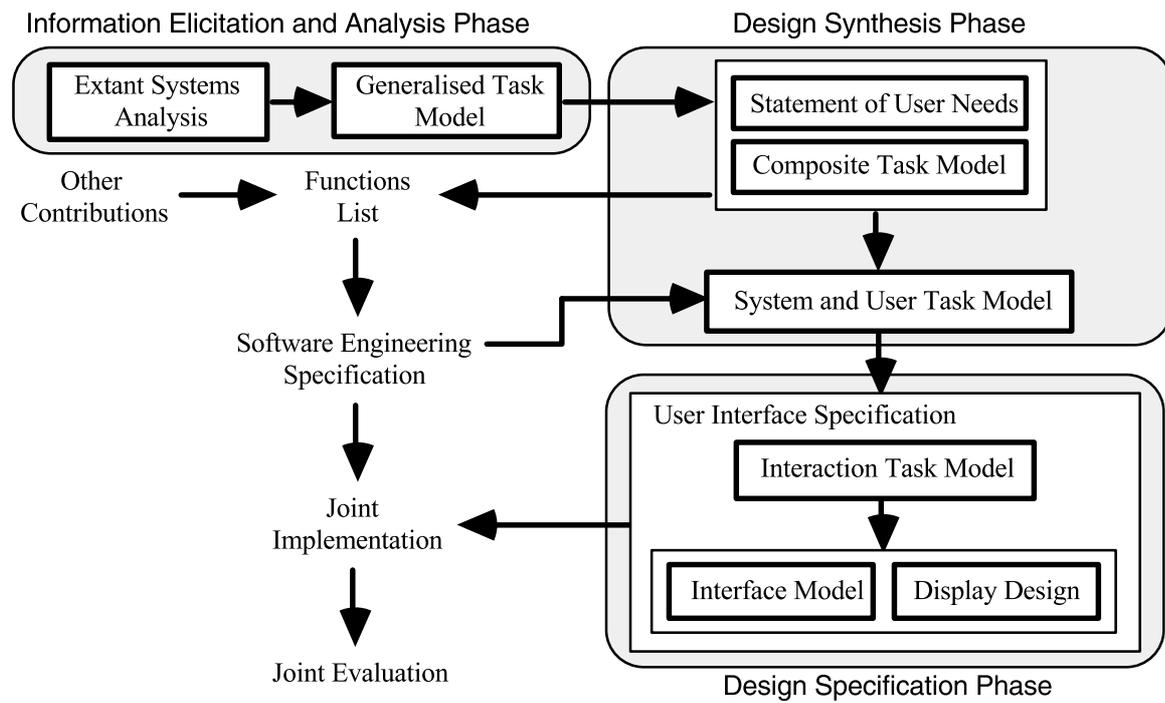
At this stage, background information to support system
development is derived from users and other sources; e.g. critical
user needs and problems, salient characteristics of current tasks,
features and rationale of the existing user interface design, etc.
Related extant systems may also be analysed as appropriate. The
objective of the analysis is two-fold. First, information is gathered
to set new design requirements against the context of the current
system. Second, extant system designs are assessed with respect to
new system requirements. On the basis of the information, the
consequential implications of porting (or non-porting) of particular
design features from the extant system to the new system, may be


Figure 1. A simple representation of! MUSE: a structured human factors method

considered. For instance, assessments of possible transfer of learning effects (both positive and negative effects) would be supported.

2.2. Generalised Task Model Stage

This design stage is concerned with processing the information gathered at the preceding stage. The objective is to generate (predominantly) device independent descriptions to support analytic mapping between specific extant design features and new system requirements. To this end, generalised task models are derived to characterise the conceptual requirements of the new system and of each extant system analysed. By comparing the models, appropriate extant design features may be identified and selected for porting to the new system. Similarly, new design features that conflict with the current system may be avoided.

2.3. Statement of User Needs Stage

Conclusions drawn from extant system analysis are collated and summarised with respect to the user. The statements derived constitute an explicit set of human factors requirements for the new system. The information documented should include problems experience!d by users; design requirements, constraints, and rationale of existing and new design features; performance criteria; domain semantics; etc. A user-centered design basis is thus established.

2.4. Composite Task Model Stage

A conceptual design of the new system is generated at this stage to support function allocation between the human and computer. To this end, a composite task model is synthesised from compatible sub-sets of the generalised task models derived earlier. On-line and off-line tasks are then designated in the composite task model.

2.5. System and User Task Model Stage

This stage addresses the decomposition of on-line and off-line tasks (see sub-section 2.4 above). Specifically, on-line task components of the composite task model are decomposed to generate a system task model to define the cycles of human and computer actions entailed by the interactive task. Similarly, off-line task components are decomposed to gen!erate a user task model to describe tasks not supported by the computer. During decomposition, design features of extant systems that are consistent with the statement of user needs, may be incorporated.

2.6. Interaction Task Model Stage

At this stage, an interaction task model is derived by decomposing the human action components of the system task model. A device level description of user inputs required by the interactive task is derived. Points for triggering and removing screen displays may then be defined by locating the start- and end-points of coherent groups of user inputs (corresponding to interactive task actions). The resulting specification provides a user-oriented perspective of the error-free execution of the interactive task (errors are addressed later in sub-section 2.8). Note that the development of training programmes and user manuals would be supported by such a task model.

Generally, two rules of thumb guide the derivation !of an appropriate interaction task model. First, the model should be decomposed to a level understood easily by design team members and end-users. Second, the terms used in its description should be consistent with the user interface primitives (e.g. screen objects and actions) of the chosen implementation environment and hardware (e.g. basic keystrokes). On the basis of an appropriate interaction task model, design activities of the remaining stages of the method may then be undertaken.

2.7. Interface Model Stage

At this stage, a set of human factors descriptions (termed interface models) of the behaviour of user interface objects, is derived by decomposing computer action components of the system task model. The models specify how appearances and behaviours of user interface objects would change in response to user inputs, and to changes in attribute states of corresponding real world domain entities. The specification derived provides a computer-orie!nted perspective of the interactions required to execute the on-line task.

2.8. Display Design Stage

This design stage addresses three aspects of human factors design. First, potential user errors are identified by examining each input prescribed by the interaction task model. Design modifications may then be considered to remove the causes of error. Problems that can not be solved may be accommodated by a more tolerant or forgiving design, and as the last resort, by a greater emphasis on user training and selection (if applicable). To address these concerns, design iterations may be required with the two preceding stages described above.

Second, static characteristics of computer displays are specified; for instance the composition and layout of screen displays and computer support functions, and the design of error, feedback and help messages. Finally, the dynamic characteristics of screen displays are then specified; for insta!nce the context for actuating particular displays to support human-computer dialogue and the interactive task. The set of human factors design descriptions thus derived specify how, when and what computer functions and messages are presented to support each stage of the user's task.

It should be emphasised that the MUSE method provides detailed design procedures and notations for each of the design stages described above. Space constraints, however, preclude an account of these procedures here. For a more detailed account of MUSE, the reader should refer to Lim and Long (1994).

Note also that MUSE has been integrated with JSD (a structured software engineering method) in 1991, to support more effective cross-disciplinary design collaboration. The integrated method derived is named MUSE•JSD. For a more detailed account of the latter, the reader should refer to a related entry in this encyclopedia and to Lim and Long (1994). Since the completion of MUSE development in 1992 and its official introduction in 1994, follow-up work on the method has been undertaken at several locations and across different countries. In particular, MUSE has been applied in several system development cases by researchers as well as designers from large commercial companies that participated in a European Community project. Derivative versions of MUSE have also emerged to tailor the method more specifically for particular application domains (e.g. safety critical process control), and for cross-disciplinary integration with particular object oriented design methods and structured software engineering methods. The results of some of these projects have been published and reported at conferences. Other projects are ongoing including the development of basic tools to support method application.

MUSE–JSD: Structured Integration of Human Factors and Software Engineering Methods

K.Y. Lim

Nanyang Technological University, School of Mechanical & Production Engineering, Nanyang Avenue, Singapore 639798

1. MOTIVATION AND RATIONALE FOR DEVELOPING MUSE–JSD

The typical involvement of human factors only at the evaluation stage of system development often results in poor realization of its design contributions. Contributions may be "too-late" because human factors activities are not presently basic to design specification. The lateness of human factors involvement makes it more difficult to formulate contributions, as information on the decisions made during conceptual design are frequently poorly documented. As a result, human factors recommendations may be incorporated ineffectively during system development. Worse, no action may follow human factors recommendations because the desired modifications might be too far reaching, and hence too difficult and expensive, to implement at later stages of system development. Further, the possibilities for modification may become restricted due to interlocking design dependencies. Developed designs may thus become "frozen" and more resistant to change. Consequently, late human factors involvement may result in contributions which are little more than advice, i.e. "too-little". The overall outcome is often an inefficient system design cycle skewed heavily towards design maintenance (which includes design modification).

This "too-little-too-late" problem of human factors input to system development prompted a growing awareness that early and continued human factors involvement in the system development process is vital for effective uptake of its contributions. Early involvement is more effective since appropriate user requirements may be established to constrain design at later stages of system development. An early definition of user requirements is particularly important because human-related design issues predominate at early stages of system development. Continuous human factors involvement then supports the appropriate interpretation and translation of user requirements into system design specifications. Continuous involvement also ensures that human factors inputs are timely and contextually relevant to system development concerns that evolve through the design cycle. In this way, human factors contributions to system development may be optimized.

A basic requirement for ensuring comprehensive human factors input is to define and locate explicitly its design concerns against existing conceptions of the system development process. To this end, system development methods that provide life-cycle support and well-developed methodological characteristics would

provide an explicit design framework against which human factors inputs could be located and timed appropriately. These requirements are met by a class of methods named structured analysis and design methods. These methods are characterized by systematic design stages defined explicitly in terms of their scope, process, product and notation. Further, the framework provided by structured analysis and design methods could also guide the development of a similarly explicit, complete and structured human factors method. Indeed, a structured human factors method named MUSE was developed in this way (Lim and Long 1994).

By developing a structured human factors method, cross-disciplinary design concerns may be coordinated more effectively by integrating human factors and software engineering methods. The benefits that would accrue from a structured integration of human factors and software engineering methods are:

- A structured integration of cross-disciplinary design processes would facilitate explicit representation of human factors design in the overall agenda for system development. Project resources may then be budgeted appropriately to accommodate human factors design. Design schedules and deliverables may also be specified better. By making explicit at project outset the resource requirements and allocation for human factors design, the frequently reported encroachment of its resources may be avoided. In addition to improved project planning and resource management, incorporating an explicit human factors design process would facilitate the recruitment of existing standards and guidelines. Similarly, an explicit design process would help define specific contexts for recruiting particular declarative human factors knowledge for application at each stage of system development.

- A structured integration of cross-disciplinary design processes could potentially support the use of a common notation for describing human factors and software engineering design specifications. Thus, human factors design inputs may be communicated more effectively to software engineers. The use of a common notation is indeed realizable, since existing structured analysis and design methods often include well-developed notations that are also appropriate for human factors descriptions.

- As the methodological characteristics of structured methods are well-defined, structured integration of design processes would enable cross-disciplinary reference/contact points to be defined. In this way, collaboration between human factors designers and software engineers would be facilitated, leading to improvements in the uptake of human factors contributions.

These benefits motivated the selection of structured analysis and design methods as substrates for integrating human factors and software engineering design processes and methods. Presently, a number of conceptions of structured integration of cross-disciplinary design methods have been developed. A leading example of such an integration is MUSE–JSD, an integration of MUSE with the Jackson System Development method (a structured human factors and software engineering method respectively). Preliminary conceptions of the MUSE–JSD method were published by Lim *et al.* (1990, 1992). MUSE–JSD is the first and arguably the most explicit and complete conception of

a structured integration of software engineering and human factors methods.

Generally, MUSE–JSD comprises parallel streams of human factors and software engineering design contributions to interactive systems development. The design streams are elaborated at a lower level of description to characterize their design stages in terms of their scope (and associated products); process (and associated procedures); and notation (and associated description schemes). In addition, design interdependencies between the two streams are specified to check any design drift that may arise. Specifically, identifying locations at which human factors and software engineering design intersect specifies obligatory contact points. At these points, human factors designers and software engineers are required to agree on the design scope, assumptions and information to be used in the development of the system. In other words, the design basis is defined and adhered to at subsequent stages of system development. A more efficient convergence of cross-disciplinary design outputs is thus ensured by the MUSE–JSD method.

A brief account of the integrated method follows. Before reading this account, it is best that the reader refers first to the MUSE chapter in this volume. For a detailed account of procedures of the MUSE–JSD method, refer to Lim and Long (1994).

2. OVERVIEW OF THE MUSE–JSD METHOD

Figure 1 shows a schematic representation of the integrated method. Some characteristics of MUSE–JSD are immediately discernible. For instance, it can be seen that the integrated method comprises parallel streams for software engineering and human factors design (supported by JSD and MUSE respectively). These

streams are structured into design stages, which are interlinked at several locations.

Figure 1 should not be interpreted as indicating MUSE to be more complex than JSD. The present manner of representation is only intended to show MUSE in greater detail, since the JSD method is already well reported and is maintained largely unchanged in the integrated method. Other characteristics of MUSE–JSD are:

1. The structured human factors method, namely MUSE, comprises three design phases that address information elicitation and analysis (such as user requirements and task analysis); followed by design basis definition and conceptual design synthesis; and finally user interface design specification. For a detailed account of the MUSE method, see the related chapter in this volume and to Lim and Long (1994).

2. The design scope (and associated products), process (and associated procedures) and notation (and associated description schemes) for all stages of the integrated method (i.e. MUSE–JSD) are defined explicitly. Thus, design collaboration between software engineers and human factors designers is facilitated. In particular, the well-defined characteristics of the method facilitate the specification of cross-disciplinary requirements for collaboration in respect of the scope, format, granularity, timing and communication of intermediate design inputs.

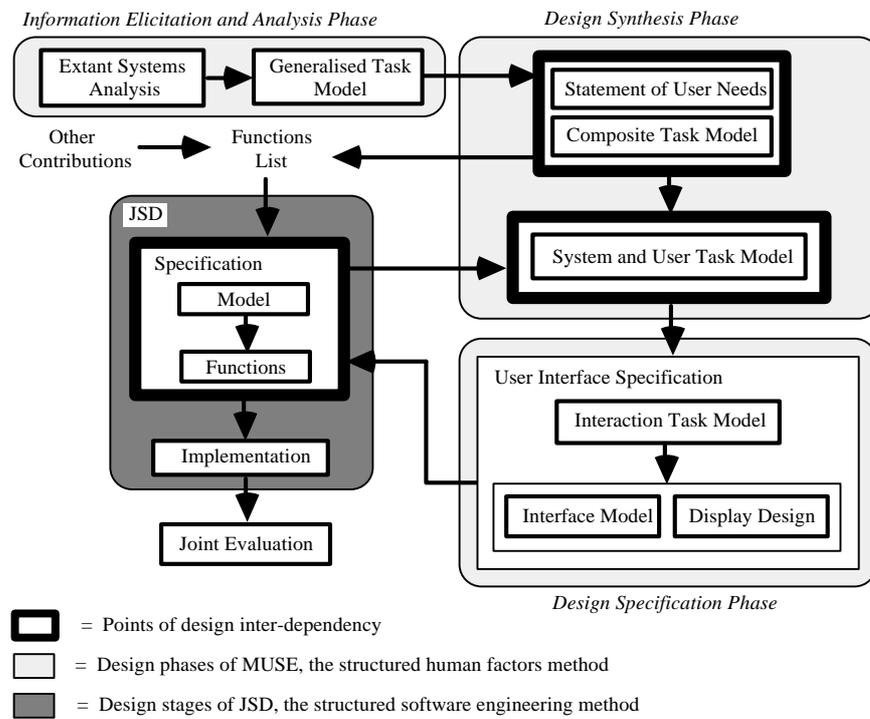
3. The methodological structure of MUSE–JSD supports the application of accepted design principles such as:
   - avoiding premature design commitment by emphasizing conceptual design before detailed design;
   - conducting of early evaluation, either analytically by the


Figure 1. Representation of the MUSE–JSD method.

designer(s) or empirically through prototyping. Both types of evaluations are facilitated by design descriptions to be derived at each stage of system development as defined explicitly by the method; and

- iterative design which is facilitated by the well documented design rationale and descriptions generated by the method;

4. To exploit positive transfer of learning by designers (hence facilitate uptake of the method), appropriate existing human factors methods and techniques have been incorporated into MUSE. For the same reason, the software engineering method chosen for integration (namely JSD) has been maintained largely unchanged in MUSE–JSD.

5. Design interdependencies have been identified explicitly in MUSE–JSD by comparing the information requirements and design concerns addressed at each stage of software engineering and human factors design (as defined by the JSD and MUSE methods respectively). To account for these design interdependencies, *obligatory* contact points have been specified to ensure convergence in the scope of system development advanced in parallel in the individual design streams. In this regard it should not be construed that informal contacts between the two groups of designers are precluded. Such contact points are not specified explicitly in the method since they tend to be situation-specific. For a generally applicable method it would be more appropriate to leave informal contact points as *discretionary*.

The two *obligatory* contact points specified in MUSE–JSD occur between the Design Synthesis Phase of MUSE and the Modeling and Functions Stages of the JSD method. The nature of the contact points is described below.

2.1. Contact Point 1 between the Modeling Stage (JSD Method), and the Composite Task Model and Statement of User Needs Stages (MUSE Method)

At this contact point the human factors descriptions derived are discussed with software engineers. The objective is to augment the design information to be used later to construct a JSD Model to define the subject-matter of the system. Generally, the design information discussed comprises object and action attributes, user needs and problems, event lists, user task semantics, user task support requirements, etc. Following the discussions, a functions list is drawn up to characterize the scope of system development. The functions list is then carried forward to constrain design activities undertaken in succeeding stages of both streams of the integrated method.

2.2. Contact Point 2 between the Functions Stage (JSD Method), and the Composite Task Model and Statement of User Needs Stages (MUSE Method)

At this contact point JSD analysts would address the specification of information flows among JSD Function processes, JSD Model processes, and the external world. These software engineering concerns intersect human factors concerns addressed at the System Task Model Stage of MUSE. Specifically, intersections occur between the functional sequences described in the system task model (design product of MUSE), and JSD specifications of information functions and the input subsystem. Since both streams of the integrated method are presently concerned with conceptual design extension and functional definition, close contact is particularly important to ensure a convergent scope of system development. It should be emphasized that inadequate contact at this stage may incur additional design iterations, when human factors and software engineering specifications are integrated. The result is thus less efficient design.

For a more detailed account of MUSE–JSD and its cross-disciplinary design interdependencies, see Lim and Long (1994).

Noise: Metrics and Equipment

S.E. Lee, G.S. Robinson and J.G. Casali

Virginia Tech Center for Transportation Research, Blacksburg, VA 24061, USA

1. INTRODUCTION

Over time, exposure to noise above a certain level (generally accepted to be in the range of 75–85 dBA) will cause hearing damage in humans. For this reason, most developed countries have established limits on noise exposure for industrial workers. In the USA these limits are found in the Occupational Safety and Health Administration's (OSHA) Occupational Noise Exposure Standard and Hearing Conservation Amendment (Code of Federal Regulations 1983), as well as in other regulations for mining, construction and the military. The application of these standards requires a basic knowledge of the physics of sound, the common metrics for noise measurement and the equipment to be used. Other considerations include: measurement of high-level, impulse noises (such as explosions) which can cause instantaneous hearing damage; the frequency characteristics of the noise in question; and the correct settings for the equipment used.

2. SOUND PRESSURE LEVEL

Sound is defined as oscillations in pressure in a medium (i.e. gas, liquid or solid) which has both mass and elasticity. Sound is caused by a disturbance from an equilibrium condition (e.g. in air, the pulsating airstream from rotating fan blades). In air, the equilibrium condition is the ambient air pressure. Sound is also sometimes defined as the human auditory sensation evoked by these oscillations in pressure (from the human perspective rather than the physical perspective). *Noise* is usually defined as unwanted sound and, more technically, as sound of a random nature.

The most common unit of measurement for sound and noise is sound pressure level (SPL), measured in micropascals (Ostergaard 1986). Because common sounds measured in micropascals (mPa) have a range of ~1 000 000, a compressed log scale called the decibel (dB) scale is almost always used. Correspondingly, common sounds measured in dB have a range of ~120, which is much more convenient for calculations. The formula for SPL in dB is:

$$SPL = 20 \log_{10}(P/P_0), \qquad (1)$$

where P is the maximum measured acoustic pressure and i_0 is the reference pressure, usually 20 mPa.

3. BROADBAND VERSUS NARROW BAND VERSUS TONAL NOISE

In describing a noise, its frequency characteristics are also important. The oscillations in ambient pressure produced by a noise source travel outward from the source in waves, and the number of waves emanating from the source per time unit defines the frequency of the noise. The usual unit for frequency is Hz or cycles per s. For example, for a pure tone (i.e. single frequency) sound of 200 Hz, the sound source is vibrating 200 times per s. Sounds do not have to be pure tones, and in fact, most noises are complex; that is, they are composed of many frequencies occurring simultaneously. These are also known as broadband noises. Still other noises may be narrow band, or composed of a few tones near a certain frequency, so that the overall effect is very close to tonal. An example of a common pure-tone sound is the sound made by striking a tuning fork. The noise of a vacuum cleaner is a broadband sound, while a car horn is narrow band in nature. The young, healthy human ear is capable of detecting sounds with frequencies ranging from ~20 to 20 000 Hz, but is most sensitive from ~1000–5000 Hz. Frequency correlates roughly with pitch, so low-frequency noises are thought of as deep or bass (such as a foghorn), while high-frequency noises are thought of as high-pitched or treble (a whistling tea kettle, for example).

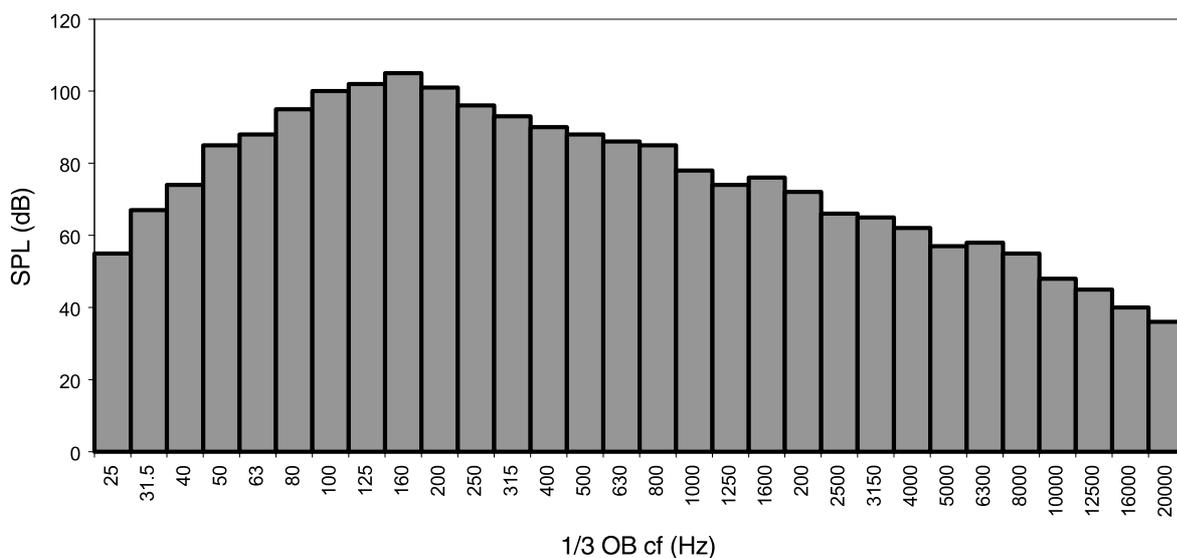
In measuring sound pressure levels, it is often possible to


Figure 1. Example of low frequency industrial noise measured in one-third octave bands.

use electronic filtering to measure the different frequency bands of the broadband noise in question. For instruments that will provide this type of measurement (see Section 7 for details on instrumentation), the most common filter sets are either octave band and one-third octave band, where an octave represents a doubling of frequency. When this type of measurement is employed, the result is often portrayed graphically, with amplitude in dB on the vertical axis and the octave or one-third octave band center frequencies along the horizontal axis (Figure 1). By noting at which frequencies the amplitude is greatest, one can characterize the broadband noise as high or low frequency biased (and in some cases, the noise will be nearly flat across frequencies). In figure 1, the noise is biased toward the lower frequencies, a common finding in measuring industrial noise.

4. A- AND C-WEIGHTINGS

The human ear is not equally sensitive to all frequencies, and in particular, it is more sensitive in the range of ~1000–5000 Hz (Ward 1986) due to several anatomical mechanisms which amplify these frequencies. As a result, the ear is not only made more sensitive, but it is also more susceptible to hearing loss resulting from noise exposure in this frequency range. In order to account for the differential sensitivity and damage risk at these frequencies, the A-weighting scale was developed. A-weighted noise measurements (usually expressed as dBA) take the basic SPL measurement and weight the different frequencies in a manner similar to how the human ear processes the sounds; in other words, sounds from 1000 to 5000 Hz are given extra weight, but sounds outside this range are de-emphasized (Earshen 1986). The resulting metric is thought to be a more accurate predictor of the risk of hearing damage, and also closer to how the human auditory system processes low SPL. The dBA metric is so commonly used that some people mistakenly think that any dB measurement is implicitly A-weighted. The correct practice, however, is to make the weighting scheme explicit, and for the remainder of this paper the two are distinguished, where dB is the same as dB(linear), or unweighted, and dBA indicates an A-weighted measurement.

