In a study involving 23 countries (USA, Yugoslavia, Thailand, Spain, Singapore, Saudi Arabia, Poland, North Ireland, Mexico, Kenya, Japan, Italy, Israel, Indonesia, India, Hungary, Greece, Germany, Egypt, Czechoslovakia, Belgium, Australia, Argentina), Weil and Rosen (1995) found that many countries showed a majority of technophobic students while others showed very few technophobes. CE was negatively related to technophobia in the majority of country samples. A Discriminant Function Analysis measure and a composite technophobia score were sufficient to provide maximal discrimination between the 23 country samples.

Dyck *et al.* (1998) administered the CAS (Marcoulides 1989) to 311 younger and 324 older subjects, and found that the construct of computer anxiety may have changed, since they found two factors (direct and indirect involvement with computer). These were different from Marcoulides' (1989) two factors (general CA and equipment anxiety), but similar to the first two factors of Rosen and Weil (1995) (interactive computer learning anxiety and observational computer learning anxiety), while items consisting of "consumer technology anxiety" factor were not included in their study.

Nine thousand people from eight countries (France, Germany, England, Italy, Norway, Spain, USA, Japan) were surveyed for their opinions concerning computers, with particular emphasis on the impact of technology in the workplace (Vine 1985). "There are very great differences in country attitudes toward information technology. These differences reflect a whole range of cultural attitudes and the data must be interpreted with that in mind" (cited by Rosen and Weil 1995: 46). Omar (1992) indicated that the US college students' ATC were more positive than those of Kuwaiti students.

Combined with other mixed features concerning CA and ATC from other studies, further study needed. There were several other studies conducted in countries other than the USA (see Weil and Rosen 1995 for a short review), but the results of these investigations do not permit direct cross-cultural comparisons due to the use of different measurement instruments and different research designs.

5. THEORY AND INTERVENTION

In overcoming the negative effect of CA and, even more importantly, preventing it from developing, specialized user training is essential. Several models were proposed to explain the phenomenon and to develop the intervention program (see Rosen, Sears and Weil 1992 for a short review, Maurer 1994, Todman and Monaghan 1994). Treatment should be in accordance with the different type and degree of CA in the population or culture. Individual computer training has proved quite effective in the prevention and cure of computer discomfort. Schoolteachers may be the ones with the power to change that trend, because the attitude of the technology "introducer" was important in predicting later psychological reactions to computers. Individuals' computerphobia problems can be resolved within time (from 5 h to 2 years) and users can approach technology in a confident manner (Russell and Bradley 1996). Programming resulted in the lowest degree of CA and increased problem-solving (Liu 1997) compared with general CL instruction.

6. DISCUSSION: CROSS-CULTURAL STUDY ON CA

Most of studies focused on the diagnostic issues of CA (measurement development and effect of related variables investigation); others focused on the intervention in practice, while very few have proposed theoretical models. Unfortunately, "much of the related studies is significantly flawed and making it difficult to support any particular claim" (Maurer 1994: 369).

Fear of technology has been a human concern for hundreds of years, and discourse on this has been firmly embedded in a culture that simultaneously embraces and rejects machines. Technophobia is not only a consequence of the competition of machines, but also is a cultural construct. Such a kind of fear was apparently improved given the much higher capacity and intelligence of the modern computer. A fear of computers has complex cultural and historical antecedents. When students enter a course of teacher training they bring with them a set of values and attitudes towards technology that will partly determine their approach to computers in education. Only through an examination of cultural and historical antecedents concerning fears of technology can student teachers' anxiety about computers be properly understood (Russell and Bradley 1996). Teaching the myths can teach CA to people, although the validity of common myths may varied in different culture (Rosen and Maguire 1990, Yeamen 1993).

Wording changes can make significant differences in the factor structure of scales and item validities. This should be investigated under more subject groups for checking the stability of earlier inference and conclusion, and for providing reliable measures for the future study. Strict procedure (double blind and back translation) should be applied when translating measures to another language for cross-cultural comparison.

CA is definitely implicated in performance (Anderson 1996). The extent to which CE and CA influence one's willingness to use a computer may depend upon the task to be accomplished with the computer. For the sake of comparability between studies and to stabilize the conclusion, on one hand a more clarified definition between the characteristics of task and required skills should be given, and on the other hand the possible effective but uncontrolled variables should be given more attention.

Nearly every segment of society is at risk for computerphobia. This were proved by the fact that technophobic students were less interested than non-phobic students in any form of computer interaction, both in their personal lives and in their academic careers, despite their age (old/young), ethnic (Asian/black/Hispanic/white), major (social science/humanities/business/science) and experience (have/have not). Most of the CA studies were conducted in Western countries, especially in the USA. Many studies used a certain and often small number of subjects, typically those enrolled for a psychology course. This induced less control to the variables like gender, age, education, academic major, profession or culture. It is obvious that the generalization of cross-cultural comparison can only based on a certain number of subjects that can represent the population in a given culture with respect to both demographic and cultural variables.

More carefully defined research questions and treatment should be used to answer larger questions (Maurer 1994). The differences between results imply the need to explore all these variables within a broader model encompassing a range of computer variables, rather than by studying each variable in isolation (Levine and Donitsa-Schmidt 1998).

This chapter is one part of an extensive review on studies of CA in the 1990s, which is beyond the limited space here. Further study needs to be made on the theoretical background with respect to the related variables and mechanisms, at both personality and cross-cultural level. Cultural specific intervention or coping strategy to CA should be developed. The fast population of NII and related computer technology may have an effect on CA by affecting experience, education, cognition and CU, etc.

7. CONCLUSION

As a phenomenon with as high as 33% morbidity rate in the population, CA attracted attention of researchers. Two decades of studies have accumulated findings that have led to a clearer understanding about CA and its effect on CU than ever before. The quality of CE and introducers' ATC are important to current CA. A treatment program has been developed and practiced successfully for > 10 years, but only in Western cultural settings. Given the more and more popular of CU at home, class, office (either intuitively or passively), CL is becoming a basic requirement for today's job seeking. The CA (or technophobia more generally) will be the key issues among educators, employers and business people in all cultural settings. However, systematic developing and validating of measures through carefully manipulating demographic and cultural variables are rare.

Cybersickness in Virtual Reality

K. M. Stanney† and R. S. Kennedy‡

1. INTRODUCTION

Motion sickness is familiar to most individuals. A common experience while sitting in a car or plane is suddenly to feel like you are moving as the vehicle beside your stationary plane or car starts backing out. This can lead to a somersault sensation in the stomach or to a sense of postural instability. Another familiar problem is for a person to experience, at times being severe and long-lasting, sickness when attempting to read in a car. While the consequences of these two experiences are oftentimes similar sensations of motion sickness, this common outcome is rendered by quite different sensory conflicts. In the first instance the vestibular system senses that the person is physically stationary but the visual system senses motion as the adjacent vehicle moves. In the second instance the vestibular system senses that the person is physically moving in the vehicle while the visual system indicates non-motion as the stationary reading matter is viewed. The motion sickness experienced in virtual environments (VE) can be of either type but is more commonly of the former, where the visual system senses motion without corresponding stimulation of the vestibular system. More specifically, when one dons a head-mounted device, one is often inundated with a plethora of visual stimuli that indicate motion throughout a virtual world. Yet, there is oftentimes a lack of concordant physical motion to stimulate the vestibular system. Thus, a sensory conflict occurs between what one sees as motion and what one feels as non-motion. Such sensory conflicts are thought to lead to motion sickness. This sickness can be of many forms, including cerebral (e.g. headache), gastrointestinal (e.g. nausea, burping, emesis), psychological (e.g. anxiety, depression, apathy) and other less characteristic indicators of motion sickness such as fullness of the head (Kennedy *et al.* 1993).

2. TYPES OF MOTION SICKNESS

Sensory conflicts have been used formally to classify motion sickness into three main types (Reason 1978). The first presents conflicting signals A and B together, such as if a VE system were to be used on a ship for training or entertainment purposes. In this case the true bodily motions as influenced by the ship would not correspond to the virtual motion of the individual throughout the virtual world. The second type of sickness occurs when signal A occurs in the absence of signal B and was exemplified above by the airplane scenario. The third type involves signal B occurring in the absence of signal A, of which the car reading example was representative. This type of mismatch could occur in a VE that had a motion-base where a user was looking at instrument panels (e.g. "flying" on instruments only) and had no visual motion

stimulation to correspond to the vestibular stimulation provided by the motion-base.

Why do these sensory conflicts lead to motion sickness? Reason (1978) suggests that the conflicts that arise between the sensory signals of the body, eye and image as compared with those conditioned by past experiences are an inherent characteristic of all forms of motion sickness. The degree of sickness experienced is generally proportional to the severity of the sensory discordance. Through continued exposure to, and particularly interaction with, a displaced environment the plasticity of the human sensory system allows humans to adapt to the new stimuli. This adaptation will then allow the individual to perform effectively in the displaced environment. This can, in turn, lead to after effects when an individual returns to normal conditions, such as on terminating exposure to a virtual environment. In this case the individual, whose functioning was modified to accommodate the virtual world, may be compromised for a period of time when returning to the "real" world. These after effects, which can take the form of balance and visual disturbances or displaced hand–eye coordination, can present safety concerns.

3. INDIVIDUAL AND TECHNOLOGICAL FACTORS INFLUENCING MOTION SICKNESS

There is concern that continued development of VE technology may be compromised by the presence of these maladies and safety concerns, often referred to as "cybersickness". As much as 95% of those exposed to VE systems experience some level of discomfort and ~15% of those exposed must curtail their exposure, some to as little as 10 min. While there is no definitive determinant of who will become ill, age, gender, motion sickness histories, prior experience and individual factors have been shown to be useful in identifying persons who are susceptible to provocative motion environments (Stanney *et al.* 1998). With the high incidence rate and diversity of individual factors contributing to cybersickness, the practicality of screening for susceptibility is compromised. Thus, developers often look to technological solutions. Means of assessing the strength of a VE stimulus (i.e. how likely it is to cause cybersickness and after effects) are currently not available but there are several contributing factors that have been identified including update rate, lag, system consistency, mismatched interpupillary distance, field-of-view and spatial frequency content. While the contribution of many of these variables to cybersickness has been evaluated, to date there are no definitive technological solutions.

4. MEASURING CYBERSICKNESS

Systematic means of measuring cybersickness are needed to facilitate the development of technological or adaptive countermeasures (Stanney *et al.* 1998). It is important for developers of VE systems to determine if there will be after effects from the use of their systems and what percentage of the user population will be affected. The most common form of measurement is subjective self-report of symptomatology after exposure. Another form is objective measurement of physiological adaptation of the vestibular, visual and proprioceptive systems.

4.1. Subjective Measures

The Simulator Sickness Questionnaire (SSQ) (Kennedy *et al.* 1993) is the most commonly used tool to assess subjective symp-

tomatology from VE exposure. The SSQ consists of a checklist of 26 symptoms, each of which is designated in terms of degree of severity (none, slight, moderate, severe), with the highest possible total score being 300. A weighted scoring procedure is used to obtain a global index, known as the Total Severity (TS) score, which reflects the overall total discomfort level, as well as scores along three subscales (i.e. nausea, oculomotor disturbances, disorientation). By means of these subscales cybersickness can be more fully characterized. The average SSQ score for HMD-based VE systems is ~29 (with a range over several different VE systems of 19–55) on the TS scale (Stanney *et al.* 1998). In general, VE users report nearly 2.5 times more sickness after exposure than do users of military flight simulators and nearly twice more than astronauts during space travel. The first impulse might be to attribute these severity differences solely to susceptibility differences between the select military and space flight individuals as compared with the general population. An examination of the profile of SSQ symptoms engendered by these systems, however, indicate some interesting differences in symptomatology (Stanney *et al.* 1998). VE systems using HMD generally tend to produce more disorientation (D) than neurovegative (N) symptoms, and least of oculomotor-related (O) disturbances. This D > N > O profile does not match the profiles of either simulators (i.e. O > N > D) or space flight (i.e. N > D > O). Thus, VE systems tend to engender both a greater severity, as well as a different profile of symptoms as compared with other provocative environments. Means of managing these ill-effects are thus essential if VE technology is to fulfill its potential.

4.2. Objective Measures

Objective measures of after effects from VE exposure include measuring postural equilibrium (i.e. sway magnitude), adaptation of the vestibulo-ocular reflex (i.e. the ability to stabilize an image on the retina), changes in the kinesthetic position sense (i.e. hand–eye coordination), visual functioning (i.e. visual acuity, heterophoria, near point of convergence, amplitude of accommodation), as well as changes in EEG, salivary cortisol composition, and heart rate levels and variability (Stanney *et al.* 1998). These measurement approaches could be used both to determine if a user has adapted physiologically during VE exposure and to determine at what point the effects have dissipated after exposure. It may also be possible to take several of these measures during VE exposure, and to determine the relative sequence of physical versus subjective effects. This might permit development of on-line measures that could be used to predict and minimize sickness during interaction with a virtual environment.

While sickness as measured by the SSQ and objective measures of after effects are usually statistically increased after exposure, correlations between these measures are generally insignificant (Stanney *et al.* 1998). This implies that to characterize comprehensively cybersickness it is necessary to obtain both types of measures. Once cybersickness can be accurately measured, efforts to manage this malady can be implemented.

5. MANAGING CYBERSICKNESS

Currently, probably the simplest way to control for the problems associated with cybersickness is to institute usage protocols. Both exposure duration and number of repeat exposures have been shown to affect the level of motion sickness experienced by users,

with sickness increasing with duration and decreasing across repeated exposures (Stanney *et al.* 1998). Based on studies in our laboratory we have found that if exposure is limited to < 10 min ~95% of the population should endure exposure. Further, if short duration repeated exposures are provided, with a 2–7-day intersession interval, tolerance should be extended by the fourth to sixth exposure. Unfortunately, repetition may not be an efficient or practical means of adaptation because the time required for re-adaptation to one's normal environment is proportional to the time spent in adapting to the virtual world (Baltzley *et al.* 1989). Thus, if an individual must undergo numerous exposures to a VE to achieve adaptation a considerable amount of time may be necessary for re-calibrating to normal functioning once the exposure ceases. In many operational settings this may not be viable. Also, when used for entertainment purposes users may not have the opportunity for repeated exposure to the same virtual environment. The goal, therefore, should be to achieve adaptation in as little time as possible, while attempting to lessen the severity of the initial sickness experienced by users. This may be achieved through easing user interaction. Means of easing VE interaction include streamlining the degrees of freedom through which VE users can move about the virtual world, blanking the visual stimulus and manipulating image abstractness (Stanney *et al.* 1998). To ease interaction, tasks requiring high rates of linear or rotational acceleration and extraordinary maneuvers (e.g. flying backward) should be avoided during early exposure. Blanking involves graying-out a head-mounted display above a threshold level of head velocity, which selectively eliminates the effect of visual update delays during head movements. The degree of abstractness of virtual images can be manipulated through the use of polygonal versus texture gradients. In general, the greater the abstractness the more severe the sickness experienced. It is important to note that reducing the information content of a VE, either through blanking, manipulating abstractness, or other means, may compromise task performance such as the ability to detect direction of heading, steer effectively or make precise judgments of impeding arrival or collision in VE settings. Any changes in the information content targeted at reducing cybersickness must thus be balanced against removing the information that users would ordinarily rely upon for accurate judgments.

As tolerance is gained through repeated exposures or interaction techniques and exposure duration is extended, after effects may become more prevalent. Thus, before the identification of technological solutions that minimize after effects a means of managing after effects must be identified. The best way to eradicate VE after effects is to require users who have just exited the VE to engage in the same activities performed within the VE, but without the sensory conflicts imposed by the VE (Stanney *et al.* 1998). This should provide users with the opportunity to readapt their functioning to their natural environment by "unlearning" the adaptation they acquired in the VE (see the sensory rearrangement research of Welch 1978).

6. CONCLUSIONS

The cybersickness associated with VE technology is characterized by sickness and discomfort during or after VE exposure, postural, visual and coordination disturbances upon post-exposure, and interference with performance within the VE or on other tasks afterwards. While it is undeniable that some individuals

experience some after effects within some VE systems, it is not necessarily the case that VE technology is implicitly harmful. Careful consideration of individual and technological factors, usage protocols and design of VE interaction techniques may minimize any potential for sickness or harm. The contributions from ergonomics and human factors practitioners will be of particular relevance in addressing the multiplicity of human issues central or related to cybersickness in virtual environments.

Databases for Psychophysically Acceptable Maximum Weights and Forces in Manual Handling Tasks Developed by Liberty Mutual

W. Karwowski and R. Jang

Center for Industrial Ergonomics, University of Louisville, Louisville, KY 40292, USA

1. BACKGROUND

Over the past 30 years Dr S. Snook and colleagues have performed numerous studies of human capabilities in the performance of manual handling tasks using the psychophysical approach (Snook and Irvine 1967, Snook *et al.* 1970, Snook 1971, 1978, 1987, Snook and Ciriello 1974, 1991, Ciriello and Snook 1978, 1983). This research resulted in development of the comprehensive databases for evaluation and design of manual handling tasks in terms of the maximum acceptable weights (MAW) and forces for lifting, lowering, pushing, pulling, and carrying tasks.

The databases presented here are based on integration of the results of several experiments that utilized the psychophysical methodology, along with measurements of oxygen consumption, heart rate, and consideration of the human anthropometric characteristics (Snook and Ciriello 1991). All of the experiments were conducted in an environmental chamber, with the dry bulb temperature of 21°C and relative humidity of 45%. The studies employed industrial workers who were instructed to work on an incentive basis, working as hard as they could without straining themselves, or without becoming unusually tired, weakened, overheated or out of breath.

2. SCIENTIFIC BASIS FOR THE DATABASES

The presented databases are based on a sample size of 119 participants (68 males, 51 females) who participated in the experiments for a minimum of 10 weeks. The original tables (Ciriello and Snook 1983) were based on a sample of 57 particpiants (42 males, 15 females).

The presented databases are based on the series of studies addressing the following issues:
- Effect of task frequency on the maximum acceptable weights and forces (Ciriello and Snook 1983).
- Female responses to the object size (width), vertical distance of lift, and height of push/pull (Ciriello and Snook 1983).
- Effects of task duration on the maximum acceptable weights and forces and a combination task, consisting of a lift, carry, and lower, performed separately and in combination (Ciriello *et al.* 1990).

- Effects of using box handles, and lifting with the extended horizontal reach, on the MAW values at different frequency and height of lift (Ciriello *et al.* 1991).
- Effect of different box sizes for carrying tasks, and a longer distance (15.2 m), for the pulling task.

To complete the developed databases several assumptions were made to in order to approximate the values of response variables for the task conditions that have not been studied experimentally (Snook and Ciriello 1991). The databases include six distances for the pulling tasks, and the pushing and pulling frequencies that are the same for both males and females. It was noted that some of the weights and forces in tables exceed recommended physiological criteria when performed continuously for 8 h or more.

According to Snook and Ciriello (1991), the revised databases represent the best estimates of maximum acceptable weights and forces for industrial workers, and are intended to help industrial practitioners in the evaluation and design of manual handling tasks. As such, these databases should contribute to the reduction of disability from low back pain, and help in the evaluation of disabled workers in rehabilitation programs (Snook 1987).

W: Box width (the dimension away from the body) (cm).
D: Vertical distance of lift (cm).
P: Percentage of industrial population.
Italicized values exceed 8 h physiological critiera.

Table 2. Maximum acceptable weight of lift for females (kg); from Snook and Ciriello (1991).

W: Box width (the dimension away from the body) (cm).
D: Vertical distance of lift (cm).
P: Percentage of industrial population.
Italicized values exceed 8 h physiological critera.

Table 4. Maximum acceptable weight of lift for females (kg); from Snook and Ciriello (1991).

W	D	P	Floor level to knuckle height — One lift every								Knuckle height to shoulder height — One lift every								Shoulder height to arm reach — One lift every

Databases for Psychophysically Acceptable Maximum Wrist Torques in Manual Tasks for Females Developed by Liberty Mutual

W. Karwowski and R. Jang

Center for Industrial Ergonomics, University of Louisville, Louisville, KY 40292, USA

1. BACKGROUND

Snook *et al.* (1995) used the psychophysical approach to determine maximum acceptable forces for various types and frequencies for repetitive wrist motion, grips, and repetition rates that would not result in significant changes in wrist strength, tactile sensitivity, or number of symptoms reported by the female subjects.

A total of 29 paid subjects participated in the study (the number of female subjects for experiments 1 and 2 was 15 and 14 respectively). All participants were instructed to work as if they were on an incentive basis, getting paid for the amount of work they performed. They were asked to work as hard as possible without developing unusual discomfort in the hands, wrists or forearms.

The reported soreness, stiffness and numbness symptoms were recorded every hour by indicating the intensity of each symptom on a scale of 0–3 at a given body location where each symptom occurred.

2. DATABASES

Three levels of wrist motion were used: (1) flexion motion with a power grip, (2) flexion motion with a pinch grip, and (3) extension motion with a power grip. The dependent variables were the maximum acceptable wrist torque, maximum isometric wrist strength, tactile sensitivity and symptoms. Experiment 1 utilized exposure of 2 days per week, while experiment 2 utilized 5 days per week.

The maximum acceptable wrist torque (MAWT) was defined as the number of Newton-meters of resistance set in the brake by the participants (averaged and recorded every minute). The maximum isometric wrist strength (MAWS), a measure of maximum voluntary contraction (MVC), was recorded in Newton-meters of torque with the handle fixed in the horizontal position (maximum exertion over 5 s).

3. DATABASES
3.1. Two Days per Week Exposure

Experiment 1 utilized exposure of 2 days per week. The maximum acceptable wrist torque for each repetition, rate and type of motion, as well as the combined means and standard deviations for each type of motion (regardless of the repetition rate), and for each repetition rate (regardless of the type of motion) are

Table 1. Maximum acceptable torque (Nm) (two days per week exposure); from Snook *et al.* (1995)

		Repetition rate					
		2/min	5/min	10/min	15/min	20/min	combined*

presented in Table 1. The maximum isometric wrist strength and tactile sensitivity for each type of motion and repetition rate are shown in Tables 2 and 3. The symptom data are presented in Tables 4–6. The results for each hour during the day are presented in Table 4 for all dependent variables (regardless of the repetition rate and type of motion).

3.2. Five Days per Week Exposure

Experiment 2 utilized exposure of 5 days per week. Here, in addition to the four dependent variables measured in the 2 days per week exposure, the performance errors and duration of force were also measured. The results for each of the six dependent variables are shown in Table 5. The results for each hour during the day (across all days of exposure) as well as the significance

Table 4. Hourly results (two days per week exposure); from Snook et al. (1995).

	Hour

Exten: Extension with power grip

testing for maximum acceptable torque, tactile sensitivity and duration of force are shown in Table 6.

4. DATABASE EXTENSIONS

The data for maximum acceptable wrist torques for the 2 days per week exposure was used to estimate the maximum acceptable torques were estimated for different repetitions of wrist flexion (power grip) and different percentages of the population. This was done by using the adjusted means and coefficients of variation from the 2 days per week exposure. The original torque values were converted into forces by dividing each torque by the average

Table 7. Maximum acceptable forces for female wrist flexion (power grip) (N); from Snook et al. (1995)

Percent of Population	Repetition rate				
	2/min	5/min	10/min	15/min	20/min
90	14.9	14.9	13.5	12.0	10.2
75	23.2	23.2	20.9	18.6	15.8
50	32.3	32.3	29.0	26.0	22.1
25	41.5	41.5	37.2	33.5	28.4
10	49.8	49.8	44.6	40.1	34.0

length of the handle lever (0.081 m). The estimated values for the maximum acceptable forces for female wrist flexion (power grip) are shown in Table 7.

Similarly, the estimated maximum acceptable forces were developed for the wrist flexion (pinch grip; Table 8), and wrist

Table 8. Maximum acceptable forces for female wrist flexion (pinch grip) (N); from Snook et al. (1995)

Percent of Population	Repetition rate				
	2/min	5/min	10/min	15/min	20/min
90	9.2	8.5	7.4	7.4	6.0
75	14.2	13.2	11.5	11.5	9.3
50	19.8	18.4	16.0	16.0	12.9
25	25.4	23.6	20.6	20.6	16.6
10	30.5	28.2	24.6	24.6	19.8

Table 9. Maximum acceptable forces for female wrist flexion (power grip) (N); from Snook et al. (1995)

Percent of Population	Repetition rate				
	2/min	5/min	10/min	15/min	20/min
90	8.8	8.8	7.8	6.9	5.4
75	13.6	13.6	12.1	10.9	8.5
50	18.9	18.9	16.8	15.1	11.9
25	24.2	24.2	21.5	19.3	15.2
10	29.0	29.0	25.8	23.2	18.3

extension (power grip; Table 9). The torques were converted into forces by dividing by 0.081 m for the power grip, and 0.123m for the pinch grip.

Snook et al. (1995) note that the estimated values of the maximum acceptable wrist torque presented in Tables 7–9 do not apply to any other tasks and wrist positions except those that were used in their study.

Design Cognition

M. G. Helander

Nanyang Technological University, Singapore 639798

1. INTRODUCTION

Ever since Herbert Simon's *The Science of the Artificial* (1969), there has been an increasing interest in design research. His expression "The proper study of mankind is the science of design" remains a challenge to ergonomics since ergonomics has not produced much research. Cognitive scientists have performed most of the research on design cognition. This chapter reviews design cognition. It draws from studies of designers, as they were involved in the design of software, architecture or mechanical artifacts.

Much of the research has addressed either *descriptive models* or *prescriptive models* of design. Descriptive models analyze design behavior and cognition. Contrary to what one may believe, design is not a very systematic activity. There are few procedures and no established logic — not even in engineering design. Design work is an activity that is driven by the knowledge and experiences of the designer, and to the outside observer it is a fairly chaotic process. Design is basically an opportunistic activity.

Several prescriptive models have been proposed in engineering research. The purpose is to give structure to design; what should a designer do first and what activities should follow? A good prescriptive model could have many advantageous side effects, such as improved creativity in design solutions and streamlining the communication processes in concurrent design. The aim is to describe prescriptive models and descriptive models in design. Following this description, I will argue that prescriptive models are useful, since they structure not only design activity, but also communication among collaborators in design. Finally there is an overview of the most common research methods in design cognition.

2. PRESCRIPTIVE MODELS OF DESIGN ACTIVITY

Prescriptive models for design is a very large area of research, particularly in mechanical engineering. Since the primary concern of design is to meet the functional requirements of the intended use(r), most design methodologies emphasize functional requirements or user requirements. One of the earliest and most recognized is the Structured Analysis and Design Technique, which was developed by Ross and Schoman (1977) as an aid in software design. SADT was a precursor to object-oriented design. It uses graphical techniques to provide a basic set of primitive constructs from which analysts and designers can compose orderly structures for the system or task to be designed. The system is decomposed top-down in several abstraction hierarchies — from the highest level of System Purpose to the lowest level Components.

Mainly based on the graphic representation of SADT, the US Air Force developed a system, which has become the industry standard: IDEF$_0$ Functional Modeling Methodology. As in SADT, each function in IDEF$_0$ contains inputs (material or information to be processed), outputs (outcome of the processing function), mechanism (resource) and constraints (conditions the function is subject to). At any level of the hierarchy, a function consists of three to six subfunctions, each having the same structure as its parent function. In this way, the graphic model of the hierarchical structure of a system can be decomposed continuously until sufficient details are revealed so that the decomposed tasks become manageable.

Another set of notable development efforts in design theory is the German School of Mechanical Engineering Design. Total Design was presented by Hubka and Eder (1988) and the Systematic Approach by Pahl and Beitz (1988). The methods are similar in that they both partition the design life cycle into four stages: (1) design problem definition; (2) conceptual design; (3) design embodiment; and (4) detail design. Specifying the relationships between functions to be designed and function carriers supports the selection at the conceptual stage.

Suh (1990) introduced Axiomatic Design (AD). This was an attempt to develop a design methodology, which specifies a complete set of functional requirements at the early stages of design. With its clear and strong emphasis on Customer Needs, AD offers a systematic approach, which is particularly well suited to design problems in ergonomics.

2.1. Use of Abstraction Hierarchies, Functional Requirements and Design Parameters

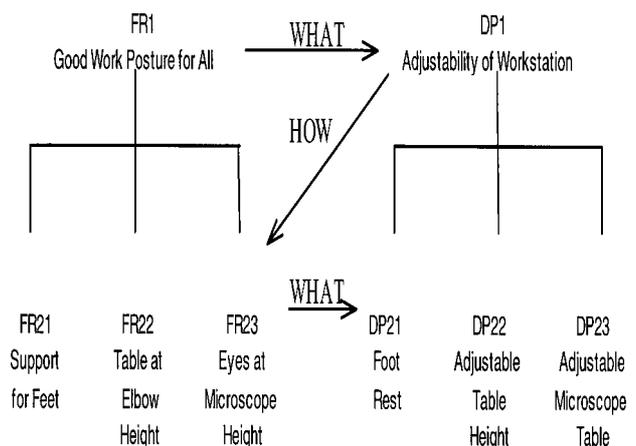
According to Jens Rasmussen any system can be described using at the most five levels of abstraction: purpose, abstract function, generalized function, physical function and physical form. Figure 1 illustrates the design of an ergonomic workstation. Two levels of abstraction are illustrated. The top level is the "Abstract Function" and the lower level is the "Generalized Function." For each abstraction level functional requirements (FR) and corresponding design parameters (DP) are formulated. The FR for the two levels is (a) FR1 and (b) FR21, 22 and 23. Corresponding DP are (a) DP1 and (b) DP21, 22 and 23. Note that for each FR there is only one corresponding DP; DP1 corresponds to FR1, DP21 to FR21, etc. To arrive from FR1 to DP1 one asks the question WHAT. In other words, what type of design parameter DP1 would fulfill FR1.


Figure 1. Use of functional requirements (FR) and design parameters (DP) in ergonomics design. There are two levels of abstraction. DP is derived from FR and FR at the lower level from a combination of DP and superordinated FR.

DP1 is then expanded at the lower level into three FR: FR21, 22 and 23. Considering the combination of the requirements stated in FR1 and DP1 derives this expansion. DP21, DP22 and DP23 are then derived from respectively FR21, FR22 and FR23 considering the constraining effect of DP1.

The structured, top-down approach does simplify design work, since the design parameters at the lower levels are easier to identify. Yet, the search for solutions at higher levels of abstraction will still require as much ingenuity as before; design synthesis is not simplified by design procedures.

FR1 could have been satisfied using other design parameters than DP1 — "Adjustability." For example one could have proposed DP1 — "Use standing postures" or DP1 — "Use reclining furniture." In either case there would be totally different design solutions. The choice of DP1 therefore has a constraining effect — once DP1 has been specified many potential design solutions can be ignored (for the better or worse).

Although design synthesis is not simplified by AD, there are other advantages. The functional requirements are emphasized throughout the design work, and the resulting design will be more appropriate and more creative (see below).

Incorporating specifications at the levels FR3 and DP3 can extend the abstraction hierarchy in Figure 1. DP3 would entail a specification of design elements. Corresponding to FR331, 332 and 333, a microscope table has a surface (DP331), legs (DP332) and an adjustability mechanism (DP333). DP4 would specify the materials used in the design. These specifications at the lower level are of interest for manufacturing and determine the price of the finished product. Where such details are considered the ergonomist may have to negotiate design solutions in a concurrent engineering team. All members of the design team must then consider benefits and costs of adjustability, and expensive propositions are traded off against less costly design solutions.

To summarize:

- Design problems are partitioned in an abstraction hierarchy, with discernable input and output.
- Most design methodologies analyze user requirements or customer needs in order to generate a design that satisfies the functions of the intended use.
- To realize both the functionality and the ergonomic aspects of a design, a consistent mapping from user requirements to final design is indispensable.

3. DESCRIPTIVE MODELS OF DESIGN

Designers rarely use systematic top-down design analysis and synthesis, as described in the previous section. Below I will explain why this is the case. I will then propose that it would be a good idea deliberately to impose a top-down design procedure — at least for some types of design.

Several researchers have investigated the problem-solving behavior of designers (Guindon, Helander, Rasmussen). The common conclusion is that designers jump back and forth between abstraction levels driven by their associations and opportunities for problem-solving. Typically a designer may be working with a specific subproblem. She may then have an association related to another subproblem. As a result she will abandon the original subproblem and devote herself to the new subproblem. The alternative would be to take a note about the association and return at a later time. According to Guindon

(1990) this would imply too much trouble. We are reminded of Simon's parable: The complex path of an ant traversing a beach does not reflect complex behavior, rather the complex environment — and the short legs (author's addition). Likewise with design. The complex behavior is not because of complex goals and complex design procedures, but because of the interactions with colleagues and the limitations of the short-term memory. This will lead to situated cognition, with frequent reformulation of goals and constraints. Design solutions may thus be driven by social and mental constraints of the designer, rather than by design logic.

Associations drive the designer and Raymonde Guindon characterized design behavior as opportunistic — rather than systematic. Opportunistic behavior may, however, have detrimental effects on the quality of design. As mentioned, designers may be better off following a top-down design procedure.

Goel and Pirolli (1992) noted several strategies that designers adopt in problem formulation and generation of solutions.

- *The problem is better understood as the solution emerges*
  Designers often explore the problem-and-solution together. Chuck Eastman at Carnegie Mellon University noted that architects instead of generating functional abstractions first generated a design element through sketching and drawing and then determined the implications. The nature of the problem emerges as proposed solutions are examined.
- *The reluctance to discard a design proposition and start anew*
  One problem in engineering design is that premature solutions are adopted. Engineers must be encouraged to abandon the first design and produce alternatives. This helps in staking out the design space and fully understand different trade-offs in design solutions.

As Heckel (1984) noted: "If Ernest Hemingway, James Michener, Neil Simon, Frank Lloyd Wright, and Pablo Picasso could not get it right the first time, why should a designer?" Frank Lloyd Wright noted that the two most important tools an architect has are the eraser in the drawing room and the sledgehammer at the construction site.

However, even when designers encounter severe problems there is a considerable effort to make the initial idea work, rather than to stand back and adopt a fresh point of departure.

- *To arrive at design solutions designers change goals and impose additional constraints*

A design problem is often ill defined or only partially defined (Goel and Pirolli 1992). Many of the design requirements emerge during the design process — new goals are added and new constraints emerge.

Goals and constraints are often not sacrosanct. Many goals are negotiable, such as performance goals and safety goals. Designers understand that additional information must be added in order to generate and justify design solutions. Particularly at the low levels of the abstraction hierarchy, there are often missing constraints, such as geometrical form or color.

Waldron and Waldron (1988) noted in engineering design that "the premises that were used in initial concept generation often proved, on subsequent investigation, to be wholly or partially fallacious. Nevertheless, they provided a necessary starting point. The process can be viewed as entirely self-

correcting, since later work tends to clarify and correct earlier work."

Some researchers claim that design is merely a process to identify constraints. Given all the possible design solutions in a design space, constraints have the valuable property of reducing the design space. Constraints occur at different levels of the design hierarchy: The truck must be able to transport 50 tons (high level) The truck must be yellow (low level). The implicit knowledge of "what not to do" simplifies the design task, but it does not solve the problem in proposing good design solutions.

4. DESIGN CREATIVITY

Creative design is of great economic interest to industry, and has inspired many publications particularly in management and economics. This literature is largely phenomenological. Many procedures are proposed with the intention that they will enhance creativity in groups as well as individually. There are good reasons to be critical to many of these propositions (Finke *et al.* 1992). Designers with extensive experience and knowledge (a rich associational network) create good design and by individuals who possess certain cognitive abilities, which makes it easier to design. Individuals with long experience and knowledge have a greater base for associations, which is necessary for creative design.

According to Donald Norman successful design is driven by a rich set of associations which is coupled to a rich set of emotions. Creativity in design is not a logical undertaking — it is driven more by emotional processes. Philip Johnsson-Laird (1993), a noted researcher in artificial intelligence, pointed out that the emotional and associational nature of design is why artificial intelligence may not succeed. It would be impossible to program the millions of associations of a human designer, and such information would be necessary for creative design. Artificial intelligence will have to resort to common or simple solutions.

In addition to knowledge and experience Fricke (1996) suggested that some cognitive abilities are particularly important; spatial imagination and heuristic competence. The latter refers to the ability of a designer to plan her activities for new types of problems, to recognize subproblems and place them in a correct order of importance. Other factors of importance include the ability to produce sketches and drawings in problem-solving and the level of motivation for design problem-solving.

4.1. Importance of Top-down Procedures for Creative Design

Several researchers have pointed to the importance of adopting top-down procedures in design. Finke *et al.* at Texas A&M University conducted a series of experiments of factors that enhance creativity. Their recommendation is summarized as follows: in designing a new product the designer should dwell at the higher levels of abstraction as long as possible. The designer should formulate the purpose and the top functional requirements and design parameters. Then reformulate them a few times. Any temptation to be sidetracked by associations at the lower levels of the abstraction hierarchy should be avoided. Out of this focus on higher level goals will follow creative design.

It is detrimental to good design if designers in a concurrent team are drawn into discussions of "How it was done last time," such as materials that were chosen, machines that were used in manufacturing, esthetic form and the types of fasteners that were used. These aspects are irrelevant at the early stages. Besides they will eventually follow, once the design formulations at the higher level have been settled. I once observed a design team getting sidetracked by a designer who, without much reflection, offered the statement: "Last time we used spot welding." The ensuing discussion took several hours until one of the team members observed that the team was off track.

Fricke agrees with these recommendations. An experimental study in our own laboratory imposed different procedures for design of displays in an automobile (Caldenfors 1998). Test persons who followed a top-down design procedure and spent much time formulating the top FR and DP produced more creative design as compared with those who did not.

5. TOP–DOWN HIERARCHICAL DESIGN IN CONCURRENT ENGINEERING

One may then conclude that top-down hierarchical design is a process that promotes good design solutions and enhances creative solutions. It seems that these procedures would also be useful in engineering teams. In concurrent engineering several experts such as manufacturing engineers, marketing, electrical engineers, software engineers, human factors engineers, management, industrial design, etc. sit around a table to identify *satisfying* design solutions (Simon 1981). Among the team members there is a give-and-take to identify solutions that can satisfy several different criteria, such as customer needs, low costs, ease of manufacturing, usability, maintainability, etc. Although no research has yet compared different procedures in the concurrent engineering, it would seem that top-down design procedures would be even more important in this case. To be effective, a design team must establish a set of common rules or procedures for their design deliberations, and they may want to keep track of the "level of abstraction" as the discussion proceeds. Not only would this enhance creativity but it would also minimize mis-communication between team members.

5.1. Web-based Design

Web-based design will be common in the future. Here team members may be selected from various parts of the world based on their expertise and expected to interact on the web. If concurrent engineering is difficult around a common table, web-based design will be even more difficult.

There is a great need to establish procedures for web-based design. This would include using a moderator in the design team, who can take notes and monitor the level of abstraction and inform team members when they get off track. There is also a need to communicate sketches and drawings, which enhance communication between team members.

6. NEED FOR SKETCHES AND DRAWINGS

It is common practice to differentiate between "language-like" and "picture-like" representations and to assign them to different cognitive functions. During design work the designer will encounter both. The design brief is usually given as verbal document, but the output of the process is a set of documents including both words and figures.

Several researchers have investigated the needs for sketches and drawings. The conclusion is that designers often need to

make sketches by hand, which seems to clarify thought processes. Sketches develop slowly and support the step-wise progress in thinking about a design. Goel and Pirolli (1992) concluded that present CAD systems cannot be used for sketches. Their systematic symbolic notations to not promote free thinking and exploration of ideas. Sketches must be drawn by hand!

Sketches and drawings are very important for the concurrent engineering team to promote a common language and communication. The problem is that different professionals refer to design elements using different professional lingo. Visualization helps since team members can simply point at design features — there is no need to name them.

7. RESEARCH TECHNIQUES IN DESIGN COGNITION

Design activity is usually unstructured, and designers improvise as design progresses. Momentary intentions, new associations, modifications of constraints and goals will appear as the work progresses. Given the purpose of the research several different methods can be used to study capture and design activity: experiments, verbal protocols, ethnographic methods, observational studies, and the use of interviews and questionnaires. These methods have different advantages and disadvantages. In many cases they may complement each other.

7.1. Verbal Protocols

To formulate cognitive models Verbal Protocols may be the most appropriate technique. The research could involve the investigation of a specific cognitive skill — to be modeled, then a carefully selected design task, which will allow the skill to be observed and a method for recording performance. Verbal protocols provide richness in data, which makes it possible to study complex interactions, which are common in design. As an example Beth Adelson's (1989) protocol studies showed that designers undertake mental simulations to investigate the appropriateness of design features.

Design is inherently complex, and to use cognitive models it is necessary to select a simple design task. The task must fit the purpose of the investigation.

Yet there are difficulties with verbal protocols; they are typically not complete. Subjects must be taught to verbalize their thoughts. This is not easy; some thought processes are visual in nature and difficult to verbalize. Other thought processes may have become automated and are not available for inspection and verbalization. Finally there are problems in deciding what should be evaluated in the verbal stream of information. Verbal protocols are not easy to use.

7.2. Ethnographic Studies

Anthropologists and sociologists employ ethnographic methods to study people "in the wild," as they go about their everyday activities in offices, homes, schools, or wherever they live (Nardi 1997). The main methods are interviews, observation and participant-observation. The methodology developed in the beginning of this century for the study of Indian Native Americans. The researches will live together with the group and participate in activities in daily life.

Ethnographic studies are time consuming — in the case of Indians it took a year of daily interaction. Ethnographic studies have become increasingly used for design of office tasks and human–computer interaction. For a design task a trained ethnographer could spend about six weeks in the design office. One could, as Bucciarelli (1988), study how engineers communicate in design and how they make decisions. Bucciarelli found, among other things, that > 50% of the working time is used for verbal communication between designers.

Ethnographic studies are qualitative; the results are used to obtain information about structures of knowledge, attitudes and behavior. Once this is understood it may be possible to formulate theories of behavior and cognition. These can then be used for controlled experiments to collect quantitative data and perform statistical testing.

Many researchers are attracted to ethnographic studies because of their "political correctness." Nardi pointed out that ethnography is not an excuse to avoid education in statistical methods. Frequent mistakes are done by untrained "ethnographers," the most common of which is to generalize beyond the study's sample population.

7.3. Experimentation in Design Research

Experimentation has one major advantage over other research methods: it is possible to attribute cause and effect. Ideally a theory should be the basis of experimentation and should dictate the design of the experimental task as well as the selection of test persons. Typically one or several factors (independent variables) are investigated as a function of some dependent variable, and analysis of variance is used to evaluate results. The studies by Finke *et al.* (1992) are prominent examples of this approach. They performed a series of experiments to investigate how creativity (dependent variable) can be enhanced in design. Their conclusions were that designers should focus on the functional requirements at the top levels of the abstraction hierarchy (independent variable).

Three types of dependent variables are used in human factors experimentation:
- Human performance data — time to perform a task and Errors in performing a task.
- Physiological data (e.g. heart rate as indicators of workload and/or stress).
- Subjective data from interviews and questionnaires.

7.4. Observational Studies

Observational studies are often performed in ergonomics. Sometimes they are conducted as experiments; sometimes they are merely observations of a "problem" group. In the first case there could be several experimental groups; for example one group in which test persons are exposed to the experimental variable, and one control group.

Often, however, ergonomists perform simplified studies, and many of them are from a scientific perspective substandard (Helander *et al.* 1984). Frequently data is collected from a problem group, without the use of a comparison group. The results from such so called one-shot case studies can not be interpreted.

8. CONCLUSION

Design cognition may be characterized as a situated cognition. The designer relies on knowledge and experience to propose

appropriate and creative design solutions. The process of design, as observed, is seemingly chaotic.

Top-down procedural design offers several advantages, since design intentions are easier to communicate to other designers. In addition, a careful elaboration of functional requirements at the top level promotes creative design.

Designing for Body Strength

K. H. E. Kroemer

Professor Emeritus of Industrial and Systems Engineering, Virginia Tech, Blacksburg, VA, USA

1. INTRODUCTION

The engineer or designer wanting to consider operator strength has to make a series of decisions. These include:

Is the use mostly static or dynamic?

If static, information about isometric capabilities, listed below, can be used. If dynamic, other considerations apply in addition, concerning for example physical endurance (circulatory, respiratory, metabolic) capabilities of the operator, or prevailing environmental conditions. Physiologic and ergonomic texts provide such information.

Is the exertion by hand, by foot, or with other body segments?

For each, specific design information is available. If a choice is possible, it must be based on physiologic and ergonomic considerations to achieve the safest, least strenuous and most efficient performance. In comparison to hand movements over the same distance, foot motions consume more energy, are less accurate and slower, but they are stronger.

Is a maximal or a minimal strength exertion the critical design factor?

"Maximal" user strength usually relates to the structural strength of the object, so that a handle or a pedal may not be broken by the strongest operator. The design value is set, with a safety margin, above the highest perceivable strength application.

"Minimal" user strength is that expected from the weakest operator which still yields the desired result, so that a door handle or brake pedal can be successfully operated or a heavy object be moved.

A "range" of expected strength exertions is, obviously, that between the considered minimum and maximum. "Average user" strength is usually of no design value.

Most body segment strength data are available for static (isometric) exertions. They provide reasonable guidance also for slow motions, although they are probably too high for concentric motions and a bit too low for eccentric motions. Of the little information available for dynamic strength exertions, much is limited to isokinematic (constant velocity) cases. As a general rule, strength exerted in motion is less than measured in static positions located on the path of motion (see this volume, Static and Dynamic Strength).

Measured strength data are often treated, statistically, as if they were normally distributed and reported in terms of averages (means) and standard deviations. This allows the use of common statistical techniques to determine percentiles — data points of special interest to the designer (see below). However, in reality, body segment strength data are often in a skewed rather than in a bell-shaped distribution. This is not of great concern, however, because usually the data points of special interest are the extremes. The maximal forces or torques that the equipment must be able to bear without breaking are those above or near the strongest measured data points. The minimal exertions, which even "weak" persons are able to generate, can be identified as given percentile values at the low end of the distribution: often the fifth percentile is selected.

Determination of percentiles can be done either by estimation or by calculation.

Estimation is used when the data set is not normally distributed or too small. In this case, the data point is estimated by counting, weighing, or sample measurement according to the best possible judgment.

Calculation is used based on statistical considerations.

A normally distributed set of n data is described by two simple statistics:

The 50th percentile is by definition the same as the mean m (also commonly called average)

$$m = Rx/n$$

where Rx is the sum of the individual measurements.

The Standard Deviation SD describes the distribution of the data

$$SD = [R(x - m)^2/n-1]^{1/2}$$

It is often useful to describe the variability of a sample by dividing the standard deviation SD by the mean m. The resulting Coefficient of Variation CV (in percent) is:

$$CV = 100 \, SD / m$$

To calculate a percentile value p of a normal distribution you simply multiply the standard deviation SD by a factor k, selected from the table below. Then subtract the product from the mean m if p is below the mean:

$$p = m - k \, SD$$

If p is above the average add the product to the mean:

$$m = m + k \, SD$$

Examples:
To determine 95th percentile, use k = 1.65.
To determine 20th percentile, use k = 0.84.