Another (slightly less common) weighting scheme is the C-weighted, or dBC, scale. This weighting scheme is also loosely related to the response of the human auditory system, but at fairly high SPL. At these high levels, the auditory system is still more sensitive to sounds in the 1000–5000 Hz range, but the curve is not as pronounced. In fact, the C-weighting curve, when drawn, is nearly flat, and thus very similar to dB(linear). One useful application of dBC measurements is that when compared with dBA measurements of the same source, a higher dBC reading indicates that the sound source has significant low frequency components, thus providing a very rough form of frequency analysis.

4. TIME CONSTANTS

The time constant is an important consideration in measuring sound pressure levels. There are three commonly used time constants: fast, slow and impulse. Basically, the sound level meter dynamics are such that when an input (sound) is introduced, the system's response rises exponentially towards the maximum, and reaches 63% of the final, steady-state reading within one time constant. For "fast," it reaches this point in 0.125 s, for

"slow," in 1.0 s and for "impulse," in 0.035 s. When a sound level meter is set to "slow," for example, the needle or digital display is providing a snapshot of the noise that has entered the instrument in the last second.

5. COMMON METRICS

In the field of acoustics and hearing conservation, several types of measurements are commonly available from the various types of sound measurement equipment. In this section the most common types of measurements will be discussed, along with the appropriate usage for each type. Some of these measurements are instantaneous (or over very short periods) while others average the measurement over an extended period.

5.1. Instantaneous Metrics

5.1.1. L_{max}

L_{max} is the maximum sound pressure level (dB) measured over a stated period, using an exponential time constant (fast, slow or impulse). When the exponential time constant is not provided, it is assumed that the fast response has been used. The L_{max} measurement can only be obtained with sound-measuring equipment with a "maximum-hold" feature, which serves to capture and store the L_{max} data. This metric is useful in exploring the maximum levels encountered in events which occur quickly, such as the slamming of a door or the noise emitted by a passing truck (Yeager and Marsh 1991).

5.1.2. Peak

By contrast, the peak sound pressure level is given by:

$$PEAK_{SPL} = 20 \log_{10}(P_{max\text{-}inst}/P_0), \qquad (2)$$

where $P_{max\text{-}inst}$ is the maximum *instantaneous* sound pressure that occurs during a given time period and P_0 is the reference pressure (20 mPa). Peak measurement thus truly captures the highest instantaneous SPL occurring during a specified time period. No time constant is used, unlike L_{max}, for which the measurement is usually taken over 0.125 s. For this reason, peak measurements can exceed L_{max} measurements of the same noise by as much as 20 dB. As with the L_{max} metric, a "peak-hold" feature can be found on many types of sound-measuring equipment (Yeager and Marsh 1991). Peak measurements can be useful for describing high-level, instantaneous sounds, such as explosions or gunshots, which cause instantaneous hearing loss.

5.1.3. L_{min}

Both PEAK and L_{max} are useful in describing noise in industrial and leisure environments, but it is also occasionally useful to know the minimum noise levels. The L_{min} metric is measured similarly to the L_{max} metric, including the need for a special "minimum-hold" feature (Johnson *et al.* 1991). This setting is most often used in laboratories, when it is sometimes desirable to conduct experiments in a very low noise environment.

5.2. Average Metrics

5.2.1. L_{eq}

In most cases, some sort of an averaging metric is needed; the metrics described above do not indicate any sort of average noise level, but instead only provide very brief snapshots of the extremes of the noise in question. Because of the logarithmic nature of

decibels, ordinary arithmetic operations (such as addition and division) cannot be used. Perhaps the most common averaging metric is L_{eq}, or equivalent continuous sound level, which can be thought of as the equivalent steady-state (unvarying) sound pressure level (usually A-weighted) which has the same energy as the time-varying, averaged sound. In other words, the L_{eq} provides an average sound pressure level for a noise which varies over time, and which possesses the same acoustical energy as another unvarying noise. The formula for L_{eq} follows:

$$L_{eq} = 10 \log_{10}\{1/T[S(10^{Li/10}t_i)]\}, \qquad (3)$$

where i is the ith interval, T is the total time, t is the duration of the ith interval, and L_i is the SPL during t_i (L_i is usually A-weighted). The L_{eq} metric is used frequently, and may be encountered in determining the average noise level within a work area, community noise issues, and some government regulations concerning noise and hearing protectors (Earshen 1986).

5.2.2. TWA

Although some government regulations use the L_{eq} metric, OSHA has developed its own metrics for measuring noise exposure in the workplace. One of the more commonly encountered OSHA metrics is the time-weighted average, or TWA. Since OSHA is concerned about the noise exposure of workers in a standard, 8-h day, the TWA is always referenced to 8 h (in other words, 8 h is the time weighting applied to the average noise levels in the workplace). The formula for TWA is:

$$TWA = 16.61 \log_{10}\{1/8[S(10^{LAi/16.61}t_i)]\}, \qquad (4)$$

where i is the ith interval, t is the duration of the ith interval in h and L_{Ai} is the A-weighted SPL during t_i. People working in industrial hearing conservation are most likely to encounter the TWA metric. Dosimeters, or personal noise exposure monitoring devices, provide the TWA as one of the main data outputs. Note that regardless of the actual duration of exposure, it is always weighted against an 8-h standard, so take care *not* to replace the eight with the actual exposure duration (Earshen 1986).

5.2.3. Dose

OSHA, as well as regulatory agencies from other industrialized countries, have established standardized limits on the amount of noise exposure a worker can receive in any given shift (usually taken to be 8 h). This can either be expressed as a TWA, discussed above, or noise dose. Basically, once a regulatory agency sets a limit for noise exposure (in the USA, current OSHA regulations limit noise exposure to an 8-h TWA = 90 dBA), this limit is considered to be a 100% dose, and a mathematical formula can then be used to derive doses above and below the 100% benchmark. An important concept in dose calculations is the exchange rate, which is the number of decibels which is considered to result in a doubling or halving of noise dose. For example, OSHA uses a 5 dB exchange rate (most other countries use 3 dB); this means that while a worker can be exposed to 8 h of 90 dBA noise, if the noise level goes up by 5 dB to 95 dBA, he or she could only be exposed for 4 h. Conversely, the same worker could be exposed to 85 dB noise for 16 h. The formula for dose is fairly simple, as it is simply the sum of the ratios of the actual noise exposures to the allowed noise exposures, where the allowed noise exposures may be obtained from a table or calculated; the

resultant sum is then multiplied by 100 to put it into percentage form. See Casali and Robinson (1999) for further detail on noise dose calculations. If the noise dose is known, then the TWA can be calculated using a simpler formula:

$$TWA = [16.61 \log_{10}(D/100)] + 90, \qquad (5)$$

where D is in percent.

5.2.4. SEL

Sound exposure level, or SEL, is a metric that has been advocated for use in the regulation of hearing protection (Casali and Robinson 1999). It basically takes the SPL formula (equation 2) and multiplies P by the number of seconds exposed and P_0 by a reference duration of 1 s. If L_{eq} is known, SEL can be calculated directly by:

$$SEL = L_{eq} + 10 \log_{10}(T/T_0), \qquad (6)$$

where T is the exposure duration in seconds and T_0 is the reference duration of 1 s. SEL thus provides an indication of the level of a 1-s duration sound that is equivalent to the level obtained by integrating a time-varying sound over the exposure duration (Casali and Robinson 1999).

6. EQUIPMENT

6.1. Sound Level Meters

Sound level meters, or SLM, are perhaps the most common piece of sound-measuring equipment. In their most basic form, they provide a simple sound pressure level reading, without regard to L_{eq}, noise dose, or TWA, although the measurements obtained can then be used in such calculations. Most SLM on the market today have several measurement options that can be employed. The fast/slow/impulse time constant is a common option. For steady-state noise, either the fast or slow setting will provide the same reading. For rapidly fluctuating noise, the slow response will provide a long time average reading, and also has the benefit of making the display more readable (on the fast setting, an analog display will produce a rapidly fluctuating needle in the presence of fluctuating noise, and a digital display will update rapidly, making it difficult to read; Earshen 1986). Most SLM also have the option of dBA/dBC readings; the choice is often dictated by the purpose of the measurement (for example, most OSHA measurements should be taken using dBA, slow response).

The typical SLM has an integrated microphone, with the result that the unit is relatively compact and extremely portable. Some SLM incorporate filter sets so that octave band or one-third octave band measurements can be taken; however, the filter sets found in most SLM operate one at a time, and must be accessed sequentially, which can be time-consuming when this type of measurement is required. There are ANSI and ISO standards for sound-measuring equipment according to its stated degree of accuracy and intended use; it is important that the equipment purchased meets the relevant standards.

6.2. Dosimeters

With the advent of the OSHA Noise Standard in 1971, the need arose for a small, wearable instrument to measure the individual noise dose received by a worker as he or she moved around in the workplace, and the personal noise dosimeter resulted. With microelectronics, it became possible to incorporate the circuitry

for such a device into a small package, not much larger than a deck of cards, and fairly lightweight, that could be comfortably worn by the worker through a workshift. Current advances in microchip design have reduced the size of some of these devices to just a little more than an identification badge. In some models the microphone is built in, and the dosimeter is thus worn on the clothing as close as possible to the ear, while in other devices, the microphone is external, and the dosimeter itself is worn on a belt, with the microphone clipped to the shoulder of the shirt near the ear.

Dosimeters are set electronically (usually through a software interface) to incorporate the correct exchange rate, exposure limit, and time constant. The worker then wears the dosimeter throughout the workshift. The dosimeter often has a protective covering to prevent the worker from changing the settings during the workshift, and the microphone usually has a windscreen covering to alleviate the effect of someone blowing on the microphone and to provide some protection from physical damage. After the workshift is complete, the dosimeter is removed and stopped, and the data are downloaded into a personal computer via a software interface. The data that can be obtained from dosimeters typically include noise dose, TWA, peak sound level, actual running time, L_{eq}, L_{max}, L_{min}, SEL, and various histograms of sound pressure level versus time.

6.3. Spectrum Analyzers

As mentioned previously, it is often desirable to have a breakdown of the noise in question by frequency, and this is often done with real-time spectrum analyzers. The most commonly encountered filter sets are the octave band and one-third octave band. In these devices, the filter sets run in parallel, in real time, so that both instantaneous and long-term average measurements can be obtained. (Mathematically based analyzers, called fast Fourier transform or FFT analyzers, are also available, and these provide analysis down to pure-tone resolution.) The typical spectrum analyzer is quite expensive and includes measurement options such as all of those discussed for SLM. Spectrum analyzers typically allow measurements to be viewed in either tabular (alphanumeric) format or graphically (Figure 1). Many analyzers include computer interfaces so that data can easily be downloaded. Also, many spectrum analyzers have a memory function that allows large amounts of data to be stored so that the computer download can be delayed until a convenient time (especially useful when taking industrial measurements). The data obtained from spectrum analyzers can be used to assess hearing damage risk, to pinpoint the source of a noise, and to perform various calculations that require data in this format (e.g. to determine the masked threshold in the field of warning signal design, or to determine the materials need for industrial noise control).

6.4. Microphones

Microphones are an integral part of all sound-measuring equipment. They may be incorporated into the equipment or attached to the device using a cable to allow remote equipment location. When a cable is used, care must be taken that the device is calibrated correctly, as longer cables may result in "cable resistance drop," an increasing attenuation of measured sound pressure levels as the signal is carried through the cable. Most

microphones have an in-line preamplifier to provide a boost to the signal on its way to the measuring device, as the actual sound pressure levels are quite small. Microphones should not be placed too close to the noise source; a good rule of thumb is that they should be placed no closer than _ wavelength away from all reflecting surfaces, including the sound source itself. For a 100 Hz sound, for example, this rule means that the microphone would be placed at least 76 cm away from the sound source and all reflecting surfaces (Earshen 1986). OSHA regulations also state that many of the required noise measurements must be taken in the vicinity of the operator's head position. In addition, microphones are not equally responsive at all angles of incidence to the sound being measured, and some are designed to be used only in certain environments. Two of the most common types of microphones are briefly discussed below.

6.4.1. Free-field

Free-field microphones are meant to be used in free-field environments (those with no meaningful reflections of sound). These microphones have directional properties and must be aimed toward the noise in question. This type of microphone is required to be used by European noise measurement standards, and so is commonly found in instruments designed for use in European countries (Earshen 1986).

6.4.2. Random-incidence

Random incidence microphones, on the other hand, have a response that is independent of the angle of arrival of a sound wave, so that they need not be pointed directly at the sound source. These microphones are meant to be used in reverberant or semi-reverberant spaces (spaces with significant reflection of sound waves; Johnson *et al.* 1991). Most USA (e.g. ANSI) standards specify the use of random-incidence microphones, but it is essential to check any relevant standards before beginning measurements to make sure the correct microphone is being used. This is especially important when using equipment made or purchased in another country.

7. CALIBRATORS

Although calibration has been left to the end of this paper, it is perhaps the most important element in obtaining correct and valid noise measurements. The sound measurement equipment itself is fairly stable, and should be returned to the factory or service center for bench calibration every year (every 2 years for some types of equipment), or if a problem is detected. The weakest link in the sound measurement chain is the microphone, as it is a delicate component susceptible to damage or skewed readings due to atmospheric conditions, rough handling, moisture, or large electromagnetic fields. It is therefore essential that the microphone be calibrated to the device with which it is being used at *both* the *beginning* and *end* of every measurement session. If the device is turned off, the microphone must be recalibrated. Likewise, if the microphone is removed and attached to another device, it must be recalibrated to that device. The calibrator is usually a cylindrical device into which the microphone is inserted and tightly coupled. The calibrator emits a pure tone at a specific sound pressure level (most commonly 1000 Hz at 94 dB), and the measuring equipment is read and adjusted if necessary to match this level. The calibrator usually runs on batteries, and care should be taken

that the batteries are fresh. In addition, the calibrator itself should be sent to the service center to be checked and calibrated on a schedule prescribed by its manufacturer.

8. CONCLUDING REMARKS

This has been only a brief overview of noise measurement, metrics and equipment. As can be seen, this is a complex topic that requires specialized knowledge. Some important factors to review before beginning any noise measurement are:

- Are there any standards or laws that apply to this type of noise measurement?
- What type of measurement is appropriate for the intended purpose?
- What is the appropriate piece of equipment to obtain this type of measurement?
- Which equipment settings should be used for this measurement?
- What type of microphone is appropriate?
- What is the appropriate calibration protocol for the measuring equipment, especially the microphone?
- What data records are necessary for the application?

In-depth answers to these questions can be found in the relevant standards as well as in the cited references.

The OCRA Method: Assessment of Exposure to Occupational Repetitive Actions of the Upper Limbs

E. Occhipinti and D. Colombini

Research Unit "Ergonomics of Posture and Movement" EPM – Milano, I-20145 Milan, Italy

1. GENERAL ANALYTICAL MODEL AND DEFINITIONS

The description and assessment model of tasks that imply potential biomechanical overload for the upper limbs is aimed at identifying and quantifying the following four main risk factors: repetitiveness (frequency), force, awkward postures and movements, lack of recovery periods. These factors, when taken together, characterize work-related exposure as related to time pattern (duration).

Additional risk factors that are to be considered as enhancers of the actual risk should be added to these. Each risk factor is to be properly described and classified (that is assessed, even if roughly). This means on the one hand to detail every single working action and on the other to consider all the factors contributing to the overall "exposure" in a general and integrated frame. The definitions regarding tests, cycles and technical actions reported in Table 1 are important to this end.

Table 1 lists the main terms used in this section, together with the definitions that best fit the author's operational choices for exposure assessment and for the description of the main risk factors.

The suggested procedure for assessing the single risk factors and the overall exposure follows the general phases listed hereunder:

- Pinpointing the typical tasks of any job, and — among them — those that take place in repetitive and similar cycles for significant lengths of time.
- Finding the sequence of technical actions in the representative cycles of each task.
- Describing and quantifying the risk factors within each cycle (frequency, force, posture, additional factors).
- Reassembling of the data concerning the cycles in each task during the whole work shifts, taking into consideration the duration and sequences of the different tasks and of the recovery periods.
- Brief and structured assessment of the risk factors for the job as a whole (exposure index).

1.1. Organizational Analysis

Organizational analysis should come before the analysis of the four main risk factors and of additional factors. It is essential to focus on the real *task duration of repetitive tasks* and on the existence and distribution of *recovery periods*.

The first phase of the analysis is finding the distribution of work times and pauses within the work shift/s.

If the task is characterized by cycles with mechanical actions

Table 1. Main definitions of recurring terminology in exposure assessment.

ORGANISED WORK:
the organised grouping of work activities that are carried out within a single working shift; it may be composed of one or more tasks.

TASK:
specific working activity whose objective is the attainment of a specific operational result. The following are identified:
REPETITIVE TASKS: characterized by repeated cycles with mechanical actions.
NON–REPETITIVE TASKS: characterized by the presence of non-cyclical mechanical actions.

CYCLE:
a sequence of technical, mainly mechanical, actions of relatively short duration, that repeats itself over and over, always the same.

TECHNICAL ACTION (mechanical):
an action that implies a mechanical activity; not necessarily to be identified with the single joint movement, but rather with the complex movements of one or more body regions that enable the completion of an elementary operation.

MAIN RISK FACTORS

RECOVERY:
period of time within the workin/g shift or within a cycle, during which no repetitive mechanical actions are carried out. It consists of relatively long pauses after a period of mechanical actions, during which the metabolic and mechanical recovery of the muscle can take place. Lack of recovery is the relating risk factor.

REPETITIVENESS:
the presence of events (cycles technical actions) that are repeated in time, always the same.

FREQUENCY:
number of technical (mechanical) actions per given time units (no. of actions per minute).

FORCE:
the physical effort required by the worker for the execution of the technical actions.

POSTURE:
the ensemble of postures and movements used by each of the main joints of the upper limbs in order to execute the sequence of technical actions that characterize a cycle. Awkward posture: risky postures for the main joints of the upper limbs.

ADDITIONAL RISK FACTORS:
the additional risk factors may be present in repetitive tasks but are not either necessarily or always present. Their type, intensity and duration leads to an increased level of overall exposure.

it will be defined as a *repetitive task*. If it is characterized by control operations, and therefore without mechanical actions, it will be defined as a recovery for the upper limbs. The tasks with non-repetitive mechanical actions remain and shall be defined as *non-repetitive tasks*.

The number of foreseen cycles within a *repetitive task*, and the net duration of each cycle, must be counted at this point. The number of cycles often coincides with the number of pieces to be worked in each shift.

1.2. Frequency of Actions (Repetitiveness)

The characterization of repetitiveness can be used to discriminate in general the tasks that must be assessed. To this end, the presence of a repetitive task for the upper limbs can be defined as the consecutive activity, lasting at least 1 h, in which the subject carries

out work cycles similar to each other and of relatively brief duration.

Once repetitive tasks have been submitted to analysis, there is the more important problem of quantifying and assessing the level of repetitiveness.

A frequency measurement proposal that is applicable in the field is the analytical counting of technical actions (mechanical) as defined above. After that, an analysis of postures and movements will make it possible to estimate the duration and frequency of even single joint movements (the type of qualitative and quantitative joint involvement, the static or dynamic component of a movement).

A description of the technical actions requires often the filming of the job, which must then be reviewed in slow motion. Often, the company already has records available in which the task is described and numbered, and the elements constituting successive technical actions are timed (methods–time measurements) .

From the technical action description it is possible to obtain: the number of actions per cycle, the action frequency in a given time unit: number of actions per minute; the overall number of actions performed by the upper limbs (right; left) during the task/tasks, and consequently in the shift.

In this model, the contents of individual or grouped technical actions (by contents we intend the force and the postures associated with technical actions) are described qualitatively and quantitatively when the risk factors "force" and "posture and movements" are studied.

1.3. Force

Force more directly represents the biomechanical involvement necessary to carry out a given action — or sequence of actions. Force may be intended as being external — applied force — or internal — tension developed in the muscle, tendon and joint tissues. The need to develop force during work-related actions may be related to the moving or the keeping still of tools and objects, or to keep a part of the body in a given position. The use of force may be related to static actions (contractions) or to dynamic actions (contractions).

Force quantification in real implementation contexts is a problem. Some authors use a semi-quantitative estimation of external force via the weight of the objects being handled. In other cases, it has been suggested to use mechanical or electronic dynamometers. The quantification of internal force is suggested by means of surface electromyography techniques. All of these methods present implementation difficulties. In this proposal we suggest to use a specific Scale developed by Borg (Category Scale for the Rating of Perceived Exertion). It can describe muscular effort as subjectively perceived for any body region. The results of the implementation of CR-10 RPE Borg's Scale, when used for an adequate number of workers, have turned out to roughly be comparable to those obtained with surface electromyography.

The actions that require minimal muscle involvement could be identified as 0.5 in Borg's Scale; then the involvement description procedure could only describe those actions, or groups of actions, that require more force than the minimal amount, always by using Borg's Scale. Once this procedure has been carried out, the average weighted score for the whole of the cycle must be calculated.

1.4. Posture and Types of Movements

Upper limb postures and movements during repetitive tasks are of basic importance in contributing towards the risk of various musculoskeletal disorders. A definite agreement is found in literature as to the potential damage coming from extreme postures and movements of each joint, from postures maintained for a long time (even if not extreme), and from specific, highly repetitive movements of the various segments.

On the other hand, the description of postures and movements of each segment of upper limbs during technical actions of one cycle completes the description of "the repetitiveness" risk factor.

The analysis of postures and movements shall be concerned with each single segment of upper limbs (hand, wrist, elbow, shoulder): it is aimed at checking the presence and time pattern in the cycle (frequency, duration) of static postures and dynamic movements involving each segment/joint considered.

The description may be more or less analytical but has to be able to appreciate at least the following items:

- Technical actions requiring postures or movements of a single segment beyond a critical level of angular excursion. The angular excursion critical level can be determined according to criteria available in the literature.
- Technical actions involving static postures and/or movements which, also in acceptable angular excursion, are maintained or repeated in the same way.
- The duration expressed as a fraction of cycle/task time of each condition reported above.

Joint combination of such description factors (posture/time) will provide the classification of posture effort for each segment considered.

1.5. Additional Factors

There are other factors that are considered important, apart from those which have already been discussed here. They always have their origin in work, and must be taken into consideration whenever assessing exposure. They have been described as additional here, not because they are of secondary importance, but because each of them can be either present or absent in the various occupational contexts which are examined and assessed.

The list of these factors — albeit not exhaustive — includes the following: (1) the use of vibrating tools, even if only for some of the actions; (2) the requirement for extreme precision (tolerance of ~1 mm in positioning an object, for instance); (3) localized compressions on anatomical structures of the hand or of the forearm, due to tools, objects or fixtures on the workplace; (4) exposure to cold; (5) the use of inadequate gloves for the task at hand; (6) objects with slippery surfaces; (7) rapid or sudden wrenching movements are required; and (8) gestures implying return shock (such as hammering hard surfaces).

This model only considers factors of physical or mechanical origin. It does not include psychosocial factors because they are not easy to quantify.

1.6. Distribution and Duration of Recovery Periods

A recovery period is the period during which one or more of the muscle groups which are usually involved in the working tasks are basically inactive. The following may be considered as recovery periods:

- work breaks, including the lunch break when taken;
- those periods during which tasks that do not involve the usual muscle groups are carried out; and
- those periods within a cycle, during which actions implying the total rest of the usually active working groups are carried out; to be significant, these periods must be at least 10–20 s consecutively.

Hence, the analysis of the recovery periods is first and foremost a check of their presence, duration and distribution within the cycle, and a macroscopic examination of their presence, duration and frequency within the whole shift.

In tasks implying high action frequency of the upper limbs (e.g. 40–50 actions per min), recovery periods within the cycle are basically non-existent. Analysis must therefore be targeted to quantifying the duration, distribution and frequency of "light" work periods and pauses. Apart from the partial exception as represented by recovery periods for actions implying protracted static contractions, the description and assessment of recovery periods should be based on the following:

- a description of the actual sequences of tasks implying an overload of the upper limbs, of "light" non-repetitive tasks, and of the pauses;
- frequency of the recovery periods with reference to the actual number of working hours per day; and
- ratio between the "total recovery time" and the "total repetitive working time".

No definite univocal criteria for the assessment of recovery periods exist in the literature.

For practical purposes one can refer to an Australian Health and Safety Commission document which established that work periods with repetitive movements and without recovery periods, extending > 60 min, cannot be acceptable. This document also supplies general criteria supporting the ratio of 5:1 between working time with repetitive movements and recovery periods. These two guidelines seem wholly acceptable as far as current knowledge goes. Their *critical* use offers an interpretation of the descriptive data collected on sequence, duration and frequency of recovery periods relating to cycles with a prevalence of dynamic actions.

2. OCRA: A CONCISE INDEX FOR THE ASSESSMENT OF EXPOSURE TO REPETITIVE ACTIONS OF THE UPPER LIMBS

2.1. Introduction

A procedure is here reported for calculating a concise index of exposure to the risks of musculoskeletal disorders associated with Occupational Repetitive Actions (OCRA) of the upper limbs. The report is based on the quantification figures for the various risk factors proposed in the previous pages.

The OCRA index is based on three premises:

- There is a need for an integrated assessment of the contribution of the main occupational risk factors (i.e. repetitiveness, force, posture, lack of recovery time, additional factors).
- Interest has been displayed in the development of a "model" for a concise index along similar lines to the one proposed by Waters *et al.* for the assessment of manual lifting tasks.
- In the present proposal the technical action is identified as

the specific characteristic variable relevant to repetitive movements of the upper extremities. The technical action is factored by its relative frequency during a given unit of time. The "exposure index" (OCRA) is the ratio of the number of technical actions (derived from tasks featuring repetitive movements) effectively performed during the shift to the number of recommended technical actions. In practice:

OCRA =
(total number of technical actions actually performed during the shift)/(total number of recommended technical actions during the shift).

The following general formula is used to calculate the total number of recommended technical actions to be performed during the shift:
Number of recommended technical actions =
$$\sum_{1}^{n} \times [CF \times (Ff_j \times Fp_j \times Fa_j) \times D_j] \times Fr \qquad [1]$$

in which

1,n = task(s) featuring repetitive movements of the upper limbs performed during the shift;
CF = frequency constant of technical actions per minute, used as a reference;
Ff; Fp; Fa = multiplier factors, with scores ranging between 0 and 1, selected according to the behavior of the "force" (Ff), "posture" (Fp) an "additional elements" (Fa) risk factors, in each (j) of the (n) tasks
D = duration of each (j) repetitive task in minutes;
Fr = multiplier factor, with scores ranging between 0 and 1, selected according to the behavior of the "lack of recovery period" risk factor, during the entire shift.

When the exposure index is less or equal to 1, exposure can hypothetically be assumed to be non-significant, or at least acceptable.

Exposure becomes significant when the exposure index is > 1. The higher the index, the greater the exposure.

Since the values of all the variables included in the equation for calculating the index are still hypotheses awaiting validation, for practical purposes it is advisable to adopt a prudential classification system of the results of the exposure index, based on the "traffic light" approach (green/yellow/red).

In practice, given the current status of experiences in the use of the index and the related results of WMSD surveys in real contexts, the following statements may be made:

- OCRA index scores < 0.75 indicate that the condition examined is fully acceptable (green area);
- OCRA index scores from 0.75 to 4.00 (yellow area) are borderline (uncertain). However, though exposure is not substantial, it may be significant and therefore careful monitoring for induced health effects should be introduced (health surveillance); and
- OCRA index scores > 4.00 (red area) are definitely significant, and the higher the value the higher the risk. Actions should be undertaken to improve working conditions (for which the analytical data will help determine priorities), as well as close monitoring for induced effects.

2.2. Procedures for Calculating the Total Number of Recommended Actions in the OCRA Index

The action frequency constant (CF) has been set at 30 actions per min under optimal conditions (i.e. other risk factors not significant); this solution is based on a critical review of literature suggestions and on practical considerations. However, it is to be underlined that the criteria suggested for the interpretation of the results of the index, with an extensive borderline zone, are primarily due to the uncertainties deriving in the choice of the constant value. The elements for determining the multiplier factors for force, posture, complementary factors, lack of recovery periods are reported in Table 2. For the analysis of the different risk factors, reference is to be made to description and quantification procedures reported by Occhipinti (1998) and Colombini (1998).

Annex A reports a data sheet for calculating the OCRA Index.

2.3. Final Remarks

The concise index of exposure proposed in this report represents a preliminary endeavor to organize the data obtained from the descriptive analysis of the various mechanical risk factors. However, it must be emphasized that the proposal is entirely experimental. At this juncture, its value lies in its ability to: (1) classify or at least group together the various scenarios which might give rise to different degrees of exposure to the various significant risk factors, and thus steer priorities of preventive actions; and (2) identify situations which do not constitute a problem, at least as far as is currently known. The design of the index is based on indications contained in the literature. The proposed index cannot under any circumstances be used in its present form as a standard, or as the expression of threshold values.

The OCRA index naturally still requires validation, particularly by means of parallel studies of induced effects in groups of exposed workers. To this aim a preliminary study was performed in 8 different work contexts in which 462 workers were exposed to different conditions of repetitive movements of upper limbs. The preliminary study showed, among others, a good agreement ($r^2 = 0.88$; $p < 0.001$) between the OCRA index

and the overall occurrence of WMSD of the upper limbs as calculated in the different work contexts.

The linear regression line best expresses this agreement:

$$y = 0.614 + 0.858x,$$

where $y = \log_{10}$ of the overall frequence (%) of WMSD and $x = \log_{10}$ of the OCRA index.

The exhaustive description of the risk factors associated with a given repetitive task, the quantification of consequent exposure in a concise, albeit approximate, index and the need to perform parallel studies on the clinical effects on exposed workers, all represent both an opportunity and a commitment to carry out further researches and investigations.

ANNEX A

Data sheet for calculating exposure risk

The first part of the data sheet lists the main items characterizing the repetitive tasks analyzed, followed by the second part which serves more specifically to calculate the OCRA index.

In particular, the first part of the data sheet identifies and quantifies the following:

- production department or line and type of work performed by the exposed workers;
- items characterizing each repetitive task (up to a maximum of four repetitive tasks per shift) such as average cycle duration (s); average action frequency (number of actions per min); total duration of each task (min);
- total number of actions performed in each repetitive task and during the entire shift;
- breaks and non-repetitive tasks that could be regarded as recovery periods;
- sequence of tasks and breaks as they occur during the shift; and
- number of hours spent in the shift without recovery periods.

The second part of the data sheet is used directly to calculate the desired index. For each task analyzed the calculation starts from the frequency constant (CF) of 30 actions per min. This constant is multiplied by the perceived effort factor (Ff), as obtained from the relevant conversion table, for each task.

Now another multiplier is calculated, this time for the posture

Table 2: Elements for determining the multiplier factors for Force (Ff), Posture (Fp), Additional Factors (Fc) and Recovery Periods (Fr).

Force Factor	R.P.E. (Borg scale)	≥0,5	1	1,5	2	2,5	3	3,5	4	4,5	5
	mean effort ≥5 (% of m.c.v.)	10	15	20	25	30	35	40	45	50	
Multiplier Factor (Ff)		1	0,85	0,75	0,65	0,55	0,45	0,35	0,2	0,1	0,01
Postural involvement Index score		0-3	4-7	8-11	12-15	16					
Multiplier Factor (Ff)		1	0,70	0,60	0,50	0,3					
Additional Element index score		0	4	8	12						
Multiplier Factor (Ff)		1	0,95	0,90	0,80						
No. of hours without adequate recovery		0	1	2	3	4	5	6	7	8	
Multiplier Factor (Ff)		1	0,90	0,80	0,70	0,60	0,45	0,25	0,10	0	

PART A – Summary of data for calculating index of exposure to repetitive movements of the upper limbs.

| Department or line........................ | Station or task .... | Shift........................ |

Characterization of repetitive tasks performed during shift

	A	B	C	D
• duration of task in shift (min)				
• mean cycle duration (sec)				
• action frequency (no. of actions/min)				
• total actions in task				

• total actions in shift (sum of A, B, C, D) ☐ Ae

Characterization of non-repetitive tasks performed during shift

	X	Y	Z
• duration (min)			
• comparable to recovery			
• not comparable to recovery			

Total no. of minutes of non-repetitive task comparable to recovery ☐ min ☐

Characterization of breaks during shift

FR   π   Ar

$$\text{OCRA Index} = \frac{\text{Total no. of actions observed in the repetitive tasks}}{\text{Total no. of recommended actions}} = \frac{Ae}{Ar} = \boxed{}$$

---

factor (Fp). Here too, the factor is chosen on the basis of a conversion table that matches descriptive values with multiplier factors. The values for the factors pertaining to the four segments of the upper limb at greatest risk for each limb (i.e. hand, wrist, elbow, shoulder) must be entered into the appropriate spaces. It is advisable to select the lowest multiplier factor for elbow, wrist and hand (since the index is designed specifically for repetitive actions performed by these segments).

The next multiplier to be calculated is for the additional items factor (Fa).

The result of these three multipliers (not indicated in the data sheet) represents the frequency constant per minute weighted by the factors for force, posture and additional elements. The result, multiplied by the duration (min) of each task analyzed, is used for calculating the number of recommended actions for each individual task and, when added together, for the entire shift (p).

At this stage, it is necessary to weight the total number of recommended actions (p) obtained in the partial result indicated above, using the factor relative to the presence and distribution of recovery periods. This is achieved by obtaining the factor for recovery periods (Fr) from the conversion table. This factor is then used as a multiplier of the figure resulting from the previous equation (p).

In this way, the total number of recommended actions for the shift can be obtained (Ar).

This factor is the denominator of a fraction in which the numerator is the total number of actions effectively performed during the shift (Ae) calculated in the first part of the data sheet. The ratio represents the index of exposure to repetitive movements (OCRA).

OWAS – A Method for Analysis of Working Postures

M.K. Mattila

Occupational Safety Engineering, Tampere University of Technology, FIN-33101 Finland

1. INTRODUCTION

OWAS method (the Ovako Working Posture Analyzing System) is one of the simpler observation methods for postural analysis (Karhu *et al*. 1977). The OWAS method has proved to function well in practice on the plant level, and it has proved to be fruitful in achieving improvements in the work system and in preventing health problems (Karhu *et al*. 1981).

The OWAS method has proved to be easily adaptable to daily workplace analysis and is capable of evaluating numerous postures at a variety of workplaces. The OWAS method can be used for the following purposes (Mattila *et al*. 1993):

i   standardized ergonomics evaluation of the postural load
ii   improvements and planning of workplaces, work methods, tools and machines
iii   use by the occupational health services in planning of work for disabled individuals
iv   scientific research to be used with other field methods.

The OWAS method is widely used as the ergonomics analysis method because (Kivi and Mattila 1991):

i   it is intended to serve as a practical tool for daily analysis at workplace level
ii   it is oriented to correcting measures, not only to problem identification
iii   it has been developed to analyse a wide range of different postures, as in the case in building construction
iv   it has proved to function as a tool for fruitful cooperation between different specialties in the company — e.g. occupational safety and health professionals, managers and engineers
v   it is an observational technique well suited to the current methods of occupational health care.

2. FUNDAMENTALS OF THE OWAS METHOD

The theoretical background of the OWAS method is in job and task analysis, in observational techniques, and in risk assessment. When using the OWAS method in job analysis the job is usually divided into tasks. By analysing the working postures at all the tasks the whole posture analysis of a job will be carried out. The OWAS method is based on observations done by trained specialists and is therefore aimed to be an objective method for analysis. High reliability coefficiencies have been reported in several studies.

The OWAS method includes the idea of risk assessment also when the idea of risk acceptance and the emergency of risk reduction by work improvements is integrated in the interpretation of results.

3. THE STRUCTURE OF THE OWAS METHOD

The OWAS method is based on the idea of making momentary observations of postures at certain intervals of the jobs studied and, after receiving sufficient observations, reliable material is available to describe the postures of the job as a whole. It requires only a few seconds to perform an observation and to record it.

The original OWAS recommendation is to make the observations at 30 second intervals. In some studies however shorter intervals, e.g. 15 seconds, have been used. Recently the OWAS method has also been used based on videotaped information of the task and even then 5-second intervals have been used for tasks with short time-spans. When using videotape recordings for the OWAS analysis, special attention has to be paid to the validity, reliability, and correctness of the work-posture information.

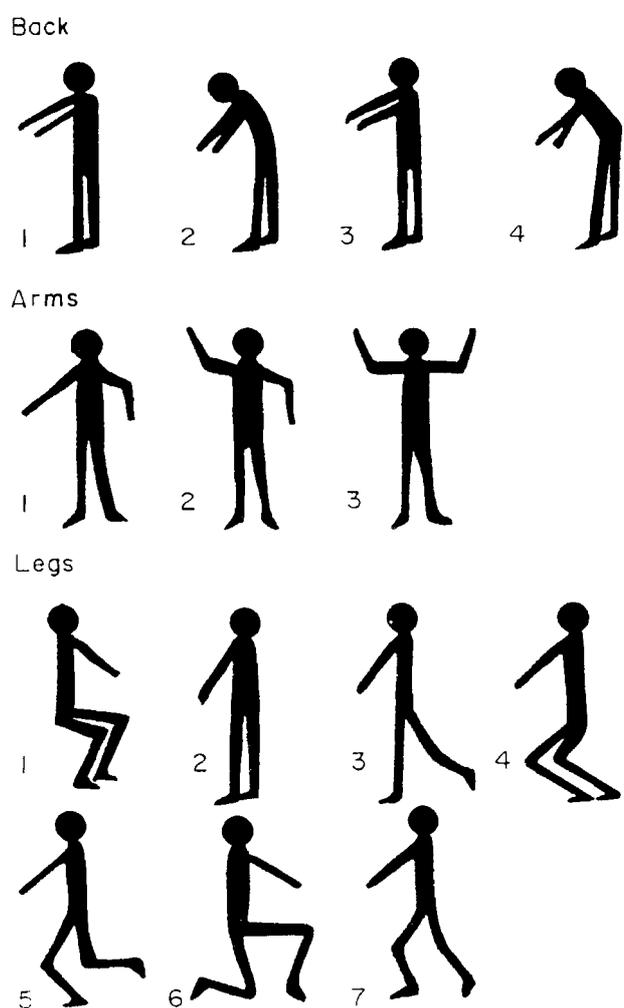
The OWAS method identifies the most common postures


Figure 1. OWAS codes for different body parts (Karhu et al. 1977)
Back code: 1, straight; 2 , bent; 3, twisted; 4, bent and twisted
Arms code: 1, both below shoulder level; 2, one above shoulder level; 3, both above shoulder level
Legs code: 1, sitting; 2, both straight; 3, one straight;4, both bent; 5, one bent; 6, kneeling; 7, walking
Load effort code: 1, ≤10 kg; 2, ≤20 kg; 3, >20 kg

for the back, arms, and legs, and estimates the weight of the load handled or the (extent of the) hand force muscle (effort). The OWAS method utilizes a four-digit code to describe various postures of the back, upper limbs, lower limbs, and the force needed (figure 1).

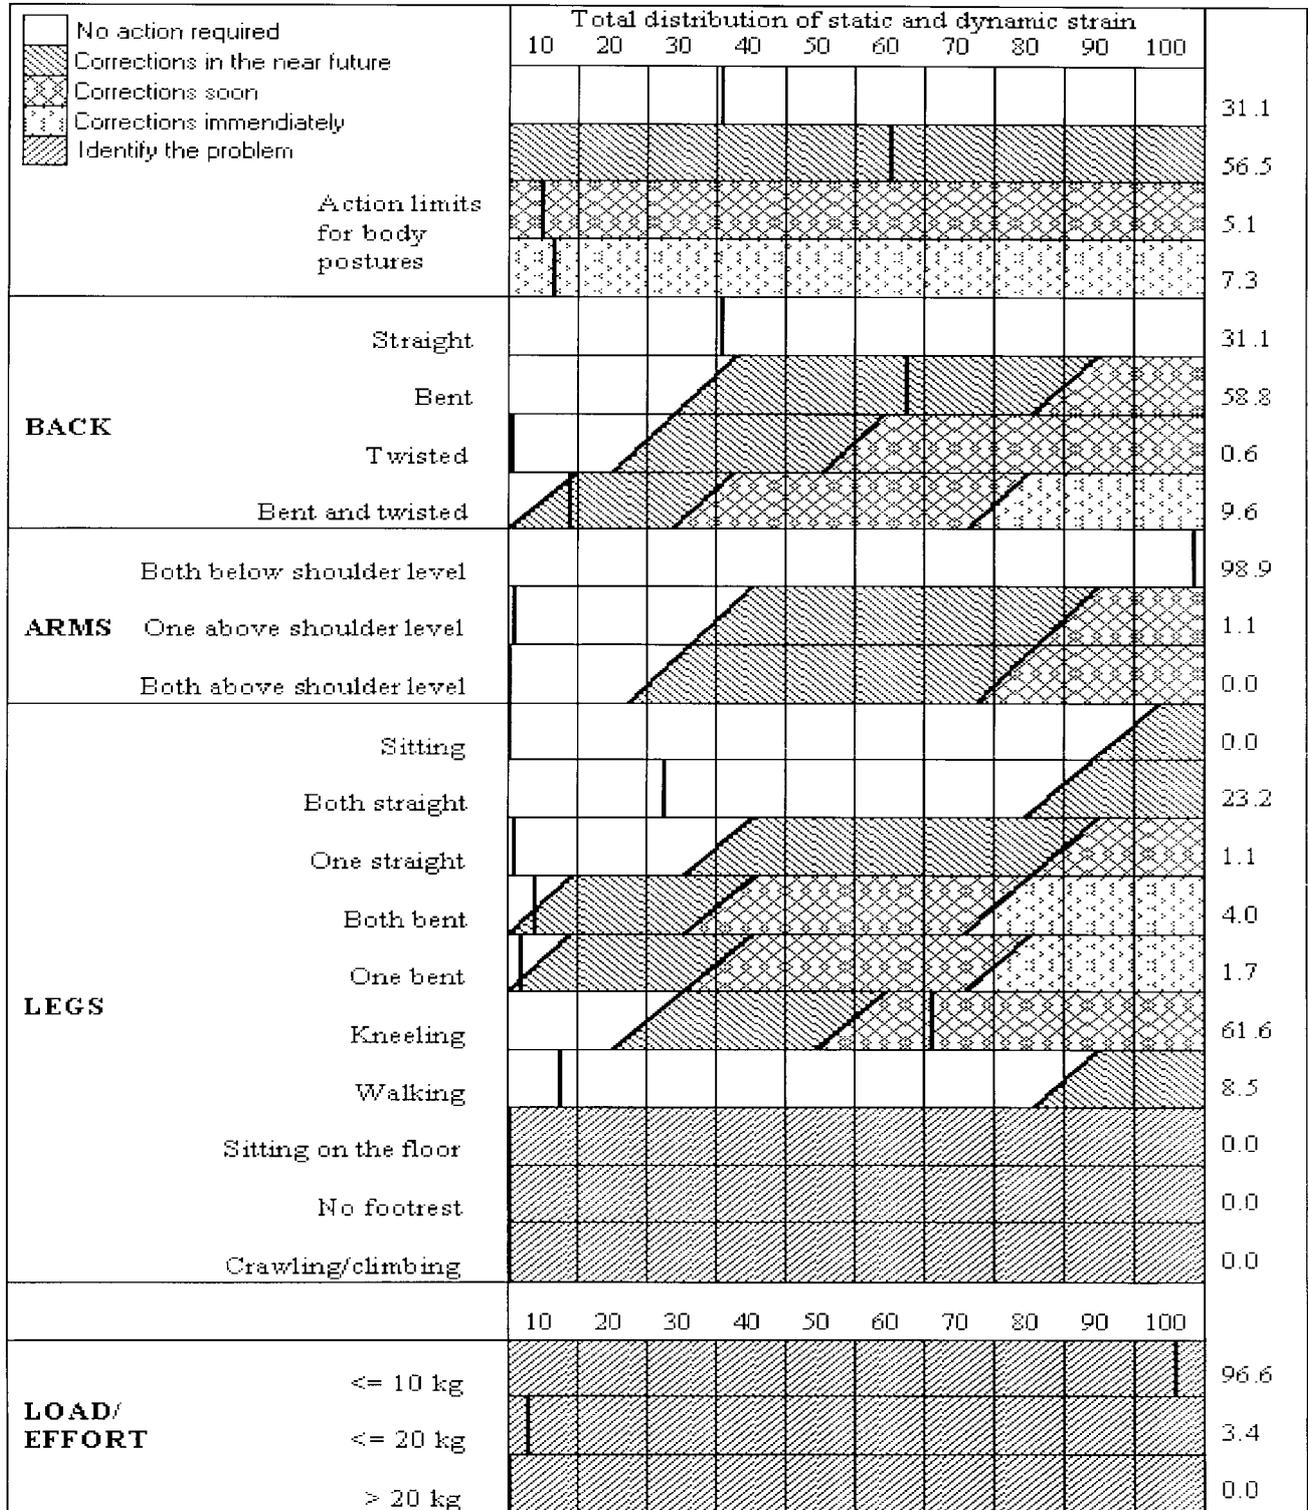
In the analysis of posture observations the amount of different posture codes will be calculated and their relative distribution presented. The presentation of the result shows the percentage distribution of observations according to observation criteria in all four posture determinants: back, arms, legs, load/effort (figure 2).


Figure 2. Distribution of the postures observed in the task analysed, with recommendations for corrective actions (Mattila *et al.* 1993)

Table 1. The OWAS action categories for evaluation of working postures

OWAS category	Description
Action category I	Work postures are considered usually with no particular harmful effect on musculoskeletal system. No actions are needed to change work postures.
Action category II	Work postures have some harmful effect on the musculoskeletal system. Light stress, no immediate action is necessary, but changes should be considered in future planning.
Action category III	Work postures have a distinctly harmful effect on the musculoskeletal system. The working methods involved should be changed as soon as possible.
Action category IV	Work postures with an extremely harmful effect on the musculoskeletal system. Immediate solutions should be found to change these postures.

The observed posture combinations are classified according to the OWAS method into four ordinal scale action categories. This classification of postures (see table 1) is based on experts´ estimates of the health hazards of each work posture or posture combination on the musculoskeletal system.

4. COMPUTER SYSTEM

Originally the coding and analysing procedures of OWAS were carried out using handwritten forms, which required a lot of paperwork. ADP applications have therefore been developed for OWAS, and it has been shown that these offer new possibilities for data analysis. Knowledge of the activity carried out during different postures has been mentioned as being useful for prevention, and this has been added to the traditional OWAS record forms (Kivi and Mattila 1991).

The computer system which has been developed consists of three elements: (1) posture coding in the field, (2) data transfer to the PC, and (3) data analysis and presentation through the PC.

The OWAS program developed for data analysis and presentation consists of the following functions:

i   printing the summary form for all observations according to the classification of measures needed

ii   distribution of postures into evaluation classes according to postures and according to body parts

iii printing the form for the job or the task, including analysis of the acceptability of postures

iv   the most critical postures of subtasks

v   analysis of jobs and tasks according to the percentage of unacceptable work postures.

Based on the computer-aided analysis, it is possible to identify the tasks causing the highest risk estimations. It is also possible to discover which really are the riskiest posture codes and the sub-tasks at which they occur.

5. THE PARTICIPATIVE PROCEDURE

The participative procedure has proved to be fruitful in introducing the improvements based on OWAS analysis. The results of the OWAS analysis have been discussed by a cooperative team, an approach which has proved to be fruitful in improving

prevention. In one experiment in the construction industry, the occupational safety manager (who also served as the head of the production unit), the workers´ safety representative, the physician, the nurse, and the researchers took part in a meeting of the cooperation team. The team discussed the possibilities for preventive measures, which were then presented in the form of written suggestions to the employer.

6. RECOMMENDATIONS

i   The OWAS method has proved to be successful in safety-oriented risk assessment based on workplace settings where working posture is one of the main problems.

ii   The OWAS method has proved to be suitable in situations where the previous hazard screening has shown that work postures are a major risk factor for the health of personnel.

iii The computer-aided application of the OWAS method has enlarged the possibilities for the analysis of OWAS results, and it has made it possible to organize participative meetings of work groups very soon after the analysis is completed.

iv   Good documentation of the OWAS analysis, supplemented with videotapes and slides, has offered a powerful and reliable basis for teamwork in developing corrective measures.

v   The OWAS documentation simplifies the transfer of knowledge obtained by ergonomics analysis to the designers of production methods and to machinery and product designers (Vilkki *et al.* 1993).

vi   The OWAS documentation provides practical training material for new employees and for retraining experienced workers. This training material is considered especially effective as it is based on a company's own production technique.

vii The OWAS documentation, accompanied where possible by videotapes, supports the participative approach in occupational health and safety for the development and introduction of preventive measures and improvements.

viii Worker involvement is crucial in order that everyone´s work interests are recognized and the aims and principles of the analysis are understood.

ix   Team work and group problem-solving have proved to be requirements for successful intervention. The group should include representatives of management, employees, safety experts and health professionals.

x   Feedback to employees concerning the results and follow-up steps is necessary to motivate a continuous process in developing the work environment.

xi   The implementation of the corrective measures must be performed quickly by the line management in order to manifest the management's interest in improving the work environment, whether in changes in working methods, planning, or delivery.

1. INTRODUCTION

The object of this article is to discuss the specificities of the preventionist's job based on an ergonomics point of view of their practice. The prevention function has developed within enterprises and control organizations, both private or public, to take into account factors such as the increase of industrial activities, new risks for workers, the nearby population, and the environment. This has led to an increase in the number of the participants involved in these matters (doctors, ergonomists, toxicologists, health and safety officers, etc.). In this article we will focus on health and safety preventionists operating within enterprises in France and Québec and highlight some of the difficulties encountered in their daily lives. Although managers, designers, and workers have a tendency to restrict the work of preventionists to health and safety matters, we will indicate the additional functions they could fulfill within organizations.