2. DESIGNING FOR HAND STRENGTH

The human hand is able to perform a large variety of activities, ranging from those that require fine control to others that demand

Table 1. Factor for computing percentiles from mean x and standard deviation s.

Percentile p associated with X		
K	X = X – KS	X = X + KS
2.576	0.50	99.5
2.326	1	99
2.06	2	98
1.96	2.5	97.5
1.88	3	97
1.65	5	95
1.28	10	90
1.04	15	85
1.00	16.5	83.5
0.84	20	80
0.67	25	75
0	0.50	0.50

large forces. (But the feet and legs are capable of more forceful exertions than the hand, see below.)

One may divide hand tasks in this manner:

- Fine manipulation of objects, with little displacement and force. Examples are writing by hand, assembly of small parts, adjustment of controls.
- Fast movements to an object, requiring moderate accuracy to reach the target but fairly small force exertion there. An example is the movement to a switch and its operation.
- Frequent movements between targets, usually with some accuracy but little force; such as in a assembly task, where parts must be taken from bins and assembled.
- Forceful activities with little or moderate displacement (such as with many assembly or repair activities, for example when turning a hand tool against resistance).
- Forceful activities with large displacements (e.g. when hammering).

Of the digits of the hand, the thumb is the strongest and the little finger the weakest. Gripping and grasping strengths of the whole hand are larger, but depend on the coupling between the hand and the handle. The forearm can develop fairly large twisting torques. Large force and torque vectors are exertable with the elbow at about right angle, but the strongest pulling/pushing forces toward/away from the shoulder can be exerted with the extended arm, provided that the trunk can be braced against a solid structure. Torque about the elbow depends on the elbow angle.

The literature (see below) contains many sources for data on body strength that operators can apply. While these data indicate "orders of magnitude" of forces and torques, the exact numbers should be viewed with great caution because they were measured on various subject groups of rather small numbers under widely varying circumstances. It is advisable to take body strength measurements on a sample of the intended user population to verify that a new design is operable.

Note that thumb and finger forces, for example, depend decidedly on "skill and training" of the digits as well as the posture of the hand and wrist. Hand forces (and torques) also depend on wrist positions, and on arm and shoulder posture. Exertions with arm, leg, and "body" (shoulder, backside) depend much on the posture of the body and on the support provided to the body (i.e. on the "reaction force" in the sense of Newton's Third Law) in terms of friction or bracing against solid structures.

It is obvious that the amount of strength available for exertion to an object outside the body depends on the weakest part in the chain of strength-transmitting body parts. Hand pull force, for example, may be limited by finger strength, or shoulder strength, or low back strength; or it may be limited by the reaction force available to the body, as per Newton's Third Law. Often, the lumbar back area is the "weak link" as evidenced by the large number of low-back pain cases reported in the literature.

3. DESIGNING FOR FOOT STRENGTH

If a person stands at work, fairly little force and only infrequent operations of foot controls should be required because, during these exertions, the operator has to stand on the other leg. For a seated operator, however, operation of foot controls is much easier because the body is largely supported by the seat. Thus, the feet can move more freely and, given suitable conditions, can exert large forces and energies.

A typical example for such an exertion is pedaling a bicycle: all energy is transmitted from the leg muscles through the feet to the pedals. For normal use, these should be located directly underneath the body, so that the body weight above them provides the reactive force to the force transmitted to the pedal. Placing the pedals forward makes body weight less effective for generation of reaction force to the pedal effort, hence a suitable backrest should be provided against which the buttocks and low back press while the feet push forward on the pedal.

Small forces, such as for the operation of switches, can be generated in nearly all directions with the feet, with the downward or down-and-fore directions preferred. The largest forces can be generated with extended or nearly extended legs; in the downward direction limited by body inertia, in the more forward direction both by inertia and the provision of buttock and back support surfaces. These principles are typically applied in automobiles. For example, operation of a clutch or brake pedal can normally be performed easily with an about right angle at the knee. But if the power-assist system fails, very large forces must be exerted with the feet: in this case, thrusting one's back against a strong backrest and extending the legs are necessary to generate the needed pedal force. The largest forward thrust force can be exerted with the nearly extended legs which leaves very little room to move the foot control further away from the hip.

Information on body strength has been compiled, for example, in NASA and US Military Standards; by Karwowski and Marras (1999); Kroemer, Kroemer, and Kroemer-Elbert (1997, 2000); Weimer (1993); and Woodson, Tillman, and Tillman (1991). However, caution is necessary when applying these data because they were measured on different populations under varying conditions.

Driver Perception and Response

P. L. Olson

3545 Sulgrave Pl., Ann Arbor, MI 48105, USA

1. INTRODUCTION

With some regularity drivers encounter situations that impose demands over and above those represented by routine operations. In each of these the driver must perceive a potential hazard, meaning they must become consciously aware of it, and then diagnose it. With that done they must then respond, the first phase of which is to arrive at a decision as to what, if any, response is called for. If a response is indicated, the driver must then carry out the required action. Owing to the mental processing involved, each of these encounters takes time, even in those cases where no discernible response is made. In most driving situations events are spaced sufficiently and there is adequate time available. In others they come thick and fast, placing the driver under some stress and increasing the likelihood of error.

The time that it requires for drivers to perceive and respond to unexpected hazards is of considerable interest to civil and traffic engineers, who must design roadways and traffic control systems that take into account human performance capability. Organizations such as The American Association of State Highway and Transportation Officials (AASHTO) have formulated guidelines for driver perception and response for various conditions. One example is stopping sight distance (SSD), which establishes such things as minimum radii for curves and hill crests to ensure that hazards will not be hidden from the driver until he/she is too close to stop. The equation for SSD includes an estimate of driver perception and response time, currently set at 2.5 s.

Not only does a driver face numerous events requiring his/her attention, but also these will differ in the ease with which they can be detected, identified and dealt with. That being the case, it should be clear that the time required for the driver to resolve each will vary significantly. The research on driver perception and response has focused on relatively straightforward situations, telling us something about the minimum times required to respond to unexpected events. Left largely unresolved is the question of times associated with those characterized by greater complexity.

This chapter is intended to provide an overview of what is known about driver perception and response. It will begin with a definition, then progress to a description of basic and applied research on the subject. There will also be a discussion of situations that do not fit the basic model of driver perception and response.

2. BACKGROUND

2.1. Definition

Perception–response time is an interval that starts when some object or condition enters the driver's visual field and ends when the driver has made a discernable response (e.g. foot on the brake pedal and/or the hands start to turn the steering wheel). The time to complete the elected maneuver is normally not included.

Some situations of interest are not characterized by a clearly defined entry of the hazard into the driver's field of view. These are discussed later. It is also recognized that the start point for a perception–response interval may not be a visual stimulus. For example, the driver may hear a sound or sense that his/her vehicle has struck or run over something. Sometimes a driver will perceive an immediate threat and initiate a prompt response to this type of stimulus. In the absence of such a perceived threat the usual response is a visual search. With one exception, all of the research on driver perception and response has used visual stimuli. In the one exception drivers anticipated that a sound stimulus would be used.

2.2. Stages of Perception and Response

The time between the appearance of some hazard and a response is filled with certain activities. It is helpful to divide the perception–response interval into stages as a means of understanding both the nature of these activities and how altered circumstances can change the time required to respond. Not all authors agree as to the number of stages and the labeling. What follows is commonly used.

1. Detection. The detection interval starts when a hazard enters the driver's field of view and ends when the driver has become consciously aware that something is present. It is possible for the hazard to be in the field of view for some time before the driver becomes aware of it. This is more likely to happen when the driver is very much burdened, when the stimulus is small, has poor contrast, or first appears well off to the side. In such cases the detection interval may be lengthened.

2. Identification. Having become aware of something, the driver must next acquire sufficient information to be able to decide what action is appropriate. Identification in detail is not necessarily required. The driver may simply decide it is something he/she doesn't want to hit. If the object is moving or capable of movement the driver must also make an estimate of its speed and probable trajectory as part of the identification process. The identification stage is a frequent source of difficulty, with consequent lengthening of response time, particularly under adverse visibility conditions such as nighttime, fog, blowing dust, snow and rain.

3. Decision. With identification complete the driver must decide what action, if any, is appropriate. In most of the perception–response studies there was a choice between steering and braking. Sometimes there is no real choice available, so the decision interval may be shorter. On the other hand, the choice might be complex. Where the driver shows evidence of considering alternatives the decision interval may be lengthened appreciably. If, for example the driver says that he/she wanted to steer but checked and found the adjacent lane occupied, a minimum of 1 s must be added for each mirror checked.

4. Response. In this stage instructions are issued by the brain to the necessary muscle groups to carry out the intended action. The perception–response interval ends when the foot contacts the brake pedal and/or the hands begin to turn the steering wheel. Because the hands are already on the steering wheel, steering response time is slightly shorter than in the case of braking, where the foot must be moved to the brake pedal from the accelerator. Research has shown that foot-

movement time under emergency conditions is typically in a range from 0.15 to 0.25 s.

The first two of these stages are commonly referred to as perception, the last two as response. Time estimates are often given for each separately. There is no justification for doing so, since everything is internalized between the appearance of a stimulus and the driver's response.

3. DRIVER PERCEPTION AND RESPONSE

3.1. Background

Investigations of human perception–response time have been carried out for nearly 200 years. Much of this work has been directed toward a variety of basic issues and has no direct bearing on motor vehicle operation. In the simplest of such studies the subject may rest a finger on a telegrapher's key with instructions to release it as soon as a stimulus (light or sound) is presented. Clearly, detection, identification and decision are reduced to minimum values by such a procedure. An approach such as described will typically yield response times ranging from 0.16 to 0.25 s.

Among the conditions examined have been so-called "choice" studies. For example, the subject may be given a number of possible stimuli and required to respond to only one of them, which requires identification. Or the subject may be required to respond differently to different stimuli, which requires decision. Expanding the identification and/or decision requirements lengthens response time, as would be expected. It has been found that one choice yields an average perception–response time of 0.2 s. Faced with two choices response time increased to an average of 0.35 s. Additional choices added ~0.05 s each, up to a maximum of nine, at an average of 0.65 s.

3.2. Driver Perception and Response

Early investigations of driver perception and response were often carried out in simple simulators or a vehicle operating in light traffic. A signal (light or sound) would be presented and the driver was instructed to respond by pressing on the brake pedal. It has typically been found that 85 percent of subjects in such investigations respond within 0.75 s. While it is true that this technique complicates detection by requiring the subject to cope with a driving task, the nature and location of the stimulus are known and the response has been specified by the experimenter. Because detection, identification and decision are greatly simplified in such a test, the response times measured should average shorter than under real-life conditions.

Most of the better investigations of driver perception and response have been carried out using one of two approaches:

- Take experimental subjects who have been misled concerning the purpose of the study and arrange for them to have a surprise encounter with some apparent hazard.
- Create some situation on a normal highway and measure the response of passing drivers.

A number of investigations have been reported using these approaches. The results of one of these are shown in Figure 1.

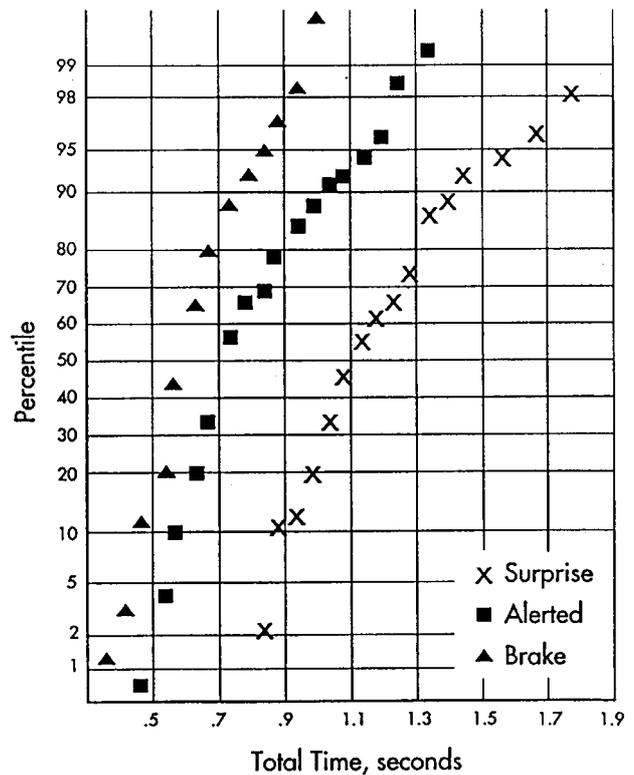
Three situations are depicted in Figure 1. The one labeled "Surprise" shows the range of response times from a group of subjects who had an unexpected encounter with an apparent hazard in the road over a hillcrest. The shortest time recorded was ~0.8 s in this test, and 95% of the subjects had responded


Figure 1. Distribution of response times from 49 young subjects fewer than three conditions. (Reproduced with permission from *Human Factors* 1986, 28. Copyright: Human Factors and Ergonomics Society. All rights reserved.)

by 1.6 s. The subjects were next told to retrace their path, and tap the brake pedal when they saw the hazard (alerted condition). There was some uncertainty in detection, because the hazard was moved each trial, but identification and decision were greatly simplified. Of the responses, the shortest was ~0.5 s and 95% of the responses were 1.15 s or less. Finally, in the so-called "brake" trials, a light was attached to the hood of the car and the subjects were instructed to tap the brake pedal each time it came on. Detection, identification and decision were reduced to minimums in this approach. The shortest response time recorded under this condition was 0.35 s and 95% of the responses were ~0.8 s or less.

The results of this investigation were typical of a number of others that have been reported. In general, they suggest that for a straightforward situation (i.e. a reasonably clear stimulus, and no problems in identification or decision) approximately 90% of drivers will respond within a range of 0.75–1.50 s. Obviously, not all situations are straightforward. In the discussion of the stages of perception and response a number of conditions that can affect the total time required to respond were briefly covered. The following discussion is intended to describe several driver-related factors that can affect performance.

4. DRIVER-RELATED FACTORS

4.1. Expectancy

Expectancy refers to a predisposition on the part of people to believe that something will happen or be configured in a certain way. All drivers have expectancies about roads, signing and the

behavior of other roadway users. So long as expectancies are met drivers will respond promptly and appropriately, resulting in greater throughput and fewer conflicts. Violations of expectancy adversely affect the detection and identification stages. As a result people take longer to respond to a given situation, thus increasing the likelihood of error.

4.2. Chemicals, Driver Fatigue

There are a great number of drugs, most of which are legal, that have an effect on the central nervous system and, potentially at least, on perception and response. They can affect detection, identification and decision. There is little research on most of these as concerns their effect on driving-related skills. An exception is alcohol, which can have a marked effect on information processing, and hence on perception and response. Alcohol has long been known to be a major factor in traffic collisions.

Fatigue is a common problem in motor vehicle operation. It happens that sometimes driving is a fairly boring activity that can continue for many hours at a stretch. A number of investigations have shown that response time does increase with driving exposure. There is also evidence that fatigue exacerbates the effects of alcohol.

4.3. Age and Sex

There is much information to suggest that perception–response time increases with age. Data from one very large study, using a simple simulator, found that average perception–response time ranged from 0.44 s in a 20-year-old group to 0.52 s in a 70-year-old group.

On average, women respond slower than men in standard perception–response tests, although the differences are small. For example, one large study found the average difference between males and females in a choice response time test was ~0.08 s.

5. WHEN THE CONDITIONS OF THE PERCEPTION–RESPONSE MODEL ARE NOT MET

Perception–response time was earlier defined as an interval that starts when some object or condition enters the driver's field of view and ends with a discernable response. Some situations do not fit this model. Probably the most common are cases where there is no clearly defined entry of the object or condition into the driver's field of view. This would most often occur under conditions that restrict visibility, such as nighttime. Typically under these conditions the hazard gradually becomes better defined as the distance closes. From the point where it just becomes possible to discern something to where all reasonably alert drivers will have detected it can cover hundreds of feet and a number of seconds. Picking a start point for the detection interval in such cases is an exercise in futility. In many such cases the simplest solution is to start the perception and response time after detection has been accomplished, i.e. start with the

identification stage. The question now becomes how much time should be allowed for perception–response absent a detection interval? Since there are no data on the length of the detection interval itself, it is necessary to estimate it. It is probable that under the circumstances of a straightforward situation the detection interval will be fairly short. Thus, a reasonable estimate of perception–response time absent the detection interval is 0.6–1.25 s.

The second case comes about generally from instances where the driver initially makes an erroneous identification. As an example imagine a vehicle proceeding along a through street, approaching an intersection. The driver sees a vehicle approaching on the cross street and notes that it slows to a stop, as appropriate. The next thing the driver realizes is that the vehicle is moving forward again and is on a collision course.

There are actually two perception–response intervals here. In the first the driver on the through street detected the car on the cross street, identified its actions as stopping, decided that it would properly yield right of way and no action was called for. The second interval starts with the realization that the car has not yielded right of way and a collision is imminent. The second interval actually started with an identification, i.e. that the car is coming and is on a collision course. All that remains for the driver is to decide what to do and do it.

In such cases, without detection or identification stages, the response time should be fairly short. Once again, absent data, one can only approximate what it would be. For straightforward situations a reasonable estimate would probably be in the range 0.40–0.75 s.

6. CONCLUSIONS

The time for a driver to perceive and respond to a hazard is a matter of some concern to persons involved in traffic engineering as well as those who are in the business of accident investigation. The matter is complex, due to the great variety of situations that can occur while operating a motor vehicle. It should be very clear that perception–response time is not a one-size-fits-all number.

Research on the time to respond to unexpected hazards has tended to concentrate on straightforward scenarios. The result is that there is information about the response of drivers to relatively simple situations. These data indicate that most drivers will respond to such situations within ~1.5 s. Many situations are not straightforward and, other than the fact that responses will take longer, little is known about how much longer. Unfortunately, given the complexity of carrying out realistic perception and response investigations, and the great variety of situations that can arise in the world of transportation, this is not something that is likely to be resolved in the foreseeable future.

Dynamic Situations

J.-M. Hoc

CNRS, University of Valenciennes, France

1. SUPERVISORY CONTROL

Dynamic situations are found in those work settings where the human operator partly controls a technical or physical process which has its own dynamics and which is most of the time also controlled by automatic machines (Hoc, J. M., Cacriabue, P. C. and Hollnagel, E. (eds), 1995). In such situations, the operator's tasks can vary from supervision (high automation and normal operation) to control (low automation and incident recovery) and are currently qualified as supervisory control (Sheridan 1992). Dynamic is used in contrast with static. A static situation does not change unless the operator acts on it (e.g. using a text editor). Various examples of dynamic situations can be found in industry (nuclear power plants, refineries, iron and steel industry, manufacturing, etc.), mobile driving (car, aircraft, or ship), traffic control (air or car traffic control), crisis management (fire-fighting or disaster management) or medicine (anesthesiology, but also patient management by general practitioners).

For a long time many studies have been devoted to industrial situations qualified by the term process control, where there has been a rapid shift from manual control to remote control bearing on automation. This shift was shown to have a direct implication on human–machine system reliability. Recent accidents in nuclear power plants or aviation reveal that, although high progress has been realized on the machine reliability side, the accident rate remains stable and can be attributed to the human–machine cognitive coupling (Hollnagel 1993).

Several authors have enlarged this process control category trying to characterize these various situations by their inherent complexity. For example, Woods (1988) describes four sources of complexity in dynamic situations. Problems are not stable (as in electronic troubleshooting, for example, where the system is out of work during diagnosis), but evolve along time (most often a dynamic system cannot be stopped during incident diagnosis and recovery). These systems are composed of numerous and interactive components (multiple incidents, causes, goals, tasks, and artificial and human agents). Their behavior is subjected to a large amount of uncertainty due to uncontrolled factors. They are subjected to various risks, and different levels of action must be considered to manage these risks. Static situations also can be complex to deal with and the management of a temporal structure is probably the main feature of the dynamic situations. In addition, the operators must adjust the dynamics of their own cognitive processes to the dynamics of the technical or physical process.

2. COGNITIVE DIMENSIONS

Most of the cognitive dimensions that are used to classify dynamic situations refer more or less to time. They are useful for making choices of appropriate observational or experimental methods in order to identify cognitive problems and find the best solutions. Five dimensions are selected here (a more complete account would need greater detail) that define situations taken as actual interactions between operators and tasks. The same task can result in very different types of situations when different kinds of operator are confronted with it. For example a task can be a problematic situation for a beginner and a routine situation for an experienced operator (expert, but in the sense of action-relevant knowledge).

2.1. Supervision Span

Supervision span at the same time concerns information and action. From the information point of view, the operator can have access to the process variables through a limited window that can be defined in temporal, causal, or spatial terms, sometimes isomorphic. A restricted information span can result in difficulty to anticipate and to make decisions at the right time. However, operator expertise plays a major role in determining the information span. A beginner can be unable to process a large information span due to having too high a level of complexity to manage. In contrast, an expert may reduce such complexity by using chunks or high-level schemas. From the action point of view, the supervision span can be defined as the set of variables accessible, more or less directly, to action. Restrictions can lead to an inability to act on the causes of the phenomena or prevent their occurrence, and also to restrict the action needed to deal with their consequences in the best way possible. The size of air traffic sectors is a typical example of the problems caused by a restriction of the supervision span. As the workload increases in a sector, it is possible to break it down into smaller ones — but there is an obvious limit. Due to the high speed of aircraft, too narrow a sector can result in an impossibility to anticipate conflicts and act in time.

2.2. Control Directness

The partial control inherent to dynamic situations implies that operator actions on the crucial process variables are very seldom direct. They trigger causal chains with intermediary effects on mediated variables before producing their results. At each node of such a chain, some factors can intervene and interact with the operator action without being fully controlled or predicted. That is why diagnosis is strongly intermixed with monitoring. Intermediary effects on intermediary variables are used as intermediary feedbacks to correct the action and to adjust it to the actual situation, which can be quite different from the anticipated situation. In addition, response latencies must be considered in the choice of action time. Causal chains and response latencies result in planning needs, integrating the operator actions and the dynamics of the process at the same time. Beginners are shown to act on the basis of present data with a risk of getting an effect at the wrong time whereas experienced operators are able to anticipate a future state and to act in order that the action effect occurs at the right time.

2.3. Process Information Accessibility

Many dynamic situations are opaque in the sense that the crucial variables used by operators to make decisions are not directly accessible. Often these variables must be calculated or assessed on the basis of surface variables, which can sometimes play the role of symptoms enabling operators to diagnose syndromes. Some effort has been devoted in control room computerization to make "visible" such hidden variables, for example, through "ecological interfaces" (see this entry). However, before being routinely used, such interfaces require deep knowledge to be understandable .

2.4. Process Continuity

A dynamic situation is continuous when the operators process trends, discontinuous (or discrete) if they process discrete states (e.g. discrete manufacturing). In the first case, the temporal functions representing the trends are interpreted in semantic terms (e.g. a particular phenomenon inferred from the curve shape) and action is decided to change the trends (e.g. to modify the phenomenon if it is undesirable). In the second case, the traditional state-transformation models are applied (networks where the nodes are the states and the arrows the transformation to go from a state to another). This distinction is related to the kind of representational system used by operators and has implications on the design of human–machine interfaces. However, discrete manufacturing, for example, opens another source of complexity when parallel operations must be considered when scheduling.

2.5. Process Speed

Process speed can be defined in relation to the sampling frequency (band width) necessary to avoid the risk of omitting to notice an important event or omitting to act at the right time. When this frequency is low, the process is slow (e.g. a frequency of 10 min is largely sufficient to supervise a blast furnace), rapid if not (e.g. fighter aircraft piloting requires an almost continual monitoring). Process speed introduces temporal constraints in the development of cognitive processes. Real-time planning is possible when the process is slow, whereas pre-planning is needed when the process is rapid. In the latter case, pre-planning implies risk anticipation to prepare appropriate responses to possible dangerous events

in order to use routines compatible with the process speed and the operator's skill.

3. REPRESENTATION AND PROCESSING SYSTEMS

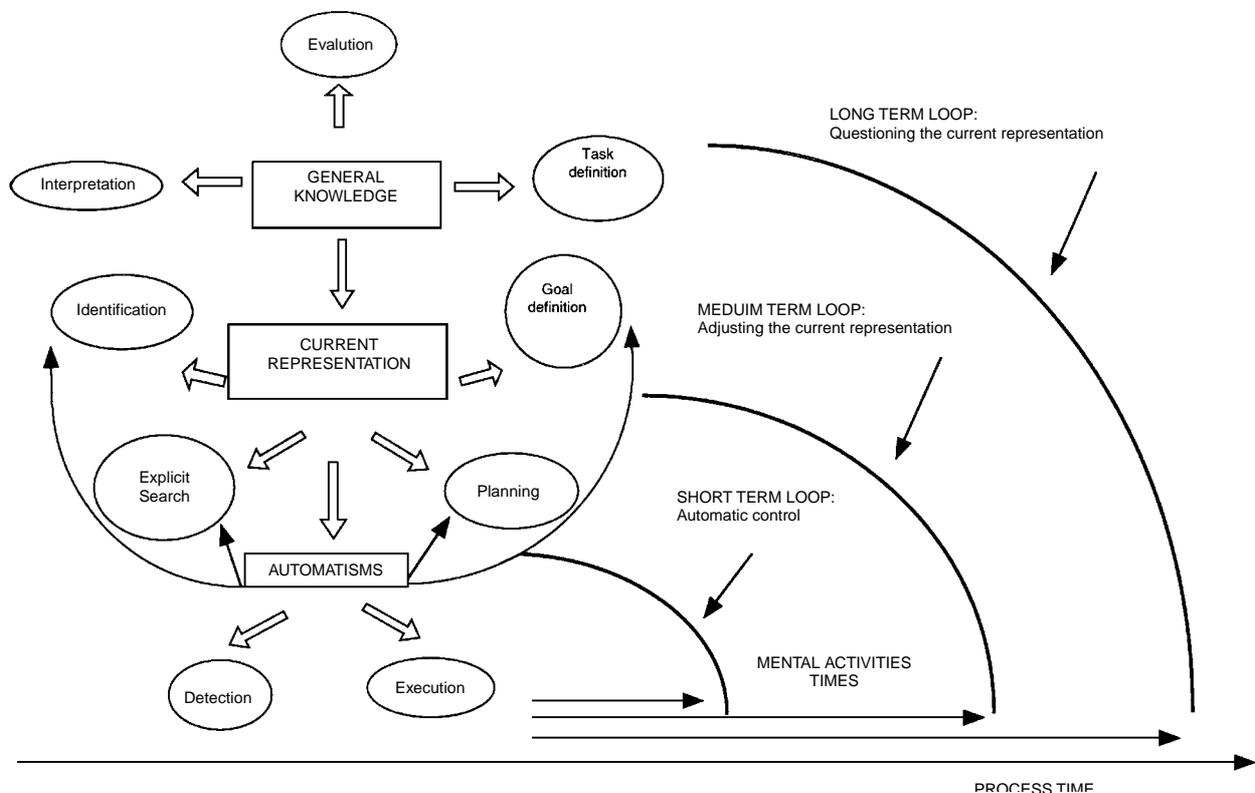
Within many kinds of (dynamic or static) situation where machines are implied, operators have been shown to make use of mental models (Moray 1988) to manage them. These models have been proved to be strongly dependent upon action repertory and objectives (e.g. a motor mechanic has a representation of a car that is very different than that used by a common driver). They ensure a tight coupling between representation (objects, properties, including procedural properties) and processing, and can be called Representation and Processing Systems (RPS). In dynamic situations frequent shifts between different types of RPS have been demonstrated, which imply the design of different kinds of interfaces and of links between them. A Causal RPS enables operators to process causal (and temporal) relations between variables, especially in problem-solving situations where the supervised process can deviate considerably from its normal operation. In this case, the causality introduced by the designer can be invalid and a new and valid causality must be discovered to understand what is going on. A Functional RPS gives access to a break down of the process into goals and subgoals and can play a major role in planning and focusing on deficient functions. A Topographical RPS can guide topographical search towards the appropriate physical components upon which to act concretely or towards the deficient component to repair. A Transformational RPS is appropriate to support procedure discovery or application, especially in discrete situations, but also


Figure 1.   The dynamic situation management architecture (after Hoc, Amalberti, and Boreham 1995).

Note: Rectangles represent cognitive control levels, ovals elementary activities, arrows influences.

in continuous ones (e.g. the extended use of procedures in nuclear power plants).

4. COGNITIVE CONTROL

After Rasmussen (1986), cognitive modeling of operators bears on a multi-processor conception of cognitive activities, roughly defined at three levels. Knowledge-based (KB) behavior relies on symbol (or concept) processing in problem-solving situations. Rule-based (RB) behavior processes signs requiring attention before triggering rules to be applied routinely. Skill-based (SB) behavior does not require attention and can be done automatically without suffering the well-known limitations in the attention channel. Rasmussen has proposed a model of diagnosis and decision-making of a sequential and procedural kind, from alarm detection to action implementation, including diagnosis, prognosis, and planning, except for some shortcuts permitted by the activity automatization (in experienced operators) from KB to RB, and SB behavior. More recently, Hoc, Amalberti, and Boreham (1995) have enlarged this model by a parallel cognitive architecture (see Figure 1) to deal with the necessary compromise between comprehension (diagnosis and prognosis) and action in dynamic situations. A certain level of comprehension is needed to act appropriately, but the priority to the short-term control of the situation does not always enable the operator to comprehend the situation fully before acting.

At the center of this architecture a Current Representation (CR) of the situation plays a major role in triggering different kinds of activity, on the basis of comprehension or incomprehension. This notion is close to that of Situation Awareness (Endsley 1995) — representation of the past, present, and future technical process evolution. But CR also integrates operator mental processes — plans and action decisions, data for risk and resource management (including internal risk and resource management by the means of metaknowledge — knowledge of one's own cognitive processes). CR can make use of general knowledge (KB level), can trigger different kinds of activity submitted to an inner determination (including RB level), and can supervise human automatisms (SB level).

In parallel, human automatisms can be executed to control the technical process without attentional control. However, SB behavior traces can activate some representations that will be processed at the CR level. These representations could be either confirmation or invalidation of the actual comprehension and play a role in error detection.

Because they are adaptive, cognitive processes need more or less frequent feedbacks to be effective. Roughly, three feedback temporal spans can be considered. A short-term feedback is necessary to the adaptation of human automatisms. This loop can be very efficient even if the comprehension of the situation does not correspond exactly to the current situation (e.g. the pilot will continue flying the aircraft even if some problem is not understood). Local action adjustments can be sufficient before solving the problem at the attentional level (CR). In parallel, the CR must be adjusted to comprehend the situation, but the feedbacks necessary to comprehend and to test the diagnosis/prognosis need the creation of a medium-term loop before reconfiguring the automatisms to be really adequate. Sometimes, different possible explanations of the problem or different problems are triggered that must be processed in a time-sharing way at the attentional level. Finally, RC can be deeply questioned. Adjustments are necessary, but not sufficient, to account for the new situation. In this case, a long-term loop is engaged that will produce its feedbacks at a late stage and reconfigure RC.

Such coupling/decoupling between the different levels of control will vary in relation to situation features. Very roughly, the coupling is at a maximum when the situation is well known and/or the process is slow. Conversely, the decoupling can be very deep when the situation is novel (a long time is needed to reach an appropriate representation and the technical process continue evolving in the meantime) and/or the process is rapid.

Ergotoxicology: towards an Operational Prevention of Chemical Risk in the Working Environment

B. Mohammed–Brahim

Laboratoire Santé Travail Environnement, Université Victor Segalen
Bordeaux, France

1. PREVENTIVE ACTION IN INDUSTRIAL TOXICOLOGY

In his definition of industrial toxicology, Robert R. Lauwerys (1990) makes a distinction between *toxicity* and *risk* associated with industrial chemical hazards. Toxicity is defined as the inherent capacity of a substance to produce a harmful effect on the organism. Risk is the probability with which a toxic effect may occur in the conditions of use of a given substance. Curtis D. Klaasen (1986) uses the notion of *safety* defined as the probability that a toxic effect may be avoided in given conditions. Industrial toxicology, defined by Robert R. Lauwerys (1986) is therefore the science which, from the study of toxicity and determination of the risk, establishes measures of safety: "This objective [of industrial toxicology] can be attained if the conditions of exposure and the workers' tasks are defined in such a way that they do not cause an unacceptable health risk."

Yet, although toxicology has been a discipline founded on the discoveries of biology, on the one hand, and the development of industrial analysis, on the other — a fact which has led to the understanding of the metabolism and the mode of action of a large number of toxic substances — it has paradoxically been restrained in terms of condition of exposure to consideration of the immediate environment surrounding the workstation. Thus, there is a list of *environmental factors*, such as noise, light, climate, gravitation or irradiation (Lauwerys 1990), determining *exposure factors*, i.e. mode of administration, duration and frequency of exposure (Klaasen 1986). It has thus been stated that "much more data is needed to characterize the toxicity of a chemical substance than to characterize the risk associated with its use in a given situation" (Doul and Bruce 1986). Whenever explicit reference is made to working conditions, this concerns prescribed conditions: "The evaluation of risk takes into account the harmful effects on individuals . . . which may occur through the use of a substance at a prescribed dose and manner" (Klaasen 1986). In this case, all reference to work activity is avoided. This approach presupposes that the operator is passive, not active, in his own activity, and that he is reduced just to his physical and even biological component. There is an opposition between *real risk*, which is what toxicologists study, and the *risk perceived* by the worker, which may be only slightly or not even correlated with the former (Lauwerys 1986). Safety measures are therefore defined outside of the scope of man and with two possible approaches:

1. The admissible limits of exposure, defined as qualitative hygiene norms for protecting workers. These norms are respected by collective and individual action such as working in a closed environment, ventilated places, wearing masks and protective clothing.

On the one hand, these norms are the result of a decisional process in which the economic and social stakes are at least as important as scientific and technical knowledge. On the other, in a more mass-orientated or even Taylorian approach, they are imposed without taking the specific context or situation into account; the norm is applied to an asexuated human, who is biologically healthy, works eight hours a day, without interruption, five days a week, and is exposed to only one substance at a time. Of course, no situation corresponds to this fictional norm.

2. The medical, clinical and, if possible, biological monitoring of workers. Here, the worker is his own risk indicator. In fact, it is only when the clinical and biological indicators are significantly shifted from the "norm" that preventive action is called for. The occupational doctor therefore prescribes a temporary or permanent halt to the worker's activity according to the official requirements regarding his medical aptitude to continue. The industrial toxicologist then performs metrologic readings and recommends collective (ventilation, humidification, etc.) and individual (protective equipment, safety recommendations) action.

This process is what may be referred to as a "screening model" (figure 1) to prevent toxic risk. The potential risk associated with a prescribed task is in effect contained by the safety recommendations and the protective equipment (first screen). Their role is to maintain the level of exposure at an admissible limit (second screen) depending on the potential toxicity of the substance. Regulation is then achieved on the level of the individual, yet outside his own scope of action, in the way the doctor decides whether or not the worker is able to work in view of his organic status and the potential effect that the substance might have. Medical selection, therefore, constitutes the third and final component of this screen against risk.

2. ERGOTOXICOLOGIC ALTERNATIVE FOR OPERATIONAL PREVENTION

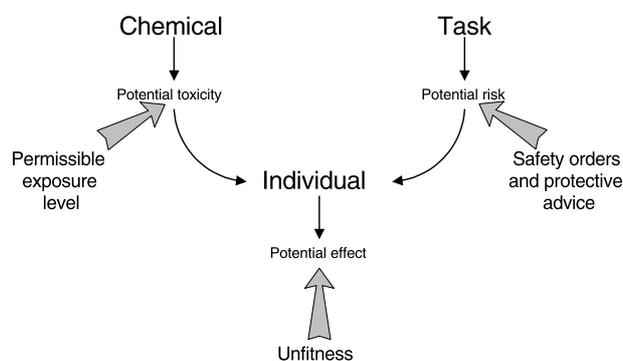
In the 1980s, Alain Wisner (1997) developed an approach called ergotoxicology which included the ergonomic analysis of work within the concept of occupational risk associated with exposure to chemical substances. In this approach, *factors linked to the job itself* and evidenced by ergonomic analysis are taken into consideration to the same extent as the factors of dispersion of the toxic effects produced by the same substance as described by


Figure 1. Occupational toxicology preventive model

toxicologists, i.e. factors such as the variability due to extrapolation from an animal model or inter-individual biologic variability. Ergotoxicology, therefore, is a major step forward in relation to the ambition of classical industrial toxicology, i.e. preventing alone, and efficiently, the toxic risk. When speaking of phytosanitary protection, Wisner (1997) adds that "ergotoxicology does not replace the study of biocides less dangerous for man" but that "it tends to prevent or reduce the existing risks". He implicitly recognizes that although toxicology remains the science of the study of poisons, prevention can only stand to gain from ergotoxicology.

Nevertheless, most of the latter developments have borne out the soundness of this cooperative approach in which work and the factors linked to it are considered not at the heart of the process itself, but rather in a complementary manner, just like the other factors already mentioned by the toxicologists. L. Sznelwar (1991) thus speaks of cooperation with the toxicologist to transpose the results of experimentation to the reality of the workplace. The process of prevention is therefore assisted by analysis of work, but in parallel to the toxicological approach according to the model under study.

Since then, many studies have concerned, at the same time, the ergonomic analysis of work, the metrology of the atmosphere, and/or biometrology and epidemiological investigation. With starting points as diverse as the evidencing of a relationship between the occurrence of health problems and the level of exposure or the working conditions (Khaleque *et al.* 1991) or the implementation of a new working process or the substitution of one toxic substance by another less toxic one (Jacobsen *et al.* 1991), these studies try to show beyond the visible activity any factors which might be linked to skill or experience (Bobjer 1991), to the representation and the perception of risk by the operators (Six *et al.* 1991). Other authors have developed techniques for instantaneous measurement coupled with video recording of activity in order to evidence variations in level of exposure with different operative modes in real time (Gressel *et al.* 1983; Heitbrink *et al.* 1983). Films have been used to train operators in chemical risk management (Rosen and Anderson 1989). Beyond the immediate determinants of the work situation, Sznelwar (1992), in an essay on exposure to pesticides in agriculture, discusses aspects relating to anthropotechnology.

We have also analyzed the work situation upstream, in particular, the stages of project design and consideration of the work of the preventers themselves in analyzing the work situation. Another of our research themes has been the wearing, pertinence, and efficacy of individual means of protection against chemical risk in relation to work activity, and the representations and perception of these that the workers may have.

3. ERGOTOXICOLOGY: A SIMPLE SEMANTIC CONSTRUCTION ?

The process in which there is the simultaneous but parallel involvement of various disciplines such as ergonomics, toxicology, and sometimes epidemiology, a characteristic of most of the above-mentioned studies, bears witness to this view of the question. Ergotoxicology is not just a matter of cooperation between the toxicologist and the ergonomist, nor just negotiation of a neck of the woods for the science of ergonomics within the traditional grounds of industrial toxicology. Ergotoxicology could be defined

as a process of analyzing work activity in the light of toxicological knowledge, and destined to evidence the determinants of chemical risk for the health of workers with a view to adopting preventive action in an operational perspective.

Ergotoxicology, therefore, is an alternative model with methods for understanding what is happening for a worker when he is more or less exposed to toxic risk owing to his professional activity. It is an approach which centers on the process of prevention within the activity of work.

Any scientific approach to man at work involves implicit considerations about models of man and the concepts of technology and work (Dejours 1995). Seen in terms of ergotoxicology, and since prevention is to be considered not only in terms of a dose–effect relationship but also as a work activity–response relationship, this notion should also apply to the prevention of toxic risk at work. We will not discuss here, however, the internal debate among ergonomists regarding the models of man and the relationship between work and health (Daniellou 1998).

Beyond the biological dimension underlying the dose–effect relationship, ergotoxicology involves cognitive, mental, and social dimensions in the occurrence of risk in the workplace, and therefore in its prevention. Thus the challenge is to highlight these dimensions in the understanding and prevention of chemical risk.

Since there are many ways in which a chemical substance is used during a transformation process, or when the worker is accomplishing several acts, the notion of exposure is a complex one and it cannot be understood in a deterministic linear manner according to the paradigm chemical substance — level of exposure — health risk. Ergonomic analysis evidences a number of individual factors of a biological, cognitive and mental nature, together with parameters external to the worker. Their interrelation is complex and evolutive, and will involve the material elements of the situation and the representations and perceptions that the worker has of them. Work activity, therefore, involves individual and collective regulations which become manifest in the avoidance strategies adopted by the worker. These regulations lead to a compromise favorable to the continuing state of good health of the worker, or may lead to delayed or chronic effects. They may even fail, causing an accident or illness, or even a renouncement, i.e. the worker's premature retreat from the workplace, accomplished with the worker's tacit complicity, and which corresponds to the *healthy worker effect* as described by epidemiologists.

The following model (figure 2), which places work at the center of the process, includes the norms and protective means recommended by industrial toxicologists within the overall framework of the work situation. It is more likely, in our opinion, to provide fruitful directions for prevention.

4. WHAT HAPPENS IN PRACTICE ?

4. 1. Design of Work Systems and Toxic Risk

We have examined the stages preceding the organization of work as a result of a request to analyze the toxic risk in a viticultural environment. The study centers on phytosanitary treatments and the risks involved in the removal of asbestos from a building.

The preoccupation of a regional health care mutual fund and the regional chamber of agriculture was to reduce the toxic risk

Individual determinants:
- biological: sex, age, health status...
- cognitive and psychic: motivation, training, experience...

External determinants:
technology, organization, norms, safety orders, protective advice, living conditions.

Figure 2. Ergotoxicology preventive model

inherent in the use of pesticides. For this, the suggestion was to replace chemical treatment with what is known as "rational" treatment. Whereas in traditional pest control, treatment is performed systematically against all harmful agents and as blanket coverage over the whole vineyard according to a pre-established schedule, rational treatment involves selective applications according to forecast models for infection based on real-time diagnosis.

For this, we analyzed the organization of work and the treatment strategies over a year in two vineyards, one using traditional methods and the other the rational strategy. We used available data (timesheets, treatment programs, daily schedules), discussions with winegrowers, vineyard managers, foremen, and workers. Activity regarding vine protection (cropping techniques and pesticide applications) were assessed by observation.

These observations showed that rational treatment saved on the use of the most toxic substances. Nevertheless, analysis of the activity revealed a transformation in the organization of the work, with infrastructural and equipment modifications, a new know-how, more flexibility in the management of work and the staff with risk-taking both for the crop and the workers.

Without a rational approach to the new rational strategy, it was clear that the transformation itself was generating new constraints, with new moments at which the workers were exposed to levels of pesticides sometimes exceeding those to which they had previously been exposed.

The multiplication of the number of applications by staff who were not always qualified, and at moments which were not foreseeable, since they were precisely dependent upon natural conditions, meant that the number of occasions on which

exposure was possible increased. Moreover, the requirement of immediacy involved the mobilization of staff sometimes at a moment's notice. In any respect, chemical treatments were replacing manual prophylactic procedures, and were being conducted in conditions which did not respect the usual rules of efficacy for crops and safety for the workers (e.g. excess dose owing to slowing of tractor when blocked by heavy foliage still in place).

Management of the critical periods, in which the results of the model are at the limit of the admissible risk, represents a gamble taken exclusively by the vineyard manager with possibly disastrous consequences. We noted a case where the decision was taken not to treat: infestation was then suddenly triggered by a storm with continuous rain, so treatment was performed in a hurry with little protection against the leaching of the plants that the rain induced, which in turn represented a subsequent source of contamination for the workers.

It is clear, therefore, that the infrastructure, equipment, and procedures used may constitute constraints. Thus, in the vineyard which was using the rational strategy, an area was set aside for storing and preparing the pesticides. The reduction in quantity prepared and the higher frequency with which the preparations were mixed up quickly made the investment unsound. Consequently, the decision was taken to revert to the traditional mode of application in which the tractor driver both prepared and applied the chemical. Apart from the fact that he had to manipulate the products more, he also came more into contact with them: skin contact with froth from the mixture and the manual elimination of lumps, small-volume reservoirs requiring frequent refilling, etc.

Moreover, the products were stored for a longer period, with a concomitant phenomenon of overdosing at the moment of mixing; in effect, the operators felt that they should add a little extra to ensure the efficacy of a product whose expiry date would otherwise be attained.

In the other observation concerning the steps preceding the removal of asbestos from a site, we analyzed the process of the call for bids. As soon as the budget was made available, it was clear that the process of competition favored the choice of the company making the lowest estimate. Since the implementation of safety measures can represent between 60 and 80% of the total cost of this sort of job, it is easy to see where the savings are made. Moreover, the analysis showed the inadequacy at all stages of the consideration of the wide variability of worksites due to a great number of factors — state of the premises, type of surface asbestos is on, surface to be deflocculated and additional applications, immediate environment of the site, etc. Moreover, there was a lack of anticipation, and an ad hoc solving of problems as they arose, leading to a sense of improvisation undermining the collective and individual mobilization necessary to handle the omnipresent risks. This in turn led to delays with a concomitant lengthening of working time.

Whatever the sector of activity, this example shows that if organizational constraints are not taken into consideration, then the way in which the work is designed and managed can ride roughshod over any reference to exposure norms, the respect of safety recommendations, and the wearing of protective clothing, which are all part of the strategy of prevention.

4. 2. Protective Equipment against Toxic Risk

The issue of protective means against toxic risk may be examined in a number of ways.

4.2.1 Intrinsic quality of equipment

The supply of exterior air is strongly recommended for respiratory protection on sites from which asbestos is being removed. Yet there is still no set of rules applying to devices for producing air, even considering the latest revisions. And in our observations of asbestos defloculation procedures, we noted traces of oil on the protective masks. Levels noted were as great as three times the accepted threshold for divers. Such values were also found during sanding operations using respiratory protection by the supply of external air.

This is a typical example of what we term the screen model for the prevention of toxic risk: a filter is placed between the origin of the asbestos and the lungs of the worker, yet the possibility that there might be some other form of contamination (here, oil residues and carbon monoxide) was overlooked.

4.2.2 What happens in the work situation

In the same example, analysis of the efficacy of respiratory protection in the large number of asbestos defloculation sites now underway has shown the presence of fibers inside the masks worn by the workers, including those equipped with an external air source. Levels range from 0.01 to 7.8 f.cm^{-3}. While dry defloculation leads in all cases to a high level of airborne fibers in a confined zone, the use of wetting agents (water or other impregnating agent) does not notably reduce the level. Indeed, contrary to what might be expected, contamination levels in masks are independent of the degree of airborne contamination. Therefore, it is likely that the relationship between the degree of wetting used and the extent to which contamination is reduced is not a linear one.

On the other hand, contamination is strongly correlated with the following:

- the quality of the instruments used, which may either peel away whole layers of asbestos or serve only to disperse the particles by a ripping or powdering action. This parameter is also dependent on the skill of the worker in using the equipment or on the nature of the support.
- situations in which the worker has to temporarily unplug his external air source because the pipes have become entangled, or others in which special effort is required; such situations call for extra air to be breathed, resulting in an air depression within the mask allowing some fibers to slip through between mask and skin.
- the water jet used to clean the masks should be sufficiently strong to eliminate all traces of asbestos. This is rarely the case, and fibers may remain in the mask and be released at the subsequent moment of use.

4.3. Representations and Perception of Workers and Toxic Risk

Studies in ergotoxicology have shown how the worker not only attributes a meaning to his work but also to the risk to which he is exposed, how he identifies the people who are involved in the risk and the preventive means implemented, and how he interprets these factors through his own operative modes and safety behavior.

It is thus possible, through observation and speaking with the worker, to give substance to the risk that workers perceive. Avoidance strategies have been observed, such as working upwind to avoid pesticide clouds or shifting back when highly irritant sulfur is being prepared. Workers have even been seen to wet the ground where carbon-free copy paper is being unloaded, in order to "avoid the irritating effect of the dust" (in this case, formaldehyde is released but is neutralized by the presence of water). Workers are also known to describe odors as being "strong", "bad", or "sickening", and in a more colorful and perhaps even more discriminating way describe the "sharp" odor of chlorine or ozone, the "rotten hay" smell of phosgene or the "rotten eggs" whiff of hydrogen sulfide. All such odors give warning as to the level or imminence of the danger. Another example is the stench of "bitter almond in the mouth", a characteristic signal for those working with electrolysis and galvanization baths where levels of cyanohydric acid may suddenly rise.

Apart from the perception that workers may have of the presence of a given risk around them, the very representations that they have of them may differ:

- The danger may be perceived outside of the geographical area of risk. For example, a worker may describe how he "carries the danger with him" (e.g. marks on the skin like tattoos, stains or incrustations; bad breath if the product is excreted by the airways) or "takes the danger home to his loved ones" (fibers stuck on clothing worn home).
- The concomitant presence of other risks. The worker may suffer from more perceptible manifestations such as noise or a postural defect.

- The way the preventers behave or speak to the worker as if underestimating the risk, e.g. "I don't wear gloves when handling fungicides because my doctor at work says that they are less dangerous than the insecticides", or an overestimation of the type "if no preventer ever comes into the confined zone, then they can't be as sure of themselves as that!"
- The pertinence of the operative references: the perceived disproportion between the prescription of a few milligrams of insecticide for one cultivated hectare leads to a systematic overdosing by the workers; the trade names thought up by the manufacturers to signify the power of such insecticides (Apollo, Karaté K, etc.) do not offset this form of behavior, and are even more derided by the workers because of their sound.

The underestimation and the non-recognition of the interpretative system of the worker regarding the risk explain, at least in part, the limitations of preventive policies developed and implemented only through the know-how of the industrial toxicologist. In a recent publication, Stewart-Taylor and Cherrie (1998) describe the absence of relation between what they wrongly call the perception of the risk by the worker and the level of exposure to asbestos that they are subjected to on deflloculation sites. By re-assessing the items that they consider as important in explaining the perception that workers have of risk, it becomes clear that this perception is in fact a re-statement of risk as initially perceived by the preventers themselves. In effect, what these authors demonstrate substantiates our hypothesis, i.e. if it is not linked to the representational models of the worker, information on risk has little chance of being applied in the field of prevention.

4.4. Preventers and Toxic Risk

Irrespective of the undeniable impact of such information in improving working conditions, the analysis of activity may evidence practices which run counter to the avowed objective of the preventive measures.

The examples described above show that preventers frequently believe that they are acting upon virgin terrain which is simply to be transformed mechanically in order, in turn, to transform its behavior patterns. In this view, the worker is occulted, becoming a "reflexive agent", i.e. someone who not only develops his own representations of risk in an ongoing manner but also who never totally questions his own interpretative system, however much the preventer may insist on the degree of risk concerned.

The building of a relationship of confidence between employers, bosses and employees is based on a wager; a wager that is made in each interactive situation that may become very difficult to win whenever there are conflicts, which are often very costly for all concerned. Some situations leading to ineffective prevention are the direct result of the difficulties experienced by the preventers themselves:

- managing to keep up with ever-changing rules regarding safety;
- adopting a position between advising and coercing;
- protecting oneself against the risk, which limits ones own fine understanding of the worker's activity;
- hesitating between taking decisions in emergency situations and prudence in view of the fear of being sanctioned for inappropriate decisions.

By developing a risk analysis procedure which includes the action of risk preventers, ergotoxicology not only assesses that action but also examines the messages that it conveys.

4.5. Ergotoxicology and Risk Assessment

The hypothesis of a relationship between the determinants of activity, the regulations set up individually and collectively, and the level of expression of workers to toxic substances has been demonstrated during the search for a system of evaluating the retrospective exposure to pesticides of viticultural workers. Such a tool needed to be developed to demonstrate the relationship between the repeated contamination of workers by pesticides during treatment procedures in the vineyard and the long-term

Activity	Level of exposure *(mg/h)
Preparation with liquid/solid substances in open air	15
Pulverization with manual equipment	50
Application with pulverizer mounted on any type of low-vine tractor or high-vine straddler	1
Appllication with pulverizer mounted on intervine tractor for high vines	20
Application with pulverizer mounted on any type of tractor alternating between low and high vines	10
Etc.	

* Values obtained by extrapolation from documented meta-analyses

occurrence of neurologic symptoms. Unlike classical epidemiological approaches for estimating exposure, we used ergonomic work observations. This allowed us to identify the determinants of exposure defined as constant or repeated observables having an impact on the biological factors of contamination recognized in toxicology, and leading to a measurable level of exposure comparable with those described in the literature (figure 3). These observables were sought by a questionnaire given to workers at different phases of their professional life. The next stage was to classify typical homogeneous actions with respect to the factor of exposure. Each action was compared to a level of exposure established from a meta-analysis of published data (table 1). This tool was then applied to 1000 exposed or unexposed workers in order to evidence a relationship between a calculated level of exposure and the development of neuro-behavioral disturbances.

5. CONCLUSION

It would seem that by proposing a *modus operandi* allowing new hypotheses to emerge regarding the investigation and prevention of risks for workers, ergotoxicology is able to transform considerably the traditional notions of risk management in industrial environments.

The norms, safety recommendations, and individual protective equipment that represent the customary arsenal in the fight against risk are now showing their limitations. Neither the training of workers in safety measures nor official obligation to wear protective equipment have proved sufficient to transform risk behavior patterns or to make them be transformed. Preventers are wasting their time if they continue to speak in terms of "all you have to do is . . ." and call into question the impermeability of workers.

Processes which involve the full integration of the work components in an individual's activity, which offer a different model of man as both operator and actor in his work and in the construction of his health, are becoming more frequent in the analysis of a number of risks such as musculoskeletal disturbances of hypersolicitation. On the other hand, this is not the case where chemical risk is involved, partly because the normative approach is powerful in the representation of toxicologists and because ergonomists are reticent to tread a path which indeed seems complex.

Fatigue and Driving

L. R. Hartley

Institute for Research in Safety and Transport, Murdoch University,
Western Australia 6150

1. INTRODUCTION

Over the past few years there has been renewed international interest in the impact of fatigue on transportation safety, although research dates back some 80 years. The reasons are several: a better understanding of the causes of fatigue; better information on the numbers of fatigue-related crashes; increasing globalization leading to longer trips; increasing deregulation leading to 24-h operations in many industries including transport; and increasing "just-in-time" delivery of products.

Despite the interest there is no complete agreement on a definition of fatigue. Unlike metal fatigue, human fatigue leaves few telltale signs in a crash. Its presence has to be inferred. It was not until 1947 that Bartley and Chute distinguished between the physiological consequences of prolonged activity, which they termed impairment, and the psychological consequences including poor performance and negative feelings, which they termed fatigue. More recently it has become clear that poor performance reflects the impact of fatigue on the effectiveness of task performance and not a decline in the efficiency of performance. Well before performance has declined there may have been an increased cost to the operator in maintaining good performance when fatigued. This process is recognized in the still widely held view that sufficient motivation will overcome fatigue; a position that is no longer tenable. With this consideration in mind some authors have emphasized that fatigue is a state where the individual declares him/herself unwilling to continue the task any longer, because of the increased cost to them of doing so and their declining performance. This has merit in drawing attention to fatigue as a graded condition of which the end point is sleep, and to its subjective nature. People with practical concerns may want a more operational definition such as "fatigue is a state of declining alertness which eventually ends in sleep". Such a definition has merit in drawing attention to the key deficits which occur such as the decrease in the speed with which decisions are made, including making control maneuvers in a vehicle. The definition suggests an envelope of performance capability that stretches as the individual suffers fatigue increasing both the mean and variability of the performance measure.

Vehicle drivers, both commercial and private, are engaged in a task requiring their continuous attention, they may spend many hours behind the wheel, the environment may be monotonous, they may have less sleep than they would wish and they may be driving at a time when they would normally be asleep. The US National Transportation Safety Board (1995) examined 107 single truck crashes where the driver survived and records were available for the previous 4 days. Of crashes, 58% was said to be due to fatigue and in 18% the driver was found to be asleep. In the fatigue crashes drivers had an inverted sleep-waking cycle, had driven at night with lack of sleep, had < 6 h of sleep or had fragmented sleep patterns. This article is concerned with the three common causes of fatigue: long hours of work, lack of sleep and the time of day, and the two consequences of driver impairment and crashes.

2. THE SIZE OF THE PROBLEM

Most is known about truck crashes and fatigue. In 1985 the American Automotive Association examined 221 truck crashes where the truck was towed away. Surviving drivers and families were interviewed and records tracked to determine working hours. Crashes were determined to be due to fatigue if the driver had worked > 16 h and if the characteristics of the crash were consistent with falling sleep such as running off the road or on to the wrong side of the road. It was estimated that fatigue was the primary cause in 40% and a contributory cause in 60% of crashes. One study concluded that in articulated vehicles the incidence of fatigue crashes ranges between 5 and 10% of all crashes, ~20–30% of injury crashes and ~25–35% of fatal crashes. Studies of car crashes where the crash had similar characteristics of running off the road or a head-on collision when not overtaking show much the same prevalence. A UK study revealed 20% of freeway crashes were attributed to fatigue by car drivers.

These figures show fatigue to be comparable with alcohol in its impact on safety. Alcohol is estimated to be involved in ~5% of all crashes, 20% of injury crashes and 40% of fatal crashes. A recent study demonstrated that 24 h without sleep produces comparable impairment to a blood alcohol concentration of 0.05%. A blood alcohol level just in excess of 0.05% doubles the risk of a crash. Despite the comparability between the crash risk of alcohol and fatigue, the former cause has received a great deal of attention the latter has not. This is undoubtedly due to past ignorance of the contribution of fatigue and the difficulties inherent in measuring and predicting fatigue. There is no breathalyzer for fatigue.

3. LONG HOURS OF WORK

There have been studies of long hours of driving a truck, driving performance and crashes. But there are few studies of the impact of long hours of non-driving work on the crashes and performance of private motorists. Most developed jurisdictions limit working hours for truck drivers presumably in the belief that this controls fatigue. But these limits vary widely across jurisdictions and there is scant evidence they are effective in controlling crash rates.

One of the first studies of the effect of hours of work on crashes found that there were about twice as many crashes during the second half as there were in the first half of the trip, irrespective of how long it was. This suggests length of driving hours does cause fatigue. Another study used a case control approach where details of > 300 trucks which crashed were matched with details of trucks from the same place and time 1 week later. The relative risk of a crash for drivers who did > 8 h driving was twice that of drivers who drove fewer hours. A European study found that accident risk is relatively low when drivers are on the road between 08:00 and 19:00 hours, and have completed < 11 h of work. However, these same drivers show approximately twice the risk of accident when driving between 20:00 and 07:00 hours. Drivers who have accumulated > 11 h of driving and non-driving work show twice the risk of accident between 08:00 and 19:00 compared with those who have worked < 11 h. For those drivers who have completed > 11 h of work, accident risk is doubled

again when driving between 20:00 and 07:00 hours as compared with daytime driving.

The most well-known on-road study of performance examined 12 truck and six bus drivers over 1 week under a range of schedules. Vehicle control, drowsiness, hazardous incidents, performance on tests and subjective ratings were all measured. When differences in the road geometry were taken into account vehicle control deteriorated after 8 h on regular schedules and after 5 h on irregular schedules. A more recent North American study using similar measures compared 10- and 13-h schedules but failed to find any differences in vehicle control between the schedules. However, the latter study has not controlled for road geometry. This study did find a major impact of time of day on vehicle control, drowsiness, subjective ratings and tests. All measures were worse when driving between midnight and dawn as compared to daytime.

So there is convincing evidence that long hours of work are an important cause of crashes and that poor vehicle control is a factor here. But there is also evidence that the timing of work, especially at night, is at least as an important a problem and drowsiness and vehicle control are the factors here.

4. TIMING OF WORK

The pattern of human behavior follows a 24-h cycle through sleep, awakening, increasing alertness during the daylight hours to preparation for sleep in the evening. A large number of biological functions demonstrate this pattern. For drivers the cycle of alertness is of most interest. A very large number of studies are now available that show alertness, especially vigilance, to be lowest during the hours we normally sleep, and the propensity to fall asleep is conversely greatest at this time. As when changing time zones, adaptation to a regular pattern of night work takes place. But no one has ever observed complete adaptation of the biological rhythms and alertness to a life of night-shift work; quite possibly there are too many external cues such as daylight to permit this to occur. With the exception of overnight delivery drivers few drivers consistently work nights. So it would not be expected that they would show much adaptation to night work but would have reduced alertness and increased drowsiness at night and the pattern of drivers' propensity to fall asleep show just that.

There are studies of crash risk at different times of day in which the number of crashes is adjusted to take account of the number of vehicles on the road. Truck crashes in which drivers were dozing were seven times more frequent between midnight and 08:00 hours than at other times of day and the highest risk was between 04:00 and 06:00 hours. A Swedish study found single vehicle truck crash risk increased by a factor of four between 03:00 and 05:00 hours and the increase in single vehicle car crashes was considerably greater. In a UK study of car drivers fatigue is reported as a factor in 36% of the crashes before dawn and declines to 4% of crashes during the morning, rising again through the afternoon and evening. A European study which showed a 4-fold increased risk of a truck crash when driving at night was described above. There is also evidence that successive periods of night driving pose a further increase in risk of a crash.

In the studies referred to under Long Hours of Work the physiological records of drivers' brain waves showed greater sleepiness when working at night, especially after midnight. And

video recordings taken of drivers' faces in a recent North American study showed drowsiness in 5% of the recordings and virtually all of these episodes occurred at night. Records of vehicle control also showed it deteriorated at night. The North American study concluded that night driving was a more important determinant of drowsiness and poor vehicle control than long hours of work alone.

5. TIMING AND DURATION OF SLEEP

As for other biological rhythms sleep is of the best quality and quantity if taken at night. Nightshift workers typically get 2 h less sleep than dayshift workers and some studies of night drivers have shown values as low as 4 h of sleep are obtained.

In the previously referred study of 107 single-vehicle truck crashes by the National Transportation Safety Board the most important factors in predicting night-time fatigue crashes were the duration of the most recent sleep period, the amount of sleep in the past 24 h and split sleep patterns. Truck drivers in fatigue crashes obtained an average of 5.5 h sleep in the last sleep period before the crash. This was 2.5 h less than the drivers involved in non-fatigue crashes. In split sleeps drivers typically work 4 h and sleep 4 h by sharing the driving. One study has found that this practice increases crash risk by a factor of 3. A study by the present author found drivers to have a 4-fold increase in hazardous incidents including crashes if they obtained < 6 h of sleep.

6. DRIVERS' REPORTS OF FATIGUE

Given that fatigue is as serious a safety problem as alcohol, how serious a problem do truck drivers think it is? In a study by the author 10% of truck drivers found fatigue to be at least "often" a problem for themselves. However, 36% thought fatigue to be at least "often" a problem for other transport drivers. This suggests a degree of over-optimism among drivers about their own capabilities as compared with every one else. In the National Transportation Board study of 107 single vehicle truck crashes in which 58% were attributed to fatigue ~80% of those drivers rated their last sleep as good or excellent. These data suggest that drivers underestimate their own state of fatigue and the impact of the causes of fatigue, despite some studies revealing that up to 20% of drivers will admit to falling asleep at the wheel in the past month.

Because it is unlikely that a technological device will be available in the near future to assess a driver's state of fatigue it is important to find out how accurate are drivers' self assessments of their fatigue, for this is the only information on which they can base their decision to cease driving. The research findings are not unequivocal. As reported in the recent North American study some drivers will drift in and out of microsleeps of many seconds. Unless these periods of sleep last minutes people are usually unaware of them occurring. However, people are aware of having to fight sleep before it over takes them. Perhaps the appropriate conclusion is that drivers will be aware they are fatigued and likely to fall asleep but do not know when this will occur and so continue driving. This problem has important liability implications.

7. CONCLUSIONS

Fatigue poses as great a safety problem for drivers as does alcohol. Crash risk starts to increase after as short a period as 6 h of driving and may be double after 11 h of driving or less. A deterioration

in driving performance may occur even earlier depending on the trip schedule. Dawn driving when the body rhythm of alertness is lowest increases crash risk by at least 4-fold and more for car drivers. Dawn driving performance is impaired and most people will demonstrate drowsiness and some drivers will move in and out of sleep at this time. Drivers who work at night will inevitably have poorer quality and quantity of sleep. Obtaining < 6 h of sleep increases risk by a factor of ~4 and splitting sleep periods imposes almost as great a risk. Most truck drivers do not recognize fatigue as a problem for them and many will be unaware of passing in and out of microsleeps.

The existing regulatory framework for controlling fatigue, termed Hours of Service, does not address the principle causes of fatigue, the timing of work and rest and the necessity to obtain adequate sleep.

1. INTRODUCTION

According to Louhevaara *et al.* (1997), ergonomics is defined as a multidisciplinary field of science based on physiology, psychology, sociology, and the application of technical sciences. It considers human capacities, needs, and limitations in the interaction of technical and organizational work systems. The integrated knowledge of ergonomics is used to develop work contents and environments through the use of job design and redesign measures for promoting health, work ability, safety and professional competence as well as the productivity and quality of work.

Fire-fighting and rescue work in emergency situations involves special ergonomic problems. Without taking into consideration work equipment and methods, it is almost impossible to influence the exposure of fire-fighting and rescue work by ergonomics. Therefore, physical work capacity is a crucial factor in a firefighter's work, and it should be sufficient for the physical stress factors of various operative tasks regardless of age. However, the exposure, safety issues, and individual work capacity in fire-fighting and rescue work can be influenced by measures related to the organization of work and management, as shown in figure 1.

2. EXPOSURE CAUSED BY ENVIRONMENTAL AND PHYSICAL STRESS FACTORS

Emergency situations are usually occasional, unpredictable, stressful, and dangerous. In these situations a firefighter must act determinedly, effectively, and safely. Every firefighter, regardless of age, needs to operate in various emergency situations at least a few times a year. Emergency situations take place under a wide range of thermal conditions because of variations in personal protective equipment, season and climate, and the intensity of the environmental heat and muscular work. Firefighters are exposed to many kinds of injuries and burns. According to a Finnish questionnaire study (n=846) of Lusa-Moser *et al.* (1997), 12% of the firefighters who responded had experienced local skin damage and 6–28% of the firefighters had repeatedly had extensive skin flushing in different body parts after the fire-fighting events.

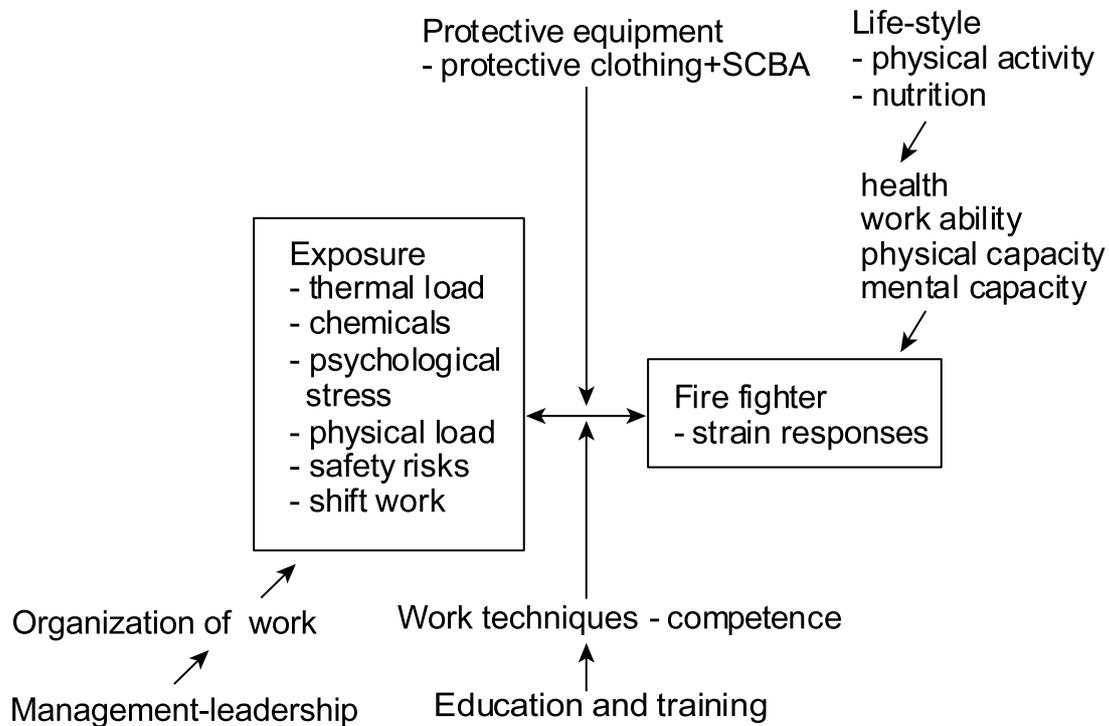
The increased risk of injuries in fire-fighting and rescue work is mainly due to the use of heavy machines and equipment, dangerous entrances and restricted spaces for moving, extreme heat stress, and rapidly changing environmental conditions. The mean annual frequency of injuries which caused at least three


Figure 1. In emergency situations of fire-fighting and rescue work the exposure and individual strain responses to the exposure can be affected by various ergonomic measures for improving protective equipment, organization of work, professional competence and work methods

days sick of leave in 3000 professional operational Finnish firefighters was 388. The main events resulting in injuries were slipping and tripping, overstrain or an accident involving human motion, and stepping on objects or being struck by objects. According to Reichelt and Conrad (1995), in the USA the incidence of work-related injuries in the fire service was reported to be 4.7 times higher than in the private industry when almost half of the firefighters (41%) reported injuries.

Firefighters need also efficient protection against combustion gas containing a variable mixture of compounds. The number of different chemicals and substances detected in fires is over 800. Their toxicity varies greatly and depends mainly on the type of fuel, the heat of the fire, and the amount of oxygen available for combustion.

In a building fire, a firefighter may have to climb stairs while wearing personal protective equipment and carrying tools weighting up to 50 kg. After climbing and clearing the entrance, a firefighter should be able to help a victim or resist the propulsive force of a water spout. In rescue operations associated with traffic accidents, a firefighter must often use hydraulic tools weighting 15–20 kg in poor working positions. Lifting and carrying tasks while using heavy personal protective equipment demands good aerobic and muscular capacity as well as motor skills. In the study of Lusa (1991), the opening of a ceiling with a motor saw was simulated. In the task, the compressive force in the low back was found to be so high that the risk for back injuries increased considerably according to the norms of the National Institute of Occupational Health and Safety in the USA. Dynamic stress can be assessed with the measurement of absolute oxygen consumption (l/min) during work. Louhevaara *et al.* (1985) reported a mean oxygen consumption of 2.1–2.8 l/min in various fire-fighting tasks and different thermal conditions. The cardiorespiratory strain varies according to an individual's cardiorespiratory and muscular fitness, body composition, as well as motor and occupational skills.

Firefighters are also exposed to psychological stress induced by unpredictable and dangerous situations, and to stress caused by their role as help providers. In addition to their own safety, firefighters are responsible for the safety of their co-workers and others involved in an event. Shift and night work markedly emphasize the effects of different environmental stress factors such as lightning and ambient temperature. A firefighter may also experience considerable stress due to the intermittent nature of the work. According to the report of Glazner (1996), a firefighter is more likely to be injured at mealtimes or during a night shift. Due to the shift-work nature of fire-fighting and rescue work, both disruption of eating patterns and fatigue increase the risk of work-related injuries.

3. PERSONAL FIRE PROTECTIVE EQUIPMENT

Personal fire protective equipment, including protective clothing and a self-contained breathing apparatus (SCBA) are necessary protection against combustion gases and heat in most emergency situations. Already in a thermoneutral environment, the use of personal fire protective equipment weighting 25 kg increases cardiorespiratory strain by 20–30% at submaximal work levels, and also increases thermal strain significantly. In the study of Lusa *et al.* (1993), two walking tests were performed on a treadmill, and experienced firefighters served as subjects. First,

Table 1. Heart rate, oxygen consumption, rectal temperature and blood lactate at the end of the treadmill exercise without and with the protective equipment. The values given are means ± SD

Variable	Without equipment	Protective equipment
Heart rate (beats·min⁻¹)	129 ± 4	169 ± 4***
Oxygen consumption (1·min⁻¹)	2.2 ± 0.1	3.0 ± 0.1***
Oxygen consumption (ml·min⁻¹·Kg⁻¹)	26.5 ± 0.6	36.4 ± 1.0***
Rectal temperature (℃)	37.6 ± 0.1	37.9 ± 0.1*
Blood lactate (mmm01·1⁻¹)	1.1 ± 0.2	2.5 ± 0.7

*$p < 0.05$, ***$p < 0.001$

the subjects wore sportswear and then, after the rest period, repeated the test with fire protective equipment. Table 1 shows that in the test with the protective equipment, heart rate, oxygen consumption, rectal temperature and blood lactate were higher compared to the control test with sportswear. In addition, the use of the SCBA hampers breathing, and may cause incomplete gas exchange (Lusa 1994).

The use of the SCBA also sets special demands on motor skills, affecting the postural control, for example, by changing the center of gravity. The face mask of the SCBA also limits the visual field and this may also have an effect on postural control. The SCBA is usually used in difficult environmental conditions. Working in smoky or dark places requires that other body control systems (e.g. the kinesthetic sense, the sense of orientation) have to be more alert because vision cannot be used maximally. Moving with the personal fire protective equipment in fire-fighting and rescue situations demands good motor skills, particularly when moving on roofs or climbing up ladders. Punakallio *et al.* (1999) reported that firefighters, regardless of age, made more errors and were slower in the functional dynamic balance test while wearing the fire protective equipment than when wearing sportswear. The youngest group of firefighters was, on average, quicker and more accurate in the test with the fire protective equipment than the oldest group was in sportswear. The good physical capacity of the young firefighters seemed to compensate for the disadvantages caused by the equipment to the motor skills.

The currently accepted multilayer fire protective suit designed to fulfill the European standard provides more effective heat isolation than the conventional fire suit. It protects firefighters effectively from powerful heat radiation, although, on the other hand, it makes heat transfer more difficult when the thick layer limits adequate body cooling through evaporation; the suit is also heavy (up to 3 kg). It is not possible to increase the weight of the fire protective equipment because of the obvious risk of both cardiorespiratory and thermal overstrain. A reduction in the weight of the protective equipment is problematic without decreasing safety and the protective properties too much. It is, however, possible to lighten the equipment by replacing the present steel air containers by containers made of lighter fiberglass materials. These containers are about 9 kg lighter than the traditional steel containers; however, they are also more expensive. The lighter containers would be useful in fire-fighting and rescue work because of decreased cardiorespiratory and musculoskeletal strain, and better control of balance.

4. WORK TECHNIQUE, COMPETENCE, AND TRAINING

In fire-fighting and rescue work, the range of duties has widened markedly in recent years; an example is the sharp increase in the daily transport of patients. This underlines the importance of continuous education and training. Good work methods also contribute to safer work, reducing, for instance, the risk of injuries due to physical overstrain. Adequate competence and skills can also compensate for a lack of physical capacity with respect to job demands.

In the questionnaire study of Lusa-Moser *et al.* (1997), two-thirds of the firefighters (64%) considered that they had inadequate training and guidance for some of their tasks. In particular, the older firefighters felt that they had insufficient training and guidance to enable them to perform the whole variety of fire-fighting and rescue tasks. This lack was also illustrated by the fact that older respondents claimed more frequently than the young firefighters that they encountered too difficult work situations. This may be due to a number of reasons. Extremely stressful and difficult situations that have occurred in the past affect an individual's experimental world, and negative memories may augment the mental burden in new situations if the past situations have not been dealt with thoroughly — for example, by means of defusing and debriefing. On the other hand, the decrease in physical capacity related to aging may also affect experiences resulting from extreme situations. The responsibility for fire-fighting and rescue tasks for which older firefighters in particular may have had inadequate training can increase the strain as well. These facts also underlie the importance of continuous education and training in fire-fighting and rescue work.

5. MANAGEMENT — LEADERSHIP

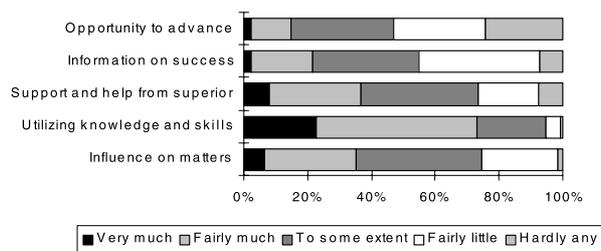
The enhancement of management was considered very important by all firefighters according to Lusa-Moser *et al.* (1997). One-quarter of the firefighters who responded (26%) get, when needed, little support and help from their superiors; the rest of the respondents felt that they got support at least to some extent (figure 2). Furthermore, almost one-half of the respondents (45%) considered that they got very little or no feed-back on their success at work. Three out of four firefighters (75%) evaluated that they could influence much, or to some extent, matters which concerned them at the fire department. Older firefighters had significantly more possibilities to influence work matters than did the younger ones. However, older firefighters felt a lack of opportunity to advance more often than did the younger firefighters. About one-half of all the respondents (45%) thought that they had only few opportunities to advance in their work. Almost everyone (95%) felt that they had at least fairly good possibilities to influence and use their knowledge and skills at work. Moreover, the firefighters having good psychological resources were more likely to feel that they could utilize their own talents and abilities at work, compared to those having moderate or poor resources.


Figure 2. The factors associated with a firefighter's well-being at work and work role (percentage of respondents)

According to Lusa-Moser *et al.* (1997) nearly three-quarters of the respondents (70%) considered that the division of labor was correct and equal at fire departments, while 18% considered that it was unfair. Within their own work crews, the firefighters felt that co-operation was good, despite differing attitudes towards work. There have been attempts to solve negative attitudes towards work that hamper the progress of work by discussing and consulting (69%), by ordering and resorting to authority (24%), while the remainder of the respondents thought that there had been no attempts to deal with negative attitudes. The psychosocial atmosphere within the work shift was considered comfortable by about one-half of the firefighters (46%), and a minority (16%) thought that the atmosphere was supportive. However, 29% felt that the atmosphere was prejudiced, while 8% felt that the atmosphere was tense and competitive.

In the Finnish study of Härmä *et al.* (1991), firefighters were able to sleep, on average, six hours during a 24-hour work shift and only a few of them slept under two hours. The quality of sleep was a little worse at work than at home, but the structure of the sleep did not differ from that registered on days off. As a matter of fact, the sleep during the work shift contained even more phases of deep sleep than that at home, which is important for the recovery of alertness. It was concluded that recovery in the studied 24-hour shifts was sufficient for the firefighters. However, if the number of alarms increases, the proportion of firefighters who cannot get sufficient sleep during a work shift increases. It was recommended that night shifts be added, for example, temporally using the rest pause for sleeping.

6. PHYSICAL CAPACITY AND HEALTH

Accidents and fires can occur at any time and place, and under a variety of circumstances. There are almost no standards (norms) to influence the ergonomics of work or the work environment. Despite improvements in professional competence, work methods, and equipment, a firefighter's work ability and safety depend largely on physical capacity. Finnish multidisciplinary studies have led to the standardization of health examinations and assessments of the physical capacity of firefighters. The minimum levels of the cardiorespiratory and muscular fitness of a firefighter who needs to carry out smoke-diving tasks have also been defined. The maximal oxygen consumption of an operative firefighter should be at least 3 l/min or 36 ml/min/kg. At these levels, there is a certain margin in the maximal oxygen consumption of a firefighter to tackle unpredictable situations without obvious risk for overstrain, disorders or illnesses.

According to the laboratory study of Punakallio *et al.* (1999), about one-half of 50- to 54-year-old Finnish firefighters did not

reach the minimum requirements of maximal oxygen consumption. The proportion of unfit firefighters increased significantly even in the 40–44-years age group as compared with the firefighters aged 30–34 years. According to the Work Ability Index, most of the firefighters had good subjective work ability (Punakallio *et al.* 1999). However, the prevalence of poor work ability increased with age. About one-fifth of the firefighters aged over 49 years (19%) rated their work ability as poor. The corresponding proportion for poor work ability among municipal male workers in Finland is 15%. The work ability of firefighters in relation to their physical job demands was perceived to decrease more steeply than the work ability related to psychological job demands. In addition to age, factors related to work and lifestyle were associated with good work ability based on the Work Ability Index. These factors explain 53% of the variability of the Work Ability Index shown in table 2.

7. WORK DEVELOPING ASPECTS IN THE FUTURE

The average age of firefighters is increasing rapidly: nowadays the average age of professional firefighters in many fire departments in Finland is over 40 years. The proportion of firefighters whose health and physical capacity are not sufficient for the job demands is increasing continuously due to the recent change in the retirement age. Nowadays, every firefighter should be able to perform smoke-diving tasks up to the age of 65 years. In larger fire departments, unfit firefighters can be transferred to physically less demanding tasks. This is not possible in smaller fire departments where only a few firefighters are on duty and where each one should be able to perform all tasks. Therefore, it should be advisable to plan, from the beginning of each firefighter's career, alternative career paths which demand less physical capacity than that required by, for instance, smoke-diving tasks. The valuable working skills and knowledge collected during the early part of the career should be utilized later in other fire-fighting and rescue tasks. Possible alternatives could be, for example, prevention of accidents, and education and counseling. With the use of this new strategy, the remaining work ability could be supported to prevent early retirement due to work disablement. The proportion of disabled firefighters is already increasing in the 40- to 49-year-old age group of firefighters, and especially in those older than 50 years. According to Lusa-Moser *et al.* (1997) there are several important factors which support coping at work (figure 3).

In the emergency situations of fire-fighting and rescue work,

Table 2. The factors associated with the Work Ability Index. The model explained 53% of the variability of the index

Factor	Connection
Age	–
Smoking	–
Daytime tiredness	–
Psychological stress	–
Physical exercises	+
Life satisfaction	+
Meaning of work	+
Perceived stress tolerance	+

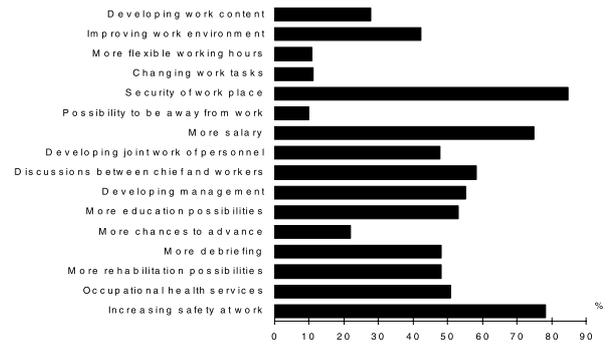
All the factors were statistically significant, at least at the p<0.05 level


Figure 3. The most important factors affecting coping at work in fire-fighting and rescue work (percentage of respondents)

ergonomics is primarily needed for developing work equipment and methods, as well as for the organization of work.

Human Control of the Behavioral Environment

T. J. Smith

Human Factors Research Laboratory, Division of Kinesiology, University of Minnesota, 1900 University Avenue SE, Minneapolis, MN 55455, USA

1. INTRODUCTION

Work is the most ubiquitous form of human activity on the planet. In the strict physical scientific sense of the term (application of energy to drive chemical reactions (internal work) or to move body effectors (external work)), human engagement in work is synonymous with life itself, beginning at the moment of conception and terminating only with death. In the behavioral sense, all conscious human activity represents work directed at some sort of goal or another. In the occupational sense, all humans routinely engage in purposeful task or job work activity throughout most of their lives. In the evolutionary sense, since emergence of the species work activity has served both as the engine of the human condition and as the means of human self-selection.

Encyclopedic treatments of the term "work" typically focus only on its physical scientific meaning, ignoring the much broader human perspective. Dictionary definitions (the term has relatively recent Old English origins dating back less than 1500 years) hint at its broader implications — Webster provides over 30 definitions of "work" used as a transitive or intransitive verb, and a dozen definitions of its use as a noun. However, it is with the historical perspective that the true human meaning of the term begins to emerge. All of the so-called prehistorical and historical ages of human development and civilization — Stone, Copper, Bronze, Iron, Classical, Medieval, Renaissance, Industrial, Information — refer explicitly or implicitly to distinctive modes and expression of human work activity.

Work serves also as a primary focus of human cultural, religious, intellectual, political and scientific thought. The emergence of human civilization essentially rested upon a series of transformations in how work was organized. The first words of the Bible — "And God created heaven and earth" — refer to work of the Almighty. Human work was an object of reverence for the ancient Hebrews, a Judeo-Christian tradition that persists to this day. The organization of work — in warfare, commerce, cultural and religious expression, and society — has represented a primary focus of the state from its earliest origins. Political thought and philosophy revolve around the best approach to such organization. Certain forms of government such as communism exalt work as the centerpiece of their design. The evolution of technology reflects the application of increasingly sophisticated artifacts to aid human work performance. All academic, intellectual and scientific disciplines concerned with human performance — from art to athletics, from business to engineering — are concerned in one way or another with how human work is organized and expressed. And of course the scientific focus of this encyclopedia — ergonomics/human factors — is concerned with all dimensions and conditions of human work. Ergonomics is defined as, "laws and customs of work."

Given the extremely broad scope of the topic, it would be impractical to consider here all of the possible human implications of the term "work." Sections therefore touch upon scientific theories of work, landmarks in the evolution of work, general conclusions about laws and customs of work, and the future of work.

2. THEORIES OF WORK

What is the purpose of human work? In light of the universal significance of work performance for defining, organizing and guiding the human condition, it is remarkable that no generally accepted theory of human work has yet been promulgated. Scientific concepts of work essentially have not been developed much beyond conventional views of labor as a means of production and source of wealth (Smith 1776), as a limited aspect of technology (Marx 1867), as an exploited competitor in class struggle (Marx and Engels 1848), or as essentially a mechanistic component of work process subject to "scientific management" (Taylor 1911). A variety of sources can be cited (Galbraith 1958, McGregor 1960, Smith 1962, 1965, Horowitz 1998) to support the conclusion that all of these viewpoints have been largely discredited as they apply to motivational behavior in the performance of work.

It is equally remarkable that despite its putative role as *the* major scientific discipline concerned with human behavior at work, Ergonomics/Human Factors science has been largely silent in addressing this question. For example, no theoretic treatment of work is to be found in handbooks concerned with Ergonomics/Human Factors (Salvendy 1982, 1987). Moreover, work receives short shrift as an object of formal academic focus by Ergonomics/Human Factors science. Among 79 North American graduate programs in Ergonomics/Human Factors catalogued by the US Human Factors and Ergonomics Society in 1997, only one (Department of Work Environment, Lowell University, Lowell, MA) has the term "work" in the title.

The perspective offered here is that purposeful work represents the principal behavioral activity by means of which humans: (1) self-control their interaction with their environment; (2) self-define themselves as individuals; (3) create and human factor new modes and dimensions of work technology and design; and (4) have self-selectively guided their evolutionary trajectory as a species (Smith 1965). That is, with its goal of human factoring the ecosystem to achieve environmental control, human performance of work has a mutually adaptive influence both on the nature of the performer as well as on the nature of work itself.

The major assumptions of this behavioral cybernetic theory (Smith and Smith 1987) of human work are summarized in Figure 1. The theory views work as a closed-loop process in which the worker employs various behavioral strategies to control sensory feedback from the physical, social and organizational design attributes of the work environment. In so doing, the worker self-organizes and self-defines his/her individual biosocial identity as a distinct member of society, both psychologically and physiologically.

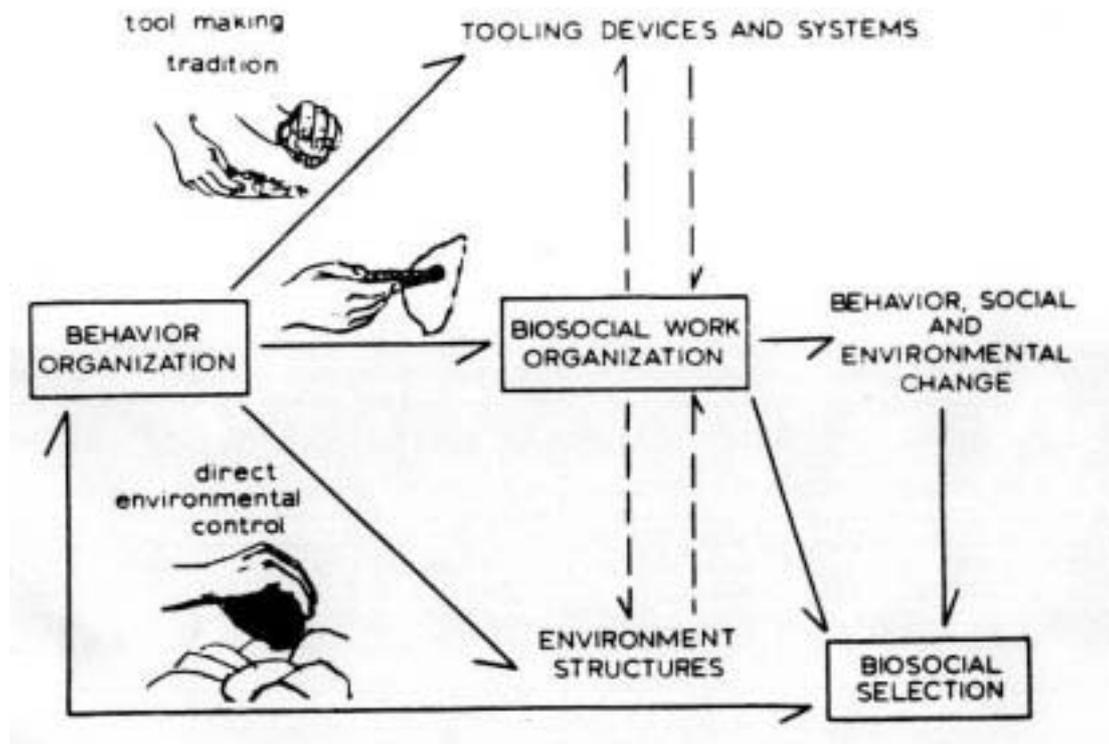
In addition to individual self-definition, another major feedback influence of work behavior assumed by the model in Figure 1 is on the nature of work design itself. That is, interaction with the work environment prompts consideration on the part of the individual worker and the organizational work system as


Figure 1. Behavioral cybernetic theory of human work. Throughout evolution, humans have endeavored to control their behavioral environment through the use of work to fabricate tools and other types of technology, and to organize and structure their society. Work activity of this sort tends to catalyze behavioral, social, technological and environmental change, which in turn feeds back to influence the primary features of behavioral organization of the individual.

to how work design features can be modified and human factored to facilitate work performance. In this manner, work itself has a positive feedback effect on cognitive creation of new modes and dimensions of work design and work technology.

Finally, the model in Figure 1 assumes that the behavioral feedback effects of work represent the principal mechanism of human self-selection in evolution. Figure 2 further elaborates upon this concept. The premise in Figure 2 is that the evolutionary emergence of all of the distinctive biological features of species *homo* — upright posture, relatively hairless body, apposed thumb and fingers mediating manipulative skill, verbal communication, distinctive modifications in neurohumoral regulation; and specialization in brain structure and function — was influenced and guided in a major way as a self-selective process through the planning, organization and execution of work, and through the fabrication of tools and other artifacts to facilitate the performance of work.

A number of lines of evidence can be cited to support the behavioral cybernetic models of work depicted in Figures 1 and 2 (Smith 1962, 1965). Various observations from behavioral science indicate that both the distinctive personalities as well as the cognitive and motor behavioral proficiencies of different individuals are influenced in a major way by their daily work activity throughout life. Indeed, the motivational behavior of work preoccupies human attention and time to a far greater extent than other sources of motivation such as eating and drinking, aggression, activity–rest cycles, sexual behavior, or relaxation. These behavioral feedback effects of work augment whatever contributions innate biological differences may make to defining

individual differences, and we may speculate that such effects date back to the dawn of the species.

A second line of evidence is that human evolutionary origins and development are closely associated with the fabrication and use of tools and other artifacts for the performance of work, a process that has shown continuous progression since the dawn of the species. That is, most of the behavioral and technological functions of modern machines employed to facilitate work performance — e.g. those of shaping, striking, cutting, smashing, forming, lifting, or turning — are derivative and can be traced back to human use of hand tools in remote prehistory for similar purposes (Oakley 1957).

Thirdly, information gathered from present-day primitive tribal and village groups suggests that transitional processes in the social, cultural and technological development of human societies and civilizations are related more prominently to distinctive adaptive changes in the organization and implementation of work than to those in other behavioral factors such as changes in patterns of plant or animal husbandry, consumption, etc. (Woolley 1946, Wolf 1954). Indeed, the latter depend upon the former. The relatively permanent nature of tools (some stone tools have been dated back over 2 million years), machines and other technological artifacts of work suggests a dominant role of behavioral feedback mechanisms of work activity and technology in defining both the direction and pattern of human development.