2. PREVENTION: ITS MULTIFOLD ACTORS AND OBJECTS

The prevention function that has developed in enterprises directly involves many participants, such as health and safety officers or technicians, occupational physicians, nurses, ergonomists, health and safety representatives (Comité d'Hygiène et Sécurité Condition de Travail in France, Comité de Santé Sécurité in Québec), and union and management representatives.

In their daily work, these men and women have a vital role to play within an enterprise so that it can develop efficiently while, at the same time, guaranteeing a reliability of operation and working conditions that is compatible with the health of the workers and nearby populations, together with a healthy environment.

Some recent studies (Brun *et al.* 1998) have revealed a great variety in the tasks and objectives dealt with by preventionists, which represent the specificities of their jobs and which can have

more, or less, importance according to the enterprises or countries involved:

- Respect of health and safety and/or environmental laws and regulations that are constantly evolving
- The management of budgets
- The follow-up of design projects, sites, the checking of facilities and devices, etc.
- Ensuring that equipment meets requirements
- The setting up of prevention policies and programs as defined by the enterprise concerned
- The drafting of safety instructions and toxicology data sheets
- The organization of training sessions for operators, foremen, designers
- Ensuring obedience to safety instructions and regulations by shop-floor workers
- Pre-planning of crises management, fire-fighting intervention, evacuation of personnel, etc.
- The completion of reports on accident investigations or on occupational diseases
- The follow-up and treatment of accident statistics
- Involvement in meetings (health and safety groups, project meetings, etc.)
- Meeting people from other control organizations and agencies; any follow-up arising from these meetings such as notices of improvements and/or changes required

These activities and contacts with the various personnel concerned with prevention are time-consuming, especially in the establishment of relationships and/or completion of documents, and this can sometimes hinder prevention actions in the field. The numerous subjects that must be dealt with within the constraints and limits of time and resources available can present a risk of fragmentation and dispersion for the preventionist. The necessary response to hazards in an emergency can prevent in-depth analyses of some situations.

3. MODELS EXISTING IN ORGANIZATIONS

To carry out their various tasks, preventionists have to adapt to work or risk models, which can be more or less developed, explicit or implicit. They guide the managers to decisions about investments, organizational change, choices of technologies, and health and safety policies.

3.1. The Paradigm of Technical Rationality

Many of the decisions taken by the participants within an enterprise, especially those of industrial designers, are strongly influenced by the paradigm of technical rationality. In this current of thought, there is a gap between human and technical factors. According to Pahl and Beitz (1984): "The engineer's main task is to apply his scientific knowledge to the solution of technical problems and then to optimize within the given material, technological and economical constraints."

Often anchored in industrial business, this paradigm gives the managers and designers the illusion that to carry out a project successfully one needs only to work from hard sciences. This approach, therefore, tends to define the objectives of a project by favoring technical aspects rather than the future work organization or the training of the operators. The latter will only be defined at a later stage without taking into account the human interaction likely to occur in work situations. Thus, many designers ignore

the fact that, when developing technological activities, they are also, without realizing it, designing the frame for organizations and hazards that will appear in the new work process. The general principles of prevention and precaution are often overlooked in the industrial design process.

3.2. The Person at Work and Hazards Models

In many industrial or service businesses, the human activity model remains focused, consciously or unconsciously, on a physical or physiological dimension, in which the person is perceived as a system of energy transformation. Often, it is also considered that people are exposed only to concrete and visible hazards which endanger the body (machine operation, falls, posture, noise, etc.); risks that could be called "virtual" (too much information to handle, work rhythm, etc.) are seldom taken into account by preventionists.

This mechanical vision accompanies a stereotype opposing manual and intellectual activities; perhaps it is a legacy of work representation from nineteenth- or early twentieth-century industries and factories, or perhaps it remains because it is the more visible, if not the most spectacular, aspect of work. Such representations of people at work and the hazards involved result in only the physical injuries, whether due to occupational diseases or accidents, being accounted as damage to health.

The cognitive dimensions relevant to any activity are thus greatly underestimated, despite awareness that the excessive demands of having too much information to explore or consider, together with the pressures resulting from having too little time in which to see through these activities, could be the cause not only of various efficiency and reliability malfunctions of the system, but also of long-term effects on physical and mental health.

3.3. From the Statute of Prescriptions to the Role of Experts

The Taylorian tradition of work organization separates design from execution. Even if more discretionary forms of work develop, giving place to the initiative of operators, due to certification procedures, the statute of prescriptions and work regulations are strengthened in other cases because of economical and legal requirements.

In order to design the procedures, the preventionist must foresee a certain number of risky situations and combine different levels of safety standards drawn from general regulations, and apply them to particular risks or to the envisaged task. The various states in which a system can exist are most frequently predefined within the framework of nominal situations, the hypothesis being that the operator has only to carry out and strictly obey the recommendations in order to meet safety, reliability, and efficiency conditions.

However, although the prescriptions and recommendations are indispensable tools for work regulation, they are not enough (Trinquet 1996). Indeed, the difficulties are manifold and can be found in the implicit aspect of recommendations which do not set out the full job specification (de Terssac 1992) since, because of variable situations, it is impossible to foresee every facet of coordination necessary between safety and production activities.

3.4. Approaches Focused on the Person

Whenever a breach of regulations prejudicial to the performance of the system or to health is discovered, the legal logic for compensation or damages resulting from work accidents, as well as the general line of thinking and social representations, is often regarded as the responsibility of the individual expert or skilled person because he or she was careless or not sufficiently alert. Prevention or training measures are then centered on the acquisition of individual safety behaviors, and little account is taken of the organization of the work, management decisions, the interaction of operators within a collective vertical job in a team, as opposed to the horizontal work of their hierarchy, the exchange of information and coordination activities (Carballeda *et al.* 1994; Reason 1990).

3.5. Accidents and Their Causes

The individual management of prevention, added to psychological defense and mourning mechanisms have a tendency, in case of accident, to look for a culprit, which interferes with the understanding of the accident mechanism in order to improve prevention modes. This causal attribution mechanism (Kouabénan 1998) is particularly clear when different groups present different "explanations" of the accident. In fact, to blame someone else for an accident, or the non-obedience to a regulation being its cause, is a psychic protective reaction (Brun 1992). This lead to neglecting the complexity of work situations, the intricacy of the conditions or actions that enabled the unwanted events to occur and that changed them into "normal accidents" (Perrow 1984).

The limits of such uni-causal approaches have led researchers in the 1980s to admit the multi-causality of accidents (Leplat and Cuny 1979; Hale and Glandon 1987). In addition, prevention organizations (such as INRS in France) have developed appropriate analysis tools that were widespread throughout enterprises and professional training courses (Chesnais 1993; Hendrix and Benner 1987).

4. THE PRACTICE OF PREVENTIONISTS: THE DIFFERENT MODELS UNDER STRESS AND THEIR CONTRADICTIONS

According to their professional background and their academic training, preventionists will interiorize and feed these models, or at least come across them. In their practice they will have to face the contradictions generated by these models because of the fragmentation of the representation of the activities suggested and the limits mentioned earlier; the preventionist then risks finding it difficult to account for the complexity of situations and assess the impact of the preventive measures decided for the activities of the people. In addition to which the lack of time and resources available leads the preventionist to relate work accidents to simple causes, i.e. the operator, rather than to complex causes revealed by more accurate analyses that often require more time and assistance from some kind of expertise that he does not necessarily have.

The preventionist then risks being caught between the mechanistic model of behavior and the necessity of integrating a strong relational dimension inherent in his functions, which supposes his daily positioning with regard to all the personnel.

One of the difficulties he then encounters is how much advice he will give rather than coercion activities, how much will he play the role of an expert rather than a mere animator.

The establishment of trusted relationships, the guarantee of his credibility rest on a gamble, which recurs with each interaction situation and which can be challenged whenever there is a conflict. New regulations insist on this advisory part and it seems that awareness of the ergonomics approach is appreciated to face new missions (Chesnais *et al.* 1995).

An important part of a preventionist's activity is based on the classification of the different actions to be carried out, according to their degree of urgency. They require the elaboration of a compromise between heterogeneous demands and logistics: safety and reliability, the will of partners, social relations within joint institutions (management, workers representatives for example with the CHSCT or CSS), but also efficiency and return after investment, etc.

5. NEW APPROACHES TO PREVENTION

The questions raised direct us towards new approaches to prevention practices. The viewpoint presented here belongs to the tradition of activity ergonomics, originally developed within the French-speaking trend of ergonomics (de Keyser *et al.* 1988; Montmollin 1992; Wisner 1994). It also rejoins the debate opened within the English-speaking ergonomics on safety and security trend (De Greene 1991; Embrey 1991; Dwyert 1996).

5.1. The Human Models pertinent for Prevention

The limits of the models that have been discussed earlier make it necessary to complete (Garrigou *et al.* 1994) by taking into account a *cognitive dimension* (looking for information, treating them, decision making, memorization, etc.), a *psychic dimension* (accounting for the identity and personality construction process through the work activity) and a *social dimension* (enabling us to account for the belonging to social groups that will convey values, as well as the coordination of actions in collective work). It is only then that the preventionist will be able to describe and explain the difficulties encountered by operators and thus contribute to changing situations.

5.2. Industrial Variabilities, Incorporated Know-how and Regulations

A great many studies in ergonomics (Faverge 1972; Laville and Teiger 1972; Wisner *et al.* 1986) have emphasized the lack of stability of work process, particularly due to industrial variabilities (sensitiveness of raw materials and processes, variations in the environment: temperature, humidity, vibrations, acidity, etc.) and of the plants working under degraded mode (which is more frequent than thought). Under such conditions the operators are brought to develop know-how and individual and collective strategies to collect information, indications, of the current operations, in order to anticipate incidents or accidents (Sanderson 1989). Such strategies contribute to various sensorial modalities that will gave rise to embodied knowledge (Garrigou *et al.*, 1998a; Aubert, to be published); we must point out that because of their characteristics, they are very often difficult to put into words. This knowledge plays a crucial part in the

efficiency and reliability of the functioning of organizations and industrial systems.

In such a context, when industrial variability cannot be reduced, work regulations or recommendations are unable to foresee everything because of the great diversity of situations, and if they are so numerous they can no longer be managed. Then it is necessary to consider regulations as supports for action and assistance in decision-making; they must be articulated around the knowledge developed by the operators: work regulations are necessary but not sufficient.

5.3. Re-thinking of the Definitions of Health

If originally the role of preventionists consisted in carrying out different actions (training, animation, change of equipment, etc.) so that certain situations could not harm people's health, the very evolution of work (in Western countries: technologies of information, more discretionary organizations, the aging of populations) makes it necessary to think about a more pertinent definition of health. Dejours (1995) emphasized that the traditional definition of health is centered on the static state of good or bad health. He defends the idea that health is a dynamic construction by or from the people; current research (Laville 1998; Antunes Lima 1995; Avila-Assunçao 1998) shows that the process of safeguarding health may require a collective construction. To achieve the objectives of the working system, tiredness and pain can be avoided or lessened to those most affected by a redistribution of tasks to younger workers, while older workers carry out non-formal functions as advisers or trainers to the younger ones. Organizational conditions which allow for individual or collective maneuvering margins (care for others, mutual assistance, etc.) thus enables health protection to become *a vital aspect of the preventionist's action* within the framework of organizational changes.

5.4. Reviewing the Operators' Risks Management

The works of Cru (1995) and de la Garza (1995) point out that operators who have to face everyday-risk situations do not wait passively for possible unwanted events to occur. The management of these risks is often integrated into their activity. This requires an individual mobilization in the way of attention, a certain form of discipline or permanent personal organization, when dressing or setting up PPES (personal protection equipment), achievement of production or maintenance operations, etc. Beyond a physical activity that can be important, this mobilization and attention requires the intake of a lot of information.

This individual mobilization is articulated around more or less developed forms of collective mobilization (Garrigou *et al.* 1998b). Thus, important research on sites where asbestos has been removed has revealed that when workers put on personal protective equipment or when they worked in risk areas, this collective mobilization is noticeable in the way that care is shown towards one another: each one making sure that his neighbor feels well, that his protection suit is not damaged, and that everything is all right for the "young workers" just starting, etc. Collective mobilization, as far as care is concerned, then, is the main guarantee that work on the site will be safe, and it reinforces individual mobilization. It is essential, therefore, that preventionists to understand the conditions better (technical,

organizational, or individual) that improve such processes and, on the other hand, those who hinder or prevent them.

From this perspective, it may be necessary for operators to show that they are in control of risks by exhibiting professional skills, and questioning hierarchy or safety arrangements (Dodier 1995). The establishment of these preventive competencies, therefore, both helps to achieve production targets and give the operator the opportunity to display his ability at controlling hazards. In this case, the relationship with danger, safety regulations, and the activity of the preventionists is reversed; the operator is no longer governed by hazard and safety recommendations, but he himself determines his own safety and destiny. This is an aspect with which preventionists are not very familiar but one which they will have to learn to work with.

5.5. To Think instead of Others or with Them?

Expertise in health and safety is indeed necessary, particularly when the preventionist intervenes early in design projects and when projects are highly confidential. However, such an approach remains unsatisfactory because the preventionist is doing the thinking instead of the workers. Decisions could be made without the operators being able to assess their advantages or drawbacks and any new constraints which might be generated in their activities. Participative approaches (Wilson 1991; Noro and Imada 1991) that have been praised in the 1980s have attempted to mobilize the workers and their competencies; the results of such experiments were often mitigated. In order that participative approaches of future users in design projects, that are presently being re-used in new design organizations (for example in concurrent engineering), have a chance of being efficient, at least three conditions seem to be necessary: (1) the recognition of what the users' representatives or the users themselves can input according to their professional experience; (2) a commitment of the deciders about objectives and means granted to such practices; (3) the existence of methodological approaches that sustain such a process. If this is not the case, these practices risk, for different reasons, facing resistance from users and designers. More particularly, according to the *"good professional's ideology"*, he should have no problems since he knows how to solve them; in this context, which is fairly frequently found not only with designers but also with others professions, anyone who admits to having problems takes the risk of being judged by his peers or seniors as someone not competent; such mechanisms can hinder feedback and cause suffering for some people.

One should expect from the participative approach a recognition of the operators' cautiousness, their professional language, codes of practice that rule their collective work, equipment better adapted to specific situations and the foreseeing of any malfunctioning in respect of organization, techniques, activities, and the overcoming of malfunctions (Cru 1995). As far as the preventionist's activity is concerned, this requires the setting up of a social construction process and rules of participation among the various actors involved in an enterprise.

6. CONCLUSION

The discussion proposed here concerning the activity of preventionists has consisted in characterizing its practice by confronting it to other modes of knowledge at work that stem from sociology, psychodynamics and, especially, ergonomics.

More questions have been raised than answers given. We think it wise, therefore, to improve understanding of what the activities of preventionists are in order to help the development of new prevention practices that would match their new applications (Brun *et al.* 1998).

A reflexive approach on their practice (Schön 1983) would enable better understanding of the complexity of the constraints and stakes where they have to find compromises. Different aspects could be tackled, such as:

- the establishment between safety, reliability, production, and criteria of rentability at shorter or long term;
- the levels of reduction of the complexity of working situations necessary for prevention;
- the possibility of conciliating the role of an expert with the recognition of the operator's competency, so that they have the opportunity to share their experience;
- efficient strategies and actions to change, at least in part, the reference models of the various actors in the enterprise (described in section 3);
- strategies enabling the preventionist to increase his credibility so that he is accepted very early on in design projects, from the technical or organizational viewpoint;
- the fact that preventionists themselves have to protect themselves from the various types of risks related to their own responsibility can breed fear and anxiety, and lead them to develop various psychical defenses to deal with these problems.

Such reflection on the activity of preventionists is vital, both for the teaching and training of preventionist's courses, the developing of methodological approaches adapted to needs of preventionists and, later on, the improvement of safety conditions, reliability, and efficient working of installations.

Psychophysiological Methods

W. Boucsein

Physiological Psychology, University of Wuppertal, 42119 Wuppertal, Germany

1. INTRODUCTION

The aim of this chapter is to introduce ergonomists and human factors researchers to the unique benefits of the psychophysiological approach. Although collecting physiological data is not unfamiliar to this field, psychophysiology has more to offer than physiological recording. One of its major goals is the integration of physiological, subjective and performance/behavioral data. Furthermore, psychophysiological theories emphasize the importance of the nervous system and explain how the neural modulation of physiological systems promotes or limits the range of work related behavior. Therefore, researchers and those who apply ergonomics in the field to create better work environments should consider complementing their methodology with relevant physiological measures. In addition, the choice of psychophysiological measures should be based on neurophysiological models providing a rationale for the use of particular measures. The present article furnishes a brief introduction to theory, methodology and application of psychophysiology in the field of ergonomy and human factors. More detailed information is provided in Backs and Boucsein (1999) on "engineering psychophysiology."

1.1. Aims and Methods of Psychophysiology

Psychophysiology studies the relation between psychological processes and physiological activity by *non-invasive recording* (e.g. Andreassi 1995). Psychophysiological techniques provide unobtrusive measures of central nervous system activity taken from the electroencephalogram (EEG), of autonomic nervous system activity such as heart rate (HR), blood pressure and electrodermal activity (EDA), of somatomotor activity such as electromyogram (EMG) or eye movements, of body temperature and of endocrine measures such as catecholamine or cortisol excretion (Table 1). Psychophysiology refers also to a certain approach to the mind–body problem, assuming that physiological response patterns reflect cognitive, emotional, behavioral and social events. This implies modeling of brain–behavior relationships that may help to generate hypotheses on the use of appropriate physiological measures for the psychological phenomenon under investigation (Figure 1). Theoretical concepts that are commonly investigated by means of psychophysiology comprehend arousal and sleep, orienting and habituation, information processing and learning, emotion and motivation, or stress and stress-related diseases. The progress in psychophysiological techniques has been fostered by international societies such as the Society for Psychophysiological Research (SPR) or the Federation of European Psychophysiology Societies.

Physiological recording techniques have been employed by work physiologists to study bodily effects of work place features and environmental factors such as noise or heat. Beyond these, psychophysiological measures have proved to be valuable tools

Table 1. Psychophysiological parameters of different categories of strain. The variables are grouped according to their respective physiological systems (central nervous, cardiorespiratory, electrodermal, somatomotor, thermoregulatory, endocrine). '≠' means that the values of the parameter in question increase with increasing strain, and 'Ø' that they decrease. More evidence is available for double arrows than for single ones. Adapted from Boucsein, and Backs (1999). Used by permission of the publisher.

Physiological measure	Category of strain		
	Physical	Mental	Emotional
EEG alpha activity (8-12 Hz)		↓↓	
EEG theta activity (4-7 Hz)		↑↑	
P3 amplitude		↑↑	
P3 latency		↑	
CNV amplitude		↑	
Heart rate	↑↑	↑	↑
Heart rate variability		↓↓	
Respiration rate	↑	↑	
Finger pulse volume amplitude		↓	↓
Systolic blood pressure	↑↑	↑	
Diastolic blood pressure	↑	↑	
EDR amplitude		↑	↑
EDR recovery time		↑	
NS.EDR frequency		↑	↑↑
Eye blink rate		↑↑	↑
Saccadic eye movement frequency		↑	
Pupil diameter		↑	↑
Electromyographic activity	↑	↑	↑
Muscle tremor	↑↑		
Core temperature	↑↑		
Finger temperature			↑
Epinephrine		↑↑	↑
Norepinephrine	↑↑		↑
Cortisol		↑	↑↑

to gain information about the worker's psyche that complements performance and subjective measures. Recently, the availability of lightweight portable recorders for multiple physiological measures has brought about an important progress for the use of psychophysiology in the field of ergonomics (Fahrenberg and Wientjes 1999). Field settings that make use of *ambulatory monitoring* comprise both work place and leisure time activities. Because of the lack of control in real life settings, field studies should be combined with experiments in the laboratory or in simulated environments. Here, psychological factors that may determine physiological responses can be manipulated in order to establish unambiguous psychophysiological relationships.

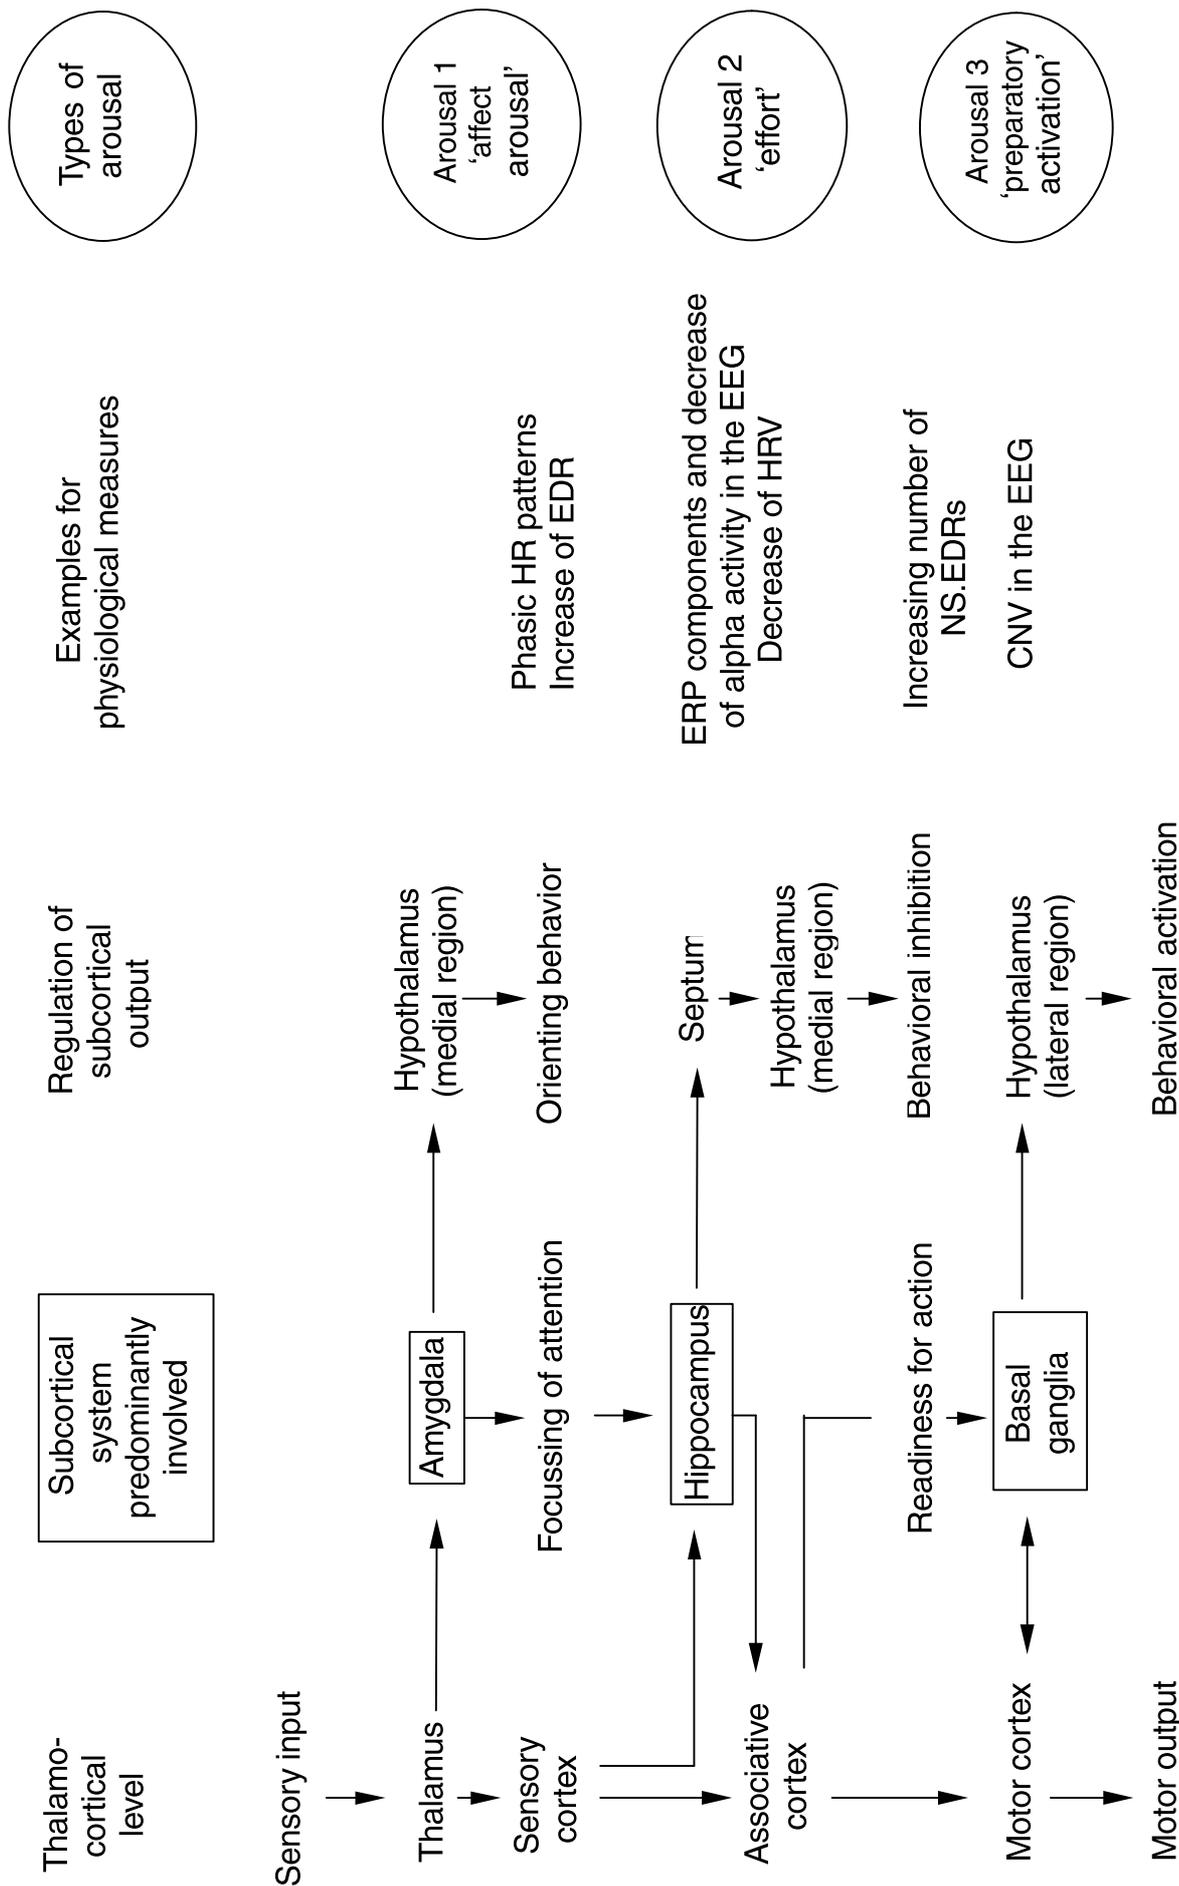
In addition to the *physiological* measures, *subjective* and *behavioral measures* constitute a genuine part of the psychophysiological approach. Subjective arousal, well-being, ratings of bodily symptoms and other stress related variables can be obtained discontinuously during working pauses by means of rating scales. As behavioral indicators, various performance measures such as speed, accuracy and amount of work can be


Figure 1. A three-arousal model for the use of psychophysiology in ergonomics. CNV, contingent negative variation; EEG, electroencephalogram; ERP, event related potential; HR, heart rate; HRV, heart rate variability; NS.EDR, non-stimulus specific electrodermal responses. continuously obtained from the task itself. In addition, behavior may be videotaped, including facial expressions and gross body movements. However, the analysis of such data is time consuming and is therefore not often performed by psychopsychologists.