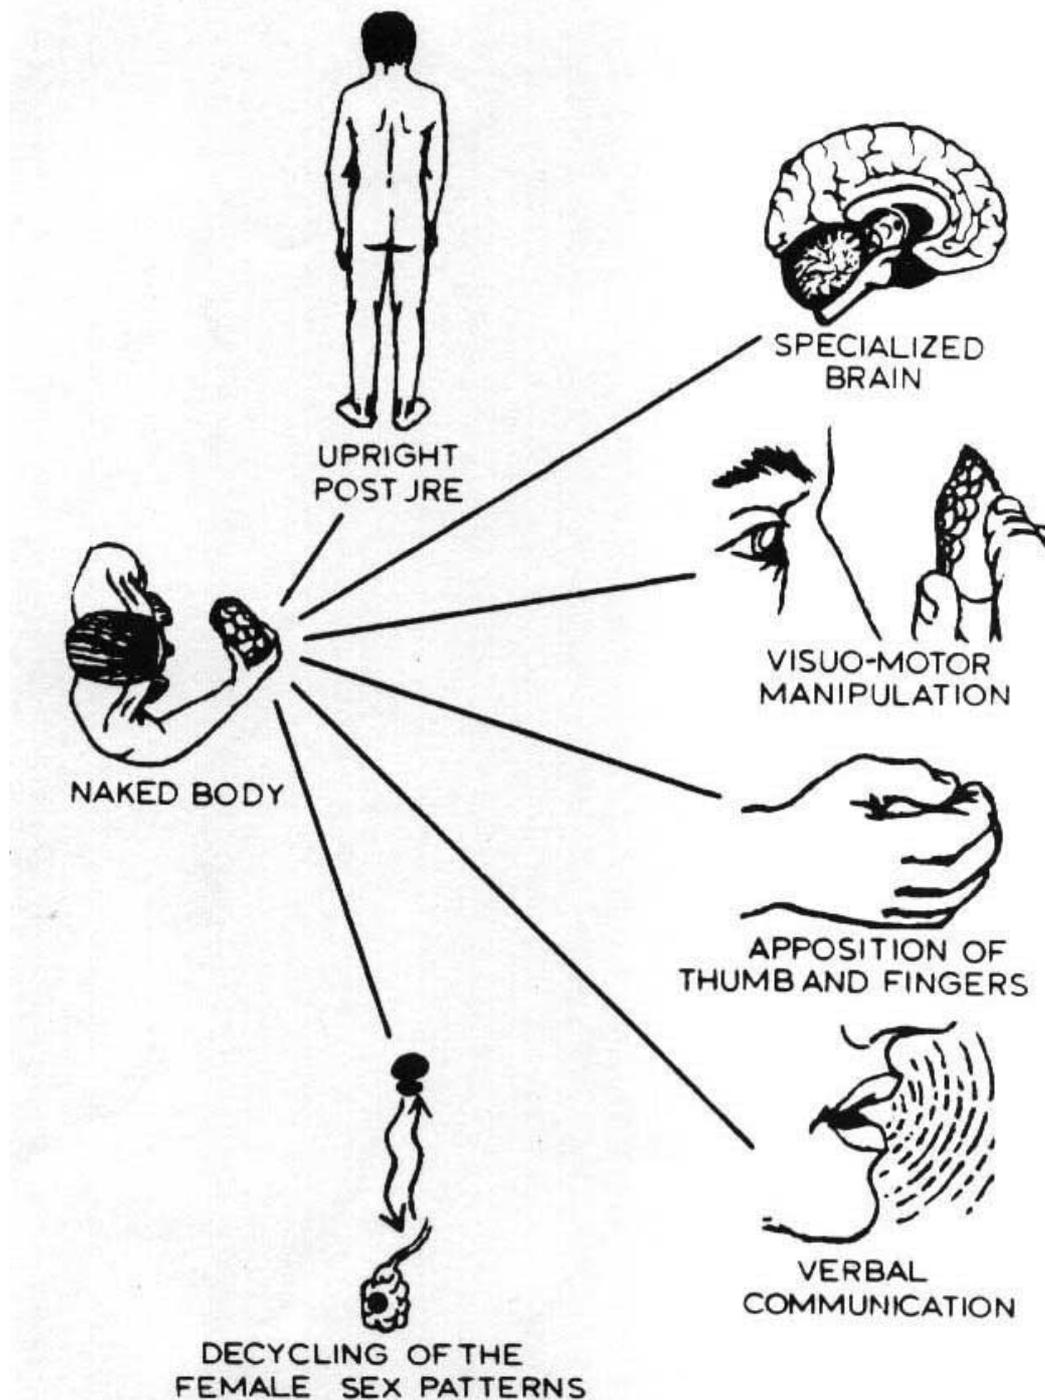
Finally, using parallels from present-day observations of human behavior, it can be argued that all of the mechanisms of natural selection invoked by classical evolutionary theory to


Figure 2. Work theory of feedback selection. Through the use of work to control the behavioral environment, humans tend to self-select anatomical and physiological attributes of behavioral organization and personality that tend to enhance such control, as a consequence of differential survival and reproductive success. Work behavior and natural selection thereby become coupled in a feedback manner.

explain the evolution of the modern humans — transformation of social and family structures, exploitation of new sources of nutrition, advantages in intra- and interspecies competition, dispersion into new ecosystems, heightened motor behavioral capabilities, improved exploitation of external sources of environmental energy — are directly linked in a behavioral feedback manner to advances in the organization, technology and conduct of work to human factor and control the environment and to thereby facilitate differential reproductive success. From this perspective, human evolution may be viewed as a self-selective process largely influenced and guided by work behavior.

What is distinctive about human work? No one who has observed a bee or ant colony can doubt that non-human species are entirely capable of intense, highly organized, and socially coherent patterns of work. What then distinguishes the special nature and outcomes of human work? Suggested answers to this question include human capacity for verbal communication and

cognition, factors that also are implicated in addressing the related question of "humanness."

An undeniably unique feature of human work performance, that both complements and underlies its other distinct attributes, relates to the use of work to track and thereby control time (Smith 1965). Human capabilities in the control of time encompass perception and comprehension of the past, the future, time continuity, time persistence, historical time, relative time (early, late, then, before, etc.), time interruption, time marking and recording, temporal change, clock time, space–time interaction, time prediction, and space–time relativity.

Humans rely upon these capabilities to control spatio-temporal feedback from prevailing conditions in the present and past, and to thereby feedforward control their actions into the future. No other species displays comparable sophistication in temporal awareness and control. However, to attain such control, humans have had to create work-derived artifacts for marking and tracking time, because innate comprehension of time apparently differs little among humans and other animals. For example, languages of extant aboriginal cultures contain no words for temporal concepts such as "early," "late," "then," "now," "past," "'future," "history," etc. One of the key events in the evolution of modern humans therefore was the augmentation of space-structured behavior (common to humans and many other animals) with capabilities for time-structured behavior through fabrication of artifacts for telling time. Marshack (1964) offers evidence that such artifacts date back some 30 000–40 000 years, anticipating by thousands of years the massive Neolithic and

Bronze Age megaliths and temples erected in Egypt, on the Salisbury Plain, and elsewhere for tracking time.

Through fabrication of such artifacts, human control of work and of time have become inextricably integrated. From a cybernetic perspective therefore (Figure 1), one of the key self-selective influences of work behavior in human evolution has been the use of work to human factor technological and social means for tracking time, thereby allowing projection of work-derived artifacts, knowledge and skill into the future to benefit generations yet unborn.

3. LANDMARKS IN THE EVOLUTION OF HUMAN WORK

Landmarks in the evolutionary progression of human work can be characterized in terms of the use of work to guide the emergence of new forms of societal organization (Figure 3), of technology (Figure 4), or of modes of symbolic communication (Figure 5). The heavy lines in the figures suggest that the development and elaboration of each of these manifestations of work has been more or less continuous and progressive throughout evolution (Smith 1965), in patterns that largely parallel the non-linear growth of human population itself. However, at certain critical periods in prehistory and history, innovative patterns of adaptive organization of work emerged to mediate the creation of new types of architecture and modes of societal integration, new tools, machines and other technologies, and new methods of symbolic communication.

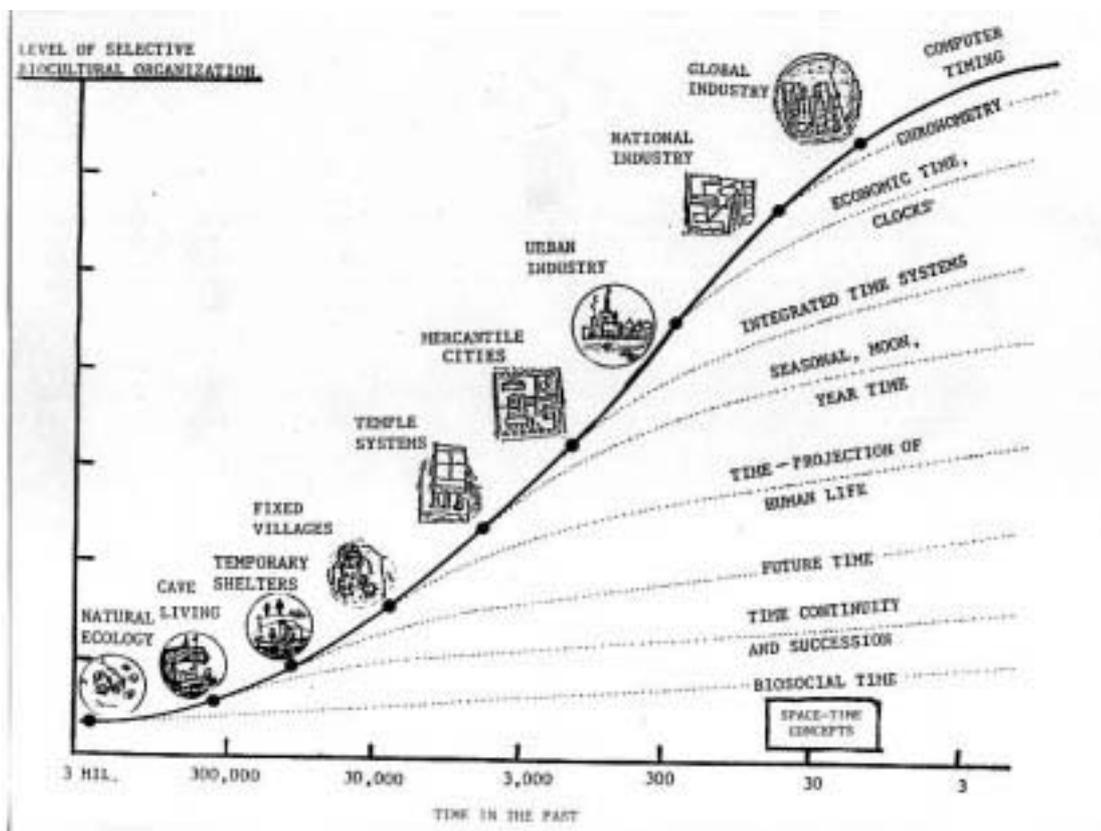
In particular, Figure 3 indicates that forms of societal


Figure 3. Progressive emergence in evolution of innovative forms of societal organization, feedback coupled to advances in work behavior and in time perception and control. As new forms of organization emerge, old forms persist and are conserved.
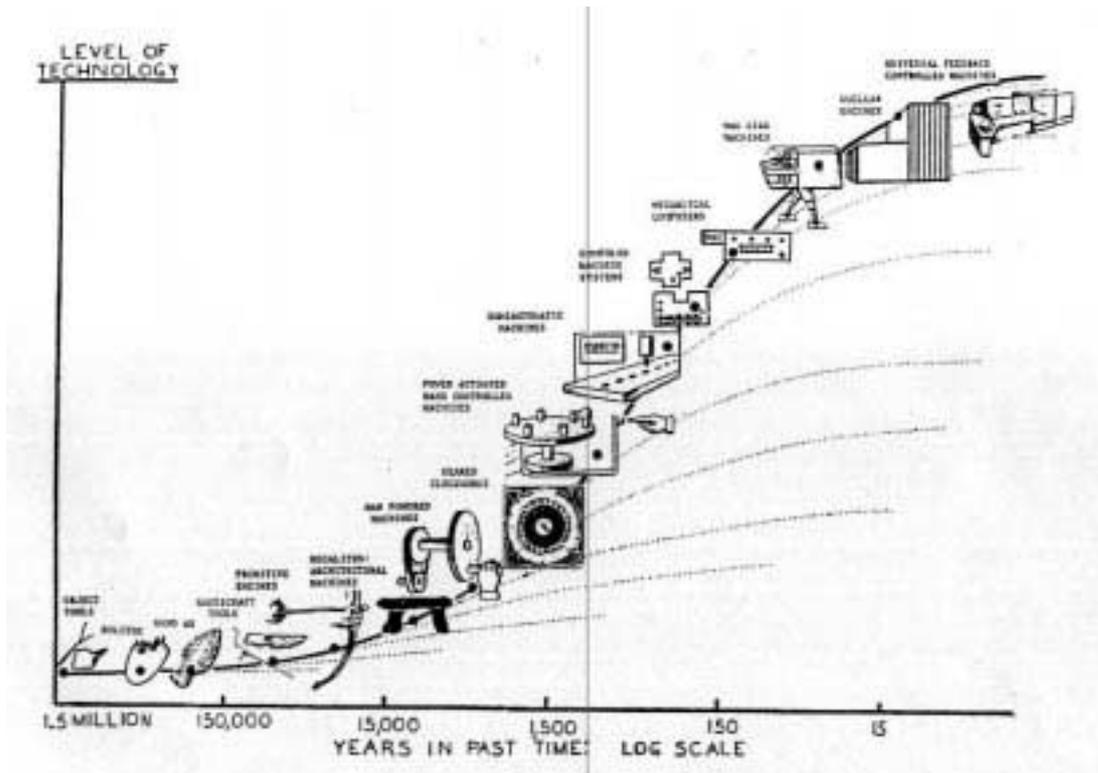

Figure 4. Progressive emergence in evolution of innovative forms of technology, feedback coupled to advances in work behavior. As new forms of technology emerge, old forms persist and are conserved.
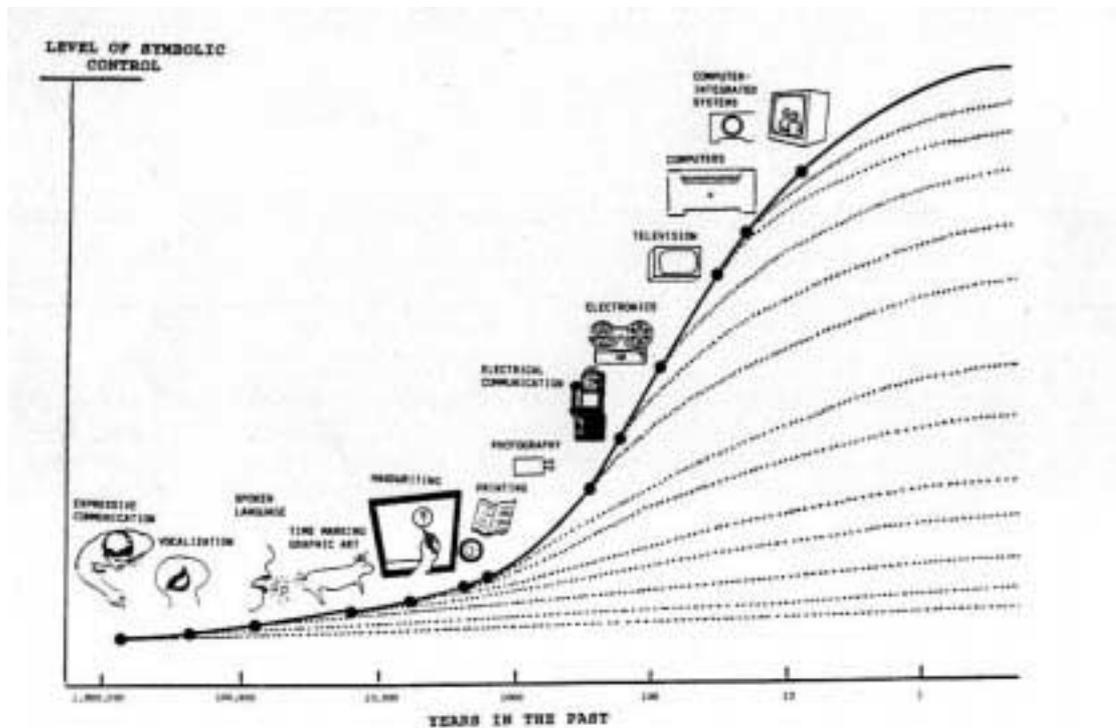

Figure 5. Progressive emergence in evolution of innovative modes of symbolic communication, feedback coupled to advances in work behavior. As new forms of communication emerge, old forms persist and are conserved.

organization have progressed from primitive shelters to fixed village and temple systems, to ramified mercantile and industrial centers, and finally to the national and global commercial systems of today. The figure also suggests that the emergence of each of these new levels of societal organizational sophistication has been accompanied and guided, in a feedback manner, by the emergence of new behavioral sophistication in the use of work to control time. Figure 4 indicates that technological innovation has progressed from primitive hand tools to megalithic temples used as architectural time-keeping machines, to human-powered and thence to human-controlled machines powered by environmental sources of energy, and finally to the semi-automated, automated and cybernetic technologic systems of today. Finally, Figure 5 indicates that modes of symbolic communication have progressed from spoken language and non-verbal communication to graphic expression, handwriting and printing, to various modes of electronic communication, and finally to the computer-mediated communication systems of today.

Figures 3–5 are meant to suggest that the innovative advances depicted are both integrated and cumulative. That is, work-related elaboration of new forms of societal organization, technology and symbolic communication has occurred in an interdependent manner. In addition, all of the innovations indicated in the figures, plus related skills, patterns and systems of work on which they depend, can be found today. Legacies in work innovation accumulate because of the unique human capacity for conserving knowledge and information about new technology and work methods over time.

Thus, many of the so-called "modern" features of work in fact have ancient origins. For example, many observers agree that a key prehistoric landmark in the organization of work was the establishment of relatively fixed settlements, facilitated in a feedback manner by innovations in agricultural and animal husbandry work. A likely behavioral feedback effect of this trend was establishment of more elaborate systems of community decision-makers, today termed administrators, managers, authorities, bureaucrats and government. This was necessary to ensure that the work of residents directed at expanding the scope of community control over critical environmental conditions — food supply, security, design and fabrication of technology, commerce etc. — was effectively organized and managed. Division of labor certainly exists in mobile hunting and gathering societies and also is apparent in non-human species. However, emergence of larger populations in more static settlements dramatically reduced the ability of a given resident to effectively control all key environmental conditions on an individual basis. Hence, the need for better defined systems of organizers and managers to organize and guide community work processes.

One of the earliest historical records of this 'macro-ergonomic' approach to work organization is that of the ancient Sumerians starting ~7000 years ago. These peoples — precursors of the Hebrews, Babylonians, Greeks and Romans — elaborated over the next three millennia most if not all of the basic concepts of work organization that we observe and practice today (Kramer 1963). These include writing and phonetic notation, laws of work and commerce, ethical principles and mechanisms of justice, organization of crafts, professions and trades, rules of fair play, concepts of freedom, and valuation of qualities of ambition and success, all hallmarks of current work practices. Anticipating

subsequent Greek and Roman developments by some 2000 years, Sumer was the first ancient civilization effectively to combine and organize labor, crafts, professions, and civil and religious authority as an integrated societal system of work.

As another example, it is likely that methods of mass production, based on what we today call factory technology and work, originated with Greek, Persian and Asian civilizations to deal with the demands of providing for burgeoning populations and of equipping large armies numbering in the hundreds of thousands (Smith 1965). For example, the largest naval battle in recorded history between the Greeks and Persians over 2000 years ago clearly points to a well-defined system of work for fabricating and equipping thousands of ships. A third example is the use of massive hydraulic, geared and levered machines for mining work in northern Europe in the fifteenth and sixteenth centuries, documented by Agricola in 1556, which anticipated by some three centuries the application of similar machines to mechanize work during the industrial revolution.

What factors prompted the emergence of successive innovation in forms of societal organization, technology and symbolic communication, depicted in Figures 3–5. Answers to this question remain a matter of speculation. Diamond (1997) points to favorable environmental circumstances. He postulates that Eurasian success in expeditions of conquest over other peoples may be traced ultimately to availability of native plant and animal species suitable for domestication in the Fertile Crescent area. This factor, coupled with suitable climatic conditions and lack of major geographic barriers, allowed early dispersal of domesticated crops and livestock from the Mediterranean basin to the Asian subcontinent and perhaps beyond, thereby facilitating early transformation of hunting and gathering modes of work in these areas to activities and systems of work associated with agriculture, mining and development of settled communities. A self-selective impetus for the innovation of new technologies plus approaches to work organization was thereby generated to address associated needs of large, established communities, such as better communication (writing), better weapons for defense or conquest (mining), and better coordination and integration of work on a societal basis (government and religion). Early success in work innovation thus is assumed to anticipate later success in subjugating other peoples. More broadly, we may postulate that there are reciprocal feedback relationships (Figure 1) between the availability of favorable environmental conditions readily controlled through work, the development of more stable and organizationally sophisticated settlements and societies, and the innovation of new modes and forms of work technologies and practices, a pattern that undoubtedly has prevailed throughout human evolution.

4. GENERAL LAWS AND CUSTOMS OF WORK

Laws and customs of work — the definition of "ergonomics" — refer to work design features and characteristics that conform to the capabilities and limitations of the worker. As evidenced in this encyclopedia and in diverse Ergonomics/Human Factors handbooks, textbooks and publications, there are literally hundreds of laws and customs of work that have been promulgated, in the form of guidelines, recommendations and standards. Customarily, these take the form of specifications pertaining to the design of any and all components of the work

system: tools, machines, equipment, work stations, software or hardware interfaces, material handling, work layout, production flow, work environment, jobs, or organizational systems. The underlying premise of such specifications is that modifications of work design to conform more closely to the behavioral abilities and skills of the worker will enhance work performance through improvements in productivity, quality, safety, health and/or efficiency of the workforce and the work system.

This encyclopedia is largely concerned with the topic of laws and customs of work. The discussion here therefore confines itself to the following series of general conclusions that can be drawn about "laws and customs" pertaining to the interaction of work design and work performance.

1. *Work performance is highly context specific*. This means that the behavior of the worker is specialized to a substantial degree in relation to the design context of the workplace and the work environment. In the domain of cognitive behavior, empirical evidence dating back ~150 years indicates that task design factors, as opposed to innate ability or learning factors, account for the preponderance of performance variability observed across a broad range of problem-solving, perceptual, and psychomotor tasks (Smith *et al.* 1984). Jones (1966) concludes that when it comes to actual cognitive performance in the workplace, as much as 90% of such variability may be attributable to task design. Evidence regarding the most robust "laws" in Ergonomics/Human Factors and psychological science — those of Hick and Fitts — shows that almost all of the variance in reaction or movement time is attributable to design of the task, namely number of choices or target size and separation respectively. Essentially all Ergonomics/Human Factors guidelines and standards pertaining to musculoskeletal performance at work reference work capacity and injury risk to design factors — weight and height of lift, task repetition and force requirements, etc. In the realm of work physiology, guidelines regarding both physical work capacity and fatigue susceptibility are referenced to task design factors such as work load and task duration. Recommendations pertaining to scheduling effects on work performance reference design factors such as when the shift is scheduled, length of shift, shift start and stop times etc. One corollary of this conclusion therefore is that "laws" of work cannot and should not be generalized across all work design contexts — instead they must be customized for different work environments and types of work. Another corollary is that insight into sources of variability in work performance for a particular type of work should be based on observations of that performance in the work design context under consideration.

2. *Work motivation also is context specific*. This means that there is no universal "law" that explains why people want to work. Although evidence on this point is less comprehensive, suggestive support is provided by observations that among a range of factors implicated in work motivation — related to opportunities that work provides for gainful return, for social interaction, for purposeful activity, for pride in accomplishment, for self-fulfillment etc. — no single factors or set of factors uniformly applies to all workers and work sectors. For slavery — a class of work quite prevalent for thousands of years until recent times — fear and intimidation were key motivators. For early humans, plus the millions of workers living in poverty today, simple survival through acquisition of food and avoidance of harm likely represents the most important motivational influence for work. The only generalization that appears to apply is that human motivations for work and for self-control of the environment essentially are identical (see Section 2).

3. *Effects of new work design on work performance are not necessarily predictable*. This conclusion follows from point 1. If work performance is context specific, new work designs (of tools, machines, interfaces, jobs, etc.) will evoke new patterns of variability in work performance which cannot necessarily be predicted from patterns associated with existing designs. To deal with this issue, there is growing acceptance of iterative design testing, in which some measure of usability (user acceptance, productivity, quality, safety risk, etc.) of a prototype design is assessed, and the design modified based on the results. This process is repeated until an acceptable level of performance with the new design is achieved.

4. *Operational validity of work performance models rests upon their recognition of context specificity*. Some models of work performance, such as ecological or various lifting and fatigue models, are based on the premise of performance–design interaction, and therefore build context specificity in performance directly into the framework of the model. Others, such as information processing, mental workload, human reliability or time–motion assessment and prediction models, disregard such interaction in their formulation. Context specificity in work performance is a matter of empirical record. The operational validity, and consequent predictive power, of models that ignore this record may therefore be questioned, relative to models that are context sensitive.

5. *Organize work as closed-loop system*. Cybernetic or closed-loop control of behavior represents an inherent biological feature of work performance at the level of the individual (Smith and Smith 1987). The same cannot be said of organizational behavior. Instead, closed-loop linkages between work effects (outcomes) and work investment (inputs) have to be built into the design — the macro-ergonomics — of work organizations. There is ample observational and economic evidence to show that if yield and investment of a work system (the ratio of which defines work productivity) are not closely coupled, the system ultimately is destined to flounder if not fail. The need to close the loop between the effort and effects of work undoubtedly was recognized by early hominid work groups, was manifest in ancient Sumerian and Egyptian work systems, and represents an organizational design imperative for successful complex work systems of today (Kramer 1963, Juran 1964). Closed-loop control of work may be implemented for a broad range of organizational design alternatives, from authoritarian to unsupervised. However, macro-ergonomic observations on organizational design and management point to strategies commonly associated with success in achieving this goal. One is clearly defined decision-making authority — every control system needs a controller. A second is the participatory approach — workers represent a good resource for tracking both the effort and effects of work. A third is to customize input and output measures of

work system performance to the particular type of system under consideration. A fourth is realistic accommodation of the inherent variability of a control system, particularly at the organizational level. Although this represents a key feature of modern quality management systems, the same cannot be said of other management domains.

6. *Human error and design error often are synonymous.* The invocation of "human error" as the underlying cause of work-related accidents and injuries is not uncommon in the Ergonomics/Human Factors and safety fields, a proclivity originating with Heinrich ~70 years ago (Heinrich 1931). From the perspective of point 1 however we might expect that hazards in the workplace, manifest as work design flaws, should be a major contributor to errors in work performance. Indeed, a variety of field observations support the general conclusion that design factors, often management-related, are implicated in about half of all work-related accidents and injuries (Smith 1999). Before invoking pure human error therefore, the possible contribution of flaws in physical and/or organizational work design to errors in work performance should be carefully scrutinized.

7. *Ergonomic standards addressing upper limb musculoskeletal injury risk should accommodate individual differences and be referenced to work design.* This conclusion is based on three considerations. First, motor behavioral theory tells us that there are essentially an infinite number of alternative trajectories that can be employed for guiding movements of the hands and arms from one point in space to another. This is because the total degrees of freedom in the combined muscle–joint systems of these effectors (7) exceeds that of the spatial environment in which movement occurs (6). Second, motor behavioral research tells us that the motor control system is inherently imperfect. This motor control variability ensures that no particular arm–hand movement is ever repeated with precisely the same spatio-temporal pattern by a given individual. Collectively, these two phenomena underlie the observation that upper limb musculoskeletal performance is highly individualized and context specific (point 1), such that in the same work design context, different individuals may perform differently, and the same individual may perform differently at different times. The idea of "general" ergonomic standards for upper limb musculoskeletal performance that are presumed to apply for all workers across all work design contexts therefore is scientifically untenable. Instead, such standards should be customized for different classes of workers (categorized by age, gender, anthropometry, etc.) and for different types of work.

8. *To modify work performance, modify work design.* As a cybernetic, self-regulated process, work behavior cannot be directly controlled by an outside force or agent. However, variability in work performance can be influenced by modifications to the design of the work environment in which the performance occurs (point 1). Therefore, modifications to work design (encompassing the design of training programs) offer the most realistic, and often the most cost-effective, avenue for modifying work performance. This conclusion represents the *raison d'être* for Ergonomics/Human Factors science.

5. FUTURE OF WORK

From a biological perspective, the basic behavioral and physiological attributes and capabilities that humans bring to the performance of work likely have remained fairly consistent over previous millennia, and are unlikely to change much in the millennium to come. Some historical support for this view is available. For example, the ergonomic guideline introduced by the ancient Greeks over 2000 years ago that packs carried by Hoplite soldiers be limited to 70 lb is retained by armies of today.

What has changed is the amount of knowledge and information that has accumulated about the organization and conduct of work, and the number of technological and communication innovations developed to facilitate the work process (Figures 3–5). However, given that variability in work performance is context specific, the nature of the impact of new designs of technology and work systems on work performance is not entirely predictable (Section 4, points 1 and 3). Hancock (1997) suggests that given the numbing effect of much computer-based work on job satisfaction, more avenues for job enjoyment and opportunities for leisure must be introduced to sustain worker acceptance of this type of work. Drucker (1999) addresses the possible impact of the newest major technological innovation in work design — the internet — on the future of work, and expresses uncertainty as to what the outcomes will be. In support of such indecisiveness, he points out that the industrial revolution, which also involved major transformations in work design, had many unintended and unanticipated consequences (Section 4, point 3) for the performance of work.

Nevertheless, at least four predictions for the future trajectory of work can be offered with a reasonable degree of assurance, all of which already are somewhat in evidence. The first is that the persistence of new work designs will rest upon the degree to which they augment work productivity, albeit with some lag built in. For example, many observers attribute recent productivity gains to the wholesale computerization of work, an effect that has taken some three decades to emerge. Work designs that do not benefit work productivity eventually will be discarded.

The second and third predictions are that work will become more disseminated on a regional basis, but more integrated on a global basis. Advances in distributed communication such as the internet will facilitate both of these transformations. The need for maintaining production facilities in discrete, physically defined locations, for purposes such as manufacturing, mining or agriculture, should not change much in the foreseeable future, although the degree of remote control of such work likely will steadily increase. However, for many other types of work across the entire commercial sphere, from education to finance to retail, concepts of the "job" and of "going to work" almost certainly will undergo fundamental modifications.

Finally, the decline in population growth and progressive aging of the workforce in most western societies, coupled with an unabated demand for workers, suggests that respect for work capabilities of older workers will undergo a resurgence, and that the concept of retirement as an expected and accepted concomitant of aging may be fundamentally revised.

Human Error

J. Reason

Department of Psychology, University of Manchester, Manchester M13 9PL, UK

1. INTRODUCTION

Error is defined here as the deviation of human performance from some intended, desired or ideal standard. Such deviations may have bad outcomes, but they can also be inconsequential or even benign – as in trial-and-error learning. Errors are not intrinsically bad, though their consequences and the conditions provoking them may be. Systematic error forms arise from highly adaptive cognitive processes. It is the circumstances of their occurrence rather than the underlying mechanisms that largely determine the nature of the outcome.

Before the mid-1970s errors were rarely studied for their own sake, although there were some notable exceptions. Two developments then occurred to make error a legitimate object of scientific study. The first was theoretical. The mid-1970s saw the reappearance of Bartlett's schema concept in several different guises (Reason 1990). Common to these new approaches was the revival of Bartlett's (1932) insight that knowledge of all kinds was stored in long-term memory as active, organized structures. A key feature of these new schema theories was the idea that knowledge structures (schemata) contain informational slots or variables. If concurrent mental processing or information from the outside world fails to provide inputs to these slots, they take on default or stereotypical values. Such a concept proved central to the understanding of a recurrent characteristic of many different error types, namely that they take forms that are more familiar and more conventional than those which were intended or appropriate at that time. In short, many errors appear as strong habit intrusions.

The second development was the growing concern over the terrible cost of human error in hazardous technologies, particularly those in which a relatively few individuals exercised centralized control over complex, well-defended systems (Hollnagel 1993; Kirwan 1994). Three overlapping eras of safety concern can be identified: the *technical failure era*, the *human failure era* and the *system failure era*. The 1950s and 1960s saw technical failures as the primary threat (e.g. failure of engines or the structural integrity of aircraft fuselages and pressure vessels). In the 1970s and 1980s, human unsafe acts were recognized as being the single largest contributor to both major and minor accidents. Between the late 1980s and the present time, however, there has been a marked shift of emphasis towards a wider acknowledgement of the situational, managerial, organizational and regulatory contributions to system breakdown. We are now in the system failure era in which people at the "sharp end" of a hazardous technology (e.g. pilots, control room operators, ships' officers, etc.) are seen more as the inheritors of "organizational accidents" than as their principal instigators.

2. VARIETIES OF HUMAN ERROR

There is no one taxonomy of human error – nor should there be, since different classificatory schemes are created to serve different purposes (Norman 1981). In what follows, errors are classified according to the type of deviation involved. The various classes of error are produced by different psychological processes, vary widely in their ease of detection and recovery, occur at different levels of the system and require different remedial measures. They are described below in order of increasing complexity.

2.1. Trips and Stumbles

This deviation is between an internal representation of the upright (generated by the vestibular system and cerebellum) and a sudden, unintentional, off-vertical body posture. The nervous system is hard-wired to detect such discrepancies and immediately initiates reflex postural corrections without the intervention of any conscious decision-making. Detection and recovery is automatic.

2.2. Slips and Lapses

These are the unintended deviations of action from current intention. They occur at the level of execution and are commonly termed absent-minded actions. Actions-not-as-planned take a variety of forms depending upon which cognitive process is primarily implicated. In general, the term "slips" will be reserved for those discrepant actions involving the deployment of an inappropriate level of attention (this may be either too much or too little) to the monitoring of actions or perceptions. "Lapses," on the other hand, are commonly associated with memory failures, either forgetting (in the case of intentions – a very common lapse) or the inability to retrieve some known memory item (e.g. failing to achieve a timely recall of the name of a familiar person). Another distinction is that action slips are publicly observable, while lapses tend to be more private events – though their consequences may be evident to others. Since the intention associated with the deviant behavior (i.e. the standard against which such discrepancies are identified) is generally well known to the actor, the detection of slips is usually fairly rapid, though memory lapses may have to wait upon a particular occasion before they are noticed (e.g. the failure to post a letter may only be realized when one has returned home to find the unposted letter).

Three conditions appear to be necessary for the occurrence of an absent-minded slip of action: (1) the performance of an habitual sequence of actions in familiar surroundings, (2) the occurrence of some change, either in the usual plan of action or in its circumstances and (3) a marked degree of "attentional capture" associated with internal preoccupation or with external distraction. Slips are thus a penalty for the ability to automatize our recurrent actions. Though such slips may occasionally have tragic consequences, they are a relatively small price to pay for the enormous benefits of performing the routines of everyday life without having to make moment-to-moment demands upon the limited resources of conscious decision-making. Continuous "present-mindedness" would be a far worse fate.

2.3. Mistakes

Mistakes occur at the higher level of formulating intentions, specifying goals and planning the means to achieve them. The deviation here is not between action and intention, but between the selected course of action and some more adequate means of attaining the immediate and longer-term goals. Since the future state of the world is uncertain and the ideal path towards a given

Table 1. Relationship between rule-related situations and types of mistake.

Type of situation	Type of mistake
Good rules	Mistaken circumvention (misvention) bad outcome successful outcome
Bad rules	Strong-but-wrong rule applied Inelegant or ill-advised rule applied Mistaken compliance (mispliance) Malicious compliance (malpliance)
No rules	Mistaken improvisation

goal is rarely known (even after the event, it can be a matter of debate), mistakes are extremely hard to detect and recover by their perpetrators.

In the world of hazardous systems, these plans of action are rarely made from scratch. They are generally guided and constrained by rules, regulations and procedures – subsumed here under the general term "rules." Every organization faces the challenge of limiting the enormous variability of human behavior to that which is safe, productive and efficient. Each does so by a mixture of external and internal controls, both of which involve rules. External controls rely heavily – but not exclusively – on prescriptive procedures. Internal controls exist primarily within the head of the individual and are acquired through training and experience. The factors that shape the balance between external and internal controls have been discussed at length elsewhere (Perrow 1967); for our present purposes, the term "rules" will be used to cover both types of control.

For any given situation, the rules (either on paper or in the head) may take one of three forms: (1) *good rules* that are appropriate for the situation, (2) *bad rules* that are either inappropriate for the situation or are inelegant and/or ill-advised and (3) *no rules* are available. The latter state corresponds to what Rasmussen (1982, 1986) has termed the "knowledge-based level" of performance. Mistakes can be conveniently classified according to which of these three situations prevail. The classification is summarized in table 1.

2.3.1. Mistaken circumventions

The operators of the Chernobyl nuclear power plant clearly committed misventions when they persisted with the electrical testing at a dangerously low power regime and then proceeded to disable successive plant safety systems. But most violations of safe operating procedures tend to go unpunished and may become routine as an easier or more convenient way of working. Such rewarded but unwise violations create the breeding ground for more dangerous misventions. The violation of good rules has at least two adverse effects: it makes the commission of subsequent errors more likely, and it increases the probability that these subsequent errors will have bad consequences.

2.3.2. "Strong-but-wrong" mistakes

These involve the use of a normally good rule in circumstances for which it is no longer applicable. The mistake lies in failing to spot the counter-indications. A simple example would be braking suddenly to avoid a pedestrian when the road is icy. The problems

are that the rule has demonstrated itself to be appropriate in most circumstance (hence it is "strong") and the counter-indications are often hard to detect (Reason 1990).

2.3.3. Application of inelegant or ill-advised rules

Many people acquire "bad" rules during the course of performing some task. The application of such rules may go uncorrected for long periods. Indeed, they may even appear to be serviceable. The problem is that they are inelegant (costing unnecessary effort or resources) or, under certain conditions, ill-advised (having dangerous consequences). A technician involved in re-wiring a signal box committed a tragic example of this type of mistake. Instead of removing the old wires, he bent them back. Subsequently, the old wire made a connection with the terminal, causing the signal failure that led to the Clapham Junction rail disaster of 1988.

2.3.4. Mistaken compliance

Procedure writers are fallible. The rules they create may prove incorrect, unworkable, unintelligible, ambiguous or unavailable when needed. Such rules can also be rendered wholly inappropriate by an unforeseen change of circumstance. On the *Piper Alpha* oil and gas platform, for example, the procedures directed personnel to assemble in the accommodation in the event of an emergency. But this area was directly downwind of the flames on the evening of 6 July 1988 when an explosion occurred onboard the platform. Most of those who died followed the emergency procedures (mispliance). Most of the survivors jumped into the water (successful violation).

2.3.5. Malicious compliance

It is unlikely that all malpliances are mistakes, but some of them certainly are. A malpliance is committed when the workforce deliberately adheres to procedures that are known to be bad or unworkable to thwart the management.

2.3.6. Mistaken improvizations

In well-established work domains most of the likely situations have either been anticipated or encountered previously and are thus covered by standard operating procedures. On rare occasions, however, entirely novel circumstances occur for which no rules are available. The blow-out of the oxygen tank on *Apollo 13* was one such case; the loss of all three hydraulic systems on a United Airlines DC10 aircraft over Iowa was another. In both instances the performance of the crews was truly inspired. More usually, however, people do not perform well in situations for which they lack both training and procedures. Mistakes are inevitable under such circumstances. The evidence suggests that when the people on the spot are both highly experienced and extremely talented, the probability of their improvizations having a satisfactory outcome is ~0.5, the chance level (Reason 1997). It could be argued that the term "error" is inappropriate in wholly novel situations, since it is only through trial-and-error learning that those involved can iterate towards an effective outcome. Nonetheless, the category of "mistaken improvizations" will be retained here both for logical completeness and to emphasize the difficulty of making hard-and-fast distinctions between error and correct performance.

3. ACTIVE FAILURES AND LATENT CONDITIONS

So far, human error from a largely person-centered perspective has been considered. The difficulty with this approach is that it encourages those in authority to treat errors as a moral issue and to focus their remedial efforts on "deviant" individuals rather than on the system at large. One of the basic rules of error management is that one cannot change the human condition, but one can change the conditions under which people work. The current trend in human factors research is to view errors and violations from a system-centered perspective. And it is from this standpoint that one arrives at the final distinction in this chapter, that between active failures and latent conditions.

3.1. Active Failures

These are the unsafe acts committed by those at the immediate human–system interface. Such errors can have an immediate impact upon the safety of the system, though their effects may be relatively short-lived. Not so long ago these proximal errors tended to be the main focus of accident inquiries. In recent years, however, the scope of such investigations has extended both "upstream" of the front-line operators and backwards in time.

3.2. Latent Conditions

These are the product of decisions made by designers, builders and top-level managers. Such decisions may later prove to be mistaken, but they need not be. Nearly all such strategic decisions, good or bad, have the potential for seeding latent conditions into the system. Latent conditions (or organizational pathogens) have two kinds of impact: they can translate into error-provoking conditions in the workplace (e.g. time pressure, inadequate tools and equipment, insufficient training, etc.) and they can also open up long-lasting gaps or weaknesses in the system's defenses (e.g. unworkable procedures, weak containment, inoperable engineered safety features, etc.). These conditions may lie dormant for many years before they combine with local triggering events to create a breakdown of the system's defenses. They are called "conditions" rather than "failures" because they are present in all systems and do not differentiate between an organization that has just had an accident and one that has not. While their specific forms may not be made manifest until after a bad event, they are rooted in generic organizational processes such as designing, building, managing and maintaining. Although it may not be possible to prevent the introduction of latent conditions into the system, it has been demonstrated that their likely hiding places can be identified and remedied before they contribute to an adverse event (Reason 1997).

4. ERROR MANAGEMENT

Errors and violations at the "sharp end" may be likened to mosquitoes. It is possible to swat or spray them one by one, but they keep on coming. The only effective remedy is to drain the swamps in which they breed. The swamps, in this case, are the latent error-provoking and accident-producing conditions present in all technical systems.

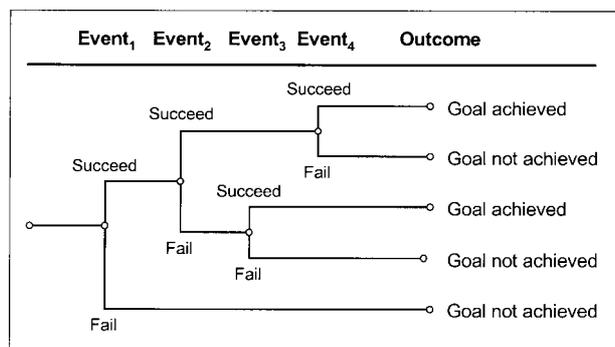
Human Reliability Analysis

E. Hollnagel

Graduate School of Human-Machine Interaction, Linköpings Universitet,
S-581 83 Linköping, Sweden

1. INTRODUCTION

The term "human reliability" is usually defined as the probability that a person will correctly perform some system-required activity during a given time period (if time is a limiting factor) without performing any extraneous activity that can degrade the system. The historical background for the development of the set of methods that are commonly referred to as Human Reliability Analysis (HRA) was the need to describe incorrect human actions in the context of Probabilistic Risk Assessment (PRA) or Probabilistic Safety Analysis (PSA). The premises for HRA were, and are, therefore that it must function within the constraints defined by PRA/PSA and specifically that it can produce the human action probabilities that are needed by the PRA/PSA. The accident sequence that is analyzed by a PRA/PSA is typically represented as an event tree (see Figure 1). A node in the sequence of events that may lead to the accident represents a specific function, task, or activity that can have two different outcomes, usually denoted *success* and *failure*. A node can either represent the function of a technical system or component, or the interaction between an operator and the process. For example, if the analysis considers the sequence of events that are part of landing an aircraft, the event "*timely extraction of flaps*", which is an action that must be taken by the pilot, is represented by a node. From the perspective of the PRA/PSA there is a need to know whether it is likely that an event will succeed or fail, and further to determine the probability of failure in order to calculate the combined probability that a specific outcome or end state will occur. If the node represents the function of a mechanical or electronic component, the failure probability can, in principle, be calculated based on engineering knowledge alone. If the node represents the interaction between an operator and the process, engineering knowledge must be supplemented by a way of calculating the probability that the human, as a "component", will fail. Historically, the role of HRA has been to provide the


foundation for calculating this probability. The sought for value has traditionally been called a human error probability (HEP), but as the following will show this is both a misunderstood and misleading term.

2. HUMAN ERROR PROBABILITIES AND PERFORMANCE SHAPING FACTORS

The practice of HRA goes back to the early 1960s, but the majority of HRA methods were developed in the middle of the 1980s — mainly as a consequence of the concern caused by the accident in 1979 at the nuclear power plant at Three Mile Island. Partly due to the conditions under which it was developed, HRA methods from the beginning used procedures similar to those employed in conventional reliability analysis. The main difference was that human task activities were substituted for equipment failures and that modifications were made to account for the greater variability and interdependence of human performance as compared with that of equipment. The traditional approach is first to determine the HEP for a node, either by using established tables, human reliability models, or expert judgement. The characterization of human failure modes is usually very simple, for instance in terms of "error of omission" and "errors of commission". Since human actions clearly do not take place in a vacuum, a second step is to account for the influence of possible Performance Shaping Factors (PSF) such as task characteristics, aspects of the physical environment, work time characteristics, etc. This influence is expressed as a numerical factor that is used to modify the basic HEP. The resulting formula for calculating the probability of a specific erroneous action (P_{EA}) is shown below:

$$P_{EA} = HEP_{EA} * \sum_{k=1}^{N} PSF_k * W_k + C$$

From the standpoint of behavioral sciences, this formula makes two fundamental assumptions. First, that the probability of failure can be determined for specific types of action independently of any context. Second, that the effects of the context are additive, which is the same as saying that the various performance conditions (such as interface quality, stress, level of training, task complexity, etc.) do not influence one another. Neither of these assumptions are reasonable, and either alone constitutes a grave deficiency of the approach. Quite apart from these principal objections, HRA methods in practice turned out not to be sufficiently effective and the need for substantial improvements was gradually realized. In 1990, this was expressed as a criticism against HRA on the following points (Dougherty 1990):

- Existing empirical data are insufficient to support quantitative predictions of human performance in complex systems. This problem had actually been recognized by HRA practitioners since the early 1960s. As alternatives to empirical data, HRA often relied on either expert judgement or data from simulator studies.
- Expert judgements can be used *in lieu* of empirical data, but there is a lack of agreement in the use of expert judgement methods. The methods neither have satisfactory between-expert consistency, nor produce accurate predictions.
- Data from simulator studies can be used instead of empirical data, but the calibration to real life situations is inadequate.

Figure 1. A simplified event tree representation.

The veracity and validity of simulator data have not yet been convincingly demonstrated.

- The accuracy of predictions from HRA methods is debatable and generally unproved, particularly for non-routine tasks. Benchmark studies usually produce divergent results, for many different reasons.
- The psychological realism in most HRA methods is inadequate, and the assumptions about human behavior are often highly questionable from a psychological point of view.
- The treatment of important Performance Shaping Factors is inadequate, there is too little emphasis on PSFs relating to management, organization, culture, etc.

Considering the historical basis for HRA methods, it is reasonable to suggest that one improvement should be a better integration of psychological theory with HRA models and methods. In particular, it is strongly felt by many with a behavioral science background that quantification should await an improved theoretical foundation.