1.2. A Brief History of Psychophysiology in Ergonomics

Early in the 1910s the German psychologist Hugo Münsterberg suggested the use of scientific psychology to improve every day life. Collectively, he referred to the application of psychology to address problems in education medicine, law, business and industry as *psychotechnics*. Its major application started to become military personnel selection and training during World War I.

Consistent with this tradition, psychologists in the USA and UK made valuable contributions to the design of weapons systems and personnel protection equipment during World War 2. Psychologists had been involved in personnel selection and training for many years, but their involvement in ergonomics was something new. Descriptors of these activities that appeared in the USA were terms such as *engineering psychology*, *human factors* engineering or just human engineering, along with the term *ergonomics* in the UK. All these terms are still in use and often used interchangeably. Perhaps the beginning of the use of psychophysiology in ergonomics was in 1939 with a study of psychophysiological "tension" in flight using what was probably the first airborne polygraph. For the next two decades, psychophysiological research in the field was limited by both the technology available and the *Zeitgeist* of this period and tended to emphasize muscular measures during skilled psychomotor tasks, including eye movements. An example is the classical study of Fitts and colleagues of pilot's eye movements during instrument landings in 1950 that helped to determine the arrangement of the basic flight instruments to what is called a standard "T" arrangement that is still generally used today (for more details, see Boucsein and Backs 1999).

In the 1970s the use of psychophysiology in human factors flourished in the USA, in part because of technological advancements in data acquisition and analysis equipment, and in part because of the Department of Defense funds for "biocybernetic" research. In particular, research on EEG measures and the recently discovered event-related brain potentials was supported because of the common belief that physiological correlates of psychological events should be measured as close to the brain as possible. Unfortunately, the applicability of EEG derived measures in the field did not meet the probably unrealistically high expectations. This may have lead to some disillusion with psychophysiological methods in general. As a consequence, psychophysiological research in human factors in the USA waned during the 1980s.

Whereas the use of psychophysiology in ergonomics in the USA continued its traditional focus on defense, especially aviation, applications during the 1970s and 1980s, research in Europe had a different focus. European research during this period was concerned with the psychophysiological effects of increasing workplace automation and adopted a *stress-strain* theoretical approach, unlike the information processing approach of most of the human engineering psychophysiology in the USA. More recently, the ongoing computerization of work places has shifted the attention of European researchers from physical stress to the

issues of mental workload and emotional strain (Gaillard and Kramer 1999). Following this line, psychophysiological research continues to gain influence on the organization of work settings, as well as on the identification and prevention of stress related disorders.

In 1993, an international scientific organization "Psychophysiology in Ergonomics" (PIE) has been formed by the present author and others to promote and advance the understanding of psychophysiological methods and their application to ergonomic environments.

2. METHODOLOGICAL ISSUES

2.1. Theoretical Concepts

Despite the great technical advances in recording and data evaluation that have been made in psychophysiology during the past decades, only limited progress has been made in the development of psychophysiological theory. Very seldom psychophysiologists have made attempts to integrate their measures into theory. Instead, rather simple theoretical frameworks such as the one-dimensional *arousal* concept from the 1950s are still used in the field (Boucsein and Backs 1999). Arousal has, however, proved to be a complex and *multi-dimensional* phenomenon that can be best taken care of by modeling different neurophysiological systems for different kinds of arousal as proposed by Pribram and McGuinness (1975).

Figure 1 depicts a simplified model of the three major kinds of arousal and their neurophysiological origins (for more details, see Boucsein 1992, Figure 48). Arrows indicate the principal information flow within the system.

Arousal System 1 is centered around the amygdala and is labeled the "affect arousal system." If is responsible for focusing attention and for generating hypothalamic reaction patterns. For example, if a novel or unexpected event occurs in the environment, an orienting response is generated. Such a response can be characterized by a phasic HR deceleration followed by an acceleration and/or by an electrodermal response (EDR), sometimes labeled "skin conductance response," due to a phasic increase in sweat gland activity. Attention is shifted towards the new event that may be supported by somatomotor responses such as head- or eye-movements.

Arousal System 2 is centered around the hippocampus and is labeled the "effort system." It has the property to connect or disconnect input and output. The physiological patterns generated by this system can be regarded as concomitants of central information processing. For example, the positivity in the event related potential (ERP) labeled "P3" that peaks in the EEG ~300 ms after presentation of a stimulus increases with the increasing amount of processing capacity assigned to that particular stimulus. Furthermore, diminishing EEG activity in the alpha-band (8–12 Hz) and decreasing heart rate variability (HRV) are regarded as indicators of stimulation or situation that requires greater information processing.

Arousal System 3 is centered around the basal ganglia and is labeled the "preparatory activation system." Its activation results in an increased readiness of brain areas involved in somatomotor actions such as grasping or other body movements. Its physiological concomitants are the contingent negative variation (CNV), an increase in cortical negativity that can be observed before the execution of a motor response, and a tonic increase in HR.

The rather straightforward chain of input–output relationship indicated by arrows in the left part of Figure 1 can be modified by situational contexts such as additional emotional load caused by imminent danger or time pressure. In such a case, the "effort system" disconnects Arousal Systems 1 and 3 to prevent an immediate action and facilitate a deliberate analysis of the situation. This is performed by certain cortical–subcortical brain areas including the so-called Papez Circuit. In such a case, an increase of spontaneous, non-stimulus specific electrodermal responses (NS.EDR) will indicate the emotional load that comes with the situation (Boucsein 1992).

Although far from covering the whole range of psychophysiological relationships in the field of ergonomics and human factors, the model depicted in Figure 1 provides a framework for generating refined hypotheses for the use of psychophysiological measures in the field. Boucsein and Backs (1999) have exemplified this with respect to workload. From a psychological point of view, the issue of workload may be embedded in the broader concept of stress-strain processes. Although not very familiar to most North Americans, the use of the term "strain" for the impact of stress is gradually spreading over from Europe. A common distinction has been made between *physical* and mental workload or strain. Mental load may be further split into *mental* and *emotional strain*. Mental strain in this narrower sense refers to the concept of mental effort, while emotional strain refers to the excess mental effort that comes from anxiety-evoking cognitive aspects of the task such as the imposition of deadlines, worries about one's capacities to perform the job, etc. Table 1 provides hypotheses concerning the sensitivity of physiological measures for the three different kinds of strain as derived from a literature analysis (for more details, see Boucsein and Backs 1999, Tables 2–7).

The rows in Table 1 are grouped according to the various physiological systems. If there is evidence from the literature that a particular physiological measure is associated with a specific kind of strain (i.e. physical, mental or emotional), an upward or downward pointing arrow is inserted in the appropriate column to indicate that the measure increases or decreases with an increase in that kind of strain. Two arrows indicate greater evidence for the relation.

Researchers who want to apply psychophysiology in the field may use the theoretical model depicted in Figure 1 together with the empirical framework provided in Table 1 to determine the *specific validity* of their designated physiological measures. Stimulus- or situation-related emotional strain will mainly affect Arousal System 1 (i.e. "affect arousal"), while mental strain will very likely be a result of an increased activity in Arousal System 2 (i.e. "effort") or in Arousal System 3 (i.e. "preparatory activation"). If emotional load is going to persist, certain measures related to System 2 such as spontaneous EDR will be affected. Thus, if the situation under investigation is thought to exert some emotional load on the subject, care should be taken to include measures that reflect both the "affect arousal" and the "effort" system. If the physiological measures are chosen accordingly, the sensitivity and diagnosticity of the psychophysiological approach to ergonomics can be considerably improved. Furthermore, hypotheses about what kind of physiological changes might be present in the work setting can be formed more accurately.

2.2. Psychophysiological Recording and Evaluation

The majority of psychophysiological responses are measured by means of sensors placed on the body surface. Some oculomotoric measures can be recorded by video monitoring. Endocrine measures are obtained by collecting samples of body fluids such as urine or saliva. Recorded signals may be distorted by noise and other *artifacts* resulting from electromagnetic fields, body movements, etc. in particular under real life conditions. Signal amplification, filtering processes and analog–digital conversion (e.g. sampling rate) may exert additional influences on the recorded signal (Luczak and Göbel 1999). Therefore, any application of psychophysiological methods requires training in both methodology and evaluation of data.

As a rule of thumb, sampling frequencies of > 100 Hz are required for each physiological measure. Hence, a huge amount of data will result from a long-term recording that is typically applied in the field. Pre-processing during recording can, however, considerably reduce the amount of data to be collected (e.g. recording HR instead of the raw electrocardiogram). Averaging over a certain period of time will further reduce the amount of data. However, valuable information can be lost during such a procedure that may be needed for further evaluations. For example, the calculation of HRV requires the length of each interbeat interval. Those would have been lost during an early averaging procedure.

Most physiological measures require *parametrization* before being ready for statistical evaluation. In some cases, standard procedures such as frequency analysis (e.g. fast Fourier transformation) or averaging over a certain time span may be sufficient. However, it is more likely that custom software has to be applied, e.g. for obtaining certain parameters of an EDR from electrodermal recording such as amplitude or recovery time (see Boucsein 1992, Appendix). Integration or low-pass filtering and rectification is required to determine the total muscle tension from the electrical spikes recorded in the surface EMG and an additional high-pass filter may be applied to attenuate motion artifacts (Luczak and Göbel 1999). In any case, data sets should be scrutinized for all kinds of distorted or missing data that requires an interactive evaluation.

Unfortunately, the use of certain psychophysiological measures by a particular researcher or research group is frequently determined by the availability of appropriate equipment and past experience. However, the investigation of complex human organisms in complex environments requires a *multi-level* (i.e. physiological, behavioral and subjective), *multivariate* approach (i.e. recordings from different systems with specific sensitivity such as demonstrated in Table 1).

3. ERGONOMIC APPLICATIONS

The following three sections provide information about selected applications of psychophysiological methods in ergonomics and human factors. A representative selection of studies can be found in two special issues of *Ergonomics* (Gundel and Wilson 1993, Boucsein *et al.* 1998) and in a special issue of *Biological Psychology* (Gaillard *et al.* 1996).

3.1. Psychophysiology and Traditional Work

Both HR and EMG have been successfully used as continuous psychophysiological measures for energy expenditure and physical strain in traditional work. Long lasting cardiovascular and muscular strain without appropriate recovery during rest breaks and/or leisure time after work may result in so-called psychosomatic disorders over the long run. Traditionally, psychophysiological research has primarily focused upon *cardiovascular disorders* such as coronary heart disease (Gaillard and Kramer 1999). Unfortunately, one-dimensional arousal concepts still prevail in this kind of research. As a consequence, successful stress management has almost become identical with the reduction of general arousal and the activity of the sympathetic nervous system. However, some types of arousal may have adverse effects for health while others do not. For example, "effort" and "preparatory activation" are necessary for an adequate job performance. They can be accumulated with low health risk while a large amount of "affect arousal" may constitute a considerable risk. Factors such as decision authority and social support may exert their stress-reducing properties by preventing excess "affect arousal." Psychophysiological indices of orienting and defensive behavior seen in cardiovascular and electrodermal patterns can be used to determine the effectiveness of stress-reducing factors (Figure 1). Defensive responses being temporarily evoked by an increased mental workload are characterized by increases in HR and blood pressure and a decrease in HRV and blood pressure variability (Mulder *et al.* 1999). The decrease of finger pulse volume has proved to be a sensitive measure of defensiveness for laboratory studies and may be applied in that context as well.

The development of *musculoskeletal disorders* is also an important issue in long-term consequences of stress during traditional work. Lack of relaxation of certain muscle groups may constitute a health risk in both repetitive muscular work and in modern computer work (see section 3.2) and can be continuously monitored by means of EMG. Muscle tremor constitutes a specific indicator of physical strain and fatigue. Highly demanding and repetitive work (such as performed by cash register operators) emerges a combination of physical and mental strain. Elevated systolic and diastolic blood pressure, increased trapezius muscle tension as well as epinephrine and norepinephrine levels constitute the typical psychophysiological pattern during and after this kind of work. A high percentage of such workers develops neck–shoulder problems in the long run.

Lundberg and Johansson (1999) summarized the effects of *assembly work* and other types of repetitive work on psychophysiological stress indicators. Traditional assembly work is associated with physical constraint, machine pacing, piece-rate remuneration and often with under utilization of human resources. A comparison of such repetitive work at an assembly line in a car factory with a more flexible type of assembly work in autonomous groups (six to eight people who had a considerable amount of freedom and variety in their job including responsibility for work organization and quality control) yielded about the same mean urine epinephrine and norepinephrine levels in both groups. However, psychophysiological stress responses during work in the assembly line showed an increase that was not seen in the more flexible type of group work. The autonomous group kept a moderate and relatively stable levels of epinephrine and norepinephrine throughout the shift. In addition, their urine

epinephrine levels were significantly lower after the shift as compared with the traditional assembly line workers. The inability to recover from psychophysiological strain after work in the assembly group was even more pronounced for female than for male workers. This may be partly due to the multiple roles of women that do not allow for recovery after work.

The amount of cortisol that can be reliably obtained from saliva probes now is not merely an indicator of short-term emotional strain (Table 1). Moreover, cortisol excretion constitutes a major endocrine indicator of long term stress. This relation has been demonstrated in highly demanding jobs such as air traffic control.

3.2. Psychophysiology and Automated Work

Major changes in various work places occurred during the last three or four decades as a consequence of increased automation. Supervisory monitoring without considerable physical load constitutes most of the work in process industries such as chemical plants, power stations, etc. In particular, the shift from man–machine interaction to a mere man–computer interaction has diminished physical workload but increased mental workload. *Office automation* is probably the most obvious example of pervasive spread of human–computer interaction (HCI). However, the transition process from industrial to information-age office designs has been slow and incomplete in most large institutions, since elements of computer technology were superimposed on relatively unchanged work structures. Work has become more mentally challenging in some kinds of jobs, whereas boredom and dissatisfaction prevail where the human role has been diminished to mere monitoring or data entry tasks.

Psychophysiology has been successfully used to determine the amount of mental workload, to organize an optimal workflow and to establish appropriate schedules for rest breaks during HCI (for a summary, see Boucsein 1999). Elevated epinephrine levels have been found during and after work in administrative workers with a high amount of HCI compared with those performing mainly secretary work. Increases in EEG beta activity (> 13 Hz) and decreases in HRV were observed as consequences of increased task complexity and informational load. Inadequate temporal structures of HCI such as delays in the work flow caused by *system response times* have been a major source of stress since the introduction of time-sharing computer systems in the late 1960s. The adverse effects of involuntary delays in HCI still persist even though computers have become incredibly faster. Hardware speed is often jeopardized by bulky software packages, powerful input and output devices (e.g. graphic tablets), network functions (both intra- and internet) and huge data banks with simultaneous access for many users. Furthermore, the possibility of multi-tasking provided by Windows-based systems raises the additional problem of adequate work flow scheduling with respect to the different durations of tasks being performed in the background.

Psychophysiological investigations have stressed the need for an *optimal scheduling* of the temporal workflow in HCI. Cardiorespiratory measures such as HR, blood pressure and respiration rate show an increase if scheduling becomes too tight, together with an increase in working speed, higher error rates and task related bodily symptoms. On the other hand, if non-optimal scheduling results in temporal delays, an increase in EDA indicates emotional tension (Boucsein 1999). The adverse

influence of both kinds of suboptimal scheduling accumulate if additional cognitive demands such as time pressure are imposed on the operator. The increase of cardiorespiratory activity in the case of a too-tight scheduling indicates an overstressed "preparatory activation" system. On the other hand, the higher amount of NS.EDR found during involuntary temporal delays points to an increased effort that can not result in behavioral activation. Because behavior is inhibited, emotional strain is experienced (Figure 1).

Optimal scheduling is also important for *rest breaks* during work. As in any kind of repetitive work, time is required for the recovery from psychophysiological stress such as muscle tension and elevated HR that may accumulate during data entry tasks. Appropriate break schedules provide the opportunity for such a recovery and range from microbreaks (i.e. several seconds after several minutes of work) to 10 min every hour. However, such a predetermined work/rest schedule may not be suitable for more complex HCI tasks. In a field study performed in a rather complex computerized environment, Boucsein and Thum (1997) found an advantage for more frequently interspersed short breaks prior to the early afternoon as indicated by an increase in HRV and diminishing EDA during the break. Conversely, long rest breaks after a longer working period yielded a better recovery in the afternoon as seen in the same psychophysiological measures. Neck-EMG showed a considerable increase during breakdowns of the computer system as opposed to a decrease during regular rest breaks.

Psychophysiological measures can also be used for triggering mode changes in *adaptive automation* systems. In contrast to operator performance, that may be used as criterion as well, they do not require overt behavior and can be obtained continuously, thus allowing for a rapid response to changes in the operator's state. Both simple threshold-level indicators based on EEG, EOG and head movements, and more complex systems based on multivariate analysis of several physiological measures have been proposed for the use in process control and in long haul transport (see Section 3.3). Power band ratios taken from the EEG such as the operations beta/(alpha + theta) index have been successfully used for determining changes in task engagement in flight management simulation. Autonomic nervous system parameters such as HRV may indicate the operator's engagement in voluntary or compensatory effort. In addition, the absence of NS.EDR for several minutes has been used as a trigger for an auditory alarm in order to regain alertness (for an overview, see Byrne and Parasuraman 1996). However, this technique has not yet moved out of the laboratory. Both complex arousal theories and human information processing resource theories are used as theoretical framework within this area.

3.3. Psychophysiology and Extended Work

Working at odd hours, especially during night and after a prolonged period of wakefulness, is very common in our modern society. *Night shiftwork* or the operation of extended transmeridian flights are typical examples for situations in which a co-variation of performance decrement and increased sleepiness is observed. Sleepiness occurs as a consequence of several factors: the displacement of work to the circadian phase, an extended duration of wakefulness and the loss of sleep (Akerstedt 1995). In addition, work-induced fatigue, vigilance decrement and monotony develop with extended time-on-task.

The amount of sleepiness is commonly determined on different levels: by subjective estimates such as visual analogue scales and by using objective measures for the sleep tendency. The latter may be measured during repeated controlled opportunities to fall asleep such as the Multiple Sleep Latency Test. As physiological measures, both oculomotoric (Sirevaag and Stern 1999) and EEG recordings (Gundel *et al*. 1999) can be used to determine the amount of sleepiness or fatigue during work at odd hours such as night shiftwork or *long-haul transport operations*. During sleepiness, eye blink frequency and duration increase as well as the amount of slow eye movements. Alpha-band activity dominates in the EEG while phases of micro-sleep are characterized by the desynchronization or disappearance of alpha activity and the occurrence of theta waves (4–8 Hz). Eye blink rate as well as eye closure duration increase with time-on-task. Both frequency and velocity of saccadic eye movements decline during extended periods of work.

A multivariate study with seven oculomotoric measures performed by Morris and Miller (1996) revealed that 36% of the performance decrement in partially sleep deprived pilots during a 4.5-h flight simulator mission could be predicted by a combination of blink amplitude, blink closure duration and long closure duration blink rate. This is of particular interest for long-term monitoring because oculomotoric measures can be obtained by using unobtrusive techniques such as video monitoring. Pupil diameter can be also used for monitoring fatigue. Large and stable pupils are associated with alertness, while pupil dilatation indicates mental/emotional challenge or expectancy. Pupil constriction and pupillary oscillations are associated with sleepiness but appear to be impervious to time-on-task effects (Sirevaag and Stern 1999).

The neurophysiological mechanism underlying sleepiness is relatively well known. A pacemaker in the suprachiasmatic nuclei of the hypothalamus determines the *circadian rhythm*, bringing about a minimum of sleepiness in the late afternoon and a maximum in the early morning (~5:00 h). Body core temperature follows the same circadian pattern and is therefore frequently used as a marker for changes in the circadian rhythm. Melatonin shows the reverse pattern and seems closely related to both sleepiness and body temperature (Akerstedt 1995). The production of melatonin is triggered by light exposure, especially during the afternoon. Both sleep loss and work-induced fatigue exert their arousal-reducing influence on the "effort" system (Figure 1). Focusing of attention is considerably reduced and EEG alpha and theta activity are facilitated. As a sign of fatigue, HRV is increased. The breakdown of the "effort" system corresponds to what cognitive psychology has called the failure of an "upper" mechanism in monitoring and altering the parameters of a "lower" mechanism (Mulder *et al*. 1999). As a consequence of this failure, automated processes performed by the "lower" mechanism are subjected to deterioration by fatigue. Performance may be still sufficient which is, however, achieved by additional energy expenditure. This is shown by an increase in cardiovascular activity, EMG activity and epinephrine excretion.

Various situational and personal factors may contribute to the ability to stay alert during prolonged operational hours. Furthermore, countermeasures may be taken such as allowing for prophylactic naps, the application of caffeine, or the improvement of sleep quality by means of hypnotics in situations

where sleep is impaired by situational factors. The effectiveness of such countermeasures for minimizing the impact of sleep loss can be determined by the combination of subjective, behavioral and physiological measures.

4. CONCLUSIONS

Psychophysiology provides a unique approach to study the human being not only in the laboratory or in simulated environments but also at real work places. The ongoing micro-computerization and substantially reduced costs of commercially available data acquisition and analysis equipment facilitate the application of psychophysiological measures in the field. Two major goals can be achieved by applying the psychophysiological approach in the field of ergonomics: to create better work places and to prevent the development of work-related diseases.

Physiological measures can be recorded continuously without interrupting the workflow. They provide information that is not readily available from performance measures and subjective ratings. They have the advantage not being subjected to faking as psychological scales are very often. However, several bio-electrical and biochemical measures mentioned in table 1 are not easy to obtain at real work places. For example, the use of EEG parameters can be limited by recording artifacts in the field. Blood samples of epinephrine and norepinephrine require special medical care and compliance. It is generally recommended to test psychophysiological measures in a simulated environment first, before they are going to be applied in the field. Such a combined laboratory-field approach can be easily performed for most automated work places where the man–machine interaction makes use of a computer system.

However, a psychophysiological approach not only refers to the use of physiological measures in conjunction with behavioral and subjective data. It is also highly desirable to ascribe to a neurophysiological model such as depicted in Figure 1 as a theoretical background. This not only provides a better understanding of what is recorded by the various measures, it also avoids being trapped in oversimplified hypotheses derived from one-dimensional arousal or cognitive theories assuming only sequential information processing.

Scientific Management Influences on Ergonomic Analysis Techniques

P. G. Dempsey

Liberty Mutual Research Center for Safety & Health, Hopkinton, MA 01748, USA

1. INTRODUCTION

Ergonomics is a discipline that "borrows" from several related branches of science including, but not limited to, psychology, anatomy, physiology and engineering. Activities occurring around the time of World War II have been traditionally described as the beginning of ergonomics (Europe) and human factors engineering (USA). Comparatively, ergonomics is quite young if one uses these chronological landmarks; however, there is a fairly rich body of literature going back to even the previous century that clearly describes investigations of manual work with the purpose of enhancing human performance.

The industrial revolution had a dramatic effect on the design, analysis and management of manual work. Adam Smith's principles of the "Division of Labor" in *An Inquiry into the Causes and Nature of the Wealth of Nations* epitomized the new philosophy towards designing manual work required by the developing industrial base. Previously, craftsmen would be responsible for producing an entire product. Under the division of labor, an individual would be responsible for only a small contribution to a product, repetitively performing a narrow task or small set of tasks throughout the day. The division of labor was not as simple as arbitrarily dividing the work into equal units, but became a studied process with the goal of optimizing production. This epic change in work design required new approaches to the analysis and management of work. These new approaches provided direction to the design of work and eventually provided a feedback loop for existing designs. New products and a desire continually to increase production efficiency created the need for specialists, early on called "efficiency experts," to perform these functions. The Scientific Management movement formed the core of the early efficiency experts in the USA.

Today, ergonomic analysis of manual work plays an important role in the design and re-design of manual work for the purpose of enhancing human performance. The aspects of human performance considered by modern ergonomists extend beyond those of the early efficiency experts, but these differences may be explained to a considerable extent by the advancement in knowledge of the human responses to work. Different systems of compensation and accommodation for disabled workers and even different social values may considerably affect the focus of work analyses. Operationally, the analysis approaches used in the scientific management of work early this century are fundamentally the same as some techniques used today by ergonomists to study manual work.

An understanding of the evolution of ergonomics techniques provides more than a pedagogical history lesson. It provides insight into the goals and philosophic reasoning for analyzing work the way we do. We can then use this insight to support or question the appropriateness of the tools that we use today and develop in the future for analyzing manual work. This entry provides an overview of the contributions of Scientific Management to ergonomics.

2. SCIENTIFIC MANAGEMENT

The industrial revolution in the UK was followed by an industrial revolution in the USA. By the beginning of the 20th century, there was a substantial industrial base in the USA, particularly in the north-eastern area of the country. At that time, the Scientific Management movement was beginning to foster. The works of Frederick W. Taylor and Frank and Lillian Gilbreth formed the essence of this movement. There was a strong focus on maximizing productivity of workers engaged in industrial production, although Scientific Management would eventually find its way to non-industrial forms of work such as the surgical operating room. Similar lines of work were also being pursued in Europe and elsewhere. For an excellent example and references of work in Europe, see Amar (1920) which may also be the first ergonomics textbook.

Scientific management was an approach to optimizing the output of a facility, and was applied to almost every aspect of a production facility including accounting, line management, facilities design, as well as the production floor. The discussion here will be restricted to activities involving the design and analysis of manual work.

Two significant components of Scientific Management were time study and motion study, with the former more closely associated with Taylor and the latter with the Gilbreths. Time study predated Taylor, and was closely associated with the industrial revolution (for examples of early time studies, see Babbage 1835). Time study was used to determine work standards for task elements, whereas motion study examined task elements with the goal of optimizing efficiency through workplace design and the elimination of wasteful motion. Ideally, both techniques are used to analyze work. It should be noted that the distinction between time study and motion study was not always made, and that confusion is still made to this day.

The work of Taylor and the Gilbreths (1909) went far beyond time study and motion study, and included a systemic view of work design. As will be illustrated below, the primary goal of Scientific Management investigations of manual work focused on the effect of specific aspects of the work system design on fatigue and output. The Gilbreths' work, in particular, was focused on enhancing productivity through fatigue elimination.

Taylor (1911) described experiments to determine the optimal shovel sizes for shoveling loads of materials with varying densities (e.g. rice coal versus iron ore). The result was the provision of eight-to-ten different shovels for use at the Bethlehem Steel Company. Taylor (1911) summarized the effort as follows (comparing shoveling rice coal to shoveling iron ore): "In the one case, he was so underloaded that it was impossible for him to do a full day's work, and in the other case he was so ridiculously overloaded that it was manifestly impossible to even approximate a day's work" (p. 67 [page number refers to the 1967 edition.]) Taylor (1911) understood that either underloading or overloading the muscular system is inefficient, and focused on hand tool design in this case. The experiment provided early empirical evidence for "providing the right tool for the job," which

is a contemporary hand tool guideline. Although the goal of the experiments was to maximize tonnage shoveled per day, it appears as if Taylor (1911) at least superficially recognized the physiological responses to muscle loading, even if the recognition was a result of output concerns.

From a modern ergonomics perspective, the pig iron experiments described by Taylor (1911) have the perception of being the most "barbaric." The goal of the experiments was to maximize the weight of pig iron loaded onto rail cars. In this case, the temporal design of the work (i.e. work and rest schedules) was deemed the critical system component to manipulate. The main result of the study was the development of an equation to calculate tonnages handled. The acceptable daily tonnages were a function of distance carried (task variable), with the restriction on the grade of the plank going to the rail car (workplace variables) when applying the results. It was recognized that the limits would have to be reduced under high ambient temperatures (environment variable), and that only a small percentage of workers was capable of performing the job (administrative control). Modern ergonomic approaches to manual handling task analysis, such as psychophysical tables and equations used to predict acceptable loads, use the same approach. The difference is that contemporary methods provide loads aimed at protecting the majority of the population from injury, not maximizing the productivity of a minority of the population.

The work of the Gilbreths (1909) is even more compatible with contemporary ergonomics. Gilbreth's (1911) approach to analyzing manual work represents a modern systemic view of ergonomics: "A careful study of the anatomy of the worker will enable one to adapt his work, surroundings, equipment, and tools to him. This will decrease the number of motions he must make, and make the necessary motions shorter and less fatiguing" (p. 10). Gilbreth's (1909) study of bricklaying serves as a fine example of the ergonomic benefits of early motion studies. The results of the job design changes clearly reduced postural loading of the low back. Perhaps more important is the detailed manner in which Gilbreth broke down job elements to perform a task analysis. For instance, the act of laying one brick the "wrong way" was broken down into 18 task elements. The primary goal of the analysis was to enhance efficiency with a strong emphasis on reducing needless motion and fatigue.

These examples are by no means exhaustive, but illustrate the systemic approach to work design used by the founders of the Scientific Management movement. The approach typically involved studying tasks, or task elements, with the goal of modifying task, environment, machine and tool variables to enhance productivity, often times through the reduction of fatigue. The approach differed vastly from ergonomics in that worker selection was used extensively, whereas contemporary ergonomics promotes designing work that can be performed safely by the majority of the population, eliminating the need for selection. It should be noted that worker selection was not unique to the Scientific Management movement. Münsterberg's (1913) extensive use of psychological tests to select workers for various occupations provides an excellent example of the pervasive use of such testing, as well as a nice example of early experimental psychology research that certainly falls into what today would be considered in the realm of ergonomics.

3. TASK ANALYTIC APPROACHES TO ANALYZING MANUAL WORK

Task analysis, one of the most widely used techniques in ergonomics, had perhaps the most substantial influence of the Scientific Management techniques on modern ergonomics practice. Task analysis is a robust and powerful tool that enables ergonomists to study manual work (and many other activities) in a systematic manner. The components of task analysis include (Stammers and Shepherd 1995):
- data collection stage;
- task description stage; and
- analysis stage.

The task description contains the task requirements whereas the task analysis is the actual *analysis* of the behavioral implications of the task identified in the description (Stammers and Shepherd 1995). The analysis used in scientific management tended to focus on efficiency of activities (e.g. reduction of wasteful motion) and elimination of fatigue. Today, the analysis phase may focus on a broad range of measures that influence human performance, depending on the task and its context.

The origins of task analysis often include mention of the landmark report by Miller (1953). The purpose of the methodology reported was to provide a framework for specifying training requirements. The examples provided by Miller (1953) show the focus on breaking work into small units, just as was done by Taylor and the Gilbreths. Miller's (1953) methodology was more involved and far more advanced from the standpoint of comparing human capacity to task demands, but the general approach to describing work tasks is similar. The notion of performing a task analysis for delineating training requirements is functionally identical to Taylor's instruction cards for industrial tasks. In some regards, the task description methods form the core commonalties across time, and the analysis progressed and evolved as the knowledge of the human responses to work evolved.

4. DISCUSSION

Today, many ergonomic tools incorporate the division of manual work into tasks or task elements. This division provides a structured means of determining which tasks or task elements may result in task demands exceeding human capabilities. The control of work-related musculoskeletal disorders of the upper extremity and low back is currently a priority in many industrial organizations. Numerous analysis techniques used are indeed task analytic approaches, many of which are founded in fundamental time study and motion study techniques.

During the Scientific Management era, the task analytic approach was widely used as a means of enhancing productivity through the redesign of the workplace or the elimination of "wasteful" elements. The reduction of fatigue was a primary goal, with the assumption that fatigue was a detriment to productivity. The analysis was focused on the influence of specific aspects of the work system on efficiency and fatigue. However, today the primary goal of ergonomic analyses of manual work appears to be the prevention of disability, including the reduction of incidences and absenteeism. This shift in philosophy may be due to several factors, including better recognition of the deleterious effects of manual work on the human body, an increase in the

level of safety and health at work that the public finds acceptable, and a better understanding of the effect of workplace injuries and illnesses on organizational effectiveness and economic competitiveness.

Regardless of the reasons for the change in outcome measures focused on, we should consider the consequences of retaining essentially the same methodologies while focusing on different outcome measures. Often times, factors such as motion and productivity are easily measured, and the influence of changing a task parameter can usually be readily observed. Particularly in the case of productivity, the effect of design changes can be measured by throughput. However, disability and absenteeism are tremendously more complex, and the influence of task parameters on these measures is not readily observed or immediately realized. In fact, our knowledge of these causal relationships is lacking in many areas, in no small part because of the difficulty defining and measuring them for empirical study. As we look forward, it should remember that understanding the determinants of disability and absenteeism may require more complex analyses at the job, organizational and perhaps even societal level.

1. INTRODUCTION

Surveys or questionnaires are used to collect information from people concerning a range of ergonomics or human factors variables (Salvendy and Carayon 1997). Questionnaires can be used to evaluate human–machine system performance, e.g. usability evaluations of products or human–computer interfaces, and to evaluate demands on people, e.g. workload, fatigue, stress, and attitudes. They can also be a useful tool in implementing ergonomic programs as a diagnostic tool and in the evaluation phase. They allow the researcher to obtain large amounts of data from large numbers of people at relatively low cost and relatively quickly (Sinclair 1995). Particular attention should be paid to the development of questionnaires. The methods used to develop, implement, and use questionnaires are very important for the quality and usefulness of the data collected. Before developing a questionnaire survey, it is important to clearly specify the objective of the questionnaire: what will the questionnaire be used for? Figure 1 summarizes the issues related to survey design discussed in this article. Two issues related to measurement are highlighted: (1) objectivity/subjectivity, and (2) reliability/validity. Issues in the process of developing and conducting a survey are also discussed.

2. OBJECTIVITY/SUBJECTIVITY

Questionnaires are sometimes perceived as non-scientific because of their subjectivity. It is important to recognize that any data can be placed on a continuum of objectivity–subjectivity. Objectivity has multiple meanings and levels in the literature. According to Kasl (1987), objective data is one not supplied by the selfsame respondent who is also describing his distress, strain,

```
OBJECTIVE                         SUBJECTIVE
low in dependency         high in dependency
on cognitive and             on cognitive and
emotional processing     emotional processing
```

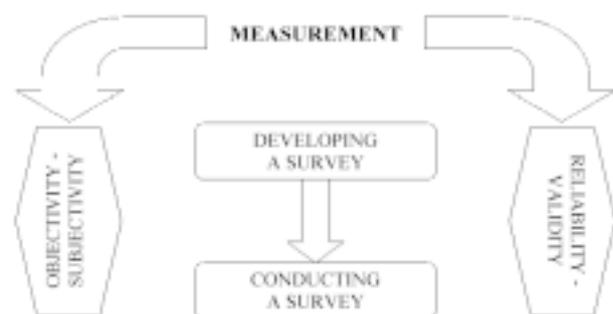
Figure 1: Issues in survey design


Figure 2: Objectivity/subjectivity continuum

or discomfort. This embraces the outsider perspective. With regard to measurement of psychosocial work factors, Kasl (1987) feels that measures of psychosocial factors can be less subjective when the main source of information is the employee, but that this self-reported exposure is devoid of evaluation and reaction. Similarly, Frese and Zapf (1988) conceptualize and operationalize "objective stressors" as not being influenced by an individual's cognitive and emotional processing. Therefore, it is more appropriate to conceptualize a continuum of objectivity and subjectivity (see Figure 2). The level of objectivity/subjectivity of a measure will then depend on the degree of influence of cognitive and emotional processing. For example, ratings of work factors by an observer cannot be considered as purely objective because of the potential influence of the observer's cognitive and emotional processing. However, ratings of work factors by an outside observer can be considered as more objective than an evaluative question answered by an employee about his/her work environment (e.g. "how stressful is your work environment?"). On the other hand, ratings of the same object by two or more experienced observers do not always achieve a good level of inter-rater reliability.

It is important to recognize that the wording of a question will determine somewhat the degree of objectivity–subjectivity. For instance, self-reported measures of psychosocial work factors can be more objective when devoid of evaluation and reaction. Any kind of data can be placed somewhere on this continuum from "low in dependency on cognitive and emotional processing" (e.g. objective) to "high in dependency on cognitive and emotional processing" (e.g. subjective). Some degree of subjectivity is also involved in so-called objective, quantitative measures. For instance, physical measurement involves decisions regarding, for instance, the timing and frequency of measures: these decisions are made by human observers, and therefore involve some degree of subjectivity. Questionnaires tend to be on the right side of the continuum; however, the degree of subjectivity/objectivity depends highly on the content and form of the questions.

3. DEVELOPING A SURVEY

The development of a questionnaire survey is important to ensure that the data collected is useful and of high quality. Fowler (1995) lists seven principles for designing good survey instruments:

1. The strength of survey research is asking people about their firsthand experiences: what they have done, their current situations, their feelings, and perceptions.
2. Ask one question at a time.
3. A survey question should be worded so that every respondent is answering the same question.
4. If a survey is to be interviewer-administered, wording of the questions must constitute a complete and adequate script such that, when interviewers read the question as worded, respondents will be fully prepared to answer the question.
5. Clearly communicate to all respondents the kind of answer that constitutes an adequate answer to a question.
6. Design survey instruments to make the task of reading questions, following instructions, and recording answers as easy as possible for interviewers and respondents.
7. Measurement will be better to the extent that people answering questions are oriented to the task in a consistent way.

The process of developing a questionnaire survey involves the following steps.

- Step 1 – Conceptualization
- Step 2 – Operationalization
- Step 3 – Sources of questionnaire
- Step 4 – Constructing the questionnaire
- Step 5 – Pre-testing of the questionnaire

3.1 Step 1

Before engaging in the process of writing questions or putting questions together, one should define precisely the concepts to be measured. This process of conceptualization is especially important when dealing with complex phenomena. Concepts often take the form of variables with a collection of related variables. For instance, the concept of musculoskeletal discomfort can be measured by the level of pain involved in various body parts: the attributes of the variable "pain experienced in various body parts" could represent different levels of pain, e.g. low–medium–high.

3.2 Step 2

The step of operationalization has been defined as the process by which one specifies empirical observations that can be taken as indicators of the attributes contained within a given concept (Babbie 1990). The operationalization process starts with a listing of the different sub-dimensions of the variable. At this stage, it is important to review previous research and work on the topic. Then, one should decide all the things that the variable represents, as well as what the variable does not represent. This avoids creating overlap between the variable of interest and some other variables. It is also important to pay special attention to the opposite of the variable.

3.3 Step 3

Before developing new questions, one should examine existing questionnaires which have been validated and used in previous studies. At this step, an extensive review of the literature is necessary. When reviewing existing questionnaires, one should examine the content of the questionnaire (what is measured?), as well as the context for which the questionnaire was developed. The content of the questionnaire should match the conceptualization and operationalization of the variables under study. It is also important to examine the context for which the questionnaire was intended. Using standardized questionnaires can be useful when one is interested in comparing data of a particular sample to already-collected data on a range of jobs, occupations, and organizations. However, whereas standardized questionnaires are interesting when one wants to make comparisons, they may not fit the objective of the questionnaire survey. In this case, the researcher needs to develop a tailor-made questionnaire.

3.4 Step 4

The construction of questionnaire items is a delicate process that requires experience and knowledge. The past experience of survey researchers and designers provides a wealth of guidelines useful in the writing of good questions and the generation of data useful to analysis. Converse and Presser (1986) provide guidelines for writing questions. First, one should decide on the type of questions:

- Rating scales: degree of agreement–disagreement, degree of satisfaction–dissatisfaction, frequency, quantity. Examples: "All in all, how satisfied would you say you are with your job: very much satisfied, somewhat satisfied, not too satisfied, not at all satisfied?"
- Semantic differential scales: simultaneous ratings across multiple dimensions. Examples: "Please indicate your reactions to the computer as a means of work. How do you find the computer interface:
  UNDERSTANDABLE 1 2 3 4 5 6 7 CONFUSING?"
- Multiple choice questions or dichotomous questions: respondents select one category. "Do activities at work make your back problem: better, worse, no change?"
- Open-ended questions.

The next stage in constructing the questionnaire involves the selection of the response scale and categories. For instance, musculoskeletal discomfort can be measured in terms of severity, frequency and duration. See Fowler (1995), Converse and Presser (1986), and Sheatsley (1983) for various response-scale categories. The balance, polarity, and number of categories on the scale are important considerations (Charlton 1996). Balanced scales with equal numbers of positive and negative alternatives are preferred. Whether or not to provide a neutral midpoint is another important decision. The number of categories on the response scale depends on the degree of discrimination required.

The following stage in constructing the questionnaire is the assembly of the questionnaire items and instructions. Dillman (1978) created "The Total Design Method" — that is, a set of guidelines for formatting a questionnaire. The format of a questionnaire can be as important as the nature and wording of the questions asked. A poorly organized and laid out questionnaire can lead respondents to miss questions, confuse them, and, finally, result in poor data quality. The order in which questions are asked can also affect the responses. If the order of questions is an especially important and sensitive issue in a given study, pre-testing of different versions of questionnaires with different ordering should be performed.

In addition, every questionnaire should contain clear instructions and introductory comments. Respondents should be informed about the purpose of the survey and procedures for filling out the questionnaire. In most instances, it is important from an ethical point of view to provide summary data to the study participants. Specific instructions may be necessary for some questions. For instance, rank-ordering a list of items is often difficult for respondents. The same information can be obtained by having respondents rate the items. However, if one finds it important to have respondents rank-order a list of items, the list should be made as short as possible and clear instructions should be given.

3.5 Step 5

The final step in the development of a questionnaire survey is the pre-test. The questionnaire should be reviewed for grammatical errors and typos, and also for content and clarity. The pre-test can involve review by experts and/or administration of the questionnaire to a small number of subjects. The latter can be performed using either focus groups or respondents filling out the questionnaire individually. Whatever method is used, several issues should be examined:

- questions: clarity, relevance, response categories
- questionnaire format: instructions, layout
- time needed for completing the questionnaire

4. CONDUCTING A SURVEY

Conducting a questionnaire survey involves a sequence of steps and a range of decisions. The opportunities for errors in the survey process are multiple. Sinclair (1995) emphasized the potential communication problems in different stages of questionnaire design and survey. At the survey stage, an important communication problem is the inaccuracy and misinterpretation of the information recorded on the questionnaire. Once a questionnaire has been designed, there are still many opportunities for error.

The data-collection method itself can lower the quality of the data collected. The researcher should pay attention to the timing of data collection. Data collected at the "wrong" time may be of lower quality. One should also think about the conditions in which the questionnaire will be filled out: on-the-job, at home, etc. If questionnaires are completed at the workplace, respondent should be given privacy and a quiet place to perform this task. Study participants should be explained the purpose of the survey, as well as the methods used by the researcher to handle the questionnaires. In particular, if respondents are asked to put their name (or an identifier) on the questionnaire, the researcher should clearly explain the way questionnaires will be handled (and by whom) in order to ensure confidentiality.

Once questionnaire data has been collected, various activities should be performed before the data can actually be analyzed:

- questionnaire "cleaning". At this stage, the researcher assigns ID numbers to the questionnaire and gets the questionnaires ready for data entry. This may involve, for instance, recoding of questions: a question on the job experience of a person ("10 years and 6 months") may need to be recoded ("10.5 years") in order to facilitate the data entry. Open questions (e.g. job title) should also be recoded and/or categorized if the data is to be entered in the database.
- setting up the database. The database should be set up to facilitate the data entry process, and to allow the researcher to perform all the necessary data analyses subsequently. This requires the researcher to know in advance the bulk of the data analyses to be performed.
- data entry and verification. The data entry process should be made as easy as possible for the data entry person. Appropriate physical working conditions should be provided to the data entry person. Full verification of data entry is rarely done, except when the sample size is small. However, verification of a sample of questionnaires can be done to evaluate the accuracy of the data entered.
- data cleaning. Once data has been entered into the database, a range of analyses should be performed to verify the accuracy of the data. For instance, frequency tables should be computed for all variables to examine the range of data and to check for outliers and extreme variables. Cross-tabulations between supposedly related variables can also be performed to verify the accuracy of the data.
- data analysis. Once the researcher feels confident about the accuracy of the data entered into the database, data analysis can start. The first stage in the data analysis involves the evaluation of the data quality (reliability and validity, see section below).

5. RELIABILITY AND VALIDITY

When constructing a survey or a questionnaire, the quality of the measurement method plays a crucial role. The quality of measurement is assessed by examining reliability and validity. Reliability refers to the issue of measurement repeatability: when we measure something at two different occasions, the two measures should result in the same outcomes. Validity refers to the content of measurement: are we measuring what we think we are measuring? There are several methods to evaluate reliability and validity (Carmines and Zeller 1990).

We can evaluate reliability by measuring a concept at two different times (test–retest–reliability), by looking at the internal consistency (of the answers) of questions that are supposed to measure the same concept, and by comparing with other methods of measurement of equal or higher level, for example standardized (and validated) questionnaires. A measure that is often used to evaluate internal consistency is the Cronbach's Alpha: it is a measure of the homogeneity of a group of items in a survey or questionnaire.

Three forms of validity can be distinguished (Nunnaly 1978): predictive validity, content validity and construct validity.

- *Predictive validity* (also known as criterion validity) refers to the comparison of the measurement under evaluation to another variable that lays outside the domain of the concept being measured. This variable is known as the criterion or "the golden standard". For example, experienced health as being measured with a survey can be compared with a medical examination. In this example, the medical examination is the criterion to which the questionnaire data (i.e. experienced health) is compared.
- The *content validity* of a measurement instrument can be established by examining the content of the questions very carefully. Are the items (in a concept) well chosen? Do they measure what we think they measure? Do they represent the entire domain of the concept? An often-used method for establishing the content validity of a questionnaire is to ask experts about clarity and completeness of a questionnaire (McDowell and Newell 1987). In addition, one can find out if the questions used to measure a particular concept are well understood by the target population (and in "their own language") by interviewing them (see discussion on pre-testing questionnaires above).
- *Construct validity* is important when measuring abstract concepts (e.g. job satisfaction, mental workload, stress). The abstract concept (the construct) is operationalized by several questions. When results of statistical analyses show that the questionnaire items show a high degree of internal consistency, one can conclude that the different questions do indeed refer to one (underlying) construct. The following statistical analyses can be used to evaluate construct validity: reliability analysis, correlation analysis and factor analysis.

6. CONCLUSION

Questionnaires can provide useful information on various ergonomic variables (Salvendy and Carayon 1997). Questionnaires are often perceived as not scientific because of

their subjectivity. However, it is important to recognize that any data can be placed on a subjectivity/objectivity continuum. In this chapter, we have reviewed principles, guidelines and methods for ensuring the high quality of data collected via questionnaire surveys. Before designing a questionnaire, it is important to clearly specify the objective of the questionnaire survey.

A Survey of Ergonomics Methods

N.A. Stanton and M.S. Young

Department of Psychology, University of Southampton, Highfield, Southampton, SO17 1BJ, UK

1. TEXTS ON ERGONOMICS METHODS

There appears to be a growing number of texts in recent years describing, illustrating and espousing a plethora of ergonomics methods (Wilson & Corlett 1995; Salvendy 1997; Stanton 1998). The rise in the number of texts reporting on ergonomics methods may be seen as a response to the requirement for more inventive approaches for assessing the user and their requirements. In many ways this may be taken to mean that the call for user-centred design has been taken seriously by designers. However, this success has forced the ergonomics community to develop methods to assist the design of products and devices. This demand seems to have resulted in the pragmatic development of methods having priority over scientific rigour. In a recent review of ergonomics methods, Stanton & Young (1998) identified over 60 methods available to the ergonomist. The abundance of methods might be confusing for the ergonomist, Wilson (1995) goes as far as to suggests that a

> . . . method which one researcher or practitioner is an invaluable aid to all their work may to another be vague or insubstantial in concept, difficult to use and variable in its outcome. (p. 21)

This quote highlights the fact that most methods are used by their inventors only. Despite the proliferation of methods, there are few clues in the literature available for ergonomists to enable them to discriminate between methods. The purpose of this article is to address some of these issues and focus attention on usability measures and methods that examine user activity and behaviour. Some researchers have attempted to address the problem. For example, an overview of the methods is presented in a number of books (Wilson & Corlett 1995; Salvendy 1997; Stanton 1998). Stanton & Baber (1996) argue that it is not suprising that the checklist is the ubiquitous method, as it is the only method that is independent of these factors.