3. CONTEXT AND COGNITION IN HRA

The above-mentioned criticism caused an intensive debate within the community of HRA theoreticians and practitioners, and pointed to two problems that need to be addressed by HRA methods: the problem of context and that of cognition. Technical systems that depend on human–machine interaction to accomplish their function, such as nuclear power plants, are typically tightly coupled and have complex interactions. Plant operators and plant components should therefore be seen as interacting parts of an overall system that responds to upset conditions. The actions of operators are not simply responses to external events, but are governed by their beliefs as to the current state of the plant. Since operators make use of their knowledge and experience, their beliefs at any given point in time are influenced by the past sequence of events and by their earlier trains of thought. In addition, operators rarely work alone but are part of a team — especially during abnormal conditions. Altogether this means that human performance takes place in a context which consists both of the actual working conditions and the operator's perception or understanding of them. It also means that the operator's actions are a result of cognition and beliefs, rather than simple responses to events in the environment, and that the beliefs may be shaped — and shared — by the group.

The problem of *context* is a noticeable feature of other current theories, such as the so-called multi-threaded failure models that describe how accidents in systems may evolve (Reason 1990). Events are described as determined by a combination of psychological, technological, and oganizational or environmental factors. The issue of organizational reliability has recently received specific attention by the PRA/PSA community, and proposals for an organizational reliability analysis have been made. On the level of human performance, which is the focus of HRA, context is important because human action always is embedded in a context. Given a little thought this is obvious, but the preferred mode of representation that the analyses use — the event tree or operator action tree — is prone to be misleading, since it represents actions without a context. One unfortunate consequence of that has been the preoccupation with the HEP, and the oversimplified concept of "human error". The consequence of acknowledging the importance of the context is that HRA should not attempt to analyze actions separately, but instead treat them as parts of a whole. Similarly, "human error" should be seen as the way in which erroneous actions can manifest themselves in a specific context, rather than as a distinct and well-defined category.

In the search for a way of describing and understanding the failure of human actions, several classes of models have been used. In brief, HRA methods seem to include one of the following types of operator model:

- Behavioral, or human factors, models that focus on simple manifestations (error modes). The error modes are usually described in terms of omissions, commissions, and extraneous actions, and the methods aim at deriving the probability that a specific manifestation will occur. Since causal models are either very simple or non-existent, the theoretical basis for predicting performance failures is inadequate. Behavioral models are therefore also weak in accounting for the influence of context.
- Information processing models that focus on internal "mechanisms" — for example, decision-making or reasoning. The methods aim at explaining the flow of causes and effects through the models. Causal models are therefore often complex, but with limited predictive power, and little concern for quantification. Error types typically refer to the cause as much as the manifestation (e.g. slips, lapses, mistakes, violations), or to the malfunctioning of a hypothetical information processing function. Context is not considered explicitly, at most in terms of the input to the operator, and information-processing models are better suited for retrospective analysis than for predictions.
- Cognitive models that focus on the relation between error modes and causes, where the latter refer to the sociotechnical environment as a whole. Unlike information-processing models, cognitive models are simple and context is explicitly represented. Cognition is the reason why performance is efficient — and why it is sometimes limited — and the operator is seen as not only responding to events but also as acting in anticipation of future developments. Cognitive models are well suited for both predictions and retrospective analyses. There are, however, only a few HRA approaches that pay more than lip service to this type of model.

The problem of *cognition* can be illustrated by the popular notion of "cognitive error". The problem facing HRA analysts was that human cognition undoubtedly affected human action, but that it did not fit easily into any of the established classification schemes or the information-processing models. One solution was simply to declare that any failure of a human activity represented in an event tree, such as diagnosis, was a "cognitive error". However, that did not solve the problem of where to put the category in the existing schemes. A genuine solution is, of course, to realize that human cognition is a cause rather than an effect, and that "cognitive error" therefore is not a new category or error mode. Instead, all actions — whether erroneous or not — are determined by cognition, and the trusted categories of "error of omission" and "error of commission" are therefore as cognitive as anything else. Furthermore, the cognitive viewpoint implies that unwanted consequences are due to a mismatch between cognition and context, rather than to specific "cognitive error mechanisms".

4. PRINCIPLES OF A CONTEMPORARY HRA

The current dilemma of HRA stems from its uneasy position between PRA/PSA and information processing psychology. As argued above, HRA has inherited most of its concepts and methods from the practice of PRA/PSA. This means, that HRA uses a fixed event representation based on a predefined sequence of steps, that the methods are a mixture of qualitative and quantitative techniques, and that the underlying models of operator actions and behavior are either probabilistic or simplified information processing models. Yet information-processing psychology is characterized by almost the opposite approach. The representation is typically information flow diagrams of internal functions, rather than binary trees of external events; the methods are generally qualitative/descriptive, and the models are deterministic (because an information-processing model basically is a deterministic device). HRA practitioners have therefore had great problems in using the concepts from information-processing psychology as a basis for generating action failure probabilities; a proper adaptation would practically require a complete renewal of HRA. Even worse, information-processing models are almost exclusively directed at retrospective analysis, and excel in providing detailed explanations of how something can be explained in terms of internal mental mechanisms. HRA, on the other hand, must by necessity look forward and try to make predictions.

Since neither classical HRA nor information-processing psychology is easily reconciled with the need to account for the interaction between context and cognition, it is difficult to find a solution to the current predicament. The main problem is that the cocneptual foundation for HRA methods either is misleading or is partly missing. The solution can therefore not be found by piecemeal improvements of the HRA methods. In particular, attempts to rely on information processing psychology as a way out are doomed to fail because such models are retrospective, rather than predictive.

The solution to the current problems in HRA is not just to develop a new approach to quantification, but to develop a new approach to performance prediction that clearly distinguishes between the qualitative and quantitative parts. The purpose of *qualitative* performance prediction is to find out which events are likely to occur, in particular what the possible outcomes are. The purpose of *quantitative* performance prediction is to find out how probable it is that a specific event will occur, using the standard expression of probability as a number between 0 and 1. Qualitative performance prediction thus generates a set of outcomes that represent the result of various event developments. The validity of the set depends on the assumptions on which the analysis is based, in particular the detailed descriptions of the process, the operator(s), and the interaction. If the assumptions are accepted as reasonable, the set of outcomes will by itself provide a good indication of the reliability of the system, and whether unwanted outcomes can occur at all. That may be sufficient in the first instance. It may only be necessary to proceed to a quantitative performance prediction if significant unwanted consequences are part of the set of possible outcomes.

5. QUALITATIVE PERFORMANCE PREDICTION

The qualitative performance prediction must be based on a consistent classification scheme that describes human actions in terms of functions, causes, dependencies, etc., as well as a systematic way or method of using the classificaiton scheme. A consistent classification scheme is essential if assignments of erroneous actions are to be justified on psychological grounds. A clear method is necessary because the analysis will otherwise become limited by inconsistencies when the classification scheme is applied by different investigators, or even by the same investigator working on diferent occasions. It can further be argued that a classification scheme must refer to a set of concepts for the domain in question, i.e., a set of supporting principles, specifically a viable model of cognition at work. The model will guide the definition of specific system failures from a consideration of the characteristics of human cognition relative to the context in which the behavior occurs. The overall approach of a contemporary HRA should be something along the following lines:

1. *Application analysis*. It is necessary first to analyze the application and the context. This may in particular involve a task analysis, where the tasks to be considered can be derived from teh PRA/PSA as well as from other sources. The application analysis must furthermore consider the organization and the technical system, rather than just the operator and the control tasks.
2. *Context description*. The context must be systematically described in terms of aspects that are common across siutations. If insufficient information is available it may be necessary to make assumptions based on general experience, particularly about aspects of the organization, in order to complete the characterization.
3. Specification of target events. The target events for the human actions/performance can be specified in several ways. One obvious source is the PRA/PSA, since the event trees define the minimum set of events that must be considered. Another is the outcome of the application and task analyses. A task analysis will, in particular, go into more detail than the PRA/PSA event tree, and may thereby suggest events or conditions that should be analyzed further.
4. *Qualitative performance analysis*. The qualitative performance analysis uses the classification scheme, as modified by the context, to describe the possible effects or outcomes for a specific initiating event. The qualitative performance analysis, properly moderated by the context, may in itself provide useful results, for instance by showing whether there will be many or few unwanted outcomes.
5. *Quantitative performance prediction*. The last step is the quantitative performance prediction, which is discussed in detail below.

6. QUANTITATIVE PERFORMANCE PREDICTION

The quantification of the probabilities is, of course, the *sine qua non* for the use of HRA in PRA/PSA. The quantification has always been a thorny issue, and will likely remain so for many years to come. Some behavioral scientists have argued — at times very forcefully — that quantification in principle is impossible. More to the point, however, is whether quantification is really necessary, and how it can be done when required. From a historical

perspective, the need for quantification may, indeed, be seen as an artifact of how PRA/PSA is carried out.

At present, the consensus among experts in the field is that quantification should not be attempted unless a solid qualitative basis or description has first been established. If the qualitative performance analysis identifies potentially critical tasks or actions, and if the failure modes can be identified, then it is perhaps not necessary to quantify beyond a conservative estimate. In other words, the search for specific HEPs for specific actions may not always be necessary. To the extent that quantification is required, the qualitative analysis may at least be useful in identifying possible dependencies between actions. The description of the context may also serve as a basis for defining ways of preventing or reducing specific types of erroneous actions through barriers or recovery.

Traditionally, quantification involves finding the probability that a specific action may go wrong and then modifying that by the aggregated effect of a more or less systematic set of PSFs. An alternative approach is to begin the prediction by identifying the context and the common performance conditions (Hollnagel 1998). Following that, each target event is analyzed *in the given context*. This means that the analysis is shaped by the defined context and that the list of possible causes of a failure contains those that are the likely given the available information. Once the set of possible causes has been identified, the need will arise to quantify the probability that the target event fails. Since, however, the target event is associated with a set of context specific error modes, it is reasonable to estimate the probability on that basis — rather than treating the target event in isolation.

Initially, it may be necessary to use expert judgments as a source of the probability estimates. But keeping the criticisms of HRA in mind, it is crucial that the expert judgemnts are calibrated as well as possible. Meanwhile, every effort should be made to collect sufficient empirical data. Note, however, that empirical data should not be sought for separate actions but for types of actions. When the observations are made, in real life or in simulators, both actions and context should be recorded, and a statistical analysis should be used to disentangle them. This may, eventually, provide a reliable set of empirical data to supplement or replace expert judgements. The principles of data collection are thus fundamentally different from a traditional HRA. Furthermore, data collection can be guided by the classification scheme, since this provides a consistent and comprehensive principles according to which the data can be organized and interpreted. That by itself will make the whole exercise more manageable.

1. INTRODUCTION

Learning is a phenomenon of people where human performance *improves with experience*. As tasks are repeated elements of the task are better remembered, cues are more clearly detected, skills are sharpened, transitions between successive tasks are smoothed, eye-hand coordination is more tightly coupled, and relationships between task elements are discovered. The aggregation of these and other personnel improvements will offer faster performance times, fewer errors, less effort, and there is often a better disposition that results. Several historical studies on individual person learning include Barnes and Amrine (1942), Knowles and Bell (1950), Glover (1966), Hancock and Foulke (1966), and Hancock (1967).

The detection of learning follows the observation of these changes in performance due *solely* to experience. Clearly, changes in the methods of performing a task, automating jobs, imparting information about the job, training, new incentive systems, and many other things can cause performance changes other than just learning. Thus, detection involves the identification of an improvement trend as a function of more experience. It also involves the elimination of other explanations for this improvement. Like a theory, *learning* can never be proved; it can only be disproved. After detecting learning, its measurement involves fitting mathematical models, called *learning curves*, to describe performance data changes with experience. This description involves the selection of the most accurately fitted model and the determination of the parameters so that improvement can be predicted.

Some of the same causes that contribute to an individual person's improvement with experience are similar to the causes of improvement by crews, teams, departments, companies, or even industries with experience. As a result, similar mathematical models are often fit to organizational performance changes. However, the term *progress curves* is more often applied to cases involving assembly lines, crews, teams, departments, and other smaller groups of people. (Professor S. Konz (1990) champions this terminology without necessarily distinguishing between individual person learning and the learning by small groups of people.) Whereas the term *experience curves* is often applied to larger organizational groups such as companies and industries (see Conley (1970) or Hax and Majluf (1982) for studies on experience curves over industrial sectors). The principal distinction between these different types of improvement curves is that between-person activities (e.g. coordination) occur as well as within-person learning. In the case of progress curves, there are important effects due to numerous engineering changes. Experience curves also embody scientific and technological improvements as well as progressive engineering changes and individual-person learning. Regardless of the term used, the same models of learning are frequently applied. In our discussions below, only learning and progress curves will be considered and the distinction will be individual person or group changes in performance with experience.

1.1 Some Applications of Learning Curves

Learning and progress curves serve numerous important purposes. One of the more obvious applications is costing out production operations. Since part of the cost of production is direct labor and person-hours of direct labor change with learning over the production run, any substantial changes in performance over a production run will decrease the amount of direct labor. A number of US governmental activities require learning curve pricing of services and products. Accordingly, labor costs decrease with greater learning so that longer production runs exhibit greater reduction in direct labor hours.

Another application of learning or progress curves is method evaluation. When there are alternative methods for performing various tasks, the best method may depend upon learning. Some methods may produce consistently better performance on one criterion but worse on another. In those siutations one has to make a trade-off between those criteria. More often one method has an advantage for shorter production runs and another method for greater production runs. In those cases one needs to find the break-even run size for those methods and establish a decision rule for method selection based on run sizes.

A third application of learning curves is in production control where specific designs of production operations are determined. Engineers of the production control function need to identify bottleneck operations and then solve the problems causing those bottlenecks. Alternatively, they may set up parallel workstations for part of the production operations. In order to identify bottlenecks and evaluate potential solutions, engineers need models of performance changes for each operation over the production run.

Quality control is a fourth application of learning and progress curves. That functional oganization is concerned with the causes of defective product units. Since some causes of defectives are due to human errors during production and the magnitude and number of those errors change with experience, learning and progress curves are needed by quality control engineers to predict these sources of defectives and to help reduce those and other causes of defectives.

1.2 Modeling Human Learning Behavior

Modeling human behavior is complex but interesting and modeling human learning behavior is more so. As a consequence you might ask, "Why then go to the effort?" The answer is simple, to obtain quantitative estimates of performance with more or less experience.

Typically, the first time a task is ever performed, both performance times and errors are the greatest. Namely, speeds and accuracies are quite low. When the task is performed repeatedly, people think of ways to improve and their behavior follows their thinking. Accordingly, learning models show decreasing performance times as a function of more task repetitions. That chance is precisely what one would expect for performance time *averages* but not necessarily actual data changes. People do not exhibit constant performance time decreases as most models predict. That is one of the typical simplifications.

All of the commonly used models vary as the rate of performance time decreases with experience through the specification of model parameters. However, some models show constantly decreasing performance time which appears to

eventually approach zero cycle times, a ridiculous situation. Other models show performance time decreasing to a preset level but that case requires the module to predetermine the amount of learning in addition to the rate of learning. However, those more realistic models still show constantly decreasing performance times down to the limit. On the other hand, anecdotes of learning phenomena frequently show various learning plateaus of performance times along a learning function but no known models provide this realism. As with other models, learning models are simplified descriptions of reality.

1.3 Why Use a Model of Learning?

With learning data, why does one need a model? There are a number of reasons:

- Learning data may be situation specific but models are more general and may be used in other situations that appear similar.
- It is difficult to extract prediction from data. It is much easier with a model that is fit to various products, especially within the same product family.
- One would expect slower learning rates for products with more complex manufacturing requirements (e.g. more metal to cut, higher tolerances to maintain, or small and complex assembly pieces). Models where the parameters vary with those features in expected ways provide face validity of the model that in turn helps in model acceptance.
- While models may simplify a situation, even to the extent of over-simplification, many people can use the simplified basis as a first-order description.

2. PERFORMANCE CRITERIA AND EXPERIENCE UNITS

Performance *time* is the most common criterion used in industry today. Production cycles are the most commonly used variable for denoting experience. If t_i is the performance time on the ith. cycle, a learning curve should predict t_i as a function of n cycles. Since learning implies improvement with experience, one would expect $t_i t_i + 1$ and $t_i - t_i + 1 \geq 0$ for the average case of i = 1, 2, . . ., n cycles.

An associated criterion to the time on the ith. cycle is the cumulative average performance time on the ith. cycle or A_i. Cumulative AVERAGE times consists of the sum of all performance times up to and including the nth. cycle divided by N or:

$$A_n = \frac{\sum_{i=1}^{n} t_i}{n} \tag{1}$$

Note that for n = 1, $A_1 = t_1$. With learning, t_i tends to decrease as i increases and so does A_n but at a slower rate than t_i decreases. This effect can be shown by the first-forward difference of A_n which is:

$$\Delta A_n = A_n + 1 - A_n$$

$$\Delta A_n = \frac{\sum_{i=1}^{n+1} t_i}{n+1} - \frac{\sum_{i=1}^{n} t_i}{n} = \frac{\sum_{i=1}^{n} t_i + t_{n+1}}{n+1} - \frac{\sum_{i=1}^{n} t_i}{n(n+1)}$$

$$= \frac{\sum_{i=1}^{n} t_i + n t_{n+1} - (n+1)\sum_{i=1}^{n} t_i}{n(n+1)} \tag{2}$$

$$\Delta A_N = \frac{\sum_{i=1}^{N+1} t_i}{N+1} - \frac{\sum_{i=1}^{N} t_i}{N} = \frac{\sum_{i=1}^{N} t_i + t_{N+1}}{N+1} - \frac{\sum_{i=1}^{N} t_i}{N}$$

$$\Delta A_N = \left[\frac{N}{N+1} - \frac{N+1}{N+1} \right] A_N + \frac{t_{N+1}}{N+1} = \frac{t_{N+1} - A_N}{N+1} \tag{3}$$

So long as t_{n+1} is less than A_n, ΔA_n is negative and the cumulative average time continues to decrease. Another criterion frequently of interest in ergonomics is *accuracy*. This criterion can be measured in the number of correctly performed sequential tasks. However, it is usually easier to measure the inverse of accuracy as errors in operations. In a single operation case, observations over a production sequence are a series of zeros and ones, corresponding to no error and an error. When more than a single operation is performed, say **M** operations, each cycle of production will consist of e_i equal to 0, meaning no error, or 1, 2, . . ., M errors for each cycle. A more understandable practice is to define e_i as the fraction of the possible errors where the observed number of errors is divided by the **M** possible errors at an operation. In this way e_i is 0, some proper fraction, or 1. It also follows that a learning curve could be fitted to the series of e_i values over the n observations of sequential units of production or to the cumulative average errors. If learning is present, then one would expect to see a general decrease in **ei** with increases in i = 1, 2, . . . , n and also the cumulative average errors would similarly decrease but with a rate lag compared to the serial errors.

3. SOME FUNCTIONAL LEARNING MODELS

Models for learning originated as elementary mathematical functions of serial data that fit the data trend. This restriction to elementary functions tends to make the model fitting easier. Also elementary functions tend to have fewer parameters, usually making fitting easier, and they tend to be more robust but there is no guarantee of such properties with simplicity.

3.1 Powerform Learning Models

A psychologist by the name of Snoddy (1926) originally reported the powerform function as fitting an individual's learning. (This is the earliest reference to learning models known to the author.) Snoddy identified the powerform function as a model of individual learning. This function is:

$$t_n = t_1 n^{-c} \tag{4}$$

where **c** is the *learning rate parameter*. Later Wright, working for an aircraft manufacturing company in Witchata, Kansas, noticed that the direct labor in building successive aircraft reduced by a constant fraction with each doubling of the number of aircraft produced. This characteristic is a property of the powerform model that he identified. Wright used this model as a progress function in the aircraft manufacturing industry. A property of the powerform model is that t_{2n}/t_n ratios are constant for all **n**. A numerical example of this series in the form of $5n^{-0.322}$ is:

n =	1	2	3	4	5	6	8	10	100	1000
tn =	5.0	4.0	3.5	3.2	3.0	2.8	2.6	2.4	1.13	0.541
t_n/t_{2n} =	4/5 = 0.8	3.2/4.0	2.8/3.5	2.6/3.2	2.4/3.0	–	–	–	–	–

It is clear from this example that t_n tends toward zero as n increases and so the asymptote of this model is 0. The aircraft

manufacturing industry assumes that asymptote is equal to t_{1000} by agreement. The example above also demonstrates that the ratio $t_{2n}/t_n = 0.8$ for all n. That result is caused by the parameter c and other values of c give different ratios as:

c =   0.074   0.153   0.234   0.322   0.415   0.515   0.621   0.737

tn/t2n = 0.95   0.90   0.85   0.80   0.75   0.70   0.65   0.60

However, the parameter c can be computed for any ratio using the equation:

$$C = - \frac{\log \left(\frac{t_{2n}}{t_n} \right)}{\log 2} \tag{5}$$

For completeness it should be stated that A_n be substituted for t_n when this model is used to describe the cumulative average time. Not that when there is a good fir of T_n to a powerform equation, An does not behave as a powerform series and conversely.

There have been numerous reports of model-based learning reported in the literature. (The few references cases given here come from Konz (1983) and they show Conway and Shultz (1959), Glover (1966), and Hancock (1967).) A few of these studies are summarized in Table 3 showing typical values of the powerform parameters. It is icommon practive in many companies to assume that a similar job has a similar learning curve.

A variant of the powerform model was devised at Stanford University and so it was known as the Stanford model. This model is:

$$t_n = k (d + n)^{-c} \tag{6}$$

where the only changes from the classical powerform is the parameter k replacing t_1 and the additional parameter d in the last factor. The parameter d was added to slow down the early serial values. Parameter k makes $t_1 = k (d + 1)^{-c}$. Note that the traditional powerform $d = 0$ and $k = t_1$. Table 4 describes the Stanford model for $d = 0, 0.1, 0.5$, and 1.0 in order to demonstrate how it differs from the traditional powerform using the same data as above. Table 4 also reports ratios of t_{2n}/t_n for those illustrations and the parameter values for parameter c and k. It is clear that the larger the value of d, the quicker those ratios decrease.

3.2   A Discrete Exponential Learning Curve

An alternative model to the powerform is an exponential model and a discrete serial form is:

$$t_n = t_1 \, \alpha^{n-1} \, [t_1 - t^*] + t^* \tag{7}$$

where α is the *learning rate* parameter and it is restricted to $0 < \alpha < 1$. Pegels (1969) first identified this model of learning and he noted its natural asymptote at t^* in contrast to the zero of the powerform model. Later Buck, Tanchoco, and Sweet (1976) showed that basis of this model is the constant-parameter forward-difference model or:

$$t_2 = \alpha \, t_1 + \beta \tag{8}$$

That is, the next value in the series is α times the current value plus β. It further follows that:

$$t_3 = \alpha \, t_2 + \beta = \alpha[\alpha \, t_1 + \beta] + \beta = \alpha^2 t_2 + \alpha\beta + \beta$$
$$t_4 = \alpha \, t_3 + \beta = \alpha[\alpha^2 t_1 + \beta] + \beta = \alpha^3 t_2 + \alpha^2\beta + \alpha\beta + \beta$$

Table 1. Some powerform learning examples in the literature

Improvement	Number of cycles	Task and authors
68%	1,000	Test and adjust – R. Conway and A. Schultz (1950) *Journal of Industrial Engineering*, 10, 39–53
73%	11,000	Electronic assembly – as above
79%	1,000	Service time – IBM electronics
80%		Man-hours per airframe – Wright in WWII
85%	2,000	Labor hours per gun barrel on a boring machine – F. Andress (1954) *Harvard Business Rev.*, 32, 87–97
86%	12,300	Cost/model-T – Ford (1910)
88%	–	Machine labor/product unit – W. Hirsch (1952) *Int. Journal of Production Research*, 8, 293–305
90%	–	Bench inspection – G. Nadler and W. Smith (1963) *Int. Journal of Production Research*, 2, 115–135

Table 2. Examples of the Stanford model for alternative values of parameter d

d	n	1	2	3	4	5	6	. . . 8
0	$t_n =$	5.0	4.0	3.5	3.2	3.0	2.8	2.6
c = 0.322	$t_{2n}/t_n =$	0.8	0.8	0.8	0.8	0.8	0.8	0.8
0.1	$t_n =$	5.0	4.0	3.497	3.175	2.945	2.769	2.504
c = .345	$t_{2n}/t_n =$	0.8	0.794	0.792	0.789	–	–	–
k = 5.167								
0.5	$t_n =$	5.0	4.0	3.453	3.094	2.834	2.635	2.344
c = 0.437	$t_{2n}/t_n =$	0.8	0.774	0.763	0.758	–	–	–
k = 5.969								
1.0	$tn =$	5.0	4.0	3.414	3.020	2.731	2.509	2.185
c = 0.550	$t_{2n}/t_n =$	0.8	0.755	0.735	0.724	–	–	–
k = 7.322								

More generally,

$$t_n = \alpha^n t_1 + \beta[\alpha^{n-1} + \alpha^{n-2} + \ldots + \alpha + 1]$$

$$t_N = \alpha^n t_1 + \beta \frac{1 - \alpha^n}{1 - \alpha} \qquad (9)$$

By defining

$$t^* = \frac{\beta}{1 - \alpha},$$

equation (9) is equivalent to equation (8). The next serial value in this exponential series after t_n is t_{n+1} and it is descrtibed as:

$$\Delta t_n = t_{n+1} - t_n = \alpha t_n + \beta - t_n = (\alpha - 1) t + \beta \qquad (10)$$

Equation 10 shows that the change with the next serial value is a constant $(\alpha - 1)$ times the last value plus the constant β and that corresponds perfectly with equation (9). It should be stated that when this exponential series is converted to logarithmic form, the function is S-shaped. (Both Jordan (1965) and Muth (1986) observed S-shaped logarithmic functions in practice.)

It should be stated that when $\alpha = 1$, this series becomes linear with the rate of change equal to β.

An advantage of this exponential learning curve is that cumulative sums T_n, consisting of $t_1 + t_2 + \ldots + t_{n-1} + t_n$, can be easily computed for finding cumulative averages. The basic formula for this is:

$$T_n = \sum_{n-1}^{n} t_1 = nt^* + (t_1 - t^*) \frac{1 - \alpha^N}{1 - \alpha} \qquad (11)$$

A series starting with 5 times units as t_1, with $\alpha = 0.5$, $\beta = 1,5$ yields a cumulative sum of 21.9325 the same as: 5 + 4 + 3.5 + 3.25 + 3.125 + 3.0625 = 21.9375. Also not in equation (11) that the first term on the right-hand side is the steady-state time values for thee six units after all learning is complete and the second term in that equation is the transitory time or the learning effect. Since the steady state value is $t^* = 3.0$, the transitory values are t1 - 3 = 2 + 1 + 0.5 + 0.25 + 0.125 + 0.0625 = 3.9375 which is 17.52% of the total 21.9325 and the steady-state is a little over 82%. However, if this same series increases to n = 25, the cumulative serial sum is almost 79.0. The steady-state consists of 25 3 3 = 75, which is 95% of the 79.0. Hence, the learning part amounts to only 5% of this fast-acting series. A slower-acting series is described as an identical sseries with a = 0.9. The steady state component of this slower series consists of 66% of six serial values and 80% of 25, hence there is considerably more learning effect.

A variation of this discrete exponential learning curve model is the continuous version, which was developed by Bevis, Finnicat, and Towill (1970) and extended by Hutching and Towill (1975) who applied it to performance accuracy. This is

$$t_n = t_1 + [t_1 - t^*]e^{-bt} \qquad (12)$$

where the exponent t is continuous running time while the tasks is being performed and b is the rate parameter. In one version of these authors proposed the paramter g as the time duration until learning is half completed or the time savings are $(t_1 - t^*)/2$ and parameter b = 1/g, which is similar to a half-life value.

4. FITTING LEARNING CURVES TO EMPIRICAL DATA

Besides the fact that different functional forms of learning curves yield different serial shapes and possess different properties, those different functional forms are also fit differently to data. Part of the reason is that those functional forms allow different mathematical operations and provide different mathematical conveniences because of their properties.

4.1 Fitting the Powerform Model

Fitting this model to data is simplified by the fact that this function is *linear* when converted to the logarithmic form. That is, converting equation (4) to logarithmic form results in:

$$\log tN = \log t1 - C \log N \qquad (13)$$

When both N and t_N are changed to their logarithmic values of any logarithmic base, the plots are *linear* functions of log N.

The data from the previous powerform example are changed to logarithmic values and plotted in Figure 1 where a straight-line plot is evident. A simple linear regression can be made on these logarithmically transformed data where the negative slope of the regression provides a direct estimate of parameter **c**. Since this plot was made using data that were generated by a powerform equation, the fit is perfect, including that of t_1.

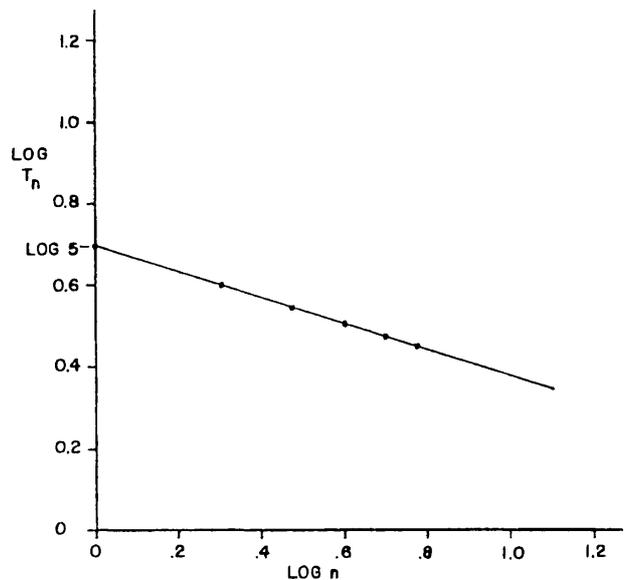
In regard to de Jong's variation of the powerform model, an identical data fitting procedure can be used if the incompressibility parameter **M** can be estimated first. Once **M** is estimated, subtract the product of **M** and t_1 from every value of t_i and continue as before. That operation will give an estimate of the compressible portion of de Jong's model; one only needs to add back the constant product of **M** and t_1. However, it is not altogether clear how one could estimate the fraction **M** except by recognizing ultimate performance of similar tasks, or perhaps using laboratory studies of a similar task.


Figure 1. A log-log graph of the powerform example with log T_n as a function of log N as used for fitting this learning curve

4.2 Fitting the Discrete Exponential Model

This action required empirical data and a different approach. It was noted during the discussion of this model that the first-forward differences Δt_N is a *linear* function of the performance magnitude t_n as shown in equation (10). Accordingly, the best linear fit provides estimates of parameters α and β. A linear regression of Δt_N, as a function of t_N, has the slope of $(\alpha - 1)$. The ordinate intercept of that regression is β and the abscissa intercept is t^* (the asymptote). To illustrate, consider the previous numeral example above where:

n =	1	2	3	4	5	6
t_n =	5.0	4.0	3.5	3.25	3.125	3.0625
Δt_n =	-1.0	-0.5	-0.25	-0.125	-0.0625	—

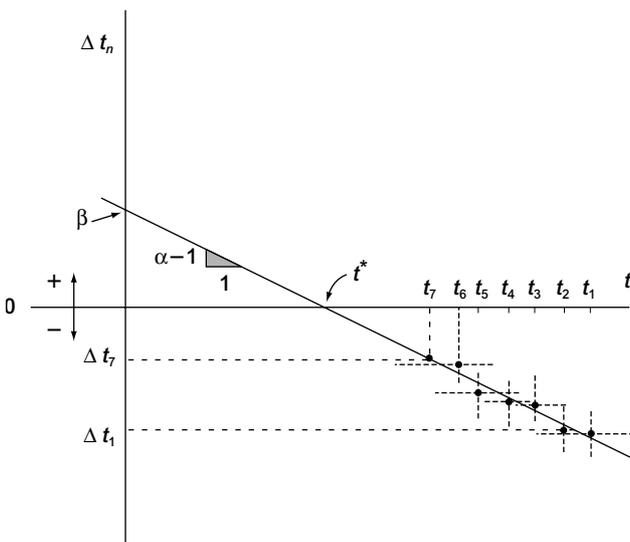
A regression of Δt_N as a function of t_N yields a slope of -0.5, an ordinate intercept of 1.5, and an abscissa intercept of 3. When the slope value is equated to $(\alpha - 1)$ and solved, then it is seen that $\alpha = 0.5$. Figure 2 shows a plot of these regression data.

The above example of fitting the discrete exponential model to data resulted in finding parameters α and β. Parameter t^* is a direct result of those parameter values. With the values of these parameters substituted in equation (7), only the value of t_1 is needed and every value of the series can be predicted. One could use the first data point for t_1, but if there is any error in that value, the entire series of predictions is wrong. A better procedure is to expand the above procedure with the least-squared-error estimate of **t1** based on many data points, not just the first one. It is easier to compute first the mythical value of t'_0 as:

$$t'_0 = \frac{\alpha^2 - 1}{\alpha^{2n} - 1} \sum_{i=0}^{n-1} \alpha^i t_i + \frac{(\alpha^{n-1} - 1)(\alpha^n - 1)}{(\alpha^{2n} - 1)} \qquad (14)$$

and then to convert back to t'_1 use the basic relationship:

$$\mathbf{t'_1} = \alpha\, t'_0 + \beta \qquad (15)$$

Equation (14) provides a least square error estimate of fit so that the whole known series contributes to the initial value for estimation. It there is error added to each of the points over the learning sequence, by finding an estimate of t_0 from each of several points, the average value of can go into equation (14) to help stabilize the resulting t'_1 in equation (15).


4.3 A Numerical Example of Learning

Consider the numerical example immediately above where the series went from 5 to 4 to 3.5, and so forth. Suppose that all we had were these first three series values. Thus, N = 3 for estimation purposes. The mythical t_0 value is 7 as $0.5(7) + 1.5 = 5 = t_1$. When is $\alpha = 0.5$ and is $\beta = 1.5$, a series starting at 7 goes exactly through those points 5, 4, and 3.5. Note the calculations below for n = 2, 3, and 4, respectively, using equation (14) and the actual data. The first equation below considers only the mythical series value and $t_1 = 5$. The second equation includes $t_2 = 4$ as well. Both equations yield the same result.

$$t'_0 = \frac{.5^2 - 1}{.5^4 - 1}\, [7 + .5(5)] + 3\, \frac{.5(.5^{2-1} - 1)(.5^2 - 1)}{(.5^4 - 1)} = 7.6 - 0.6 = 7.0$$

$$t'_0 = \frac{.5^2 - 1}{.5^6 - 1}\, [7 + .5(5) + .25(4)] + 3\, \frac{.5(.5^{3-1} - 1)(.5^3 - 1)}{(.5^6 - 1)} = 8,0 - 1.0 = 7$$

$$t'_1 = 0.5(7.0) + 1.5 = 5.0$$

If there was noise present and we would expect to estimate the same α and β, but the noise could change the whole series by changing the first few serial values.

Figure 3 shows some interesting points about fitting this discrete exponential model to empirical data. When α is very close to unity, the slope of the regression is nearly flat. If a large amount of learning takes place between the first and second observation and the slope is approaching flatness (i.e. near zero slope), the two intercepts can become negative, leading to very unreasonable implications for a learning curve. Examples of this were reported by Buck and Cheng (1992) who performed a series of experiments. For this reason, one needs to constantly check reasonableness of models. Another problem with the discrete exponential model occurs when people try to over-compensate

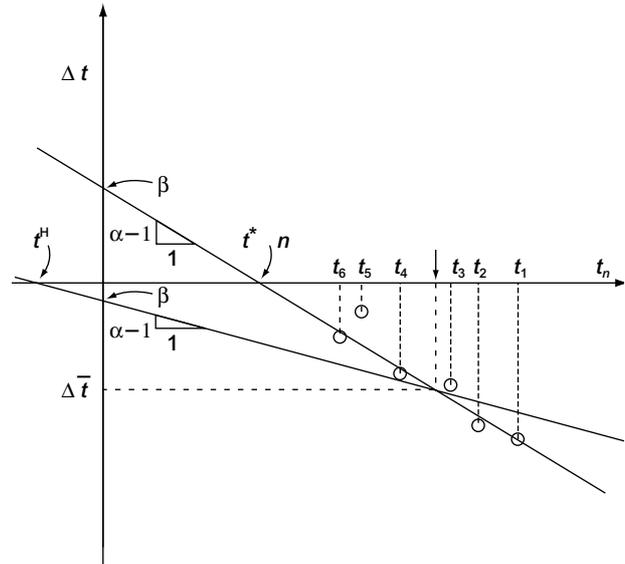
Figure 2. Fitting a discrete exponential model to data


Figure 3. Possible errors in the fitting of the discrete exponential model to data

for immediate feedback. In that case, performance time may alternate between successive cycles. With strong data alternations, α can become negative to reflective this form of behavior. The discrete exponential learning curve is more pliable than the powerform model so that the exponential will reflect those oscillations when they dominate the learning effect.

Learch and Buck (1975) demonstrated this alternation phenomena in an elementary learning situation.

5. COMPARING ALTERNATIVES FOR LEARNABILITY

One of the important features of many ergonomic designs is the capability of a user being able to use the design proficiently at the earliest possible time. As a consequence, new designs can be tested in usability. Fitting a learning curve to the performance changes of naive users provides the basis for assessing learnability. In terms of the powerform model, the learning rate is specified by the parameter **c**. The discrete exponential model describes learning in two ways; parameter a which shows the learning rate and the difference between t_1 and t^* which describes the amount of learning expected. Unfortunately, the expected amount of learning is not available directly from the powerform model but a similar estimate can be obtained by computing t_{1000} and subtracting it from t_1. A design with a greater learning rate and a small amount of learning but with a low t^* is a preferred design on the basis of learnability.

6. COGNITIVE CONTENT AND THE LEARNING RATE

Some recent studies from Arzi and Shatub (1996) and Dar-El and Vollichman (1996) have shown two interesting results. The first is that tasks with higher cognitive content tend to have lower learning rates. An immediate implication is that quicker learning (or lower performance times) occur sooner when the cognitive content is stripped from the task. This implication speaks immediately to the economics of learning which follows. The second finding of importance is that after forgetting and a transitional restarting people return quickly to the former learning curve which they terminated at the previous stopping of practice. Hence, forgetting is, to a certain extent, unlearning. This observation describes the effects of repeated practice.

7. ECONOMICS OF LEARNING

When there is improvement in performance times due to learning, there is a shorter production duration to produce **n** items. Hence, the direct labor cost is smaller with greater learning. In fact, as an individual completes more of the production, the time per unit decreases. At the same time, those future economic advantages are discounted further in time and so some of the effects are less. However, the learning curve directly states the changes in labor time as the person improves and the Department

of Defense often requires learning curve adjustments on manufacturing contracts.

8. FINAL REMARKS

Learning is the result of practice and training. The focus here is on the description of the effect using well-known functions that decrease with time or experience. Those models are classical in describing performance changes with experience but none are ordained. That is, there is no true learning curve, because there is no fully accepted theory on behavioral learning. Hence, the best learning curve is the one which best fits available data and one really needs to describe learning with available data for fitting the models. The models formalize the description of the effect and they allow one to project what future effects are likely to be.

Lifting Techniques

R. Burgess-Limerick

Department of Human Movement Studies, University of Queensland, Brisbane 4072 Australia

1. INTRODUCTION

Compensation claims for occupational injuries attributed to lifting have typically represented a significant proportion of claims (~20%), and the majority of these (typically ~70%) are for injuries to the back. This paper discusses the postures and patterns of movement used to lift low-lying objects and the implications of these postures and movements for back injuries in particular.

Current knowledge about the mechanisms of back injuries and the biomechanical consequences of different lifting techniques are described; and attention is directed toward the postures and patterns of movement normally employed to lift low-lying objects. The paper concludes by presenting recommendations for preventing back injuries caused by lifting.

Starting from upright standing, lifting a low-lying object placed in front of the person involves a cycle of movement beginning with flexion of the knees, hips and lumbar vertebral spine (and dorsi flexion of the ankles). The load is then grasped and raised against gravity by extension of the knee, hips and lumbar vertebral spine (and plantar flexion of the ankles).

Lifting technique has typically been defined in terms of the posture adopted just before the load is lifted (at the start of the extension phase). It has commonly been proposed that the postures adopted to lift loads from a low level may be characterized in terms of two extremes: one, described as a stooped posture, is where the knee joints are almost fully extended and the hip joints and vertebral column are flexed to reach the load; the second, described as a full squat, is where the knee joints are fully flexed and the trunk is held as vertical as possible. It has become a matter of dogma that the latter posture is the "correct" manner of lifting. However, on the basis of current knowledge of injury mechanisms and lifting biomechanics, it is clear that lifting from a full squat posture is not an appropriate recommendation. It is also evident that a self-selected lifting technique typically involves adopting a posture at the start of the extension phase which is intermediate between full squat and stooped postures, and that the pattern of movement normally employed reduces muscular effort.

2. MECHANISMS OF INJURY DURING LIFTING

During lifting, large extensor moments about the joints of the lumbar vertebral column are produced by the paravertebral musculature to overcome the flexor moment caused by the weight of the upper body and load. Injury to musculo-ligamentous structures commonly occurs as a direct consequence of the high forces involved.

These high forces also result in large compressive and shear forces acting between each pair of vertebra. Unless the lumbar spine is in a posture of extreme flexion, the mechanism of failure in compression is failure of the endplates of the vertebral bodies and the underlying trabeculae as the nucleus pulposus bulges upward and downward (Adams and Dolan 1995). The magnitude of compressive forces experienced during a single lift is unlikely to cause endplate failure, and an injury of this type caused by lifting is more likely to be cumulative.

Cumulative damage to the vertebral endplates may occur in a number of ways. Microdamage to vertebral endplates is likely during heavy lifting, and injury may arise if the microdamage accumulates more rapidly than can be repaired. Repeated compressive loading will also reduce the failure tolerance of the tissues, resulting in injury if repeated loading continues (McGill 1997). Damage may also be additive in that prolonged exposure to other sources of loading, and especially whole-body vibration, may render the vertebral bodies vulnerable to injury during lifting.

Lifting from postures involving extreme lumbar vertebral flexion has the potential to contribute to injury. Extreme lumbar vertebral flexion is characterized by absence of electromyographical activity in erector spinae (e.g. McGill and Kippers 1994). In this situation the anterior moment caused by the weight of the upper body and the load is balanced by an extensor moment created by tension in the paravertebral ligaments, interspinous ligaments, posterior fibers of annulus fibrosus and passive elements of the musculotendinous tissues. The first tissues to be injured in this situation are the interspinous ligaments (Adams and Dolan 1995). Disruption of the posterior fibers of annulus may follow if extreme lumbar flexion is combined with compression and lateral bending or torsion.

If damage to the posterior annulus progresses, seepage of the nucleus pulposus through the annulus may result (an intervertebral disc prolapse). While intervertebral disc prolapse only accounts for small proportion of claims for back injuries (5–10%), the injury frequently results in chronic back pain and accounts for a considerably larger proportion of claims costs.

Compressive load alone will not cause intervertebral disc prolapse, and damage to the intervertebral disc is unlikely to occur as a consequence of one-time loading (although this is possible if high compressive load is placed on the spine while hyperflexed and laterally bent) (Adams and Dolan 1995). Injury to the intervertebral disc is more likely the consequence of an accumulation of microdamage due to repeated compressive and torsional loading applied while the lumbar spine is extremely flexed.

Anterior shear forces are also very high when loads are lifted from a posture of extreme lumbar flexion and this represents a risk of injury. However, the orientation of the fibers of the erector spinae muscles (in particular, the pars lumborum fibers of longissimus thoracis and iliocostalis lumborum) is such that when tension develops in these muscles a posterior shear force is created on the superior vertebrae that counteracts the anterior shear created by the weight of the upper body and load (McGill 1997). The erector spinae are active unless lumbar flexion is extreme, and consequently the anterior shear forces are reduced in postures that do not involve extreme lumbar flexion.

Prolonged exposure to static postures involving extreme lumbar vertebral flexion will also cause the tissues to creep (the ligaments do not return to their resting length immediately upon unloading). The consequence may be a temporary loss of stability after the period of sustained extreme lumbar flexion which may lead to a higher likelihood of injury in subsequent loading in any posture (McGill 1997). The abdominal muscles normally contribute to stability of the spine, and failure to contact these muscles appropriately may also increase the risk of injury.

3. THE "FULL SQUAT" RECOMMENDATION

According to Brown (1973), the recommendation that lifting should be carried out from a "full squat" posture has been promulgated since the 1930s. Many researchers have subsequently noted that this recommendation is unjustified (e.g. Whitney 1958, Brown 1973, NIOSH 1981). The authors of the otherwise influential NIOSH Work Practices Guide for Manual Lifting (1981) observed that the full squat posture reduced stability (the heels are inevitably lifted from the ground and the knees are in an unstable "loose packed" posture when maximally flexed) leading to the possibility of injury due to unexpected perturbations; and that the technique increased the distance of wide loads from the spine (increasing the load moment and consequently the resulting extensor moment and compressive forces). It was concluded that the squat lift recommendation was based on simplistic mechanical logic that failed to take dynamic loading on the back and the knees into account.

The proponents of the full squat technique suggested that the stresses on the vertebrae are better distributed with the lumbar spine in a lordotic posture. In fact, lordosis poses several disadvantages relative to postures of partial flexion (Adams and Dolan 1995), including increased loading of apophyseal joints and increased compression of the posterior annulus. Lordosis has been advocated to reduce hydrostatic pressure in the nucleus, but this only indicates that the load has been shifted to the annulus and apophyseal joints.

An additional pragmatic problem with the full squat recommendation is that it cannot be utilized in many situations. Maximal knee flexion has the consequence of lengthening the quadriceps beyond their optimal length leading to decreased knee extensor strength. The result is that lifting capacity is reduced: submaximal loads require greater muscular effort leading to more rapid onset of muscular fatigue; maximal loads cannot be lifted at all.

From the discussion of injury mechanisms it is evident that the only appropriate recommendation regarding posture of the lumbar spine is to avoid extreme lumbar vertebral flexion, and trunk rotation and lateral flexion. There is no basis for avoiding postures involving moderate lumbar vertebral flexion.

4. SELF–SELECTED LIFTING TECHNIQUE

The traditionally recommended full squat posture is seldom, if ever, spontaneously adopted in the absence of specific instruction. Investigations of self-selected lifting technique have revealed that the postures typically adopted to lift low-lying loads are intermediate between full squat and stoop extremes, and might be termed semi-squat (e.g. Burgess-Limerick et al. 1995, Burgess-Limerick and Abernethy 1997). Lifting a low-lying load from a semi-squat posture typically involves ~45° of lumbar vertebral flexion, that is, ~75% of the normal range of movement. In conjunction with the absence of an electromyographical silent period in erector spinae, this suggests that the passive structures of the back are not substantially stretched during lifting from this posture. Some people in some circumstances adopt stooped postures involving greater lumbar flexion, although typically this occurs when the load is relatively light.

An adequate description of lifting technique requires consideration of the pattern of interjoint coordination as well as the posture adopted at the start of the lift. The posture adopted at the start of extension influences the pattern of subsequent interjoint coordination by determining the range of movement available at each joint. The semi-squat posture most commonly adopted at the start of extension allows a pattern of interjoint coordination that appears functional.

The coordination of self-selected lifting involves contemporaneous movement of the lower limb and trunk joints, that is, the joints flex and extend at the same time rather than sequentially (as is sometimes modeled). However, the joints are not perfectly synchronized: a consistent pattern of deviation from synchronous coordination is commonly observed. Knee extension typically occurs more rapidly earlier in the lifting movement relative to extension of the hip, and the onset of rapid lumbar vertebral extension is delayed substantially after the start of the lift. The moderate lumbar flexion observed lengthens the erector spinae relative to its length in normal standing, and the delay before rapid lumbar vertebral extension delays rapid shortening of the erector spinae. Estimation of the length changes of the biarticular hamstring muscles has revealed that they are also relatively lengthened at the start of the extension phase, and that the pattern of coordination between knee and hip joints also has the consequence of delaying rapid shortening of the hamstrings.

Muscles are stronger when lengthened, and when not shortening rapidly, and thus this pattern of coordination increases the strength of the hamstrings and erector spinae early in the extension phase when the acceleration of the load is greatest by both lengthening the muscles, and delaying their rapid shortening. Delaying shortening of the hamstrings has the additional functional consequence of allowing the monoarticular knee extensors, paradoxically, to contribute to hip extension through a tendinous action of the hamstrings. The pattern of coordination observed thus reduces the muscular effort required to perform the task, and the pattern of interjoint coordination is exaggerated with increased load mass.

A different pattern of coordination between hip and knee occurs when a stooped posture is adopted at the start of extension. The large range of hip flexion and small range of knee flexion involved results in the hamstrings being lengthened further than if a semi-squat posture were adopted. A stooped posture has the advantage of lowering the center of gravity of the upper body less than a semi-squat posture and thus less work is done in lifting the upper body during each lift. However, during lifting from a stooped posture the hamstrings must immediately shorten rapidly because the knee is unable to extend rapidly. This counteracts to some extent any strength advantage that might accrue as a consequence of the increased hamstring length and prevents the monoarticular quadriceps from contributing to hip extension.

5. RECOMMENDATIONS FOR PREVENTING BACK INJURIES DUE TO LIFTING

Training people to perform lifting in safer ways has been consistently proposed as a means of reducing the risk of injury; however, research evaluating the effectiveness of lifting training programs involving the uninjured worker has generally failed to find any evidence of persistent modification in lifting technique (Pheasant 1986). If it can be assumed that muscular fatigue contributes to injuries suffered as a consequence of lifting, then a technique that reduces muscular effort may be preferred. Rather than prescribing a single "best" technique that is not likely to be

appropriate in all situations, it may be preferable to provide education in general lifting guidelines and to use exploratory learning techniques (Newell 1991) to assist lifters to discover individually appropriate postures and patterns of movement.

General lifting guidelines that can be justified on the basis of current knowledge include: wherever possible, remove exposure to manual lifting by providing mechanical aids; and if manual lifting must be undertaken, one should:

- Reduce the load mass.
- Raise the initial height of the load.
- Keep the load close.
- Adopt a posture at the start of the lift that involves a moderate range of motion at the knee, hip and vertebral column.
- Avoid lifting from a posture of extreme lumbar vertebral flexion.
- Avoid trunk rotation while lifting.
- Avoid lateral trunk flexion while lifting.
- Avoid lifting after prolonged periods of extreme lumbar vertebral flexion.
- Avoid high acceleration of the load (lift smoothly).

The risk of injury to the back caused by lifting can also be reduced by reducing exposure to whole-body vibration and by strengthening the bones, ligaments and muscles by appropriate exercise.

Loads on the Lumbar Spine during Dynamic Work

W.S. Marras

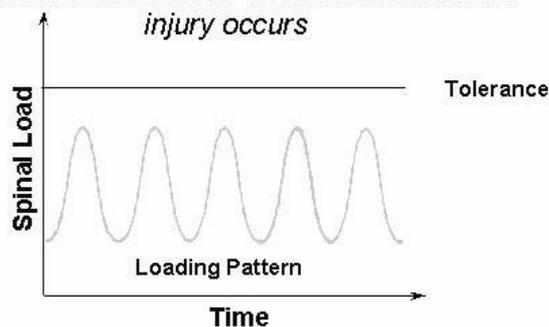
Biodynamics Laboratory, Institute for Ergonomics, The Ohio State University, 1971 Neil Avenue, Columbus, OH 43210, USA

1. WHY ASSESS LOADS ON THE SPINE?

Occupationally related low back disorders (LBD) are typically the leading cause of lost work days as well as the most costly occupational health problem facing industry today. Statistics gathered from industry have made it clear that occupationally related LBD risk is associated with manual materials handling (MMH) tasks such as lifting lowering, pushing, pulling, carrying and performing tasks in non-neutral postures. Until recently tools were available that could biomechanically analyze jobs for workers performing tasks in static postures. This greatly reduced the applicability of the models to realistic work tasks observed in industrial settings. This chapter will show how biomechanical analyses can be performed to assess spine loading during realistic, dynamic task activity of the spine.

Industrial studies have identified relationships between the load imposed upon the spine and the risk of low back disorders. The more load imposed upon the spine, the greater the risk of suffering a LBD. Thus, it is important to be able to assess the magnitude of the load imposed upon the spine if we are to develop an appreciation for the risk imposed upon a worker though the performance of a particular job task. Hence, estimates of spinal loads provide a benchmark or measure of the percentage of workers who will be at risk of suffering a LBD due to the job.

According to biomechanical logic, loads imposed upon the spine are compared to the tolerances of spinal structures to assess the risk of injury in a certain job. Figure 1a shows the magnitude of a load imposed upon the spine during several cycles of work. As the work task is repeated, the load imposed upon the spine increases and decreases in a cyclical pattern. This figure also shows the relationship of this loading to the tolerance level of the spine. As long as the magnitude of the load does not exceed the tolerance of the spine, one would not expect an injury to occur due to the work. Realistically, the tolerance of the spinal structures varies between individuals. This tolerance level can be viewed as a *distribution* if tolerances among the populations of workers. In addition, the loading imposed upon the spine can vary from cycle to cycle even if the same task is repeated. Finally, both the loading imposed upon the spine as well as the tolerance can vary over time. Figure 1b shows how biomechanical logic can account for cumulative trauma through a gradual decrease in the spine tolerance though out the work period. Thus, by considering the variability in loading and comparing this to the variability in spine tolerance over time, one could estimate the percentage of workers that would be expected to be affected by a job design characteristics.

Loading of the spine can occur in three dimensions. Figure 2 shows the three types of forces or loading that can occur on the


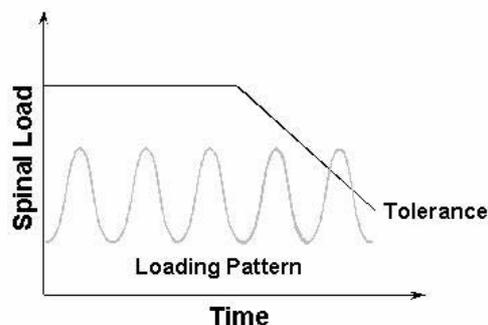


Figure 1. (a) Load–tolerance relationship assumption used for biomechanical assessments; (b) adjustment of load–tolerance relationship for cumulative trauma.
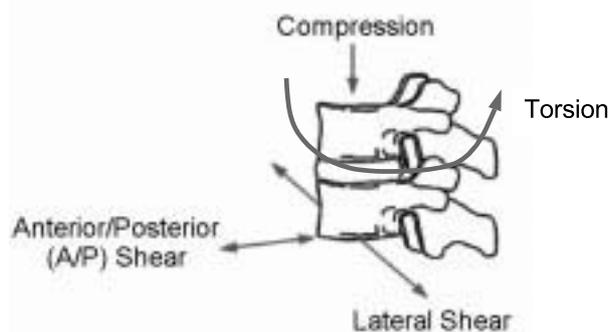

Figure 2. Forces that can affect spine loading.

spine. Loading can occur in compression, shear or torsion. In actual MMH situations, the spine is loaded simultaneously in multiple dimensions.

2. HOW DOES SPINE LOADING AFFECT SPINE DEGENERATION?

Figure 3 shows the sequence of events that occurs during work related degeneration of the spine. This sequence represents one

of the major pathways believed to occur for low back disorder. As indicated in the figure, excessive loading, generated from both within and outside the body (internal and external forces), cause microfracturing of the vertebral end plates. These end plates serve as a transport system for nutrient delivery to the disc fibers. If this loading becomes excessive and exceeds the end plate tolerance, a microfracture occurs. This microfracture is typically painless since few pain receptors reside within the disc. As healing occurs, scar tissue develops over the microfracture. Since scar tissue is thicker and denser than normal tissue, this scar tissue interferes with nutrient delivery to the disc fibers. This loss of nutrient results in atrophy to the disc fibers and weakens the disc structure. This process represents the beginning of cumulative trauma to the spine and can result in disc protrusions, disc herniation, and instability of the spinal system. It has been commonly accepted that compressive loads on the end plate of 3400 N represent the level at which vertebral end plate microfractures begin to occur. Loadings of 6400 N are expected to affect 50% of people < 40 years (NIOSH 1981).

Tolerances have also been estimated for shear loading of the spine. These are expected to occur between 750 and 100 N.

3. HOW ARE SPINAL LOADS ASSESSED?

3.1. Internal and External Loading

To evaluate the load imposed upon the spine, one must consider the mechanism by which forces are transferred to the spine. Two types of forces typically are typically imposed on the spine. External forces represent those forces due to the effect of gravity acting on the object being moved as well as the worker's body. As shown in Figure 4, external loads represent the mass of the object lifted. They can also represent the forces generated by the force of gravity acting on the workers arms and torso. The second type of force imposed upon the body are internal forces. Internal forces are those forces imposed on the spine due to the reactions of the body to the external forces. Forces generated by muscles as well as passive forces in the connective tissue represent internal forces. However, as suggested in Figure 4, the magnitude of the internal forces typically are much larger than the external forces since they must operate at a mechanical disadvantage.

Thus, the key to estimating accurately internal loads is to accurately account for the internal loads that are needed to support the external loads. The sum of the internal and external forces occurring in three-dimensional space define spinal loading. However, a major limitation in controlling the incidence of occupationally related LBD has been the inability *accurately* to assess the loading due to the internal forces acting within the torso and imposing loads on the lumbar spine. For spine loading estimates to be accurate, they must be able to assess internal forces in the torso under realistic work conditions that often involve whole-body free-dynamic MMH conditions.

3.2. Single Equivalent Muscles

Historically, researchers have attempted to estimate the activity of the internal forces generated by the trunk muscle through several methods. Early approaches assumed that a single equivalent muscle force in the back could represent the internal muscle forces. Stick figures with a single equivalent extensor muscle were used to asses the contribution of the trunk muscles to spine loading. However, latter research showed that such models could not accurately represent risk and that assuming a single equivalent muscle was a gross simplification of the biomechanical system. These approaches also were unable to account for how muscle behavior responded to realistic trunk motion.

3.3. Multiple Muscle Systems

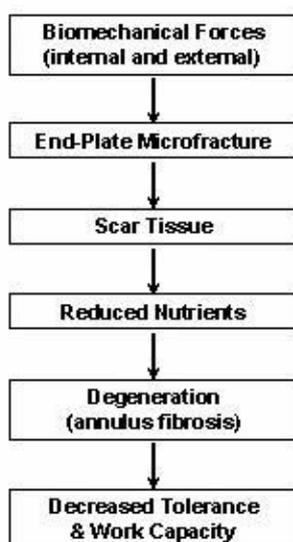
These early single equivalent muscle attempts made it clear that a multiple muscle system representation was need to describe the activity of the trunk's musculoskeletal system. However, this type of representation further complicated the issue of resolving muscle forces within the torso. Over a dozen muscles can support external forces imposed on the trunk during a MMH task. But only three external forces and three external moments can be monitored outside the body (external forces). Thus, this results in a statically indeterminate situation since there are far more unknowns (internal muscle forces) than knowns (external forces)


Figure 3. Sequence of events occurring on the spine during degenerative process.
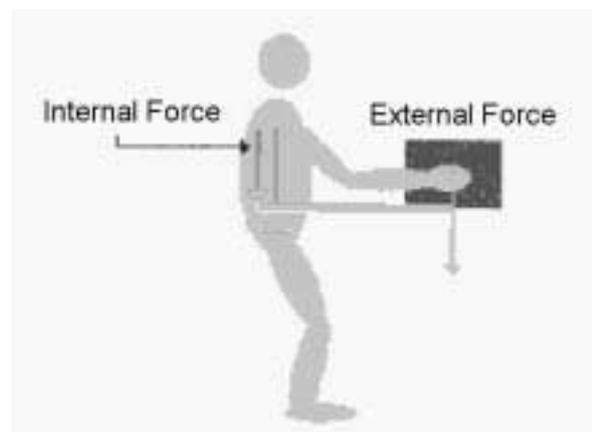

Figure 4. Internal and external forces acting on the spine.

and it becomes impossible to determine which muscle support the external loads.

Several approaches have been employed to estimate the contribution of the loads in the multiple muscle system. First, assumptions were made regarding which muscles would be active during a task and which ones would be silent. This reduced the size of the problem and permitted one to solve for the internal muscle forces and, therefore, estimate spinal loads. Unfortunately, laboratory monitoring of the muscle activities during simulated MMH rarely indicated that these assumptions were realistic. It was often the case that more muscles were active than assumed.

Second, optimization and neural network algorithms were used to assess the contribution of the internal muscle forces. In the case of optimization, no objective functions could be identified that resulted in a realistic muscle activity descriptions. Optimization often worked under static prolonged loading conditions but failed to predict the coactive nature of the trunk musculature. Neural networks used historical records of muscle activities to predict muscle how muscle would behave during lifting tasks. These networks were often used to classify muscle usage patterns but were not able to describe the range of responses between workers. In addition, they were unable to adapt to new lifting situations. Hence, these predictions tool failed to realistically estimate the response of the trunk muscles to dynamic real-world lifting conditions.

Finally, biologically assisted models were used to estimate the forces generated within the trunk muscle during a lift or MMH activity. Instead of attempting to predict which muscles were active or inactive in response to an external loading condition, biologically assisted models monitor the biological output from many muscles to directly assess which muscles are active in response to an external load. Electromyography (EMG) is often used to monitor the muscles under these circumstances (McGill and Norman 1986). EMG is a measure of the electrical depolarization of a muscle during work. The EMG signal can be calibrated to represent the force generated by a given muscle during a MMH condition.

4. OSU EMG–ASSISTED FREE–DYNAMIC BIOMECHANICAL MODEL

Over the past 18 years such an EMG-assisted biomechanical model has been under development in the Biodynamics Laboratory at the Ohio State University (Marras and Granata 1997). This model monitors the electrical activity of the 10 major trunk muscles used to support external loads and sums these forces in three dimensions to predict compression, shear and torsion loading on the spine. The model is responsive to dynamic trunk motion and can monitor complex MMH motions of the trunk.

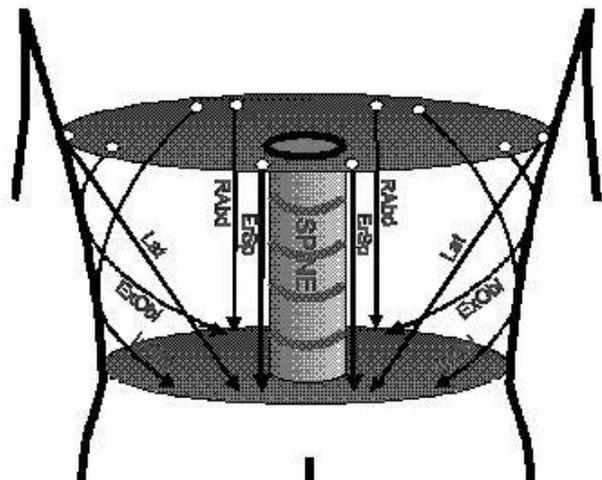
The logic behind this model is represented graphically in Figure 5. The model assumes that we can pass one imaginary transverse plane though the thorax and another imaginary transverse plane through the pelvis. According to the laws of physics, only muscles that pass through both of these planes would be capable of imposing loads on the lumbar spine. We directly monitor every muscle that passes through both of these two planes except for two deep muscles. One of these muscle is not active during lifting and the other would require needle electrodes for assessment. Because of its proximity to the spine,


Figure 5. Ohio State University (OSU) EMG-assisted spine model torso.

this muscle contributes little to spine loading, therefore, it is not monitored in the model. The maximum physiologic cross-sectional area of a muscle dictates maximum force generation capacity of a muscle. Our recent studies (Marras *et al.* 1999a, b) have documented these cross-sectional areas of the male and female trunk using MRI. Our MRI studies have also documented the lines of actions of the trunk muscles for males and females and have allowed us to accurately model the geometric locations of these internal forces within the trunk.

The EMG activity of the 10 trunk muscles is adjusted for muscle velocity, muscle length, maximum muscle activity, and the size of the muscle. Once these adjustments are made, the continuous internal force generated by these muscles during the task of interest is estimated. The resultant muscle force vector is multiplied by its distance from the spine to assess its contribution to spine loading. These forces are then summed in the vertical and horizontal directions to predict compression and shear.

The ultimate proof of whether a model is robust enough to assess loading in three-dimensional space comes from validation studies. While it is unethical to directly monitor loads on the human spine using instrumentation, we can monitor model performance using indirect validation measures. Three validation measures are used to realistically assess model performance. In these validations, the external loads imposed about the torso are monitored using a force plate. Our model also *predicts* these external loads via the EMG activity. A comparison of these measures indicates the degree of agreement between the measured and predicted external load. Tests have indicated that the model has performed very well in over 1600 trials. A recent study (Marras *et al.* 1999a, b) has also explored model variability associated with the repetition of a task compared to independent evaluations on different days. Model performance was found to be excellent both within and between days.

5. USE OF THE MODEL

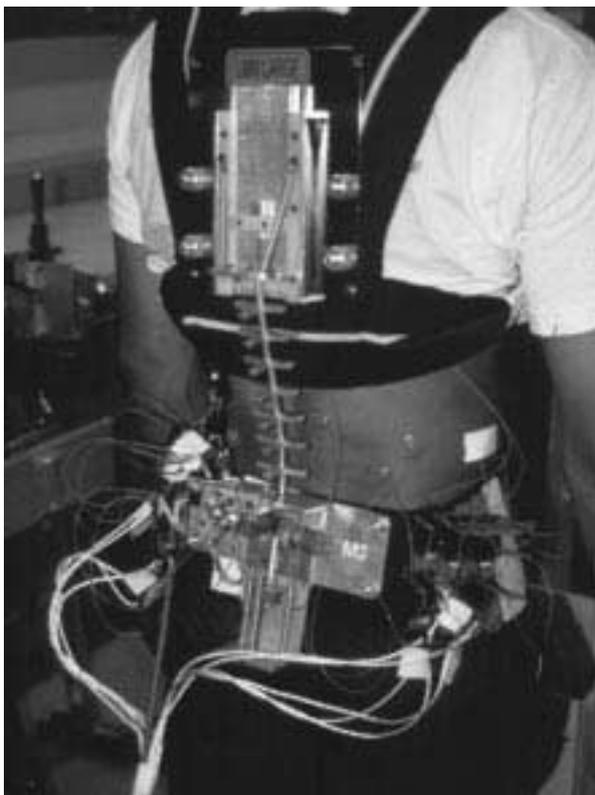
Figure 6 shows a worker instrumented with EMG electrodes so that loads on the spine can be assessed as he performs a work


Figure 6. A subject instrumented with electrodes and the lumbar motion monitor (LMM). Instrumentation is used to run the EMG-assisted model.

task. The worker has also been fitted with a lumbar motion monitor (LMM). This device tracks the motion of the torso with respect to the pelvis. In this manner, the muscle lengths can be calculated and muscle velocities can be measures. This information is used to adjust the EMG signal so that muscle force can be represented.

The model has been developed so that it can be represented in a "windows" environment. Figure 7 shows an example of this program. The model includes a video of the worker performing the task along with numerous biomechanical performance measures. Windows may be selected that show the instantaneous kinematic, kinetic, and muscle activities indexed along with the video of the task. In this manner, the model can show how the spinal loads develop through an activity, which internal forces are responsible for the load development, how the position and activities of the worker are associated with the loading, as well as model performance measures. Dozens of windows are available thoroughly to evaluate factors that contribute to spine loading during task performance. In this manner, it is possible to determine which portions of a task place the worker at risk and which portions of the task are considered low risk.

6. MODEL USE EXAMPLE

In this manner, the model can also be used to evaluate the risk associated with a particular task. The risk associated with alternative task designs can also be assessed so that the risks or benefits of a job design alternative can be objectively assessed. In addition, since the model is sensitive to individual differences between workers, the model could be used to assess how risk

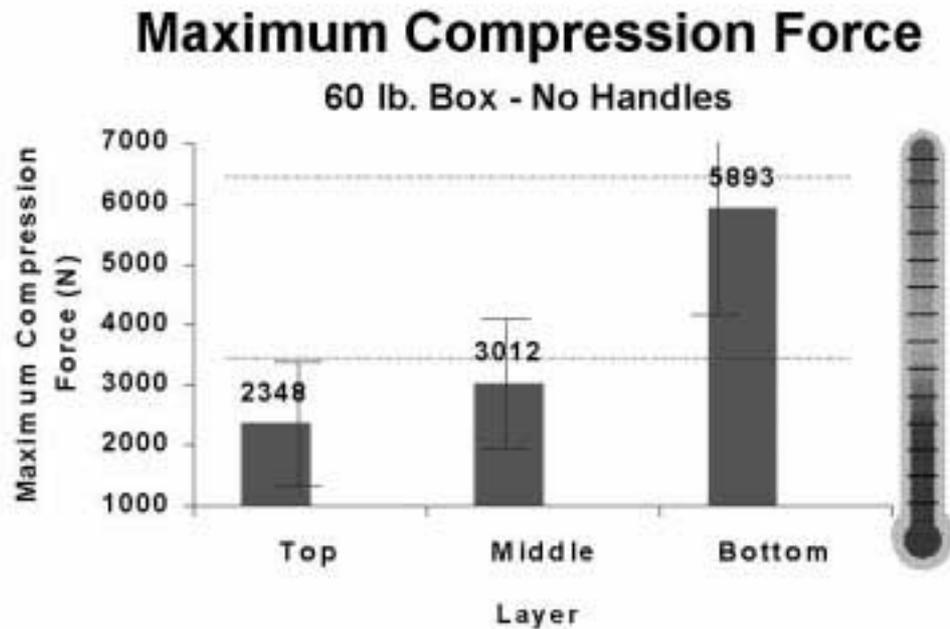
Maximum Compression Force
60 lb. Box - No Handles


Figure 8. Maximum spine compression as a function of lifting from different vertical regions of a pallet; an example of the results obtainable from the OSU EMG-assisted model.

varies for a given task between workers or between various work techniques.

Figure 8 shows how this model was used to explore how spine loading (compression) changes as loads are lifted from different regions of a pallet in a distribution center environment. For this analysis, the vertical regions of a pallet have been subdivided as top, middle or bottom levels or layers. This figure shows the magnitude of compression compared to two tolerance benchmarks mentioned earlier. In addition, to aid interpretation a risk "gauge" has been included to the right of this figure. This figure indicates that most of the risk in lifting 60 pound boxes from a pallet occurs when lifting from the bottom layer where were average maximum spine compression approaches 6400 N. Hence, the threshold of vertebral end plate microfracture tolerance would be exceeded for many people. This information also makes it possible to estimate the percentage of workers that would be at risk of these microfractures so that the magnitude of risk can be assessed. Thus, we can see, though this quantitative analysis, that some sort of lifting assistance would be beneficial but this would only be necessary at the bottom layer of the pallet.

7. CONCLUSIONS

This chapter has shown how quantitative evaluations of the workplace can be used as a tool to evaluate spine loadings

associated with tasks that comprise a given job. The benefit of such analyses is that they permit one to quantitatively evaluate 'how exposure to a work task factor is too much.' Through such an accurate and complete assessment of work it is possible to significantly reduce the risk of LBD associated with the physical demands of work tasks.

Manual Materials Handling in Unusual Postures

J. L. Smith

Texas Tech University, Lubbock, TX, USA

Early research in manual materials handling examined physiological, biomechanical and psychophysical capabilities of workers in standard lifting postures, which were usually described as two-handed, symmetric, sagittal plane lifting (or lowering). In 1981, NIOSH published *Work Practices Guide for Manual Lifting* which established recommended manual materials handling limits for such "standard postures". In 1991, revisions to the guide were published in which angle of twist was one of the components added to the recommended weight limit calculation (Waters *et al.* 1994). However, more unusual postures have received little attention. Part of the obvious reason is that, by definition, unusual postures imply that the situation is unique and hence trying to establish norms for unique postures has limited value.

In an effort to provide input data for a computerized CAD model that included a maintenance person, research efforts at Texas Tech University established capacity data for male and female subjects performing a variety of manual materials handling activities in unusual (or non-standard) postures. The capacity data were presented in terms of predictive models as well as the distribution of capacity data in Smith *et al.* (1989, 1992). The psychophysical approach was utilized to generate capacity data for the non-standard postures of interest. About 100 subjects were used for each task (50 males, 50 females, aged 18–25, selected to be representative of the US Air Force population in terms of height and weight characteristics). Each subject was asked to determine his or her individual capacity (without overexertion or lifting in an unsafe manner). In addition, each subject performed a variety of static and dynamic strength tests. Models were generated to predict handling capacity from one or more of the strength tests. A dynamic test, the incremental 6-foot lift, was the best predictor of handling capacity.

Examples of non-standard postures examined for the US Air Force study involved lifting and lowering while assuming a stooping, squatting, kneeling or sitting posture. Such postures represented those found while handling materials in restricted environments, such as aircraft cargo bays. Other unusual postures included lying face down and lifting objects through restricted openings, lying face up and lifting, and lying on the side of the body while performing a variety of activities. More common examples of non-standard tasks might include handling objects with only one hand or arm, holding an object in place with one or both hands, and carrying an object while crawling.

For the ergonomist needing capacity information for workers required to handle materials in non-standard postures, the best approach would be to simulate those activities in an environment where the testing would not interfere with production. Workers could be brought to the test area, given instructions for the test and asked to perform the required tests. Strength testing should also be conducted if capacity models are desired. To minimize data contamination and to reduce the risks of injury, subjects should be isolated during testing, not provided with feedback and be told to not discuss the test with their fellow workers.

Manual Materials Handling: Multi-person Lifting

M. A. Sharp† and V. J. Rice‡

†US Army Research Institute of Environmental Medicine, Natick, MA01760 USA

‡US Army Academy of Health Sciences, San Antonio, TX78234 USA

1. INTRODUCTION

Manual materials handling (MMH) of very heavy or bulky objects often necessitates the use of multiple-person teams. Examples of these tasks are loading large rolls of material onto or off of machines, transferring medical patients from a bed to a wheelchair, carrying injured persons on stretchers and moving furniture. More than 50% of lifting tasks and 49% of the lifting and carrying tasks performed by US Army soldiers involve teamwork in groups ranging from two to eight persons. For Army tasks, the most commonly occurring team size is two-person, followed by four- and then three-person teams. This is likely true for industrial team MMH tasks as well.

2. BACKGROUND

The majority of basic research examining team-lifting performance has concentrated on either a single maximum lift or a maximum acceptable weight of load (MAWL) for repetitive lifting. In applied research, patient transfers in multiple person teams is the task that has received the most attention.

2.1. Single Maximum Lift

The one repetition maximum (1RM) isometric (no movement) and isokinetic (controlled speed of movement) strength of teams of two and three men and two and three women and the 1RM dynamic lifting strength of two-, three- and four-person teams of men, women and mixed-gender have been examined. The team 1RM lifting strength is less than the sum of the individual 1RM lifting strengths by 10–40% for all team sizes and lifting modes examined. The difference between the sum of individual lifting strengths and team lifting strength varies with the team gender and the specific lifting task. To examine the relationship between the sum of the individual lifting strengths of team members and team-lifting strength, the percentage of the sum of individual lifting strengths relative to the team strength (% sum) is calculated: % sum = (team strength/sum individual strengths) x 100. For

Table 1. Team strength data.

	Team Size	Men	Women	Mixed-Gender
Dynamic[1]	2-person	89.8	91.9	79.7
	3-person	85.0	90.9	78.5
	4-person	86.0	90.3	83.7
Isometric[2]	2-person	94.1	79.1	
	3-person	88.6	87.0	
Isokinetic[2]	2-person	66.5	70.5	
	3-person	60.3	72.8	

[1] Sharp et al., 1997, [2] Karwowski and Mital, 1986; and Karwowski and Pongpatanasuegsa, 1988.

dynamic 1RM lifting strength, % sum was significantly greater for single gender teams (87% for men, 91% for women) than for mixed-gender teams (80%) when lifting in teams of two, three or four. Table 1 lists the % sum for three modes of lifting by gender and team size. Research shows teams of men lift heavier loads than mixed-gender teams, while teams of women lift lighter loads than mixed-gender teams.

2.2. Maximum Acceptable Weight of Lift (MAWL)

In addition to maximum lifting strength, the load a team finds acceptable for repetitive manual materials handling tasks is important. The load acceptable to 95% of the working population has been used to set limits for safe materials handling loads. MAWL is defined as the load a person is willing to work with under a given set of task conditions. For example, an individual may be asked to determine the MAWL for an 8 h work day when lifting a box from the floor to a 70 cm high table at the rate of three times per min. The person is given a box that is either too heavy or too light and asked to perform the defined task for 20 min. The individual then adds or subtracts weight from the box until it is judged acceptable. The individual adjusts the load so that s/he does not become overtired, overheated or out of breath. MAWL has been determined for repetitive lifting and lifting and carrying in two-person teams only. No information is available for larger teams. When determining the team MAWL, both team members must agree on the load adjustments and final load.

Unlike the 1RM for team lifting, the MAWL for repetitive lifting or lifting and carrying in teams tends to be equal to or greater than the sum of individual MAWL (% sum = 98 – 140%). When roughly matched for strength, team members work at the same exercise intensity (%O$_{2max}$) and perceive the repetitive MMH to be easier when working in pairs than when performing the same task alone. This is true despite the fact they may be lifting > 100% of the sum of their individual MAWL. This reduced perception of effort does not occur for the weaker individual of a pair with large differences in individual strength, such as mixed-gender teams. In this case, the lower strength person has a slightly higher heart rate, works at a slightly greater exercise intensity and perceives the repetitive task to be more difficult in a team, than when working alone. Because they are working harder, the weaker individual will fatigue faster and may be at an increased risk for injury during team MMH tasks.

2.3. Comparison of 1RM versus MAWL for Team MMH

While the team MAWL is equal to or greater than the sum of the individual MAWL, this is not true of 1RM team lifts. Task differences may be the source of these differing results. The 1RM team lift is a one time maximum effort involving little decision making. The team is either physically able or unable to lift the load. In contrast, the MAWL is a repetitive, submaximal self-selected load. The individual or team must estimate the load they are willing to handle for an extended period. Because there is a subjective element to MAWL selection, personality interactions may influence the team MAWL while not affecting the 1RM lift. One study found Type A individuals work at a higher percentage of their aerobic capacity, and is able to determine their MAWL in a shorter period than Type B individuals. A Type A individual

might be more insistent about exercising at a higher intensity by selecting a heavier load. The higher MAWL for teams than for the sum of individuals making up the team might be an expression of competitive behavior or a higher level of arousal. For social reasons individuals may be more motivated to select heavier loads when working in teams than when working alone.

Variation in lifting technique may also be a source of differences in the % sum obtained during a 1RM versus a MAWL. It is easier to standardize lifting technique during a single maximal lift (1RM) than during repetitive submaximal lifting or lifting and carrying (MAWL). As muscle groups fatigue during a repetitive lifting task, a typical strategy used to continue performing the task is to change lifting technique to allow for physiological recovery. A change in technique would not be necessary during a single maximum lift, as adequate rest is provided between lifting attempts. During 1RM testing, changes in lifting technique are often used as a criterion for test termination.

2.4. Biomechanics of Team MMH

Few studies have been conducted to compare the biomechanics of individual and team lifting. Differences in lifting technique produce differences in the spinal compression and lateral shear forces for one- versus two-person lifting. Spinal compression and moments about the sagittal plane are reduced for two-person symmetrical lifts compared to individual symmetrical lifts when the load is equated on a per-person basis. When lifting asymmetrically, however, two-person lifts result in significantly higher lateral shear forces and moments than one-person lifts. These biomechanical differences are likely due to differences in lifting technique. Changes in pelvis and trunk positioning and limitations in the ability to position one's body with respect to the load occur during two-person lifting and change the biomechanics of the lift.

Biomechanical analyses of patient handling in two-person teams have found that the maximum limits for spinal compression are often exceeded. This is due to the awkward lifting position (reaching, twisting) and the unequal distribution of the patient's body weight between the two handlers.

2.5. Prediction of Performance on Team MMH Tasks

Three prediction equations have been developed to estimate maximum lifting strength or maximum acceptable weight of lift in two-person teams. In two of three equations the lifting strength of the weaker individual was a good predictor of team lifting strength. The third equation found the lifting strength of the team member with the higher body weight (presumably the stronger individual) was a good predictor of the team load lifted. When all equations were applied to the same sample, the equations based on the lifting strength of the weaker individual were more accurate. This would lead to the conclusion that the weaker individual limits the load that can be lifted in a two-person team. These attempts were all limited by a small number of observations and only one study included mixed-gender teams.

3. CONCLUSIONS/RECOMMENDATIONS

- The 1RM for dynamic two-person team lifting is 10–20% lower than the sum of individual 1RM lifts, but little further decrease is found with the addition of one or two more people. If a recommended load for an individual performing a task has been determined, the %sum (Table 1) can be used to estimate the maximum load for two to four persons lifting as a team. For example, if a safe load for one person is 25 kg, a two-person team performing a similar lift should not attempt a load that is more than 80–90% of two times the individual load (25 x 2 = 50 x 0.8 – 0.9 = 40–45 kg). No further reduction in the per-person load is needed for three- or four-person lifting tasks, so an additional 25 kg can be added for each additional person up to four. This recommendation is based on optimum conditions where there is adequate team coordination, space and handholds.
- Team lifting and carrying MAWL tends to be equal to or greater than the sum of the individual MAWL for the same task. Therefore, doubling the individual MAWL provides a reasonable estimate of the load two-person teams will find acceptable for a repetitive MMH task.
- If at all possible, lifting teams should be roughly matched for strength and height. When a large strength discrepancy exits between two persons performing a repetitive team-lifting task, the weaker individual works at a higher relative intensity, predisposing that person to early fatigue and possibly injury.
- In two person team lifting (1RM and MAWL), the lower strength individual limits the load lifted.

Manual Work and Back Stress in Industrially Developing Countries

J. Charteris and P.A. Scott

Department of Human Kinetics and Ergonomics, Rhodes University, Grahamstown, South Africa

INTRODUCTION

While occupation-related back stress among manual workers is a global problem (Pope *et al.* 1991) it is arguably true that ergonomists of the industrially developed world, with expertise in manual materials handling situations typical of those societies, would be both appalled by, and ill-equipped to deal with, the sorts of abuses of the human spine which are so typically encountered in IDC contexts (figures 1a and b).

The issues raised in this chapter summarize the authors' experience of conditions in several countries of the Southern African Development Community (SADC: Angola, Botswana, Democratic Republic of Congo, Lesotho, Malawi, Mauritius, Mozambique, Namibia, Seychelles, South Africa, Swaziland, Tanzania, Zambia, Zimbabwe). Mindful of the sterling efforts being made in many of these countries where historical circumstances often militate against rapid improvement of working conditions, we offer these insights in a generalized form to typify SADC conditions rather than to dramatize worst-case scenarios in any specific country. Our familiarity with conditions in Far Eastern and Latin American countries, though less extensive, suggests strongly that the Southern African model is adequately representative of issues pertaining in IDCs in general.

1. COMMON DENOMINATORS IN THE LABOR-INTENSIVE ETHOS OF MANUAL WORK IN IDCS

Infrastructural deficiencies bring to the fore several issues that need to be considered in appreciating the situation to be addressed. Manual materials handling stresses in general and lift-related back stress in particular in IDC contexts are hampered by the following issues:

1.1. Unreliability of Existing Databases

While the immediate causes are biomechanical and can be dealt with at a micro-ergonomic level, this issue must also be addressed at the epidemiological level. Even in industrially advanced countries epidemiological research in occupational back stress is fraught with methodological problems of definition, classification, and diagnosis. These pall to insignificance against the problem faced in IDCs where record-keeping is somewhere between unreliable and non-existent. With defective records to go by (whether in the form of insurance, workers' compensation, hospital, occupational health clinic or factory records), there is little hope in IDCs of getting a good handle on the nature and extent of the back-stress problem. People die of aids-related diseases, not of occupational back stress; consequently poor resources and more urgent priorities deflect attention away from often insidious, cumulative manual work stresses, and this fulfills the old adage that if you're not looking for something you tend not to find it. In societies where the workforce is exploited, there is sometimes overt, and always indirect, pressure on workers to suffer in silence rather than place their jobs at risk by complaining. Under these conditions a strained back is less likely to be reported than a bleeding hand because evidence for the latter is manifest, while that for the former could be countered by an accusation of malingering.

In IDCs Workers' Compensation data are poor indicators of the real problem of occupational lift-related back stress because they typically take no account of short-term absences which are not recorded in time-loss reports. Nor do they take cognizance of the vast biomass of the self-employed in the informal sector,

(a)

(b)

Figure 1. Practical examples of loads handled in Africa
(a) An 80kg concrete block maneuvered by a 62kg manual laborer
(b) African women carry head loads of up to 80% body weight and 150% body length

of injuries exacerbated by but not caused by occupation, or of non-reported work-related incidents. Often Workers' Compensation injury statistics are produced several years in arrears, and when improvements are made it is in the direction of speeding up the process of compilation rather than improving the quality of the disclosures. In some SADC countries accident reports are listed by gross anatomical regions. Thus all injuries to the "trunk", however caused, are lumped together, making it impossible to determine spinal-stress incidence statistics in meaningful form.

1.2. Willful or Ignorance-based Misrepresentation of Evidence

In defense of Workers' Compensation databases worldwide, it must be noted that they are not designed specifically to serve purposes such as are the focus of this article; internationally they are recognized as lacking validity on diagnosis of occupational back stress (Abenhaim and Suissa 1987). Even good records contribute little of value to solving the problem. "Poor correlations between pathology and symptoms, and between symptoms and function continue to frustrate patients and their practitioners, particularly in determining work readiness" (Hazard *et al*. 1992).

As a result, what is difficult in medically sophisticated and worker-oriented societies of the industrially developed world becomes a morass of misunderstanding and apathy born of ignorance in the medically unsophisticated, worker-exploited societies of many industrially developing countries. Not surprisingly, therefore, medical writers in the IDCs can argue, as Simon (1992) and du Toit (1992) have done, that in their countries occupational back injuries are few and far between and that back-related disability is ubiquitous in industrially developed countries in part because it is engendered by medical overcare, and that in less industrialized countries less coddling results in less disability.

Contradicting these views in the worldwide experience of a high rate of back injuries among construction workers and miners the consensus of authorities is that: "The incidence of low back pain ranges from 60 to 80% of the adult population worldwide" (Pope *et al*. 1991).

1.3. Absence in IDCs of Comprehensive National (let alone regional international) Strategies to Address the Ill Effects of Occupation-related Back Stress

Why should occupational back stress reduction receive attention at the national level in industrially developing countries? The answer is as simple as it is important — to promote worker well-being and to enhance national productivity. Among the results of occupational back disorders, other than the obvious pain and disability of the sufferer, are socio-economic losses in the form of compensation payments, absenteeism, replacement, training of new recruits, continuity disruption, administrative busywork, reduced/lost earnings, reduced efficiency and increased risk of re-injury in those who suffer in silence, to mention but a few. It is generally accepted that measurable costs in this connection are but a small proportion of the total. Thus, when relatively small sums are reported as reflective of a nation's compensation costs in respect of work-related back stress, these are the superficial pay-out costs reflecting only the tip of the iceberg.

Work-safe Australia, whose national campaign to reduce back injuries at the workplace has been effectively presented for some years, is convinced, as we are, that good design/redesign of manual handling operations, in tandem with effective educational programs for all concerned, are effective preventive measures.

There is a need in IDCs to see the link between productivity and occupational back stress, particularly because the ergonomic implications of productivity are not well appreciated, leading to a failure to comprehend the extent to which an ergonomic orientation can assist in reversing the malaise. Typically in IDCs the per capita GDP has for decades remained static. Where population growth rates of over 2.6% p.a. are common and employment rates increase around 0.6% p.a., effectively this means that the sub-Sahara African population would double every 27 years while the number of people employed would only double every 117 years — the need for jobs increasing 4.3 times faster than the ability to provide them. Seen against this backdrop, poor work practices, whether in terms of inefficient production or low levels of safety, begin to spiral out of control.

2. PARTICIPATORY ERGONOMICS

Education is sorely lacking in IDC work practice; when attention is given it is often in the form of training in the pejorative sense of requiring compliance rather than inculcating understanding and a sense of personal responsibility. Even in industrially developed countries there is an obsession with absolute load-level specification, with complete disregard to individual variability and the fact that, for the same remuneration, a less well-suited manual worker is being exposed to significantly greater stresses than a physically better equipped counterpart. The immanent causative factors contributing to the high incidence of work-related back stress in IDCs and developed countries alike are the same (see table 1):

- suboptimal positions while working
- labor-intensive manual materials handling
- suboptimal work—rest ratios
- whole-body vibration exposure

In the case of the first three above, the common denominator of primary concern is, of course, the task-inherent risk factor of physical load in terms not only of the mass being moved but its location relative to the center of mass of the mover, and the manner in which it is being accelerated (Charteris and Scott 1989).

Occupational back stress can be alleviated in IDCs using what we call "no-cost or low-cost intervention strategies" that are situationally feasible improvements on current practices and which, above all, are supported by the people doing the work. This requires that "First World" criteria are disregarded, but not the sentiments behind them. "Exert less; produce more" is an attainable ethos, but it requires interventions by ergonomists who are also completely familiar with local geophysical, economic and socio-cultural conditions.

3. DISPELLING THE MYTH THAT THE BACK-STRESS PROBLEM BEGINS AND ENDS WITH SETTING OF MAXIMAL PERMISSIBLE LOAD-LIMITS

In IDC contexts what is needed are easily implementable risk-identification tools and simple risk-rating techniques, such as liftRISK proposed by Charteris and Scott, whose effect is to

Table 1. Results of a 10-year survey by the authors of Risk Factors for low-back stress in a wide range of Southern African Industries/Employment sectors.

TYPICAL INDUSTRY	SELECTED TASKS	REPRESENTATION		WORST FACTOR(S)	COMMENTS
		TASK DESCRIPTION	RISK RATINGS		
SUPERMARKET/ WAREHOUSING	BULK STORES	SHELVING CARTONS – WAIST LEVEL – LOW SHELVES – HIGH SHELVES	LOW MEDIUM/HIGH HIGH	LIFT-RATE STOOP STRETCH	HIGH WORK FOR SHORT PERIODS GREAT TASK DIVERSITY
BUILDING/ CONSTRUCTION	BRICK STACKING	CONVEYOR TO PALLET PALLET TO CONVEYOR PALLET TO PALLET	MEDIUM MEDIUM MEDIUM/HIGH	REACH REACH; RATE RATE; STOOP; REACH	HIGH WORK RATE
MINING	WETFLAP CATHODES ORE-CRUSHER	LIFTING COPPER SHEETS TO BEAT MAINTENANCE REPLACEMENT OF HEAVY BARS	HIGH HIGH	MASS; STOOP MASS	HAZARDOUS CONDITIONS EXCESSIVE HEAT
FISHERIES	UNLOAD TRAWLERS FOOD PROCESSOR FILLETING LINE STACKING BOXES LOADING TRUCK	STACKING CONTAINERS ON QUAY LOADING COMPRESSOR LOADING CONVEYOR PALLETISING CONVEYOR TO FLAT BED	MEDIUM LOW LOW LOW HIGH	STOOP; REACH REACH STOOP RATE; REACH; STOOP RATE; REACH; STOOP	CASUAL LABOUR (UNTRAINED) AWKWARD CONTAINERS PAIRS SELF-PACED INTENSE
HEALTH-SERVICE	PATIENT HANDLING	ONTO; OFF BED	LOW/HIGH	REACH; TWIST; STOOP	HIGHLY VARIABLE; LOW PREDICTABILITY
ROAD-WORKS	PAVEMENT LAYING	CONCRETE RODS (60KG) PAVING SLABS (80KG) CEMENT CURBING (96KG)	HIGH HIGH HIGH	MASS; STOOP MASS; STOOP MASS; STOOP	PAIRS, POOR UNDERFOOT SURFACES
CONSTRUCTION SITE	BRICK LAYING ROOFING	SELF-PACED BRICK HANDLING PLACING ROOF TRUSSES	LOW LOW	STOOP; STRETCH STRETCH	AS IN BRICK STACKING BUT SLOWER PACE HAZARDOUS CONDITIONS
MOTOR INDUSTRY	ASSEMBLY LINE	WINDSCREENS ENGINE MOUNTING SEAT INSTALLING BATTERY FITTING TYRE LIFTING	MODERATE HIGH MODERATE MODERATE/HIGH MODERATE	STRETCH MASS; STOOP; REACH STOOP; REACH MASS; REACH; STOOP REACH; STRETCH	AWKWARD POSTURES
REFRIGERATION	FROZEN FOOD HANDLING	LIFTING BAGS; BINNING	MODERATE/HIGH	MASS; STOOP	TEMPERATURE AWKWARD CONTAINERS

sensitize users to the need to address excessive task-inherent risk factors in realistic ways. Attention should be placed less on legislating maximal permissible loads to be lifted – in situations where, in any case, enforcement simply does not occur – and more on encouragement designed to reduce excessive stooping, reaching and stretching, and excessive rates of lifting. These, in the IDC model presented here, account for 34%, 26%, 11%, and 10% of the back-stress factors encountered in situ, while excessive mass per se was implicated in less than 20% of instances.

In IDCs in the foreseeable future issues of overpopulation, underemployment, and lack of education (particularly health-related education) transcend all other problems. They underlie even such basics as access to clean water, electricity, and housing. Against this backdrop, any implementation by isolated modern companies of work conditions typical of the developed countries would be as societally ineffectual as restricting aids education to the affluent. True, such practices serve as exemplars, but where social conditions militate against the following of these examples less idealized but feasiably attainable schemes should be followed. The best way to ensure sustainable growth of an ergonomic ethos in IDCs is via simple, feasible, and unremitting education of workers to act as co-responsible agents in their own work-related safety and well-being, while persisting with encouragement to employers to implement no-cost/low-cost changes in work practices. These small changes in working conditions, while not ideal, are manifestly implementable and do constitute improvements on current practices. Emulating the best practices of the developed

countries, while superficially laudable, is not sustainable in the IDC context where labor-intensive practices will prevail as long as the only maarketable resources on which the bulk of the populace can draw are in terms of semi-skilled physical work capability.