2. SURVEY OF ERGONOMICS METHODS

In order to evaluate ergonomists' practices in the use of methods, it was necessary to conduct a survey of professional ergonomists. In a recent survey of 6 organisations, conducted by Baber & Mirza (1998), a vrey limited range of methods were reportedly used in product evaluation. The methods typically used consisted of questionnaires, interviews, observations, checklists and heuristics. Baber & Mirza (1998) report that the frequency with which a method is used is highly dependent upon its ease of use, and most respondents reported combining three or four methods to obtain an overall picture of the product under evaluation. Stanton & Young (1998) followed up this survey with eighteen self selected respondents from a pool of 163 members of The Ergonomics Society listed on the professional register, who were asked to comment on their experience with ergonomics methods.

Stanton & Young (1998) were particularly interested in which methodologies are used, what they may be applied to, and whether such techniques are useful.

2.1 Results and Discussion of Survey

Details of 27 methods used by ergonomists are presented in Table 1. Of the 27 reported methods, only 11 were reported by 6 or more respondents (i.e. from Mock-ups to Walkthroughs in Table 1) and only these methods were treated to statistical analysis. In general terms, the results of the survey seem to confirm the analyses undertaken thus far. First, there were no references by the respondents to reported evidence for reliabilty or validity in the literature which concords with our earlier investigations (Stanton & Young, 1998). Second, the respondent's evaluations of the techniques is consistent with our own experience.

The statistical analysis of the respondent's ratings of the techniques revealed three interesting and statistically significant results. First, some methods were rated as easier to use than others (Chi-square, corrected for ties = 33.0595; $p < 0.0005$). Checklists were rated as significantly easier to use than simulation (Z, corrected for ties, = -3.3994; $p < 0.001$), guidelines were rated as significantly easier to use than prototyping (Z, corrected for ties, = -2,578; $p < 0.01$) and interviews were rated as significantly easier to use than mock-ups (Z, corrected for ties, = -2.1381; $p < 0.05$). We noted earlier that only a limited range of methods are used but there is no guarantee that these are the most appropriate. Baber & Mirza (1998) report that product designers tend to restrict their methods to interviews, observation and checklists (which was confirmed in our study). Similar to the report by Baber & Mirza (1998), our finding suggests that this is likely to be due to the space of applying the methods. Second, the reported ease with which methods are applied depends upon whether software support is used. The results show that where no software support is used, the method is rated as easier to use than where software support is provided (Z, corrected for ties, = -2.6597; $p < 0.01$). Although perhaps this is a counter-intuitive finding, our own experience suggests that software can make even a relatively easy method quite complex and cumbersome. With some irony we would suggest that developers of ergonomics software cannot afford to ignore ergonomics in the design of their product! However, it is our experience that software can make the ergonomist's activities more efficient in the long term. Finally, the data suggest that users of ergonomics methods perceive differences in ease of use of methods depending upon the level of training they have received (Chi-square, corrected for ties, = 6.0639; $p < 0.05$). Those who have received no training rate the methods as easier to use than those who have received formal training (Z, corrected for ties, = -1.9919; $p < 0.05$). We suggest that this result is probably due some misconception regarding how to use the method and would recommend formal training in any approach used.

Table 2 shows the reported links of each method with other methods. As can be seen there are strong links between questionnaires and interviews as a combined approach. Interviews are also linked with observation, HTA and prototyping. Observation is linked with questionnaires and HTA. Finally, HTA is linked with HEART. Some of these links with other methods are by necessity. For example, HTA requires observation and inter-

views as necessary prerequisites to collect and verify the analysis. Similarly, HEART requires HTA before it can be conduted. Other links between methods are shown in lighter shading on Table 2.

Table 3 shows the uses to which the methods are put. The dark shading shows that questionnaires, interviews and observations are the principal methods used in data collection. The medium shading shows that simulators, computer simulation, interviews and repertory grids are used largely for design activities. It also shows that simulators are used for assessment activities and that repertory grids are used in validation activities. The light shading indicated occasional useage of other methods for a range of activities with no clear pattern.

3. GENERAL DISCUSSION

The appropriateness of the application of ergonomics methods to points in the design life cycle of products and devices is one of continuing debate. Obviously some methods depend upon the existence of a device to evaluate (such as observation, link analysis and layout analysis) whereas others do not (such as heuristics, checklists and repertory grids). An interesting picture is painted by the survey which asks what people use the methods for. The responses showed that four main areas of application were highlighted: data collection, design, assessment and validation activities. Table 4 summarises the methods used in these general areas. The findings agree with our assessment of interviews and repertory grids, i.e. that they are appropriate for most of the design stages.

In additon, some interesting links between methods came from the survey which are shown in Figure 1.

As shown, the interview is directly and indirectly linked to five other methods. This makes the interview an important design method. Given the concern about reliability and validity of the interview in other fields of research (Cook, 1988) we would caution users of this technique to ensure that they employ a semi-structured and situationally focused approach to the device evaluation interview.

4. CONCLUSIONS

In conclusion, there is clearly little reported evidence in the literature of reliability or validity of ergonomics methods. This was confirmed by the survey. The patterns of usage suggest that there is no clear match of methods to applications, which presents a rather confusing picture when embarking upon an evaluation. Apart from a few clearly defined applications the pattern looks almost random. We would suggest ergonomists and designers would be well served by exploring the utility of other methods rather than always relying upon 3 or 4 of ones favourite approaches. However, it is an important goal of future research to establish the reliability and validity of ergonomics methods.

These data could provide the encouragement for designers to try alternative approaches.

Task Analysis for Error Identification

C. Baber
University of Birmingham, UK

1. INTRODUCTION

In order to evaluate the design of a product, one often requires a physical working prototype. While this allows measurement of "real" user performance with the product, it also means that such evaluation is delayed until well into the design process. It would be useful to be able to take paper designs and submit them to "user testing" in order to determine the usability of the product. One way in which this can be done is through the application of error prediction techniques. In this entry, an error prediction technique is described which was developed specifically for product evaluation.

A given product will be capable of being in a finite number of states and will be capable of moving from its present state to a finite number of other states. A product can therefore be described in terms of states and transitions between states within the space of operation. In using a product, there will be a limited number of correct actions which can be performed at any one time. This will limit the number of actions that need to be taken into account. If we assume that products are used to perform tasks leading to the fulfillment of goals, then the definition of specific goals will limit the actions required. From this we can also propose that there will be situations in which a number of actions may be possible, but a specific goal may only require the performance of one action. If the product presents the opportunity to perform a range of actions not related to the goal, there will be a potential for error.

Task Analysis for Error Identification (TAFEI) rests upon three assumptions:

1. that human use of products will be goal directed, i.e. guided, at some level, by plans and following intended courses of action;
2. that goals will relate explicitly to, and be modified in light of, the information supplied to the user by a product;
3. that errors are the result of a cooperative endeavor between user and product.

2. CONDUCTING TAFEI ANALYSIS ON A VIDEO-CASSETTE RECORDER

As consumer products become more complicated, there will be an increase in the number of cognitive problems people have in not only operating, but also understanding the products. It is well known that people have difficulty operating videocassette recorders, and so it is fitting that this class of device be used to illustrate the use of TAFEI. This example (taken from Baber and Stanton 1994) shows the use of TAFEI to examine the ease with which programming could be performed. VCR programming gives the appearance of a logical task sequence. However, it requires several activity loops, which can lead to confusion.

The first phase of TAFEI analysis combines hierarchical task analysis (HTA) with state space diagrams (SSDs). The SSD is based on the supposed operation of a product — for instance, the sequence of states which the designer assumes will be followed to ensure efficient operation. It is important to note here that the SSD describes the states of the product and not user actions.

Each state in the diagram takes the form shown in Figure 1. The state is identified by a number and a brief title. Any notable

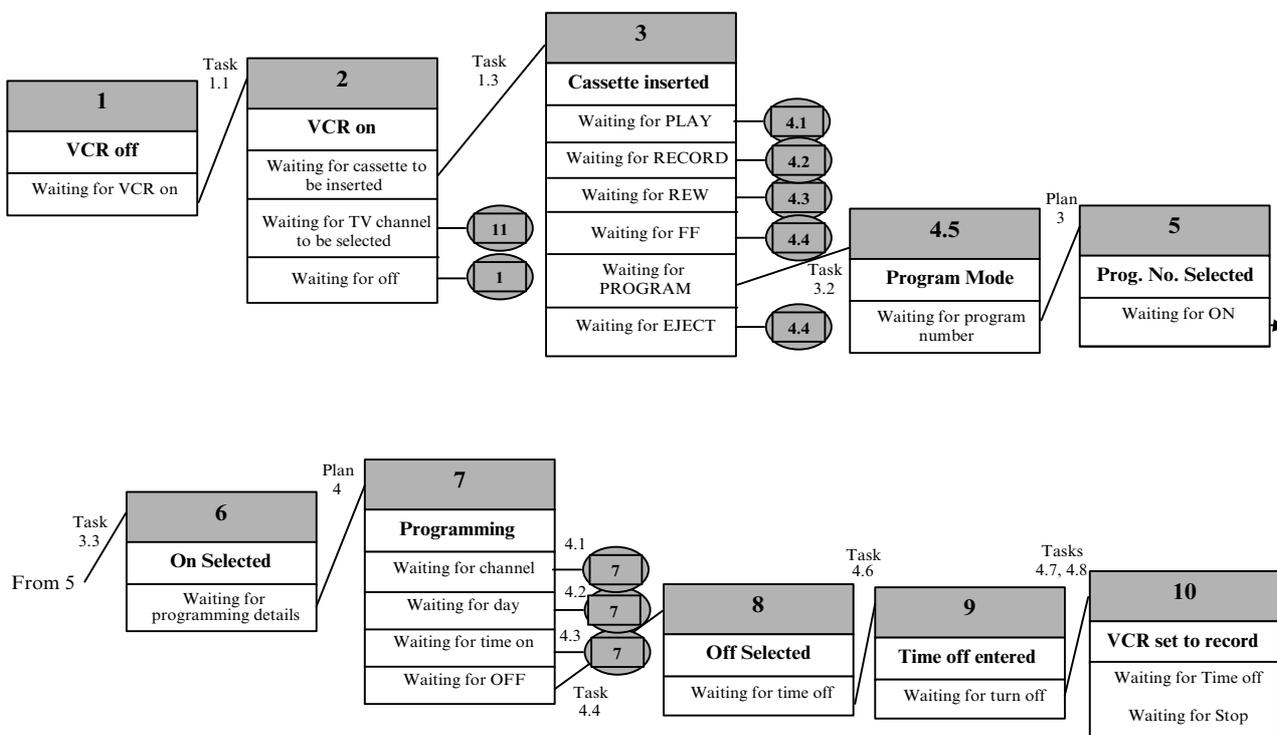

Figure 1. TAFEI diagram for programming a specific model of VCR

consequences of that state are also recorded. It is proposed that a product is capable of being in a finite number of states. By way of example, a kettle might be in one of five states: switched off, empty, full of water, switched on, boiling. Each state allows, or is "waiting for", a subsequent state, e.g. the kettle empty state is waiting for the kettle full state. Movement to any state other than the "legal" — i.e. designed for transition, such as pouring water from or switching on an empty kettle — would be considered an error on the part of the user.

The transition, or change, from one of these states to another requires action by either the human or the product. For example, the transition from kettle switched off to kettle switched on could be performed by the human pressing the on switch; the transition from kettle full of water to kettle boiling would require two steps: first, the human would switch the kettle on; second, the element in the kettle would heat up until the water boiled. It will be noted from this brief description that transitions between states are assumed to occur in sequences and that the defining feature of a particular sequence is the ultimate goal held by the user.

The SSD for the VCR was developed through careful study of the manufacturer's instruction manual. The SSD, then, represents the route through a set of actions which we assumed the designers had "designed into" their product in order to achieve a specified goal — for example, to enter details for recording a program.

HTA provides a normative description of (error free) human activity and is used as an explanation of transitions between states. In this way we can map human actions to transitions between states in the operation of a product. At present the mapping is a relatively simple process in which the transition between product states are assumed to occur as the result of either human or product actions. Where the transitions arise from human actions, we define the transition as a subgoal of product operation, and refer to the HTA for the "task" or "plan" to achieve that subgoal. For transitions requiring human action, the relevant task number or, where applicable, the plan number, derived from the HTA is attached to the transition lines in the SSD leading from one state to the next to produce a TAFEI diagram. We mapped user actions, defined by both plans and by single actions, onto product states represented in the SSD in order to indicate the means by which transitions occurred and developed a TAFEI diagram for VCR programming (see Figure 1).

3. PREDICTING HUMAN ERROR USING TAFEI

We term actions which will lead to a goal in a specific situation as "legal" in that they are allowed at that point in time, those which are permitted but will lead to outcomes other than the current goal as "illegal", and those actions which cannot be performed at that point in time as "impossible". TAFEI aims to elicit illegal actions within the closed loop of human product operation and allow the redesign of the product to make these actions impossible.

From the TAFEI diagram, we can suggest a number of illegal transitions. The definition of illegal actions is relatively straightforward. The analyst, faced with the TAFEI diagram asks whether it is conceivable that a transition can be made from one state to another state. (Note: we do not ask whether it is "sensible" to perform such a transition, only whether it is possible.) The question to ask is, can a user perform an action in state "x" which

will take them to state "z" rather than to state "y"? Some transitions will be impossible in that there will be no way in which an action can be performed to move between two states. However, other actions will be possible in the current design. In this way, we can demonstrate where actions can be performed which were not imagined or intended by the designers. The next step is to consider whether the transitions thus discovered can be accepted in product operation or whether they represent illegal activity. At present, this will be based on the intuitions and expectations of the designer, but we do not see this as a problem — after all, it is the designers who will have the clearest idea of how the product is designed/intended to be used. A transition matrix is used to define types of transition between states. Once the illegal transitions have been identified, it will be possible to begin to propose possible solutions. Furthermore, inclusion of by-products can indicate hazards which can be addressed by designers.

Entering the programming details for the VCR, state 7 in Figure 1, takes place in a poorly structured loop. After setting the timer to "program", and selecting "on", the user receives the prompt "CH". The user presses a "channel up/down" button to select the desired channel. Next, the user selects the day on which a program is to be recorded on. (Note: the "day" button must be pressed before the user can proceed; this means that if the desired program is being shown today, the user must go through the week before setting the product.) After selecting the desired channel and day, the user must then insert the start time. This is performed by selecting "set hours" and changing the time using "+" and "-" buttons. The action is repeated for the minutes, and the same process is used to set the finish time. However, after setting the start time, the user must wait for 5 seconds and then press the "off" button before setting the finish time. Once this sequence of activity has been performed, the user presses "set timer" again, and then presses the "time record" button. In addition to problems of reading the display, VCR users face difficulties in understanding the sequence of actions required. This problem is made worse when either no feedback or inappropriate feedback is given. While this interaction is largely user initiated, it is not always clear what the user should be doing.

A number of the illegal operations, such as switching off the recorder without stopping a tape playing or pressing play without inserting a tape, could be easily dealt with by considering the use of modes in the operation of the devices that would make specific actions impossible. Figure 1 also highlights the recursive transition (7—7) which required users to cycle through a sequence of data input. User reports suggested that this point was a major source of error, with users frequently failing to set the day for recording, for instance, setting the VCR to record on the day it was programmed rather than the day on which the desired television program was scheduled.

4. HOW RELIABLE IS TAFEI?

For any prediction method to be considered reliable, it must demonstrate a reasonable match with observed performance. Baber and Stanton (1996) compared predictions made using TAFEI with observed activity in the use of a ticket-vending machine. From the analysis of the TAFEI diagrams and the transition matrix, the following error types were predicted from the TAFEI analysis:
confuse next action

error in ticket selection
error in station selection
error in zone selection
error in money insertion
confuse mode
use wrong buttons
attempt to use closed machine
confuse return from cancel
attempt to use machine in waiting mode

In summary, TAFEI predicts 10 error types. From observation of users of the machine, we observed all of the predicted errors. We developed the following procedure to define concurrent validity:

(a) predicted errors from TAFEI = 10
(b) observed errors = 15
(c) errors predicted but not observed = 0
(d) errors observed but not predicted = 4
(e) errors defined as impossible = 4

concurrent validity of TAFEI

$$CV = \frac{(a/b) + [1 - (c/e)]}{2} = 0.83 \quad\quad [1]$$

If direct observation of human performance represents the "gold standard" for product evaluation, then obviously any technique which is proposed for this field should provide a reasonable match to "real" activity. We would suggest that TAFEI can produce a great deal of useful information for product evaluation; the fact that TAFEI produced around an 80% level of agreement with observed data suggests a sufficiently good relationship to warrant further consideration.

In conclusion it is proposed that human error prediction techniques, such as TAFEI, represent a reliable, cost-effective means of conducting product evaluation, and provide the advantage of allowing analysis during early stages of product development. We would also propose that such a structured technique could be both more reliable and rigorous than product evaluation checklists, which are commonly used in preference to observation as methods of speedy data collection (Mirza and Baber 1996).

Task Analysis in Industry

H. Luczak and J. Stahl

Institute of Industrial Engineering and Ergonomics, Aachen University of Technology, Bergdriesch 27, D–52056 Aachen, Germany

1. INTRODUCTION

Task analysis is a crucial step in evaluating and designing systems. It provides insights into how users and systems interact and ensures that either the task is adapted to the person or, if feasible, measures can be derived to fit the person to the task.

2. FUNDAMENTALS OF TASK ANALYSIS

2.1 Etymology and definitions

The notion "task analysis" is composed of two words. The term "task" is a conceptual construct, so there are numerous ways of defining it. There are two major dimensions in which definitions differ: breadth of coverage and external versus intrinsic definitions (Fleishman and Quaintance 1984). The latter provides a fundamental difference in perspective. Tasks are viewed either in terms of work (usually in terms of observable behavior) or in terms of people (usually in terms of cognitive processes). In terms of work, a task may be defined as a set of actions with an objective, performed by a worker, and transforming inputs into outputs. From the people viewpoint, a task may be described as a series of goal-directed transactions controlled by "programs" that guide the operations of a human operator.

The term analysis, from its Greek origin, refers to the decomposition and separation of any material or abstract entity into its constituent elements. Task analysis can therefore be defined as a study that divides human work into component tasks and systematically and comprehensively describes these components in terms of their defining "elements" or aspects:

- action, activity or behavior
- sequence of subtasks
- object
- tools, aids, or equipment
- time
- frequency
- space
- environmental conditions
- goals
- cues
- information
- rules
- feedback
- cooperation and communication
- controls used
- errors or error proneness
- criticality
- importance
- required decisions
- required knowledge, skills and abilities (KSA)

Task analysis covers a range of techniques and methods. Depending on the goals and the areas applied, these techniques and methods focus on certain defining aspects and they neglect others.

2.2 Applications of task analysis

Task analysis is applied to various areas (Kirwan and Ainsworth 1992):

- Allocation of function (to machine or operator, extent of operator involvement in the control of a system, etc.)
- User interface design (information displays, controls, tools, equipment, etc.)
- System performance (productivity, reliability, limits, etc.)
- Safety (hazards to the operator, general system safety, human reliability assessment, incident and accident investigation)
- Quantitative and qualitative requirements in terms of KSA (number of staff, personnel selection, training measures, etc.)
- Work organization (allocation of responsibility, job descriptions, communication requirements, remuneration, etc.)

2.3 Task analysis process

The term "task analysis" might suggest that only analysis methods are used. However, the task analysis process usually comprises three steps: data collection; representation or description (and in some cases also simulation); and analysis. The process subsumes a variety of techniques, which are employed for data collection and representation or simulation, and methods which are based on theoretical models that allow interpretation of data in a broader framework and are used for analysis.

3. DATA COLLECTION TECHNIQUES

The type of data to be collected in a task analysis process depends on the intention and the scope of the analysis. Usually it is a subset of the defining aspects of tasks listed in Section 2.1. The data may be subjective or objective. Examples of subjective data collection techniques are questionnaires, checklists, interviews (structured or unstructured; single or group; initial, verification, or follow-up), verbal protocols, and the critical incident technique. Possible sources comprise operators or job incumbents, colleagues, superiors, and the analysts if they themselves are executing the tasks. Objective data collection techniques include any kind of continuous or sampled observation by an analyst or any kind of technically assisted access via perception (e.g., camera, tape recorder), viewing documents (e.g., job descriptions, blueprints, job cards, schedules, incident reports, diaries, training programs), and measurement (e.g., physiological variables, environmental conditions).

4. DATA REPRESENTATION TECHNIQUES

Data that has been collected must be represented in a meaningful way to aid the analysis, so representation techniques are often directly linked with analysis methods. Data representation techniques are either static or dynamic. There are a very wide range of static techniques, such as keyword protocols, tables, charts, event trees, and task hierarchies. The diversity can be illustrated by some examples. The critical incident technique (CIT) and failure mode and effects analysis (FMEA) simply represent the collected data textually in a list or table to be analyzed. Hierarchical task analysis (HTA) and event trees represent the data in treelike diagrams. The structured analysis and design technique (SADT) graphically represents an activity model and a data model. Nodes are denoted by activities, which are related to each other by input/output relations and control flow. Necessary resources are attributed to the activities.

Static data representation techniques merely provide a systematic structure of the tasks and their defining aspects, but dynamic representation techniques also describe the behavior of systems and may be used for simulation. They fall into one of three categories: state-oriented, event-oriented, or Petri-net-based. State-oriented representation techniques represent discrete states as nodes, and actions or events as transitions from one state to another. Generic techniques within this category are sequence diagrams and state diagrams. They have been adapted to create techniques with specific applicability to task analysis, such as object charts, ADV charts, task-object charts (TOCs), and the operator function model (OFM).

Event-oriented representation techniques represent events or actions as nodes and they represent states as edges. Tasks networks are widely used; they include techniques such as input/output block diagrams, process charts, flow diagrams, SAINT (system analysis of integrated networks of tasks), SLAM II (simulation language for alternative modeling), SIMAN (simulation analysis), and Simple++ (simulation in production, logistics and engineering implemented in C++). Other event-oriented representation techniques are time-based, e.g., Gantt diagrams and timeline analysis. Layout-based representations such as link analysis are also useful for systems design.

Petri nets are a synthesis of state-oriented and event-oriented graphs. In Petri nets, places represent states and transitions represent events. High-level nets are especially useful for task analysis. Examples are generic techniques such as place/transition nets (PT nets) or colored Petri nets (CPNs). Techniques have also been developed for specific purposes, such as role-function-action nets (RFA nets), which are useful in human-computer interaction, and expanded event-driven process chains (EEPCs), which are used to design corporate information systems (e.g., SAP/R3).

5. ANALYSIS METHODS

Analysis methods can be distinguished according to the breadth of coverage of the respective task definitions. This can be done following the seven structure-oriented levels of the ordering model by Luczak and Volpert (Luczak 1997). In this context, levels are not equally relevant, and analysis methods and their respective models may be grouped with respect to subtask, task, job, and group levels.

5.1 Subtask level

The subtask level comprises analysis methods that do not take into account the goal of a task. They can be distinguished as methods for motor processes and mental processes. Analysis methods for motor processes are therbligs, systems of predetermined times (SPT), the Ovako working posture analysis system (OWAS) and Ergon-Expert. Therbligs are 17 basic motion elements from which all industrial processes are composed and were identified by Gilbreth. SPT comprises methods such as work factor (WF) and methods time measurement (MTM), and consists of rules with which working times for limb operations can be determined, e.g., manual assembly. OWAS provides a matrix of basic work postures and is used to derive measures on the basis of relative frequency and stress of the respective postures. Ergon-Expert is a computer-based expert system to analyze lifting and material handling tasks.

Analysis methods for mental processes are based either on

stage models, resource models, or combinations thereof. In stage models, information is conceived as passing through a finite number of discrete stages (e.g., the Sternberg model). Resource models (e.g., the Wickens model) are based on the notion of availability of scarce processing resources and can be used to assess human performance limits. They are distinguished as single-resource and multiple-resource models. A combined model is the cognitive energetic linear stage model by Sanders. An application of SPT to mental processes is WF-Mento, which allows the analysis of time consumption of repetitive informational processes.

5.2 Task level

The task level is at the heart of task analysis. The underlying models of analysis methods on this level may be distinguished as single-task models, multiple-task models, and human error and reliability models. A few representative models of each category are named.