Mental Fatigue and Related Phenomena

T. Marek

Institute of Management, Jagiellonian University, Krakow, Poland

1. INTRODUCTION

The term mental fatigue is used with different meanings. Mental fatigue is considered as a decrease in physical and cognitive performance. It is considered also as a condition affecting the mental processes, including feelings of fatigue. Ergonomists lay stress on consequences of fatigue. It is work decrement. Very often mental fatigue is viewed in a context of activation theory. According to this workers perform best at some optimum level of activation. If a worker is overloaded, he/she suffers from an exhaustive form of fatigue. In the case of insufficient demands the (load) worker suffers from a type of fatigue known as boredom or monotony.

2. FATIGUE SENSATION

One of the most predominant mental fatigue factors is sensation. In a tired condition workers feel tired or dull in bodily parts, are inhibited in doing work and are forced to give up. The sensation is not unpleasant until a worker can stop and rest. It is harmful when rest is impossible. Generally, sensation consists of three factors: bodily drowsiness sensation; weakened cognitive processes and motivation sensation; and physical complaints. As Grandjean and Kogi (1971:18) pointed out, "sensations of fatigue have a protective function similar to those of hunger and thirst. They force us to avoid further stress, and allow recovery to take place." The sensation of mental fatigue is a biological signal for recovery.

3. NEURAL ASPECTS OF MENTAL FATIGUE

From the cognitive neuroscience point of view mental fatigue is a decrement in the functioning of brain centers due to long-lasting work. According to the classical knowledge (Grandjean and Kogi 1971) it is state of the central nervous system induced by prolonged activity and controlled by antagonistic brain stem systems which are responsible for arousal and inhibition. Changes in arousal level in plus and/or in minus was always considered as one of the crucial symptoms of mental fatigue.

According to current knowledge the relations between mental fatigue and arousal are much more complex. There are several arousal systems (e.g. Robbins and Everitt 1996) based on the four neurotransmitter systems: noradrenergic, serotonergic, dopamine and cholinergic. These are responsible for different forms of arousal and so mental and cognitive functions. For example, dopamine systems can be identified with a process of activation that modulates the speed and vigor of responding as well as motivational states. Noradrenergic and cholinergic projections to cortex have much more subtle roles in modulating processes of attention (e.g. action selection, discrimination, and concentration of attention, as well as inflation on some aspects of memory). The functional balance between all these systems in particular work conditions is the basic factor for effective action. The balance is established due to particular work demands and

individual resources, and differs from action to action. Mental fatigue may start from the inability of the worker to establish and keep appropriate functional balance between the above mentioned systems.

The second crucial symptom of mental fatigue is attention impairment. There are three attentional networks: orienting network; executive network, and alerting network (e.g. Posner 1996). Each network subserves the different attentional processes. In the case of the orienting network, the parietal lobe disengages attention, then the midbrain areas act to shift the attention index and finally the pulvinar engages attention in a new location. The executive network consists of two parts: the part responsible for action awareness and the part that allows one to control the action. Finally, the alerting network plays a crucial role in vigilance to the task. While this network is active, the executive network is inhibited. There are many connections between arousal and attentional network systems. Some of them are well recognized but some are not. Networks of arousal and attentional systems and their functioning are crucial for mental fatigue phenomenon. Dependent on external conditions and work demands, an appropriate model of action is established for both types of networks. Changes which appear due to long lasting work in some parameters of this model cause the mental fatigue. Because of a large variety of parameters there are different patterns of mental fatigue symptoms.

Each mental action seems to be accompanied by neurochemical changes. These changes, especially related to serotonergic deactivating mechanisms, are related to mental fatigue (Grandjean and Kogi 1971, Ursin 1986). Owing to these changes, "something is built up which can only be removed by rest and/or sleep." (Ursin 1986: 62).

4. MENTAL EFFORT AND FATIGUE AND HUMAN BRAIN METABOLISM

Traditionally, two types of mental effort are distinguished (Mulder 1986, Marek and Fafrowicz 1993): one related to the difficulty of the task, processing complexity, and the second to the control of the state and adjusting parameters in case these are suboptimal. The first type of effort creates the essence of mental effort, which is related to task and environmental demands. The second type reflects adaptation and compensatory effort, which follows all deficits and suboptimal mental states of the subject.

Many authors point out that a high level of mental effort caused by a high level of task variability and complexity are crucial in mental fatigue.

There are two essential questions. The first is whether mental effort is related to human brain metabolism. The second is whether mental fatigue is a consequence of a depletion of the brain metabolic energy.

It is well known that energy is required for many functions of neurons. First, it is needed to synthesize neurotransmitters that are essential for synaptic transmission. Second, demands related to the molecular pumps of the neuron membrane. The task of the membrane is to maintain normal intracellular levels of potassium and sodium. While computational transaction occurs within the neuron, the demands for restorative action of the membrane pumps appear. The neurons consume more oxygen and glucose when processing demands are higher. The metabolic rate for glucose is a sensitive indicator of the local brain energetic

demands related to given task-specific demands. The metabolic rate for glucose is measured in humans by positron emission tomography (PET) (Roland *et al.* 1996) and functional nuclear magnetic resonance (fNMR) (Petegrew 1991). It is well documented now that the magnitude of glucose utilization by the given part of the brain or cortical regions is a function of stimulus or task complexity. The processing effort (mental effort) is correlated with increased glucose utilization (e.g. Beatty 1986, Warburton 1986). However, there is no evidence that energetical resource limitations could occur in the brain due to even the most intense mental effort. Thus, mental fatigue is not a consequence of a depletion of the brain metabolic energy. It seems to be the process that is switched on to prevent a depletion of metabolic energy at the active processing sites in the brain.

The crucial aspect for the process is the second type of mental effort that is related to the resource control (compensatory control). Mental fatigue as Mulder (1986: 190) pointed out, "may be best characterized as the inability to continue to exert executive resource control." It creates a preventive mechanism against the depletion of metabolic energy in the brain.

Mental Models

J. R. Wilson

Institute for Occupational Ergonomics, University of Nottingham, Nottingham NG7 2RD, UK

1. INTRODUCTION

Consider some typical situations investigated by ergonomists. First, an operator at a remote control task who must carry out a job from a vantage point not used before, trying to get oriented and to guide the system through its critical operations in the most reliable, safe, effective manner. Second, a factory worker at an industrial machining center who must try to understand why parts she is producing are showing hairline cracks, and what combination of the many parameters available on the machine would solve the problem. Third, a team responsible for scheduling a transport system from a control center, coping with a variety of visual and auditory on-line communications and also using their knowledge of operating procedures. Fourth, a maintenance engineer of a continuous process plant trying to integrate information from system diagnostics with data from historic print out and what he can see from visual inspection.

In all these cases the people concerned will form some kind of internal, or mental, representation of the system they are working with; this representation can be termed a *mental model*.

In fact, in most circumstances people will construct and employ several mental models, for instance of the behavior of the physical variables in the systems (electrical, chemical or mechanical), or of the structure and form of the system, or even of the rules governing the operation of the system. These mental models may vary in their degree of abstraction and may be formed from observation of the system itself, from knowledge of operating, emergency or maintenance procedures, from instructions and training, or even from experience of other similar systems worked with in the past.

The argument for the existence of mental models may seem eminently reasonable. What, though, does it mean — in theory and in practice — to ergonomists and human factors specialists?

2. WHAT ARE MENTAL MODELS?

The notion of mental models — that people at work hold in their minds a representation of the systems with which they are working, and upon which they draw to assist their understanding and operation of those systems — is an extremely attractive one in ergonomics. The idea is that, if we can find a way to identify and represent the mental models we expect to be held by operators in a particular situation, and if we can communicate these models successfully to designers, then systems would be designed with interfaces which far better match the needs and expectations of the operators. Indeed, to "know the user's mental model" is often an early guideline in advisory texts on design for human–computer interaction. This begs the question: "what is a mental model?" There is no agreement about this, but accounts from ergonomics (as against cognitive psychology) taken together indicate that mental models:

- are internal (mental) representations of objects, actions, situations or people;
- are built on experience and observation, of both the world in general and the particular entity of interest;
- are simulations that are run in mind to produce qualitative inferences;
- underpin our understanding of a system;
- allow one to describe, predict and explain behavior of a system;
- constitute topography, structure, function, operation of the system;
- contain spatial, causal and contingency relations;
- may contain grouped schemata;
- are instantiated each time they are required, and, therefore, vary over time;
- are parsimonious, being developed only to the minimum extent required for a particular purpose; and
- are incomplete, unstable, multiple and non-unique.

3. MENTAL MODELS IN ERGONOMICS

For nearly 60 years the notion that people form mental models of their environment has been a topic of psychological enquiry, starting with the work of Craik (1943). And ergonomics researchers of human–machine systems have long regarded the concept as being almost self-evident (e.g. the collection of Edwards and Lees 1974). In other domains there are parallel notions, such as naive theories, device models, mental maps and domain models. In the past few years researchers in human–computer interaction have picked up the notion, attempting to define user models as well as models of the user (e.g. Allen 1997). During all this time, developments of the mental model notion within ergonomics and within cognitive psychology (e.g. Johnson-Laird 1983) appear to have followed independent tracks, at least until recently. This is perhaps caused by the role of psychologists purely to explain behavior but the need of ergonomics to utilize such explanations to improve design.

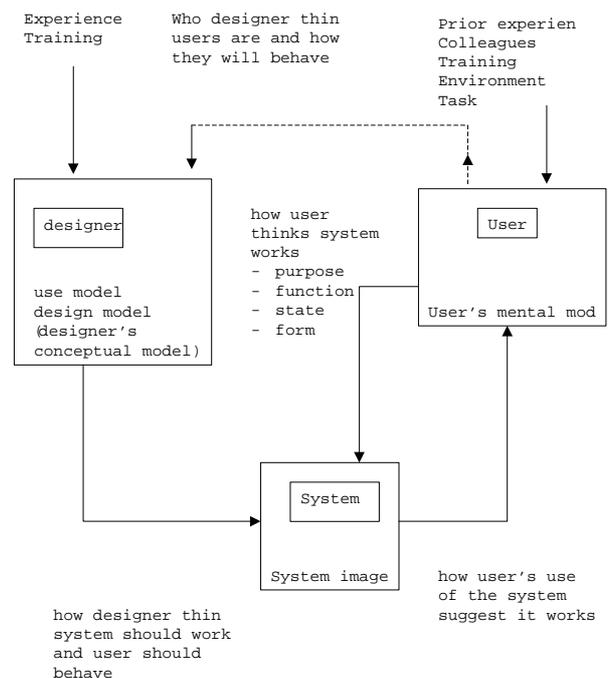
In ergonomics theories and concepts are sought, from


Figure 1. Use of mental models in design.

cognitive psychology and elsewhere, to adapt and apply them to the specification and implementation of systems in offices, services, factories, transport, the home and leisure. If we can predict or understand the mental model that a new system user might hold about that system and its domain, or what model might be built by interaction with the system, then we can improve interface design, training, operating procedures and so on. In Norman's (1983) view, by understanding the potential users' mental model, and by adapting their own conceptual model accordingly, designers might develop a system "image" that better matches, sustains and helps develop an appropriate user mental model. Figure 1 expands from these ideas, and defines — optimistically — the potential role of understanding the user mental model in design.

4. USER MODELS AND MODELS OF THE USER

As well as confusion over the different ways in which "mental model" is employed in cognitive psychology and in ergonomics, there is often also confusion over whether we are talking of *models of a person* or *models held by a person*. In the first instance we can produce a model of a person, of some of their basic characteristics or of their performance or behavior. This is what is often known as a *user model* when applied within human–machine system design or human–computer interaction; examples from the former are HOS and from the latter GOMS and TAG. In contrast to these user models, we have a user's or a persons' model, for which the term mental model is usually used, where we are talking of the model that the person holds in their mind of any entity or concept. Of course any user model may itself contain components of the anticipated mental model held by a user, but we must distinguish clearly between the two.

Adding to the confusion, the mental model held by the user, in any form, must be identified and reported to be of value in design, and, therefore, must itself actually be the model held by an experimenter or researcher of the model held by the user. At some point the investigator must have examined user performance in practice or else experimented in controlled circumstances to provide data from which they constructed a representation of the user mental model. By extension, we can talk of the designer's model of the users' mental model, the model of the user embedded in training and instructions or, going to greater extremes, the designer's model of system requirements based upon a researcher model of the potential users' mental model of the likely system design!

5. FORMS OF MENTAL MODEL

It may be practically useful to accept two distinct forms of mental model (Wilson and Rutherford 1989). First is a *Conceptual Mental Model*, a non-formal, non-computational representation of users' knowledge and how this is employed in task performance (perhaps as a "walk through" simulation). Such mental models are incomplete, unstable and may often be multiple; for example, the models instantiated by an operator to assist in fault diagnosis at a flexible manufacturing cell will vary not only in form each time but also in type since they may variously be of functional, spatial or causal relationships. Certainly there will be more than one mental model formed; these will overlap in content and use, and will have gaps or missing data depending upon the operator's experience and training.

This notion of a conceptual mental model is useful to ergonomists within user-centered design, task analysis, training specification and job design. It is also potentially a stage on the way to identifying the second form, a *Formal Mental Model*; this (with reference to Johnson-Laird 1983) being formal, computational and practically useful if it can be implemented. Such different forms of mental model are also implied by Rasmussen (1986: 140–8) and Nielson (1990: 155–6).

The majority of ergonomics literature appears implicitly to refer to the first form, the conceptual mental model. It is regarded almost as axiomatic that people form some kind of internal representation that constitutes their topographical, structural and functional understanding of a physical system and which allows them to describe, explain, understand and predict system behavior. It is easiest to conceive such a model as comprising a system simulation that can be reconstituted and run to derive or confirm understanding. Borrowing from Payne (1988), users' conceptual models may be seen as embodying a weak commitment to the notion, postponing the general questions of *how* people represent and use knowledge in favor of understanding *what* knowledge they represent and how they use it in making inferences in specific domains. Two stronger commitments proposed by Payne are that mental models may be run to produce qualitative inferences readily and that they rely on experiential knowledge. Within this view it is possible to see included such varied ideas as a mental map, an internal device model, a mental simulation, a naive (physics) theory, or a domain model (Gentner and Stevens 1983).

There is room for both types of mental model — the conceptual mental model and the formal mental model — in human factors. A conceptual model has seemingly great face validity. It is useful in itself as an encouragement and focus for user-centered design, task analyses, skill-based manufacturing and so on. The conceptual model also is an early stage in the process of identifying and specifying a computational or formal mental model. The utility of the mental model, if it can be specified computationally, is immense. This is a big "if," however, and there are many other serious questions, about what mental models are, whether the theoretical notion is necessary or if existing theories of knowledge representation and inference suffice.

6. IDENTIFICATION OF MENTAL MODELS

Given that it seems worth at least making the effort to try to identify specific mental models of systems held by potential users, how might this be done? Unfortunately, current understanding does not allow simple identification of a "best" method and researchers use many different methods to collect basic data and then to derive or interpret a "mental model." Sometimes there are doubts about the quality of such exercises. Where mental models are induced from subjects' responses, the route the investigator takes from the information elicited to the hypothesized mental model is often unreported. Experimenters also may employ intuitive rather than formal procedures to suggest possible mental models, since little is known about the creative and inductive processes underlying model generation.

One danger in exploratory studies of mental models is that preconceptions about the form and content of likely mental models may only be confirmed as a result of the choices made about relevant data, methods and analyses. The most appropriate

strategy to identify mental models may consist of two distinct stages (Rutherford and Wilson 1991), first suggesting a mental model on the basis of initial data and the experimenter's domain knowledge, and second, testing the validity of the suggested mental model, probably through controlled experimentation. Most mental models research appears to be at the first, inductive, stage, which is one reason why a variety of approaches to mental model identification and description are observed.

The methods that might be used in the process of mental model identification are many and varied, covering much of ergonomics methodology. Classical laboratory experiments, quasi-experiments in the field or observation of actual behavior can all be employed, with data collected from direct recording, interviews, questionnaires, think-aloud verbal protocols, and (two person) constructive interaction. Problem-solving experiments, in which participants perform "how to" and "what if" tasks, can be carried out, in which verbal, written, and graphical protocols are taken as well as performance measures, and other possibilities are techniques from the better documented world of expert knowledge elicitation.

7. REPRESENTATIONS OF MENTAL MODELS

Since there is a large variety of methods that can be used to identify mental models there is also a large number of forms in which they can be represented. A simple form, if of restricted value, is a textual account, either following performance observation or on the basis of experimental findings. A more valuable text form will be a natural or reduced transcription of the verbal protocols collected from one individual or two or more in a constructive interaction experiment. Commonly found in brief descriptions of the notion are pictorial representations (akin to the idea of "pictures in the mind"), and often these are used to illustrate the model people might hold of the action of physical variables such as electricity, gravity or the solar system. Hierarchical tree diagrams might be used as the representational form of systems of knowledge, showing levels and inter-connectedness of entities. More dynamic mental models might be represented by flow charts, and this form might be incorporated into a pictorial representation to produce a mental model of, say, a continuous process plant with its vessels, pipes, valves, levels and flows all included. If a more computational account is produced, this might be on the basis of logical syllogisms or mathematical notation.

8. LIMITATIONS AND CRITICISMS

Current thinking on mental models highlights a number of issues to do with limitations for the utility and usability of the notion of mental models. These include:

- The limitations in usefulness of the notion itself, particularly if mental models are incomplete and multiple. Moray's (1990) Lattice Theory was developed as one proposed way round this dilemma, but there have been critics following attempts to use this theory.
- Is the notion even needed? Mental models may be accounted for perfectly adequately within the human information processing model, particularly as regards LTM/WM (Bainbridge 1991). The relationship of mental models to schemata, frames and scripts also remains to be considered. Furthermore, one can distinguish between the notion of

mental models and the notion of interface compatibility to produce a population stereotype?

There is a paradox of inconsistencies within mental models; the mistakes people make are one of the most interesting things we can understand about their potential performance, and prominent among these mistakes are inconsistencies. However, the methods used to identify and represent mental models may well lead to operators or subjects recognizing their own inconsistencies, and accounting for them before providing the information on which the mental model is built by the researcher.

One of the main problems with mental models is to do with the methods by which we identify and represent them. All those reported in the literature have some weaknesses and potential biases. In particular, the decisions made about which method and measures to use to extract information to construct the mental model may imply that the researcher will have already made some (conscious or unconscious) decision about the form this mental model will take, therefore biasing the representational form they use. There appears to be little or no way around this dilemma, but there is certainly need for more explicit accounts of how the domain provides data which are then represented and interpreted into a mental model.

If individuals can be said to hold mental models then it seems reasonable to think that teams do also. The problems of instability and non-uniqueness, and of the methods used to identify mental models for individuals, will be just as great, if not greater, for teams. There is also an interesting question about whether a high performing team will, in fact, closely share a mental model or models; alternatively, the very existence of a number of different mental models among the team may mean that they can deal with all situations (familiar or not) and less easily get locked into the first and easy diagnoses due to information availability and cognitive lock up biases.

It may be that the use and value of mental models within human factors is higher for explanation (i.e. a fire fighting tool) than for prediction (as a design tool).

9. CONCLUSIONS

Mental models have become a concept much employed within ergonomics, a growth of interest, however, not paralleled by any greater clarity in the issues surrounding the notion! If it is truly to be useful and usable within ergonomics we need to be clear about relevant methods of data collection and analysis, procedures for conversion of data into a mental model, and the specification, test and refinement of that model.

Some fundamental questions must be answered to do with what a mental model might be, how it might be identified and represented and how it might subsequently be applied in systems analysis and design. Fundamentally, are we sure whether we are talking about anything other than "operator/user knowledge" when the term is applied within the fields of human–computer interaction and human–machine systems?

The notion of mental models will hopefully turn out not to be a sidetrack of arcane academic interest. It can allow the production of useable tools in design as well as enhancing understanding of the need for user-centered design. In the end, however, the evocative nature of the mental model concept, its tendency to be meaningful to designers, and the very process of elicitation required to represent such models may well be more

important than worrying about the exact form and content of mental models.

Mental Workability and an Increasing Life Span

R. Cremer

TNO Work & Employment, PO Box 78, 2130 AS Hoofddorp, The Netherlands

1. INTRODUCTION

Satisfactory job performance depends both on the characteristics of the individual employee and the condition of the work environment. An important characteristic of employees is their information-processing capacity. A concept which is highly related to mental work capacity. In a broad sense, processing capacity or mental resources have been conceived as the composite of both structural and energetic components of information processing. Structural processing components have traditionally been identified with specific information-processing operations (Sternberg 1969) or a limited capacity working memory system. In addition, energetic components have been associated with some form of mental energy, effort or attention (Kahneman 1973).

Generally it is expected that there is a general decline in the capacity of the information-processing system with advancing age. Results of various studies demonstrate that with respect to speed measures, the complexity effect, that is the greater slowing of old subjects in more complex than in simple RT tasks, is a robust phenomenon (Cerella 1991). Moreover it is concluded in stress and aging studies that the combined effects of task complexity and stress conditions yield a complex pattern of performance measures, which could not be explained simply on the basis of simple resource-depletion models of aging. Related behavioral problems may occur and become more obvious with aging in particular types of work activities. In discussing the relevance for work it is debatable how results from laboratory studies can be interpreted for real-world activities such as work.

2. MODERN WORK, MENTAL DEMANDS AND EFFECTS OF COGNITIVE AGING

The ongoing introduction of new technologies is expected to bring about increasingly more changes in our daily life and work activities. In modern work mental demands have an increasing significance. First automation and later emphasis on information and communication processing (ICT) made many types of work more abstract and complex. Workers have sometimes difficulty in recognizing where they are involved in the chain between input and output in production and services. Most dominant in modern work is the abundant use of information suppliers and processors.

Many human operators or employees are expected to process an increasing amount of information. In their work, high demands on the senses require shift regulation in relevance but also switches between modalities either between senses or between cognitive processes. Malfunction in selecting (problems in attention with advancing age) can then easily overburden the human system. Combined effects of slowing and poor selection mechanisms may then lead to the experience of time pressure or inadequate control over the abundance of sensory input.

Furthermore it can be concluded that the more knowledge-intensive functions are the more mental effort is required for effective performance. Knowledge handling is a so-called "fluid ability," which is particularly vulnerable with advancing age. The counterweights of such abilities are the "crystallized" abilities. Relations between workability and these abilities will be explained below.

2.1. Weaknesses and Strengths in Information Processing with Advancing Age

In following the Piagetion stages it is established that there are early periods of rapid development in childhood, a learning and experiencing phase which is prolonged in young adulthood and only in adolescence signs of decrease of function become manifest. In this cycle of change disuse of cognitive function with advancing age is often confused with biological effects of aging. Whenever knowledge is gained or abilities are learned, not using them for a while usually means forgetting resulting in reduction of efficiency and automation. However with normal aging (as opposed to pathological aging) regular use of knowledge is a guarantee for preservation of knowledge, abilities or skills. Whereas effects of unhealthy aging (pathology or disease) may interact with the normal aging process. For example, a brain-injured person may show early signs of cognitive aging. On the other hand mechanisms such as compensation, deliberate use of strategy and coping (putting more effort into a job) may, to a large extent and to an advanced age, be useful in maintaining an adequate style of performance.

Largely, mental workability is composed of the following factors: (1) processes required for information handling (or "computational" mechanisms, (2) the "carriers" for such processing: memory and attention (or cognitive "resources") and (3) the subjective interpretation (emotions) and finally the preparedness to act (motivation and effort or the "allocation of resources").

The information processes are related to: input (sensory and sensory-perceptual), central cognitive (problem solving and deciding) and output (motor preparation and motor execution). Other dimensions are the energetic resources: e.g. input of information arouses the system, and effort can strengthen central processes, whereas activation is typical for output related processes. Furthermore the effectiveness of these combined processes depend on speed, duration, alteration and interference during processing. Speed of information processing (efficiency of transmission of signals in the nervous system) is often thought to be related to cognitive aging. When older nervous systems require more time (are slowed), an additional risk is that of "lost" information traces. For example, loosing time in one process may stop the continuous flow in other parallel or simultaneously ongoing processes. Finally, sensory input (e.g. environmental noise, or social pressure) may be interfering more easily in old than young adults. Such interference may disturb attention and memory functions, a situation, which may be particularly distractive for older adults in effortful processing of new or complex information. All the changes referred to above occur over the lifespan. However, they do not only concern functional loss: structural decline but also gains: life experiences and skill development takes place when growing older.

When referring to work and age, at least two aspects are important but not always highlighted: the accumulation of effects

of mental load over time and positive changes during the lifespan. The relation between these factors is that age related change may cause a general reduction of workability leading to an increased vulnerability for stresses at work. Age-related change as main variable will be explained below in terms of positive and negative outcome.

There is substantial evidence to suggest that the decline in mental functions is most conspicuous for "fluid" abilities, in contrast to "crystallized" abilities that are much more resistant with age (Horn 1982). Crystallized abilities are associated with verbal, acquired or specialized skills. These functions depend strongly on experience, information that has been stored by a learning process. Since performance is positively related to experience, crystallized abilities may improve with age owing to gradual accumulation of experience and knowledge. Fluid abilities refer to cognitive functions such as speed of decision making, short-term memory and attention, which mainly play a role during the acquisition and transformation of information. The impact of the decline in fluid cognitive abilities with advancing age in our society is substantial, especially if we consider the increased life expectancy of elderly persons, and the many changes and often increasing demands in terms of information and communication technology.

This functional approach of (work) capacities accounts for the dynamics of changes over the lifespan. At a young age knowledge is gained about facts and procedures, in adulthood the emphasis is on the application of established knowledge, skills and experience, and the integration of new and existing knowledge. This latter style of functioning makes information-processing skills automated, less time consuming and less effortful. The use of this condensed knowledge (skills and abilities) is a useful starting point for development (learning) at later age than application of cognitive abilities that require effortful processing. Also in discussions on work, health and aging of workers, arguments are usually restricted to the phase in which changes become visible in terms of deterioration of function, both physically and mentally. In a broader approach, not just decline but also growth should be incorporated when speaking about changes over the lifespan.

It is hardly possible to map the pattern of change over the lifespan, however a general principle is that the lifespan and a professional career take place with continuous change (growth and decay) of effectiveness and potential capacities. In other words the lifespan can be considered as a continuum of development from adulthood into senescence. A variety of life events may affect the life cycle positively or negatively. Personal development, education and a job career are among such events. Also general health and the onset and progression of the aging process are major determinants.

From many classical textbooks on aging it may be concluded that in laboratory settings major effects of aging are measured. However laboratory conditions and experiments have usually little relevance for work, and research in work conditions not always have relevance for functioning in daily life. These conclusions have to do with the validity of aging studies. In daily life an individual may choose what to do (ignore tasks and activities which are difficult and complex, instead activities (e.g. hobbies) are chosen which are over-learned and highly experienced. In this respect aging at work takes place somewhere in between. Performance of elderly workers is not as strenuous and valued as in laboratory studies. Still work is not a natural situation, specific work demands determine the constraints for an aging employee. So it is unavoidable that aging at work also means confrontation with limitations of performance. Adaptation of working conditions for example in terms of cognitive ergonomics may help to solve some of the problems that aging workers encounter.

2.2. Adaptation at Work to Age-related Change

In considering adaptations at work a useful framework is the information processing chain (see the explanation above). The processes are sensitive for aging and affect practical functioning. However, ergonomic adaptations at the workplace can compensate for some of the shortcomings (Table 1).

Apart from the focus on computational processes, one can design adaptations on the level of the energetics that supports the processes. Such effects can be achieved by reducing: demands on processing speed, time-on-task, switches between modalities and processes and interfering sources.

3. DISCUSSION

Over time changes take place both in the nature of work and in attitudes towards an aging workforce. Modern work (e.g. information and communication technology) increases mental

Table 1. Information processing, ageing and adaptation: some basic principles and examples.

Information processing	Practical effect	Adaptation of the work environment
Sensory	clarity of information uptake: signal-to-noise ratio; distinction relevant/irrelevant information; visual clarity, simplicity of information	amplify signals, reduce noise; improve clarity of visual and auditory signals;
Sensory-perceptual	sensory storage capacity, processing capacity; logic and uniformity of presented information	simplicity and uniformity of information; reduce disturbance
Cognition	memory and attention functions (working memory capacity), capacity for reasoning, problem solving	reduce complexity; apply individual expertise and knowledge; apply familiar concepts; improve logical relations
Motor preparation	stimulus/response relation; preparation for action	apply direct stimulus-response relations; apply logical and compatible choices
Motor execution	response speed, accuracy of response	apply enforcement of movement (electronic) aids in order to simplify choice

demands of work. On the other hand the general attitude towards older workers becomes friendlier and more tolerant. Lifelong learning at work can be applied as a successful strategy against changes in the nature of work and individual changes over the lifespan. Continuous upgrading of knowledge, the "hardening" of mental workability during the active lifespan means the "survival" of the cognitive system. This strategy is the opposite of disuse, the process of (forgetting) to use acquired knowledge, abilities and skills.

As was referred to in the introduction, the relevance of laboratory findings for real-world activities should be taken into consideration. In his 1982 book on "adult cognition," Salthouse gave an impressive overview of studies indicating age-related functional change. In a final summary chapter categories were defined, however no statements about relative rate of decline of magnitude of the age trend were given. In his book the following list in this specific order was given about age-related decline in abilities: reasoning and decision making, memory, spatial abilities, perceptual-motor and cognitive speed and sensory factors. Moreover these five categories of specific processes are proportionally more vulnerable to overall task complexity (Salthouse 1982). All these findings are results from laboratory studies. An important question that was raised in his book dealt with the observation why these findings are not so relevant in the behaviors of everyday life. Some explanations were particularly relevant for the concept of workability with advancing age. It was suggested that the laboratory tasks may be irrelevant to the skills of daily living. Also that most of the activities of daily living are only minimally demanding, suggesting that most people will have enough in reserve to handle nearly all normal situations. Finally it is argued that more dramatic age differences have not been noted in, for example, elderly workers because tasks have been highly practised.

Arguments about the ecological validity of laboratory findings in cognitive aging studies may have changed in the past decades. For example, vulnerability in cognitive speed, memory, perceptual load and generally increasing complexity in work demands may place older worker in a weaker position than in earlier years. Also more field studies are conducted in recent years. In a book specifically devoted to "work and aging" (Snel and Cremer 1994) a fair number of studies is devoted to real work situations providing evidence for age-related decline in real work conditions. This promising development in applied research will help in finding better and proactive solutions for an extended working life of aging workers in good health.

Mental Workload

P.S. Tsang

Department of Psychology, Wright State University, Dayton, Ohio45435, USA

1. INTRODUCTION

Growing complexity and increasingly automated features of modern human-machine systems are presenting operators with fewer physical demands and greater cognitive demands. Unlike physical demands, cognitive or mental demands are not directly observable. The concept of mental workload is used to benchmark the mental demands of complex systems.

There are several broad objectives for assessing mental workload. The first is prediction. To be able to anticipate the workload level of a new system is valuable for system designs. Workload prediction is also useful when there is a modification to the system configuration (e.g., the incorporation of automated components), the operational procedure, or the personnel. The second objective is evaluation. The most common application is comparing the workload of alternative systems.

Workload evaluation is also used to determine the changing demands across different phases or conditions of a task or mission. The third objective is diagnosis. The appropriate workload assessment can potentially isolate the troublesome spot and identify the precise nature of the demand. The objective of the workload assessment is one main determinant in selecting the appropriate workload metrics.

1.1. Mental Workload Fundamentals

O'Donnell and Eggemeier (1986) defined mental workload as "that portion of the operator's limited capacity actually required to perform a particular task." All mental processing requires some resources. The greater the task demand, the greater the processing resources needed to maintain performance at a certain level. If task demands exceed available resources, performance falters. So having some indications of the expended resources would be invaluable for ensuring optimal performance.

Gopher and Donchin (1986) added: "Mental workload is clearly an attribute of the information processing and control systems that mediate between stimuli, rules, and responses. Mental workload is an attribute of the person-task loop, and the effects of workload on human performance can therefore be examined only in relation to a model of human information processing."

A common model is the multiple resource model (Wickens 1992). This model states there are specific attentional resources for different types of cognitive processing. Attentional resources are defined along three dimensions:

- *Stages of processing*: perceptual/central processing and response processing require separate resources.
- *Processing codes*: spatial processing and verbal processing require separate resources.
- *Input/output modalities*: visual and auditory processing require different resources; manual and speech responses require different resources.

When performing multiple tasks, the higher the similarity in the resource demands among the task components, the more severe the resource competition and the lower the level of performance. With extremely difficult tasks, it would be necessary to select one of the tasks to perform or else face performance degradation. Whether any additional tasks can be accommodated depends on whether there are resources not needed by the high priority task.

2. WORKLOAD METRICS

2.1. Types of Workload Measure

There are four major types of measure: subjective ratings, operator performance, psychophysiological measures, and analytic methods. Subjective metrics elicit the operator's perception of the mental demands of the system. Performance metrics are part of the system performance of interest. Psychophysiological metrics detect changes in the operator's body that are related to task demands. Analytic methods are modeling efforts. Typically, subject matter experts (SMEs) are asked to provide workload estimates in a structured way that is based on a specific workload model and detailed task/mission analysis. Each of the workload measures is thought to provide valuable information. But they all have different strengths and weaknesses.

2.2. Properties of Workload Measures

Workload measures can be characterized by a number of properties: sensitivity, diagnosticity, intrusiveness, validity, reliability, ease of use, and operator acceptance. These are important considerations in selecting an appropriate workload assessment technique.

Sensitivity refers to how well a metric detects changes in mental workload. Often the degree of sensitivity depends on the level of the workload. For example, performance measures are more sensitive at higher levels where the limit of the operator capacity is being reached and performance deficits are expected.

Diagnosticity is the extent to which a metric can reveal the precise nature of the workload. The multiple resource model provides a framework for determining the aspect of processing that is demanding. For example, if performance of a secondary task that mostly uses response processing resources deteriorates, then the output of the primary task should be examined for a potential workload problem. On the other hand, if excessive visual workload is indicated, then the system displays need to be examined.

Intrusiveness is an important consideration. If the workload assessment itself interferes with task performance or adds to the workload, then the workload measure is contaminated. For example, subjective reports that are required during the task performance can take up mental resources that should be allotted to the primary task.

Construct validity considers whether the metric is measuring mental workload. Although important, it is difficult to verify because the workload concept is complex and difficult to define operationally. Two other validity criteria should be considered. Concurrent validity is when different workload metrics correlate in a systematic fashion. For example, subjective rating tends to increase as performance deteriorates. Predictive validity is an especially important consideration for the analytic methods because SME workload estimates are analytical rather than experiential. They should be correlated with operational measures for validation.

Reliability describes the replicability of the workload measures

under similar conditions. Measures that fluctuate independently of task demands have no predictive value and are therefore not useful. One common test is the test/retest correlation. Under similar testing conditions, the metrics obtained at time t_A should correlate well with those obtained at time t_B.

With respect to ease of use, subjective measures are the easiest to administer. Since most operational systems do not have built-in performance recording, the system under evaluation must be specially modified for this purpose. Technical knowledge is required to properly analyze the mental requirements of primary and secondary tasks. Psychophysiological techniques require specialized equipment and expertise in data collection and analysis. Analytic methods require the adoption of a specific workload model and an intimate knowledge of the system to be evaluated.

Operator acceptance is crucial for a successful workload assessment. It is important to explain the nature of the assessment to the operators. Anonymity must be assured in order to gain and maintain cooperation.

2.3. Strengths and Weaknesses of the Workload Metrics

2.3.1. Subjective measures

Operators are typically asked to provide a number on a rating scale to represent the level of mental effort required to accomplish a task. One distinction enjoyed by subjective measures is their use as projective measures. Although direct performance or physiological data cannot be obtained from a system yet to be realized, operators (usually SMEs) could provide workload estimates based on a detailed description of the functionality of the new system. There are several common approaches to subjective workload assessment:

- A rating scale asks for a single unidimensional rating for the overall workload level or it asks for ratings on multiple dimensions.
- The ratings are obtained immediately after task performance or they are obtained retrospectively, having experienced all the task conditions.
- The ratings are absolute or they are relative. An absolute rating is based on the task of interest by itself. For relative ratings, operators compare the task of interest to a single standard or to multiple task conditions (the redundant method).

Descriptions of the more common subjective metrics can be found in O'Donnell and Eggemeier (1986).

Subjective metrics have high operator acceptance since operators can express their opinions. And because they are easy to use, they are the most commonly chosen of all metrics. The measurement units are not task dependent, so subjective metrics can be used to compare different tasks. The metrics are also more sensitive to information represented well in consciousness (such as working memory demands) than to demands that are not well represented (such as response execution processing demands). Multidimensional measures provide diagnostic information. Subjective measures appear to be reliable and have concurrent validity with performance measures. Ratings that are not obtained during task completion are nonintrusive.

One potential drawback is a susceptibility to memory problems if the ratings are made considerably after task performance.

Subjective estimates may also be susceptible to operator bias, past experience, and ego. It is advisable to explain to the operators the importance of responding honestly.

2.3.2. Performance measures

The primary task method assesses the actual operator or system performance. Deteriorating or erratic performance may indicate an unacceptable workload level. The secondary task method can be used when primary task performance is unavailable due to a lack of performance recording in the operational system or a paucity of performance indicators in a highly automated system. Also performance measures are insensitive to very low workload levels since a stable level of performance could be maintained by increased effort. Adding a secondary task would increase the demand to a level where performance measures would be sensitive.

The secondary task is performed concurrently with the primary task, and it is important to know the precise nature of its demands. Primary and secondary tasks should compete for the same processing resources such that changes in the primary task demand would result in changes in the secondary task performance. The degree of interference is used for inferring the workload level. Laboratory tasks such as memory and mental arithmetic tasks are often used as secondary tasks. Alternatively, a naturally occurring part of the overall task can be used as an embedded secondary task. For example, changing demands of the primary flight task would be expected to affect the response latency of the secondary task of responding to radio messages.

The primary task metric is the most direct measure. Except for extremely low workload conditions, performance is sensitive to a variety of task demands. Performance measures are reliable to the extent that performance has stabilized at the time of assessment. But primary task performance is not always available. When primary performance is available, it is specific to the system evaluated and the workload results may have limited generality. Furthermore, different units of measurement for different task performances could pose a scaling problem when comparisons are needed or when aggregating different performance measures.

The pattern of interference observed with secondary tasks of known demand characteristics could pinpoint the type of processing resources demanded by the primary task. This diagnostic information is invaluable for optimizing system performance. Considerable background knowledge is needed to properly conduct a secondary task assessment. And the addition of an extraneous task has another potential drawback: not only might it add to the workload, but it may also fundamentally change the processing of the primary task. It could be intrusive and it could misrepresent the true level of the workload. The embedded secondary task technique is proposed to circumvent this difficulty. Further ideas about the performance measures can be found in Tsang and Wilson (1997).

2.3.3. Psychophysiological measures

Two general classes of psychophysiological measures function interactively: central nervous system measures (CNS) and peripheral nervous system measures. CNS measures include electroencephalographic (EEG) activity, event-related brain potentials (ERPs), magnetic activity of the brain, and measures of brain metabolism such as positron emission tomography. One

component of the peripheral nervous system that is responsive to workload manipulations is the autonomic nervous system (ANS). Measures of ANS activity include cardiovascular measures, measures of pupil diameter, and respiratory measures. Kramer (1991) provides a comprehensive review of the psychophysiological metrics.

A distinction of the psychophysiological measures is that not only are they indicators of mental workload, they are also indicators of vital bodily functions. They are affected by a variety of environmental artifacts as well as the physical state of the operators. Elaborate controls and baseline assessments are therefore required for many of the psychophysiological measures. In addition, they are generally quite complex, consisting of multiple components. Components of the physiological signals that are indicative of mental demands could be small compared to those reflective of bodily functions. Sophisticated data analyses are often needed to extract the relevant information. If the ultimate interest of the workload assessment is system performance then it is important to establish the link between physiological measures and system performance.

A notable strength of the psychophysiological metrics is their nonintrusivenss on task performance. Most physiological measures are obtained by attaching small electrodes to the operator; the detected potentials are then amplified and recorded for later processing. Physiological measures do not require the operators to perform any additional tasks or to deliberately generate subjective workload estimates. However, some physiological techniques are equipment-intensive and may have environmental as well as mobility restrictions. Fortunately, technological advances have reduced many of these problems. Most physiological measures are available on a continuous basis. They are therefore most suited for assessing moment-to-moment or phasic workload changes and for assessing highly automated systems that provide few observable performance indicators. Selectively sensitive physiological metrics (e.g., ERP) can provide valuable diagnostic information.

2.3.4. Analytic methods

Analytic methods rely on mathematical, engineering, and psychological modeling of the workload context of interest. Most are designed to capture the workload of dynamic complex multi-task environments. For example, PROCRU (procedure-oriented crew model) was used to examine the approach-to-landing phase of commercial airflights and W/INDEX (workload index) was used to examine the design of the advanced tactical fighter. Their development is largely driven by the inordinate costs of implementing a system that eventually produces an unacceptable level of workload. Workload prediction is the primary goal of analytic methods. McMillan *et al.* (1989) provide an orientation to the analytic methods.

One distinct advantage of the analytic methods is that each parameter and assumption of the model must be made explicit. This serves several important functions: (a) it fosters careful consideration of the relevant input and output variables in the model, (b) it provides specific predictions that could be tested empirically, and (c) it makes it easier to communicate the findings

Analytic methods are used less often than the other methods, and most have been developed only recently. Current research suggests that analytic methods which assume multiple resources or multiple channels of processing account for more performance variance than the time line method (which assumes serial, single-channel processing). Models which take resource conflicts into consideration—concurrent tasks with similar types of task demand would impose greater workload than concurrent tasks with dissimilar demands—account for more performance variance than models which do not. This line of research helps to identify the parameters and assumptions needed for effective application of analytic methods.

2.4. Multiple Workload Measures

2.4.1. Benefits of multiple workload measures

Multiple workload measures are likely to be needed to obtain a complete picture of the mental workload incurred in a system. This is because mental workload is multidimensional and most real-world tasks are complex and involve multiple task components. Some workload metrics (e.g., pupil diameter) only reveal the global level of the overall demand whereas others are specific in the nature of the information they can provide (e.g., secondary task performance). Global information may not be useful for identifying individual troublesome components. Selectively sensitive metrics may fail to reveal other relevant aspects of the workload altogether. Using multiple measures based on a careful analysis of their strengths and weaknesses is recommended whenever feasible.

The selection of workload metrics should be based on the assessment's objectives, the technical constraints, the available expertise, and the properties of the different metrics. Kantowitz (1992) advocates that the selection of workload metrics should be based on theory. Kantowitz suggests that trying to interpret data without the guidance of a theory is like assembling bricks randomly when constructing a building without a blueprint. It is important to combine a theoretical understanding of human information processing with a theoretical understanding of psychometric measurements. Information processing dictates what parameters should be measured; psychometrics suggests how to measure them.

2.4.2. Dissociations among workload measures

When different workload measures provide seemingly contradictory information, they are said to dissociate. Given that mental workload is multidimensional, and different workload metrics are differentially sensitive to the different workload dimensions, some dissociations among workload measures are to be expected. Dissociations between performance and subjective measures have received the most extensive investigation. Vidulich (1988) provides a summary of these findings. The understanding of the dissociations can be very helpful in evaluating the nature of the system's workload.

3. CONCLUSION

An array of workload metrics is now available for operational use. Performed properly, workload assessment can be invaluable. This does not mean that all questions have been answered successfully. Further theoretical development is needed to better integrate the large body of existing findings and to explain the intricate relationships among the different workload metrics.

As automation escalates and managerial responsibilities multiply, there is a growing concern for operators to be able to

maintain an awareness of their whole situation. In very much the same way that the concept of workload arose out of practical needs, the concept of situation awareness has grown from a need to understand how human operators manage dynamic and complex systems (Adams *et al.* 1991). But according to researchers, situation awareness and mental workload are not interchangeable concepts. The utility of one does not diminish the utility of the other.

1. INTRODUCTION

Mental workload is a multidimensional construct, and refers to the ability of the operator to meet the information processing demands imposed by a task or system. It is generally assumed that workload is related to operator performance such that low to moderate levels of workload are associated with acceptable levels of operator performance. High levels of workload or information processing demand that cannot be effectively accommodated by the operator are associated with degraded levels of operator performance.

A major purpose of mental workload measurement is evaluation of the workload levels imposed by a task or system with the objective of identifying and eliminating workload-related performance decrements. Although numerous approaches have been used to measure mental workload, most procedures can be classified as belonging to one of four major categories: (1) performance-based, (2) subjective, (3) physiological, and (4) analytic. Each category is described below.

2. PERFORMANCE–BASED MEASURES

Performance-based measures derive an index of operator workload from some aspect of the operator's capability to perform a task or a system function. Two major categories of performance-based measures are primary task measures and secondary task methodology.

2.1. Primary Task Measures

Primary task measures assess the capability of the operator to perform the task or system function of primary or principal interest (e.g., pilot the aircraft, control the system). Speed and accuracy measures are commonly employed, and so are assessments of multiple aspects of operator performance (e.g., ability to maintain proper altitude, speed, and glide slope on final approach in an aircraft). The use of primary task measures is based on the hypothetical workload-performance relationship noted above. This relationship assumes that as workload increases beyond the information processing limits of the operator, degradations in primary task performance will result from the inability of the operator to deal with the processing demands of the task or system.

Because they represent a direct assessment of the operator's ability to perform required tasks or functions, primary task measures should always be included in assessments of operator workload. However, although primary task measures can be considered to represent sensitive indexes of workload when an information overload exists, these measures can be insensitive to variations in workload at levels that do not actually exceed the information processing capability of the operator. At low or moderate levels of workload, it is assumed that the operator can compensate for some increases in information processing demand and maintain acceptable levels of primary task performance. Because of this insensitivity, it is typically recommended that potentially more sensitive workload assessment techniques (e.g., physiological, secondary task, subjective) should also be employed in a comprehensive assessment of operator workload. Several reviews of the workload assessment literature (e.g., O'Donnell and Eggemeier 1986, Eggemeier and Wilson 1991, Tsang and Wilson 1997) provide examples of the successful use of primary task measures and describe possible sensitivity limits in more detail.

2.2. Secondary Task Methodology

Secondary task measures assess the capability of the operator to perform the primary task or function of interest concurrently with an additional or secondary task. In the typical application of the secondary task measurement paradigm, the operator is instructed to perform the primary task or function at unimpaired single-task levels, and to permit secondary task performance to decline if degradations in performance cannot be avoided under the concurrent primary/secondary task condition.