5.2.1 Single-task models

Single-task models comprise tasks such as manual control, tracking, and monitoring. Several models are based on applying control theory to human performance, such as the five-parameter quasilinear model and the crossover model, both by McRuer, and the optimal control model (OCM) by Kleinman, Baron, and Levison. They allow quite accurate prediction of task performance and control characteristics. To describe and predict human monitoring performance, specifically the way operators divide their attention among a number of instruments, the visual sampling models by Senders, Carbonell, and Smallwood may be used.

Information processing models include the model human processor (MHP) model, the goals, operators, methods, and selection rules (GOMS) model and their related models by Card, Moran, and Newell. MHP allows analysts to make general predictions about the time it will take to carry out tasks. It is based on the notion that information flows through discrete stages in order to be used and processed. GOMS provides a model of the necessary knowledge for successful execution of a task, which is assumed to be like a problem-solving process. Related models are the keystroke model and the unit tasks model.

5.2.2 Multiple-task models

Owing to increasing automation and use of advanced information technologies, there is growing interest in multitask performance, which has led to a wide variety of analysis methods and their respective models. Here are some of them:

- Predominantly aiming at optimizing system performance are simulation methods like SAINT, SLAM II, SIMAN, and the human operator simulator (HOS). The first three methods are based on task networks (Section 4), and HOS provides micromodels for human cognitive, perceptual, and psychomotor acts to predict timing and accuracy.
- Sheridan's supervisory control model is a qualitative model featuring a series of nested control loops incorporating these user tasks: plan, teach, monitor, intervene, and learn. It is especially useful in allocating functions to machines and operators.
- Rasmussen characterizes three kinds of human performance based on skills, rules, and knowledge (SRK model). From

this model, he developed a framework called the "decision ladder," which can be used to describe and analyze decision-making processes.

- Klein's recognition-primed decisions (RPD) model is a decision-making model that focuses on situation assessment rather than judgment of feasible alternatives. It distinguishes three cases: simple match, developing a course of action, and complex RPD strategy (situation evaluation).
- Cosimo (cognitive simulation model) by Cacciabue and Kjaer-Hansen is used to analyze decision-making processes in emergency situations. It comprises high-level decision making (HLDM) with higher cognitive processes like diagnosis and planning, and low-level decision making (LLDM) with predefined lines of action.
- Semiotic models are based on the work of Morris on signal theory and are used for the analysis and design of human-computer interaction. They distinguish three levels: pragmatic, semantic, and syntactic.
- The Siegel-Wolf model is based on the assumptions that operator loading is the basic element in effective human-machine system performance and that the variety of loading effects are compressed into one variable called stress. It can be applied to a wide variety of tasks and systems.
- Action regulation theory and HTA are both based on the notion that tasks can be described as hierarchies of goals, tasks, and operations, such as hierarchically coupled test-operate-test-exit (TOTE) units. HTA is quite generic in nature and application, whereas action regulation theory incorporates further concepts like the assignment of goal-action cycles to three levels (psychomotor, perceptive-conceptual, and intellectual) and is applied with the goal to design interesting and meaningful jobs.

5.2.3 Human error and reliability models

Although some of the methods mentioned above may also be used to model human error and reliability, there are dedicated techniques. Fault tree analysis combines hardware faults and human errors using AND/OR logic; it indicates potential weak links in system reliability.

- FMEA enables the analyst to consider the reliability of the operator and the consequences of errors for the system.
- Technique for human error rate prediction (THERP) is a method to quantitatively predict human error probabilities on the basis of human performance shaping models.
- Human cognitive reliability (HCR) by Hannaman and generic error-modeling system (GEMS) by Reason, both are based on Rasmussen's SRK model.

5.3 Job level

Task analysis methods at the job level are also known as job analysis methods. Some methods from the task level are also applied at the job level, with the additional aspect of considering the entire activity systems of single persons, i.e., their jobs as a

whole. Job analysis methods may be distinguished in four categories (Fleishman and Quaintance 1984):

- The behavior description approach emphasizes operators' overt behavior, i.e., what they actually do while performing a task. Well known is the position analysis questionnaire (PAQ) by McCormick, Jeanneret, and Mecham; this follows the stimulus-organism-response paradigm and additionally embraces behavioral adjustment in terms of cooperation and work context. It is quite general in nature and may be used for various applications, such as determining wages or required KSA. Many other methods rely on the PAQ for job description and expand it with additional models, e.g., Arbeitswissenschaftliches Erhebungsverfahren zur Tätigkeitsanalyse (AET), which translates as "ergonomic job analysis technique" and employs the stress-strain model.
- The behavior requirements approach catalogues behaviors that should be omitted or are assumed to be required in order to achieve criterion levels of performance. An example is Miller's task strategies approach, which is based on an information processing model.
- The ability requirements approach describes tasks in terms of the abilities that a given task requires of the individual performer. Well known is Fleishman's manual for ability requirements scales (MARS), which is based on a factor-analytical model of human abilities.
- The task characteristics approach is based on the definition of a task as a set of conditions that elicit performance. The task can be described in terms of intrinsic, objective properties. An example is Hackman and Oldham's job diagnostics survey (JDS), which employs a job characteristics model of work motivation based on five core job dimensions: skill variety, task identity, task significance, autonomy, and feedback from the job itself.

5.4 GROUP LEVEL

Although job analysis methods may also take into account the impact of group work on the individual, task analysis at the group level has an additional level of complexity, because communication and interaction among people and dependencies between their tasks must be considered. There are two distinct categories:

- Multioperator or crew models rely on very well-defined task descriptions (and are therefore mainly used in military settings) and address issues like global system performance (in terms of mission success or elapsed time), task organization, and crew size. An example is the Siegel-Wolf model (Section 5.2.2).
- Recently, in the context of computer-supported cooperative work (CSCW), models have been developed and are being developed that describe and analyze less defined tasks. Their issues are to understand cooperative processes like group work or collaborative learning and their goal is to design information and communication systems for their support. Models are taken from various backgrounds, e.g., coordination science.

Work Stress Quantification and Evaluation using ErgoMOST™

J. R. Wilk

Senior Account Manager, H.B. Maynard and Company, Inc.

1. INTRODUCTION

There has been a rising number of ergonomic-related injuries over the past decade. This increase in work-related injuries has sparked aggressive auditing activities by the Occupational Safety and Health Administration (OSHA), and introduced the prospect of a national ergonomic standard. It is clear that ergonomics has become a subject that must concern everyone who performs or manages work.

To aid the management of these ergonomic problems, many companies have assigned the responsibility for their abatement to an individual or team within the organization. In cases where the engineering group or a cross-functional team has been given responsibility to investigate ergonomic concerns, many have employed the use of tools to help them. These tools are viewed as objective measures of ergonomic stress by these teams.

In order to provide an objective ergonomic evaluation tool, H. B. Maynard and Company, Inc. of Pittsburgh, Pennsylvania has developed ErgoMOST™, a software application that provides a direct link between ergonomic and methods analysis. ErgoMOST quantifies and evaluates the ergonomic stress associated with a method and pinpoints potential ergonomic concern. After redesigning a job, ErgoMOST can be used to simulate a method improvement or job rotation that reduces the operator's exposure to ergonomic stress.

This article will discuss how ErgoMOST functions as an essential piece of a comprehensive ergonomics program and as an important evaluation tool. It will demonstrate how ErgoMOST is used to detect ergonomic concerns and simulate and evaluate possible improvements to an operation. Finally, the link between basic methods improvement techniques and the use of ErgoMOST will be explained.

2. ERGOMOST AND AN OVERALL ERGONOMIC PLAN

Ergonomic evaluation is an important part of a company's overall ergonomic program. To do this evaluation, ErgoMOST provides the user with the means to quantify the ergonomic risk of operations. Ergonomic stress evaluation is one part of a comprehensive ergonomic program that should include the following elements:

- employee and workplace audit
- ergonomic stress evaluation
- ergonomic design of products, workplaces, methods
- environmental evaluation and improvement
- ergonomic program organization
- education and training program
- fitness and rehabilitation program
- reporting, feedback, and follow-up

These elements are essential to the successful implementation of ergonomic principles into the everyday operation of a facility. The following is a description of ErgoMOST and how it functions as the ergonomic stress evaluation part of an ergonomic program.

3. ERGOMOST AND ERGONOMIC STRESS EVALUATION

ErgoMOST allows the user to attach ergonomic analysis to work that follows a definable method. This method may reside in a work measurement or standards database or can be entered directly into the system. Given this method, the user applies ergonomic analysis to each method step. This analysis includes force, posture, grip, and vibration information. The force

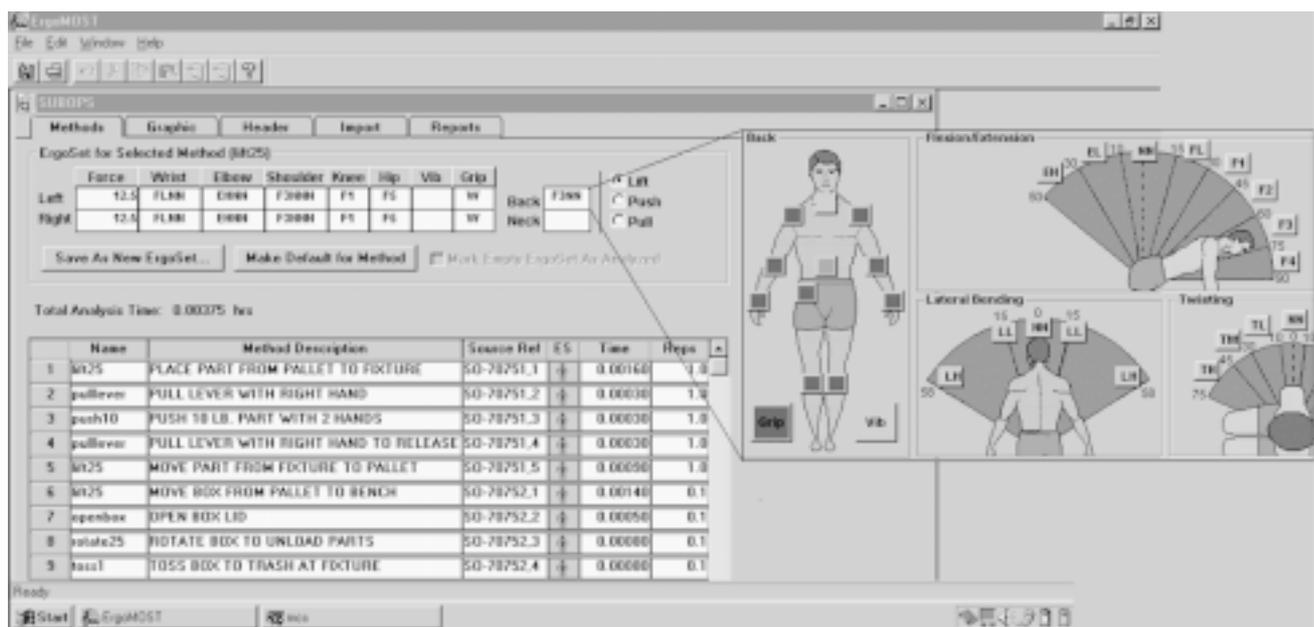

Figure 1: ErgoMOST methods screen with graphic input

Figure 2: Header information

requirement for each method is determined either by weighing the various objects handled or measuring the forces using a hand-held dynamometer, or other instrumentation. Next, the postures of various body members (wrists, elbows, shoulders, back, hips, neck, and knees) are entered for each step of a process. Then, the user classifies the grip that the operator is using in each method step as well as the vibration stress. This analysis is entered as an element called an ErgoSet™. Figure 1 shows the method definition for a job and the ErgoSet for step 1. The graphic in the inset is the posture input for the back.

After each step has an ErgoSet developed or assigned to it, job information is required, such as:
- Production period (hours in the shift)
- Profile of the operator (male or female and the percentile of the population)
- Product quantity produced in the shift

Figure 2 shows the header information with the job information that is required for the calculations.

The ErgoMOST system then evaluates this input to quantify the ergonomic stress of an operation by assigning an ergonomic stress index (ESI) for each body member in terms of force, posture, repetition, grip, and vibration stress. The evaluation criteria for the determination of the ESI values were developed in partnership between H.B. Maynard and Company, Inc. and university research partners. This approach to quantification of ergonomic risk has taken expertise and detailed modeling techniques and presented them to a user in simple terms. An ESI has a 1–5 rating system. These ratings indicate potential risk for each joint in the following manner:

A rating of 1 or 2 represents low ergonomic risk. A rating of 3 represents medium ergonomic risk, and a rating of 4 or 5 represents high ergonomic risk. Although all jobs should be monitored for feedback and improvement, operations with ESIs of four or five should be investigated for immediate ergonomic improvement. These ESI values have been developed and tested

Table 1: Ergonomic stress index table

1–2	Low Risk
3	Medium Risk
4–5	High Risk

to be in accord with current research and common ergonomic tools that are in use today, such as the NIOSH 1991 Lifting Guide.

Figure 3 shows the summary output for one analysis or job. In this case, the major areas of concern are force exposure to the shoulders as well as the posture of the elbows and back. This output reflects a job where there is lifting of heavy weight from a pallet on the floor, processing the part, and putting the finished object to the floor.

Measurement of ergonomic stress should not be considered as an end, but rather as a means for improving operations. Since absolute limits are not known and the variations of dealing with the human body are so diverse, ErgoMOST is recommended for use in a comparative sense. Method steps measuring the highest ergonomic stress levels are targeted for analysis to determine how they can be improved. Figure 4 shows a report that prioritizes the methods, which serves as a guide to making ergonomic improvement. In this case, the high force methods were the part handling steps of the operation. If the steps with the ESI of 4 can be redesigned to eliminate these high ESIs, then the job will be improved for the operator and ergonomic risk will be reduced.

After the initial ErgoMOST analysis has been completed, the ergonomic stressors contributing to the ESI ratings can be pinpointed. Finally, a redesigned solution is completed and simulated to evaluate the ergonomic improvement. Figure 5 shows the comparison of the original job and the redesigned method. The graph shows that the high ESIs for posture have been eliminated. In this case, implementing lift tables on either side of the working area so that the heavy weight could be presented in a better fashion reduced the fours and fives to threes or less.

Pinpointing problems in an operation is beneficial in identifying and documenting specific ergonomic problems of an operation in terms of force, posture, repetition, grip, and vibration. Documentation of problems and improvements is essential in having a complete evaluation of ergonomic stress. Simulating the method improvement allows the team to identify potential ergonomic stress before the operation is put into effect.

ErgoMOST can also analyze a group of processes. Since many ergonomic stressors are alleviated by job rotation, various combinations of tasks can be simulated and analyzed to assign a rating for a group of processes to determine the effects of leveling the peak stresses. ErgoMOST allows the engineer to specify exact quantities produced against each job in a rotation. After this information is determined, as we have seen earlier, the user can get feedback on the areas of ergonomic concern.

4. ERGOMOST AND METHODS IMPROVEMENT

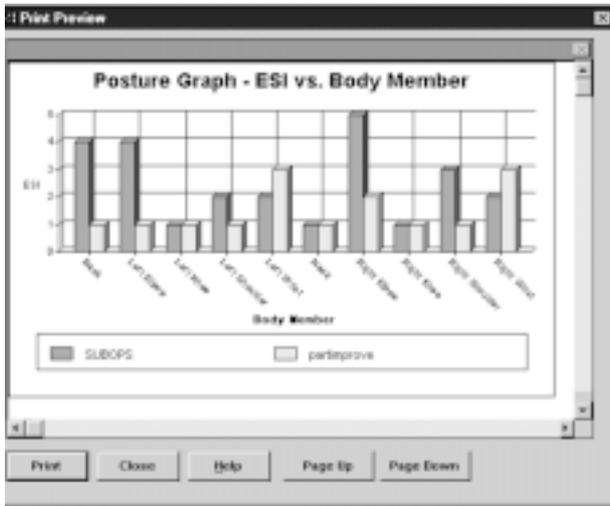
By employing methods improvement techniques, which are a basic part of industrial engineering, one can see a great deal of ergonomic improvement in a short period of time. The following are examples of basic methods engineering principles. The ergonomic analyst should evaluate:
- *Workplace Heights*: These should be adjustable to accommodate the varying heights of operators.
- *Material Placement*: Simple arrangement of materials with consideration given to wrist, elbow and shoulder postures can result in greatly reduced stress. For example, placement of material in a container with an angled opening enables an operator to remove or replace objects from the container with minimal wrist deviation.


Figure 3: Summary output

Figure 4: Top methods of concern

- *Force Exposure*: Updating equipment to use modern actuating devices such as proximity switches rather than palm buttons can reduce forces that pose risk of injury to the operator.
- *Possibility for Job Rotation:* Combinations of jobs can be devised which level out the risk of certain high-stress operations because the operation is distributed between several employees rather than concentrated onto one worker.
- *Tooling Application and Design*: Obvious posture improvements can be seen and measured when a poorly designed tool is replaced with the proper tool or a specially designed tool that meets the requirements of its application.

5. CONCLUSION

ErgoMOST is designed to provide users with a tool that can be applied easily and objectively to quantify and evaluate ergonomic stress involved with an operation. The results are presented in an easy-to-use format. Using the results of the initial analysis, ErgoMOST should be used on a redesigned method to ensure that improvements are implemented on the floor, which provide safe and efficient processes for workers to perform.

Because of the present interest in the relatively new science of ergonomics, and the attention it has received during the recent years, it can be predicted that the knowledge of work-related stress will increase substantially in the next few years. As this knowledge grows, ErgoMOST will be refined as data becomes available, and its capabilities will increase to incorporate the data. More specifically, some of the features that are under consideration for inclusion in ErgoMOST are:

- energy expenditure
- job evaluation checklist

Figure 5: Comparison graph

- enhanced graphics
- ergonomic improvements database
- composite ratings for the entire body
- economic justification of ergonomic improvement

 For ergonomic evaluation to be successful, it is up to researchers to provide the data and guidelines, and industry to apply ergonomics through a properly structured ergonomic program that uses tools which provide useful solutions to the ergonomic problems.

Published Ergonomics Literature

T. Megaw

Ergonomics Information Analysis Centre, The University of Birmingham, UK

1. INTRODUCTION

Despite the accelerating introduction of electronic methods of information provision, printed copy still remains a primary source of ergonomics information and knowledge. The printed material available to ergonomists can be broadly divided into five sources: journals, books, proceedings, reports and standards. Journals contain articles or papers which have been refereed by experts in the reported topic area. This provides a good degree of confidence in the quality of the material. However, there can often be quite a delay, sometimes as long as three years, between the initial submission of a journal article and its publication. Books may either be written or edited by one or more authors. Some books provide a general coverage of all areas of ergonomics, while a majority restrict the areas they cover. Included under the heading of books are handbooks. Although, books are not refereed to the same degree as most journal material, they are usually written by experts in the relevant topic areas. Proceedings include the papers presented at symposia and conferences, often the annual conferences of the various ergonomics societies. The extent that conference papers have been peer-reviewed varies widely. It is rare for conference papers to be reviewed as thoroughly as journal papers and it is common for them not to have gone through any reviewing process at all. For this reason the quality of conference papers varies enormously. The main advantage of conference proceedings is that they provide the reader with a good impression of whatever research is being carried out in a particular topic area at a particular point in time. In this respect, one can judge "the flavor of the month". In some cases conference papers are published as books after undergoing some editorial process. A majority of ergonomics research laboratories and centers produce internal reports of their own work, including annual reports, which they make available, usually on request, to people outside their organizations, provided there are no issues of confidentiality. Such reports enable the readers to appreciate the areas in which the various ergonomics centers specialize as well as to get more detailed information on specific projects that could not be obtained from journals or proceedings. There are now numerous publicly available standards documents (International, European, and National) on several aspects of ergonomics.

The intention here is to provide a comprehensive list of the publicly available literature in respect of journals, books, and proceedings. Because of the multidisciplinary nature of ergonomics, it is naturally difficult to be confident on what should and what should not be included in the list. However, there can be no doubting the relevance of topics such as human–computer interaction, health and safety, and job design. Hence, these areas are well represented in the list.

It is important to emphasize that in compiling the list no judgements have been made on the quality of the publications. The extent that the material has been peer reviewed has already been mentioned. If there are any obvious omissions in the list, I can only apologize.

Finally, it is important to point out that increasingly both journals and conference proceedings are being offered in electronic formats to the extent that some proceedings are often no longer available in a traditional hardcopy format. Currently, many of the main publishers are offering their journals on-line, while proceedings are appearing both in on-line and CD-ROM formats.

2. JOURNALS

These have been divided into five groups:

Primary ergonomics journals

Applied Ergonomics (Amsterdam: Elsevier)

Ergonomics (London: Taylor & Francis)

Ergonomics Abstracts (London: Taylor & Francis)

Human Factors (Santa Monica, California: Human Factors and Ergonomics Society)

International Journal of Industrial Ergonomics (Amsterdam: Elsevier)

Theoretical Issues in Ergonomics Science (London: Taylor & Francis)

Other ergonomics journals

Ergonomia (Italy) (Milan: Moretti Vitali Editori)

Ergonomia (Poland) (Krakow: ORPAN)

Ergonomics Australia (Downer, ACT: The Ergonomics Society of Australia)

Ergonomics in Design (Santa Monica, California: Human Factors and Ergonomics Society)

Ergonomics SA (Grahamstown, SA: Ergonomics Society of South Africa)

Human Factors and Ergonomics in Manufacturing (New York: John Wiley)

3. BOOKS

These have been grouped under the headings shown below. Naturally, the headings are not mutually exclusive. Accordingly, the books have been classified under the heading which most closely reflects their primary contents.

General ergonomics

Human characteristics and performance

Anthropometry

Ageing and disability

Workplace, equipment, and product design

The physical environment

Display and control design

Human–computer interaction

Complex systems

Transport systems

Musculoskeletal injuries and manual materials handling

Health and safety

Human error and reliability

Job design and work organisation

Impact of information technology

Methods, techniques and measurement

4. PROCEEDINGS

Advances in Industrial Ergonomics and Safety (London: Taylor & Francis).

Advances in Occupational Ergonomics and Safety (Amsterdam: IOS).

Analysis, Design and Evaluation of Man-Machine Systems (Oxford: Pergamon).

Australasian Computer Human Interaction Conference: OZCHI Annual Conference (Piscataway, New Jersey: IEEE Computer Society).

Aviation Psychology International Symposium (Columbus, Ohio: Ohio State University).

Cognitive Science Approaches to Process Control Conference (various publishers).

Engineering Psychology and Cognitive Ergonomics (Aldershot, Hampshire: Ashgate Publishing).

Ergonomics for Global Quality and Productivity (Hong Kong: Hong Kong University of Science and Technology).

Enhanced Safety of Vehicles International Technical Conference (Washington DC: National Highway Traffic Safety Administration).

Ergonomics Society Annual Conference, UK (London: Taylor & Francis).

Ergonomics Society of Australia Annual Conference (Downer, ACT: Ergonomics Society of Australia).

Ergonomics Society of New Zealand Conference (Palmerston North: New Zealand Ergonomics Society).

Ergonomics Society of South Africa Annual Conference (Ergonomics Society of South Africa).

European Conference on Cognitive Ergonomics (ECCE) (various publishers).

Human Aspects of Advanced Manufacturing and Hybrid Automation (Amsterdam: Elsevier, and Santa Monica, California: IEA Press).

Human–Computer Interaction International Conference (Amsterdam: Elsevier).

Human Decision Making and Manual Control Conference (various publishers).

Human Factors Association of Canada Annual Conference (Mississauga, Ontario: Human Factors Association of Canada).

Human Factors in Computing Systems Conference (Amsterdam: North-Holland, and Reading, Massachusetts: Addison-Wesley).

Human Factors and Ergonomics Society Annual Meeting (Santa Monica, California: Human Factors and Ergonomics Society).

Human Factors in Manufacturing International Conference (various publishers).

Human Factors in Organizational Design and Management (Amsterdam: Elsevier).

Human Factors in Telecommunications International Symposium (various publishers).

IEEE Conference on Human Factors and Power Plants (New York: Institute of Electrical and Electronic Engineers).

IFIP International Conference on Human–Computer Interaction: INTERACT (Amsterdam: Elsevier, and London: Chapman & Hall).

Interface, HFES Consumer Product Technical Group Conference (Santa Monica, California: Human Factors and Ergonomics Society).

International Ergonomics Association Triennial Congress (various publishers).

Pan-Pacific Conference (various publishers).

People and Computers, British Computer Society Human Interaction Specialist Group (Cambridge: Cambridge University Press).

PSAM: International Conference on Probabilistic Safety Assessment and Management (various publishers).

RESNA Annual Conference Association for the Advancement of Rehabilitation Technology (Arlington, Virginia: RESNA Press).

SAFE Association Annual Symposium (Nashville, Tennessee: SAFE Association).

Silicon Valley Ergonomics Conference - ErgoCon (San Jose, California: Silicon Valley Ergonomics Institute, San Jose State University).

Society of Information Display Symposium (Santa Ana, California: Society for Information Display).

Trends in Ergonomics/Human Factors (Amsterdam: Elsevier).

Vision in Vehicles (Amsterdam: Elsevier).

Visual Search (London: Taylor & Francis).

Wearable Computers International Symposium (Piscataway, New Jersey: IEEE Computer Society).

Work with Display Units (Amsterdam: Elsevier).