Assuming no degradation of primary task performance under the concurrent task condition, secondary task performance provides an index of any excess information processing capacity that is afforded by the primary task. High levels of secondary task performance would be associated with low primary task workload or excess processing capacity, whereas low levels of secondary task performance would be indicative of high workload and little or no excess capacity. By requiring concurrent performance of two tasks, the secondary task paradigm seeks to ensure that total task demands will exceed operator information processing capacity, thereby avoiding the potential insensitivity of primary task measures when used alone.

The secondary task paradigm has been widely applied to measure operator workload. A number of reviews (e.g., O'Donnell and Eggemeier 1986, Eggemeier and Wilson 1991, Wierwille and Eggemeier 1993, Tsang and Wilson 1997) provide examples of the successful use of this approach in laboratory and applications environments, as well as references to guidelines (e.g., matching the processing demands of the primary and secondary tasks) that should be considered when implementing this type of procedure.

Some possible difficulties with the use of this approach in applied environments include the potential for the secondary task to be associated with degradations of primary task performance (so-called primary task intrusion), lack of operator acceptance due to perceived artificiality of some secondary tasks, and the instrumentation necessary to present and record the performance associated with the secondary task.

In order to overcome these potential difficulties, some researchers have suggested the use of so-called embedded secondary tasks which are functions (e.g., radio communications in the flight environment) that would normally be performed by an operator with a lower priority than the primary task within the course of system operation. Because they are part of the normal system procedures, embedded secondary tasks can be expected to reduce potential intrusion and operator acceptance problems.

3. SUBJECTIVE MEASURES

A second major approach to assessment of workload is the use of subjective reports to assess the amount of demand or processing load imposed on the operator by performance of a task or system function. Application of this type of procedure typically involves having the operator provide some subjective assessment of the workload associated with a task or system function following its performance. Subjective procedures have been very frequently employed to assess operator workload, and the rating scale is the most commonly used subjective report procedure.

Within the past 20 years, a number of subjective rating scales have been specifically developed to assess workload and have been extensively evaluated with respect to their ability to provide sensitive indexes of subjective workload in both laboratory and applications settings. These scales include the subjective workload assessment technique (SWAT), the NASA task load index (TLX), and a modified version of the Cooper-Harper scale (MCH).

Several reviews (e.g., O'Donnell and Eggemeier 1986, Eggemeier and Wilson 1991, Wierwille and Eggemeier 1993, Tsang and Wilson 1997) provide additional information pertaining to the nature and successful application of these and other subjective rating procedures, as well as discussions of some methodological factors (e.g., potential effects of context on ratings) that should be considered in their use. In general, subjective rating scales have proven to be sensitive measures of workload that minimize the risk of primary task intrusion, enjoy a high degree of operator acceptance, and require minimal instrumentation. As a consequence, this type of approach has proven extremely popular, particularly in applications environments.

A number of the most frequently used scales (e.g., SWAT, NASA-TLX) are multidimensional. Multidimensional scales afford not only an overall estimate of the amount of subjective workload associated with task performance, but ratings of individual dimensions of subjective workload (e.g., time pressure, mental effort) as well. Information pertaining to individual dimensions of subjective workload is of potential use in identifying or diagnosing the sources of high subjective workload in task performance.

4. PSYCHOPHYSIOLOGICAL MEASURES

A third approach to mental workload assessment is the use of physiological signals from the operator's body. Changes in cognitive activity, including mental workload, are associated with changes in several measures of body function. Common measures are heart rate, blink rate, respiration rate, and brain wave activity. Measures of body fluids, such as salivary cortisol, have also been used. Typically, electrophysiological measures are implemented which require the application of electrodes to the body surface and equipment to amplify and record the signals. Further data reduction is usually required, such as deriving the heart rate from the electrocardiographic signals. However, systems are available that automatically carry out this data reduction. Because the psychophysiological signals are continuously available, they can be used to derive uninterrupted records of operator state. This is often helpful when unexpected events occur since it is possible to go back and examine the data around the unexpected event.

For the most part, psychophysiological data collection does not intrude upon the operator's primary task. Operators readily adapt to wearing the electrodes and forget that they are in place. Small, lightweight, portable recording devices can be worn by operators for ambulatory recording on the job. Wilson and Eggemeier (1991), Kramer (1991) and Tsang and Wilson (1997) provide reviews on the use of psychophysiological measures to monitor mental workload.

4.1. Heart Rate

Heart rate is probably the most widely used of the psychophysiological measures for mental workload assessment. Much of the research has been conducted in aviation settings. In general, increases in heart rate are found with increased mental demands of the task. For example, heart rates associated with landing an aircraft are higher than those recorded during lower-workload cruise periods. Even differences in the gradient of approach to a landing are associated with differences in heart rate; steeper gradients produce higher heart rates than less steep approaches.

The pilot in command of a two-pilot cockpit exhibits a higher heart rate than the nonflying pilot. The higher heart rate will switch back and forth as pilot and copilot change roles during a flight. Heart rate recordings can be used as a debriefing tool during test and evaluation trials to identify periods of high workload. These periods of higher heart rate can be used to focus debriefing discussions. Heart rate measures have been used to assess the workloads associated with telemarketing and with driving automobiles, race boats, and buses.

In general, heart rate is a sensitive measure of mental workload but may not be diagnostic with regard to the source of the workload. For example, both takeoff and landing segments of flight show roughly equivalent increased heart rates, making it impractical to discriminate between them. Assessing the variability of the rhythm of the cardiac cycle has also been proposed as a measure of mental workload. The hypothesis is that higher levels of task demand cause a decrease in the magnitude of the cardiac rhythm variability. However, this is based on laboratory results using simple, single-task paradigms and application to real-world settings does not seem to support this notion.

4.2. Eye Blinks

Visual information is critical in the operation of most systems. Eye blinks effectively render us blind for a few tenths of a second. Operators decrease their blink rate in high-workload situations having a large visual component. This has the positive effect of permitting the operator to miss less of the crucial visual input required for task performance. Blinks are typically measured electrophysiologically or with the use of small cameras. Blinks are identified and their rate, length of closure, and amplitude are measured.

High-workload conditions such as automobile driving in congested areas, landing an aircraft, and seeking a target are associated with lowered blink rates and possibly shorter duration of eyelid closure. The pattern of blinking can also be used to monitor visual demands of a task. Slow, periodic blinking patterns are related to times of visual search, with inhibition of blinking when there is extremely high visual demand.

There are also situations where blink rates may not decrease in proportion to the visual demands of a task. For example, dur-

ing certain types of aircraft landing the pilots may shift their gaze from inside the cockpit to outside. Because there is a tendency to blink when the gaze is changed, the blink rate may be higher than expected. To interpret the data correctly, it is important to know the situation. Eye blinks are both sensitive and diagnostic: they are sensitive to different levels of workload and, generally speaking, they are related only to the visual demands of a task.

4.3. Electrical Brain Activity

Brain wave activity, the electroencephalogram (EEG), is also useful for monitoring mental workload. There are two ways to analyze EEG data. One decomposes the complex EEG waveform into its constituent frequency bands and quantifies the energy in each band. The standard EEG bands are typically used: delta, theta, alpha, beta, and gamma. Increased workload appears to be associated with decreased activity in the alpha band but increased activity in the theta band. Beta and gamma band activity may also increase under conditions of higher mental demand.

In situations where discrete stimuli are presented during a task, it is possible to derive event-related potentials (ERPs). These small brain signals are time-locked to the processing of information and require several repetitions of the stimuli in order to average out the background EEG noise. A large positive-going component of the ERP has been the focus of this research, the so-called P300. Most of this research has been accomplished in the laboratory but some has been performed in simulators and in flight. The use of ERPs is still experimental in nature.

Both forms of brain wave activity are prone to artifact contamination, biological and nonbiological. The biological artifacts include blink, muscle, speech, and movement contamination. Electrical interference from power sources is the main nonbiological artifact. However, reliable methods for reducing and correcting these artifacts have been developed and they increase the utility of EEG measures.

5. ANALYTICAL METHODS

Analytical methods are typically used during early design phases of system development. Since the system does not exist, the workload estimates are predictive in nature. These methods are valuable in that they permit the estimation of workload before the system is built, hopefully avoiding later costly modifications after the system is in the field. Since the system does not exist, subject matter experts are often used to evaluate the demands the system will place upon the operator. These techniques depend upon models of the human operator and how interactions between the operator and the system result in mental workload

in the operator. Model development is valuable because it requires a specific statement of the relationship between the operator and the relevant factors.

The simplest approach is time line analysis. The procedure is to estimate the time to perform each required task then estimate the total time available to complete all the required tasks. Since most situations are time limited, it is possible to see whether the total job can be accommodated in the available time. One problem with this approach is it assumes that only one thing can be accomplished at a time. Recent techniques allow for simultaneous processing of multiple tasks and include task analysis/workload (TAWL), time line analysis and prediction (TLAP) and workload index (W/INDEX). Tsang and Wilson (1997) review these methods and give examples of their application.

Since these techniques are fairly new, they have not been extensively tested and compared to one another. However, as human-operated systems become more and more complex, analytical procedures should enjoy greater use. The complex nature of new systems places high demands upon the human operator, and the retrofit costs are very high. Therefore, inclusion of workload considerations early in the design process can help to reduce total system and operational costs.

Mental Workload: Theory, Measurement and Application

M. S. Young and N. A. Stanton

Department of Psychology, University of Southampton, Southampton
SO17 1BJ, UK

1. ABSTRACT

Mental workload is a pervasive concept throughout the ergonomics and human factors literature and it represents a topic of increasing importance. As modern technology in many working environments imposes more cognitive demands upon operators than physical demands, the understanding of how mental workload impinges on performance is critical. Practitioners should therefore know how to assess mental workload accurately and apply the results appropriately. This chapter provides a general overview of the current state of affairs regarding the understanding, measurement and application of mental workload in the design of complex systems.

2. WHAT IS MENTAL WORKLOAD?

There is no universally accepted definition of mental workload, although an analogy is often drawn with physical load. In this sense, mental workload can be broadly comprised of two components: stress (task demands) and strain (the resulting impact upon the individual).

Attentional resource theories form a useful basis for describing mental demand. These theories assume that individuals possess a finite attentional capacity which may be allocated to one or more tasks. Essentially, mental workload represents the proportion of resources available to meet the task demands. If demands begin to exceed capacity, the skilled operator either adjusts their strategy to compensate, or else performance degrades. Such a view makes clear predictions about mental workload in any given situation and observations of performance provide simple measures of mental workload.

Investing resources in a task is a voluntary and effortful process to meet demands, so performance can be maintained at the cost of individual strain or vice versa. This raises the notion of optimal state – the strain of underload or overload is caused by a mismatch between demands and capabilities. Excessive load can affect selective attention, leading to narrowed or inefficient sampling. Resource models of workload have their drawbacks. For instance, they do not consider nonattentional factors, such as experience.

An alternative perspective, then, takes into account the level of operator skill and the extent to which cognitive processing is automatic. Automatic processing is associated with expert performance and is characteristically fast, unconscious and free from attentional resource constraints. The converse is controlled processing and these two elements lie on a continuum. From this view, mental workload in real world tasks is determined by the balance of automatic and controlled processing involved. This is consistent with the attentional resources approach, as automatic

processing releases attentional resources for other tasks, with a resulting decrease in mental workload.

Thus we see that mental workload is a multi-dimensional concept, determined by characteristics of the task (e.g. demands, performance), or of the operator (e.g. skill, attention; Leplat, 1978). Collating the information obtained so far enables us to propose an operational definition of mental workload: "The mental workload of a task represents the level of attentional resources required to meet both objective and subjective performance criteria, which may be mediated by task demands, external support and past experience." In this definition, the level of attentional resources is assumed to have a finite capacity, beyond which any further increases in demand are manifest in performance degradation. Performance criteria can be imposed by external authorities, or may represent the internal goals of the individual. Examples of task demands are time pressure, or complexity. Support may be in the form of peer assistance or technological aids. Finally, past experience can influence mental workload via changes in skill or knowledge.

Although this definition is not exhaustive, it does represent a consensus of the research. Furthermore, it can be used to predict and explain changes in mental workload as a result of variations in demand, training, or other mediating variables.

There is an abundance of knowledge about what can increase mental workload. For instance, an increase in perceived work required to achieve a goal and decreased time available to complete a task, can both increase subjective workload. Furthermore, performance and workload are to some extent negatively correlated, such that performance failure is associated with higher perceived workload.

On the other hand, there seems to be less certainty about the factors which can lower mental workload. Performance feedback and reducing the number of decision options available, have both been associated with decreases in workload.

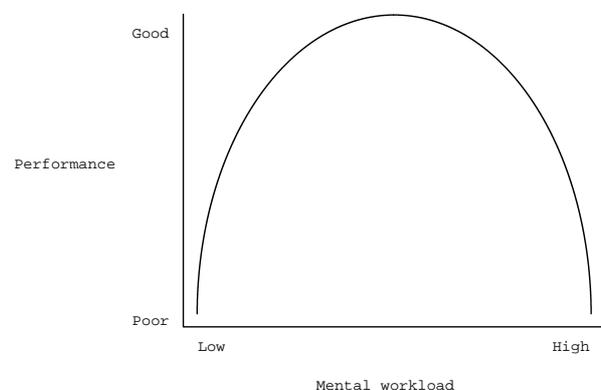
Some of these factors that affect mental workload may seem intuitively obvious, however this is not always the case. The particular problem of automation has attracted a lot of attention in recent years. It is paradoxical that simple automation can both reduce and increase mental workload. For instance, it has been observed that glass cockpits in commercial aircraft have relieved workload in some areas, such as reduced display clutter and more automated flight procedures. However, the same systems have increased workload in other areas, such as more decision options


Figure 1. Relationship between mental workload and performance.

in a given situation and confusion about the operating mode. There is now a strong feeling that mental underload can be equally detrimental to performance as mental overload. Indeed, the current opinion is that there is an optimum level of mental workload which is associated with best performance (figure 1).

Therefore, simply reducing mental workload may not actually improve performance. To be able to apply this knowledge to the design of systems, it is first necessary to measure mental workload.

3. HOW IS MENTAL WORKLOAD MEASURED?

The measurement of mental workload is as diverse a topic as its theoretical counterpart, with many techniques available. Indeed, researchers in applied domains tend to favor the use of a battery of measures to assess workload, rather than any one measure. This use of multi-dimensional devices to assess workload seems sensible given our previous understanding of workload as a multi-dimensional concept. The main categories of workload measures are: primary task performance; secondary task performance; physiological measures; and subjective rating (see Meshkati, Hancock and Rahimi, 1990, for more detail on these techniques).

3.1. Primary and Secondary Task Measures

Performance measures on primary and secondary tasks are widely used in workload assessment. The basic premise is that a task with higher workload will be more difficult, resulting in degraded performance compared with a low workload task. Of course, though, following from attentional resource theories, an increase in difficulty (workload) may not lead to performance deficits if the increase is still within the capacity of the operator. Thus a secondary task, designed to compete for the same resources as the primary task, can be used as a measure of spare attentional capacity. In the secondary task technique, participants are instructed to maintain consistent performance on the primary task and to attempt the secondary task as and when their primary task demands allow them to. Differences in workload between primary tasks are then reflected in performance on the secondary task.

Although these measures have proven useful in many operational environments, there are mixed opinions as to their application. Secondary tasks have been criticized for only being effective in assessing gross changes in difficulty and are therefore considered quite insensitive. In cases where multiple primary task measures are accessible, these can be more sensitive than a single secondary task. Moreover, researchers using secondary task measures must be aware that the secondary task itself can be intrusive, particularly if the primary task imposes low workload, (Wierwille and Gutmann, 1978). However, a simplistic secondary task can be advantageous when primary task measurement may be unfeasible or uneconomical. Furthermore, secondary tasks have been demonstrated to assess different aspects of mental workload. Where the primary task is effective in measuring long periods of workload and performance, the secondary task is useful for quantifying short periods of workload and spare mental capacity. Finally, the use of primary and secondary task measures can be effective in discriminating individual differences in attentional resources, a particular problem in mental workload research.

Researchers wishing to use a secondary task are well advised to adopt discrete stimuli which occupy the same attentional resource pools as the primary task. For example, if the primary task is driving, this involves visual input, spatial processing and a manual response. Therefore, the secondary task should have the same characteristics. This ensures that the technique really is measuring spare capacity and not an alternative resource pool. Of course, this does raise the problem of intrusiveness, in which case one might consider an embedded secondary task. This is ostensibly a part of the primary task, however is not intrinsic to overall performance (e.g. providing readings from an instrument panel while driving).

3.2. Physiological Measures

Physiological measures are many and varied. For instance, various researchers have used respiration, heart rate, heart rate variability, electrodermal response, eye movements and pupillary responses as indices of mental effort. These measures offer advantages such as continuous monitoring of data, greater sensitivity and that they do not interfere with primary task performance (Fairclough, 1993). While many physiological measures have been reliably associated with mental effort, there are a number of disadvantages involved with this method of measuring workload. First, these measures are confounded easily, as they tend to be hypersensitive to extraneous noise from sources such as muscle movements and the rhythmicity of activity in the central and autonomous nervous systems. Also, there is a certain amount of physical obtrusiveness involved in using such bulky equipment. Therefore, it is generally recommended that physiological measures are only applied if unobtrusive and reliable and in conjunction with other measures of workload.

3.3. Subjective Measures

Many authors claim that the use of subjective reports may well be the only index of "true" mental workload. Subjective mental workload scores have been related to perceived difficulty and to the presence of automation. Again, such measures materialize in many forms, however these can be categorized as uni- and multi-dimensional. Uni-dimensional measures, such as the Cooper–Harper scale (1969), tend to be simpler to apply and analyze, but only offer a general workload score (Cooper and Harper, 1969). In contrast, multi-dimensional measures provide some diagnosticity towards the sources of mental workload, but are often more complex in their procedures. For example, the NASA Task Load Index (TLX; Hart and Staveland, 1988) and the Subjective Workload Assessment Technique (SWAT; Reid and Nygren, 1988) require participants to rate subjective workload on several scales. These scales combine into an overall workload score, therefore with the advantage of providing a simple rating of mental workload, in addition to the extra information available from the subscales.

Criticisms of subjective techniques are primarily concerned with the metacognitive abilities of the operator. That is, given the fact that the measures are necessarily administered post-task, one might question their reliability, particularly for long task durations. A recent attempt to develop an instantaneous (i.e. "on-line") measure of subjective mental workload met with limited success. Unfortunately, while it correlated with other measures of workload, it was disruptive to the primary task. It is recommended that researchers use established subjective mental workload measures, which have proven reliability across applications.

4. WHAT CAN DESIGNERS DO TO COPE WITH OPERATOR MENTAL WORKLOAD?

This section uses the information reviewed so far to examine what constitutes good and bad design from the perspective of mental workload.

Designers of complex systems need to recognize that operators are not inherently flawed and so should not attempt to simply remove as many tasks as possible from them (for instance, by implementing automation). This can have the effect of creating mental underload and leaves the operator with an incoherent set of tasks that remain unautomated. Humans obviously bring a valuable contribution to the task, or else they would not be there at all. Rather than task automation *per se*, the goal should be to design tasks and use available technology to exploit the unique skills and flexibility of human operators.

Ergonomics and human factors researchers generally agree that, while physical workload should be kept to a minimum, mental workload should be optimized. Human performance is at its best when task demands are harmonized to the capacities available. Although workload optimization is not easily achieved, a number of options have been discussed in the literature.

One possibility is the use of adaptive interfaces (e.g. Hancock and Verwey, 1997). These are essentially intelligent systems that can detect periods of elevated workload and assist the operator by presenting relevant information in a prioritized fashion. Adaptive systems typically use physiological measures to monitor workload and regulate the automation appropriately. For instance, a system in a car could integrate electrodes in the steering wheel to monitor electrodermal response. This could then be interpreted in terms of mental workload and used as input for the adaptive interface.

A related approach is to adopt dynamic allocation of function. Again, this monitors the task situation for peaks of workload and, in such cases, relieves the operator of some elements of the task. These tasks are returned to the human operator when demand returns to a more manageable level. The theory behind this is to maintain workload at a consistent level, rather than cycling through peaks and troughs which may degrade performance. Dynamic task allocation holds potential for improving performance at high levels of demand. However, questions remain concerning the criteria for and methods of, transferring control between the human and machine. Nonetheless, such human–system cooperation is a forward step, as performance does improve with technological assistance.

Finally, in some cases, mental workload can be reduced without affecting performance. Technological decision aids can relieve workload with no effect on task understanding and redundant task information can actually improve understanding and performance while decreasing workload.

In summary, it is possible to use technological interventions while keeping the human at the center of the design. An example already being tested is the electronic copilot, an adaptive system to assist pilots of military high-speed aircraft. The essential features when designing automated systems are feedback, assistance and optimization. Feedback is necessary to maintain communication between the human and the machine. Assistance for operators is a preferable alternative to relieving them of their tasks outright. People are surprisingly good at a lot of tasks, only sometimes they do need a little help. Finally and perhaps most importantly given the discussions here, mental workload optimization is crucial to maintaining effective task performance. Such optimization inevitably involves a balancing act between demands and resources of both task and operator. This view, which essentially captures the spirit of ergonomics, offers a way forward for designers concerned with the problem of managing mental workload in technological systems.

Models of Human Performance for Application to Military Simulation

R. W. Pew, PhD

BBN Technologies, Cambridge, MA 02138, USA

1. INTRODUCTION

Modeling and simulation provide tools that are being widely used to support system concept development and evaluation, engineering design, training, operations concept and procedure development, and system test and evaluation. (See R. Laughery section on human performance modeling for a general discussion of how human performance models are created and used.) This section will discuss some special classes of models and simulations that are particularly applicable to large-scale system design, such as military system development and military or civilian air traffic control. How human performance models play a role in these kinds of simulations is of particular interest.

The military makes extensive use of modeling and simulation in many of the same ways it is used in research and development and in business and industry; however, there are two categories of simulation that are more specific to the military. These are wargaming, sometimes called constructive simulations, and distributed interactive simulation, sometimes referred to as distributed virtual simulation.

Wargaming refers to simulations that represent the actions of friendly and enemy forces and predict battle outcomes. Originally they were played out by hand on a large game-board representing the military terrain. Today, in the most sophisticated versions, the actions of multi-service forces are represented in computer simulations, in which models of individual military units attack and defend according to a plan, engage the enemy, move across the battle area, while the equipment and personnel losses on each side are calculated using probabilistic models. The US Army JANUS model and the Navy Simulation System (NSS) model are examples of this approach. The models do not necessarily run in real time (they may run faster or slower than real time) and they typically run to completion once a simulation has been initiated. Often multiple runs are executed in order to obtain statistically reliable probabilistic outcomes.

Usually, in constructive models, the human participants, if they are represented at all, are programmed to follow the plan rigidly and there is no provision for representation of individual decision-making or variability in human performance, other than probabilistic models of detection of the enemy and of kill-probability. However, as the introduction of information technology changes, the nature of military engagements from primarily force on force in which the greatest firepower wins, to greater emphasis on information warfare and the importance of effective command and control, there is a recognized need to add representations of human decision-making and human fallibility in the execution of plans, such as the effects of limited training, fatigue, workload, or battlefield stress to these constructive simulations. This is where human performance models come into play.

Distributed interactive simulation (DIS) refers to a relatively new approach to simulation in which simulation is used to create a battlefield environment where human participants execute the engagements just as they would in a real battle. The earliest realization of this approach, developed in the early 1980s, was called SIMNET. In SIMNET multiple mock-ups of the inside of Army tanks were created. Each included computer-simulated workplaces for all of the four crewmembers of a real M-1 tank. Each tank's battlefield environment was simulated using computer graphics. When the commander of a particular tank looked out of his viewport, he saw the terrain, significant landmarks, and the other friendly and enemy tanks within visible range in their own battlefield positions just as he would in a real battle. This was accomplished by connecting all the tank simulators in a computer network and periodically broadcasting data on each tank's position, orientation and significant events, such as firing a round or being fired upon. Every other tank simulator within visual range would process those data and recalculate the state of its own visual environment accordingly. Initially, approximately 80 such tank simulators participated in exercises, some representing friendly and some enemy forces. Later helicopter and Air Force fighter simulations were added to the mix so that the tank forces could be augmented by close air support. Because the data communication can take place over a wide-area computer network, these units do not even have to be geographically co-located. In one demonstration the friendly tank forces were located at Fort Knox, KY, the enemy forces in Cambridge, MA, and the helicopter units at Fort Rucker, AL.

The current state-of-the-art in fielded distributed interactive simulation is represented by the Close Combat Tactical Trainer (CCTT). It is a family of virtual simulations currently being deployed by the Army. It is organized into unit formations of battalion task forces equipped with M1 tank simulators, M2 Bradley infantry fighting vehicle simulators and supported by AH64 attack helicopter simulators. It supports brigade-level operations with high task fidelity down to the crew and squad levels.

Originally distributed interactive simulation (DIS) was developed for training applications, but it has been so successful that it is now forecast to be used for concept development training, doctrine and tactics development, mission rehearsal and in system evaluation. Although it began as an Army project, now all the services are developing this kind of simulation for their own missions and there are R&D level explorations of Joint and Combined Arms training capabilities. Joint training refers to the participation of multiple services. Combined Arms training includes the forces of multiple countries, such as the NATO forces. There is now also considerable interest in combining distributed interactive simulations with constructive simulations so that some aspects of a mission are carried out without human intervention and others rely on actual officer and enlisted participation. For this to work requires temporal synchronization of the two kinds of representation since the DIS components must, by definition, operate in real time.

2. THE ROLE FOR HUMAN PERFORMANCE MODELS

The need for modeling of human performance arises in a different

way in DIS. In order to reduce the number of individuals required to participate in training exercises, the concept of a Semi-Automated Force (SAF) was invented. The notion was that a single participant could control the action of a platoon of enemy tanks so that each unit would not have to be operated by a full crew. Using simple concepts of artificial intelligence, the platoon could be programmed to transit in single file, transition to firing positions, and engage the friendly forces under the control of a unit commander who only had to dial in the objective, the way points, and the type of formation. This level of automation has been achieved, but now there is great interest in extending the concept to more fully automated forces, to include both enemy and collateral friendly forces, and to extend the concept to individual soldiers (referred to as dismounted infantry) on the one hand and to aircraft support missions on the other. To accomplish this requires models that reflect the behavior of individual soldiers, vehicle crews, unit command, control and communication, planning, decision-making, battle execution and, ultimately, that reflect the behavior of larger organizations. Based on current capabilities for modeling human performance, these are tall orders indeed.

It is easy to underestimate just how challenging this is. At the dismounted infantry level, human soldiers take account of what they hear, see, and feel on the battlefield. They use their memory of the results of visual and auditory scanning to produce an integrated view of what is happening around them, sometimes referred to as situation awareness. They make decisions about where to go and what to do next on the basis of this awareness together with what their team leaders tell them in person or over the various communication channels. Models of behavior at this level of complexity are just emerging from the laboratory. Command and control involves real-time planning, replanning, and monitoring of the execution of plans. A commander issues guidance to his or her staff; the staff defines the mission and decomposes it into specified and implied tasks; they identify resources, including personnel, equipment, and supplies, enumerate the logistics to get them to the battlefield and specify the timing of the operational tasks. Models of these kinds of human activity exist as isolated capabilities, but no one has achieved even an approximate model of human behavior integrated at this level of organizational complexity.

Most models of individual or small-team behavior are currently built to represent task execution. Task network models, described in another section of this encyclopedia, simulate the execution of tasks, but typically only produce the resultant measures of performance rather than the task-execution behavior itself. To pick a military example, if the simulation assessed the movement-to-contact of an armored platoon, the outcome of the model might be the time to complete the action, the attrition in forces and the level of supplies used. In order for models to participate in an interactive simulation they must also produce, as outputs, a trace of the physical movement of the battle entities, the individual units that are lost and the final positions of each unit, and they must generate these outputs in real time.

Most of the models used today in DIS are production-rule programs that implement if-then behavioral task-level rules. These programs test to see if a pre-specified set of conditions is present, and if it is, then trigger a sequence of actions. The firing of each subsequent rule is dependent on new sets of conditions. For example, just hypothetically, a firing routine might be specified as: If an enemy target is in visual range and if it is within the field of view, then with probability, p, it is detected. If a target is detected and it is identified as an enemy tank and it is moving toward the friendly positions, assign it a targeting priority of q. If such a tank is identified and no other target has been detected having a higher priority, then execute the firing sequence. The computer architecture that is most commonly used currently for implementing these rule sets in terms of a "finite-state machine" is called ModSAF, standing for Modular Semi-Automated Forces. See the website, http://www.mystech.com/-smithr/elecsim94/modsaf/modsaf.txt for a more detailed description of ModSAF.

At the research and development level, the state-of-the-art is represented by the Intelligent Forces Models created using the Soar architecture to represent the combat behavior of fixed- and rotary-wing pilots in combat and reconnaissance missions. The FWA-Soar simulated a fleet of up to 500 fixed-wing aircraft in a context that includes such elements as enemy aircraft, surface-to-air missiles, and enemy radar installations. It was used as the primary source of air missions for STOW-97 (Synthetic Theater of War-97) a demonstration of the capability to represent a full theater of war synthetically. See http://ai.eecs.umich.edu/ifor/stow-review.html for a fuller description of FWA-Soar.

3. THE PATH TO IMPROVED HUMAN PERFORMANCE MODELS

In 1998 the National Research Council of the US National Academy of Sciences published a book-length report, *Modeling Human and Organizational Behavior: Application to Military Simulations*, that summarizes the state-of-the-art with respect to this kind of human-performance modeling. The report recommends that, in order to achieve the kind of realism goals desired by the military sponsors, much greater attention must be paid to the psychological content of the models which are used for these purposes.

It suggests five broad areas of experimental psychology research and modeling that are especially relevant to improved human behavior representation. The areas of *attention and multitasking* refer to the human ability to focus on one thing at a time but to have multiple threads of activity going on simultaneously. *Memory and learning* are fundamental to functioning in an interactive environment. *Decision-making* is a central component of military command and control. *Situation awareness* refers to sensing and interpreting the state of the operational environment. And finally, *planning* is concerned with generating detailed preparations for future actions and anticipated events.

The report summarizes ten specific architectures that have been developed specifically for building integrative human performance models having the kind of scope necessary to be applied to military simulation problems of the kind addressed here. The Soar modeling environment, referenced above is an example such an architecture.

4. MODELING BEHAVIORAL STRESS

There is also considerable interest in modeling the effects of various kinds of stressors on human performance. A stressor, sometimes called a moderator variable, is any environmental or

internal variable that changes the way behavior is carried out. For example, when soldiers are subjected to excessive workload, they may do all the tasks required of them incompletely, they may skip some tasks, or they may just queue up pending tasks and accomplish them when they have more time. The models should reflect these different effects of workload pressure. When a soldier must continue to work without enough sleep, it is likely that there will be momentary lapses of attention during which changes in the environment will not be noticed and these lapses will effect the resulting behavior. There is also interest in accounting for emotional stresses of the battlefield, but we are only beginning to understand how they will effect behavior and therefore how to model them.

5. A SUGGESTED METHODOLOGY

Experience has shown that building models of human performance is extremely challenging and requires interdisciplinary teams. Computer scientists contribute the modeling expertise, behavioral scientists contribute knowledge of the psychological literature and the understanding of the vagaries of human performance, and military subject-matter experts contribute knowledge of military doctrine and tactics for specific application domains. Because human behavior is so context-dependent, success at modeling is, at this point, most successful in limited, well-defined domains, such as executing specific types of maneuvers on well-documented terrain following specifically prescribed doctrine.

Although behavioral theory can play an important role in good models, the process should begin with intensive knowledge acquisition to define and understand all the activities and tasks that are required of the entities being modeled. Then the team needs to examine the data requirements associated with those activities and tasks. What data are used when carrying out each task and what are their sources? What outputs are produced and where do they go? How long does each task take? What are the possible mistakes and errors that are likely to occur and how do they come about?

To develop models with psychological content also requires going deeper into the processes and preparing what is sometimes called a cognitive task analysis. This kind of analysis investigates the perceptual cues that are available to support situation awareness and decision making required in carrying out each task, as well as the memory requirements and movement control associated with successful performance. Only after these kinds of information are available is it possible to begin defining the models themselves.

The most practical approach to actually building the models is to create successively more detailed approximations to the final desired outcome. One starts with the simplest basic structure of a task, and then iteratively increases the fidelity with which the task is iteratively carried out until the desired level of realism is achieved. At each stage of development the models should be compared to real human performance in order to understand the model's limitations and to focus the effort at the next stage. When the model is ready for application it should be thoroughly validated by running formal comparisons between the behavior of the model and the behavior of humans accomplishing the same activities and tasks. This is one of the most challenging phases of model development and is the one that is most often neglected. There are already too many human performance models being used that are inaccurate and poorly understood because of failures to carry out adequate validation studies.

6. SUMMARY

Modeling human performance is of growing interest in the human factors and ergonomics community in general, and there are many potential applications in the military services. Current capabilities to achieve executable models that simulate the responses of humans, rather than simply producing performance measures as outcomes, are very limited, both in scope and in robustness in the face of modest changes in context. It will be important to incorporate greater understanding of psychological theory and to undertake model development with the participation of interdisciplinary team members for further progress to be achieved.

7. FURTHER READING

The reader interested in greater detail of military human performance models is referred to Pew, R.W. and Mavor, A.S. (eds), 1998, *Modeling Human and Organizational Behavior: Application to Military Simulations*, (Washington DC: National Academy Press) from which this section was derived.

Monitoring an Operator's Psychophysiological Fitness for Work

A. Y. Burov

Center of Ecology, Ergonomics and Safety, ELAN Ltd, PO Box 3, 04214, Kyiv, Ukraine

1. INTRODUCTION

In modern times manual work has been more and more replaced by mental one. In this respect it is critical not only to design operators' work, but also to re-organize the particular operator's working process itself. This reorganization is based on comparing the general professional requirements with an operator's individual characteristics (physical, psychophysiological, social) as well as his or her capacity for adaptation. Adaptation of individual characteristics and general requirements affects the dynamics of an operator's work functional structure during his or her lifetime. An ergonomic approach to improving human interaction with the work tools and means, as well as with the environment, is to provide mutual adaptation of a human working functional structure and the work environment. The mechanisms of this adaptation may differ depending on the conditions, location and time of the operators' work, i.e. they depend not only on the interaction "human–machine–environment", but also on the dynamics of this interaction throughout the whole work cycle.

The analysis of safety and efficiency of enterprises with complex technological cycles shows that a human (an operator) is the least reliable link in the human–technology system. His or her fitness for work depends on four groups of factors:

1. Professional expertise.
2. Psychophysiological professionally important qualities (PPIQ).
3. Functional state.
4. Parameters of the environment.

These factors determine the output operator's parameters that must meet work condition requirements both in values and over time. Only these parameters of human fitness for work could ensure the proper efficiency level of the human–technology system. The efficiency of mental work to a great extent depends on a person's ability to manage varying information flows. Given the rate of information growth and the span of human life, it becomes essential to maintain human psychophysiological condition at the proper level in case it is impossible or unreasonable to replace him or her by another person.

The objective was to develop the methodology and principles of the psychophysiological monitoring of the operators' fitness for work and to develop a psychophysiological monitoring system to assess the psychophysiological state of the operators, to predict their efficiency.

2. METHODOLOGICAL BASIS OF OPERATORS' FITNESS FOR WORK

While reviewing the role of a human operator as an element of the human–technological system, human factor or ergonomics approaches to the evaluation of the operator's fitness for work have typically assumed that the functional characteristics of an operator (e.g. expertise, information processing capacity, etc.) are invariant. Presumably, these are not influenced by such variables as operators' mood swings, sleep history, work time expenditure, etc.

Some PPIQ could change and reduce below the proper level. Both theoretical analysis and the analysis of actual data show that the range of psychophysiological parameters may vary greatly within several days, hours and shorter time intervals for both exogenous and endogenous reasons, which may result in the decreasing of an operator's professional fitness level below the critical one. A pre-shift medical control is able to reveal only rough, considerable deviations in a human condition ("permission check"), but it does not reveal such functional deviations at an early state due to insignificant changes in amplitudes and the impossibility of predicting stable durability parameters over time.

Therefore, it is evident that the tests and techniques used so far do not reflect physiological maintenance of the current activity. At the same time, the vegetative maintenance of mental activity is connected with the operation of the whole hierarchy of regulatory physiological systems and at times become apparent due to significant shifts in some physiological parameters.

In this respect, there seems to be a need to use objective physiological parameters as evaluative criteria of a functional state and mental fitness for work. However, the research into these parameters is quite hard to conduct in real-life conditions. Moreover, when it is necessary to project human fitness for work, most physiological parameters cannot ensure the required precision because of their short-time forecasting basis. While the requirements for professional expertise could be defined for various kinds of manual and mental work, the evaluation of functional condition over time is much harder to make, for it depends not only on the psychophysiological parameters, but also on the changes in an operator's state, especially during different periods (year-by-year variations, day-by-day variations, work-schedule and shift variations, etc.).

The physiological mechanisms of the adaptation of an operator's activity functional system to the industrial environment may vary depending on the conditions, location and time of human activity. Hence, ergonomics may contribute to improving human working conditions if it takes into account not only macro-ergonomic requirements (spatial aspect of human interaction with the industrial environment), but also ergodynamic ones (temporal aspect). Direct or indirect measurement of psychophysiological changes makes it possible to review a functional state of the operator structure (or a moment-by-moment condition of an operator), which helps to predict an operator's individual fitness and reliability for effective work.

3. PSYCHOPHYSIOLOGICAL BACKGROUND

Selecting appropriate physiological parameters to define an operator's functional state is of utmost importance. Our data clearly show that the dynamics of mental activity, especially its biorhythmic structure (Burov 1986, 1991), plays a leading role in the analysis of professional fitness and the maintenance of the operators' functional state. When mental activity as the primary output of the operator psychophysiological condition is examined,

it becomes evident that we are able to predict relationships between the parameters of mental activity and those of physiological maintenance (Alajalova *et al.* 1975). Prior researches (Burov 1986) indicate that this relationship can be most clearly seen in rhythmical characteristics of these processes rather than in stable baselines or a tonic level of responding. Rhythmic characteristics stand for temporal rhythms such as the well-known circadian rhythm and estrous cycle rhythm, as well as other rhythms that are less frequently referred to.

A breakdown in these rhythms reflects the strains associated with adjusting to demanding activities and stressors. Hence, they may be used to evaluate a psychophysiological regulation of activity and its impact on operational efficiency, and possibly to predict an ability to function effectively. Our research is aimed at developing psychophysiological monitoring systems to assess human psychophysiological states and to predict an operator's functional efficiency. We have started to evaluate its validity during the performance of monotonous tasks under laboratory conditions as well as in applied environments (Burov 1986). The laboratory findings clearly support the idea that variations in the relationship between oscillatory components of task performance measures and physiological measures provide a useful index of operators' efficiency ($R = 0.85–0.93$, $p < 0.01$). Applied research employing the system in fossil and hydroelectric power plants as well as that of dispatchers has evaluated the validity of the predictions concerning a moment-by-moment efficiency of an operator by correlating the prediction indices with the expert rating of an operator performance as well as with operational output measures (e.g. fuel usage) during a 1-year period among 73 power plant operators. The findings show that the approach is useful in predicting operators' efficiency.

4. PRINCIPLES OF DEVELOPING THE SYSTEM OF MONITORING OF OPERATORS' FITNESS FOR WORK

The approach is based on the following principles (Burov and Chetvernya 1996):

- Test techniques used to evaluate psychophysiological parameters of an operator's fitness for work should be aimed at evaluating not the absolute levels, but the time structure of task performance.
- Information concerning the human condition should characterize him or her as a complex system.
- An adequate adaptive model should describe parameters of psychophysiological maintenance and their sets.
- Information models should describe regional, professional, group and personal characteristics of operators under survey.
- Psychophysiological test procedure control should be exercised with the data collected in the system database with adaptive algorithm.

The simulation of an operator's work in laboratory conditions enables a psychological test to be developed that is most adequate for investigating operators' work types. The test is an inspection procedure as well as information selection about the human condition and his or her fitness for work: the reliability, rate and rhythm of performance. These parameters reflect the pressure of regulative systems and physiological "cost" of activity, on the one hand, and the efficiency of the professional operators' work, on the other hand (Burov 1986, 1991).

A psychophysiological check of an operator's ability to process information is performed as the same type of cognitive tasks performance under computer control. According to the performance of all tasks, parameters of rate, dynamics and biorhythmical structure are calculated. Among these numbers, a subset of parameters that are the most informative ones in relation to human professional durability are chosen.

Our research shows that formally to describe a human work efficiency in conditions of simulating an operator's activity, the statistical models in classes of multiple regression models of 4–6 degrees with volumes of training samples of 24 supervisions are the most exact and reliable ones.

5. APPLICATION

Despite all the possible measures to make a professional selection, from 40 to 60% of accidents arise because of personnel problems. According to our data, natural fluctuations of the human functional state account for failures in cases which do not enable an operator to realize his/her qualifications completely. The approach discussed is based on using an individual, i.e. inherent in each particular person, temporal organization of mental activity in systems for a pre-shift (intrashift) check of operators' fitness for work. Thus the prediction model is not fixed: instead of a specific model, the algorithm of constructing adaptive models is used.

The system to project operators' efficiency is supposed to open up the following opportunities:

- To collect indirect information on the human psychophysiological state.
- To investigate the dynamics of the human psychophysiological state during his or her professional career.
- To give human information which could be used to make predictions of his/her professional efficiency and improve it in a certain way.

In practical terms, the use of such systems ensures psychophysiological support during the whole operator's professional life. Generally, such systems are employed to provide an organizational support (task performance, projection, recommendations), information support (condition evaluation and projection of fitness for work) and technical support (software). Information on a human's psychophysiological conditions should be preserved during his or her lifetime, so that psychophysiological parameters do not remain constant and exceed the critical limits for different people in various moments (stages).

An adequate psychophysiological model of an operator's work allows for 3–4 min of work to evaluate a human functional state and to predict his or her professional endurance for the coming work shift. Such a model of activity is used in systems of operators' pre-shift checks at energy enterprises that provide a prediction accuracy of 85–90 %.

Noise: Measuring, Evaluation, and Rating in Ergonomics

H. Strasser and H. Irle

Ergonomics Division, University of Siegen, Paul-Bonatz-Str. 9–11, 57068 Siegen, Germany

1. INTRODUCTION

Both ergonomists and practitioners responsible for occupational health and safety in a company normally use and appreciate indices of workload and environmental exposures presented in the simplest possible figures and numbers. Therefore, in traditional standards, rules and safety regulations, the physical environment is normally rated in 8-h-based mean values via connecting intensity and duration of stress by means of a multiplication, i.e. a mutual settlement of high load within a short exposure time and a low stress height within a longer lasting exposure. This principle is well-based on the experience that a low workload can be tolerated for a longer duration than a high workload. But does this confirm the hypothesis that equal energy or dose, or equal demanded output, also involves equal short or long-term human responses? It will be shown that standards and conventional guidelines for occupational health and safety are more closely related to physics than to physiology. Yet, to really protect man at work, ergonomics must be much more concerned with physiological costs of work and environmental stress than with physical principles of equal energetic dose.

2. GRADUAL ASSESSMENT OF INTENSITY, FREQUENCY AND EXPOSURE TIME OF NOISE

As shown in the upper row of Figure 1, the intensity of sound events has always been quantified in decibels by the sound pressure level in a logarithmic scale. Of course, that is a pragmatic scale because a tremendous span of > 6 decimal powers of sound pressure and even 12 decimal powers of sound intensity can be condensed into easily manageable values of only 3 digits (e.g. 0–120 dB).

However, scientists and practitioners nowadays still have to work with this scale, despite the somewhat paradoxical fact that the psychophysical basic law of Weber–Fechner has meanwhile proven to be incorrect for acoustic stimuli. Although the formula for the sound pressure level is due to Weber–Fechner's law as outlined in the upper part of Figure 2, the resulting logarithmic scale is not in accordance with human sensation. For instance, a 3 dB difference means that two intensities vary by the factor 2, and a variation of 10 or 20 dB, e.g. from 80 or 90 to 100 dB, is associated with the 10- or even 100-fold in energy; a 10 dB increase or decrease results in a doubling or halving of the loudness for the human sensation, however.

Also, a level of 100 dB can never be assessed as the double value of 50 dB. Therefore, instead of the incompatible logarithmic scale, a scale of loudness with linear units in Sone due to sensation derived from Stevens's law of power should be used (see middle part of Figure 2). The above-mentioned increase of 10 dB, e.g. from 90 to 100 dB, is then represented by the doubling of 32 to 64 Sone.

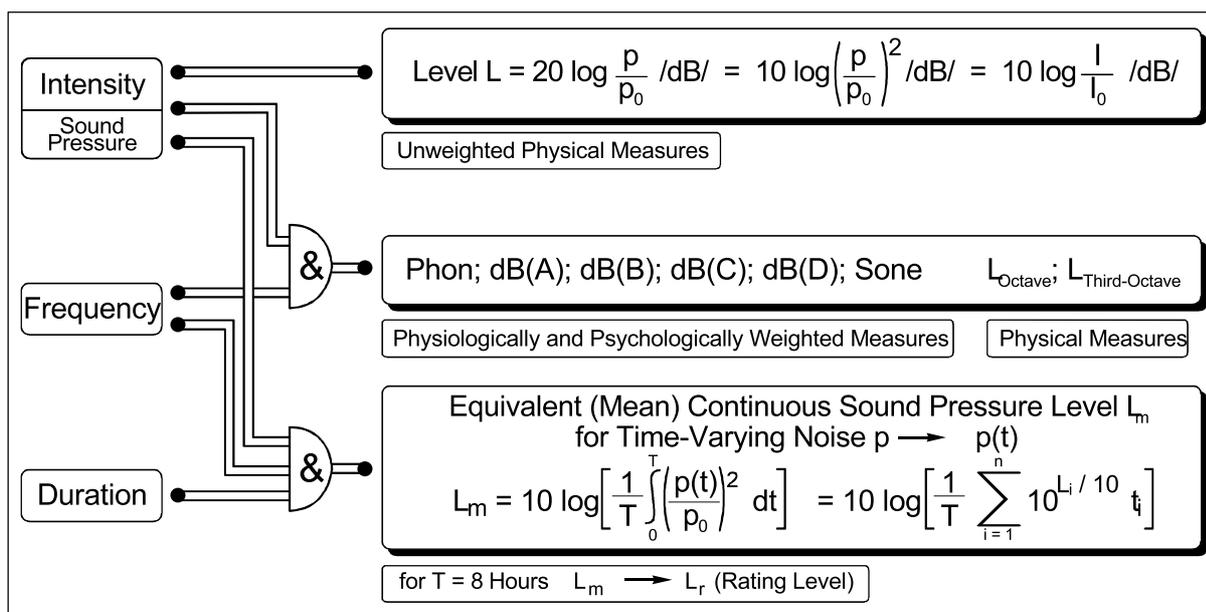
If we were to make our money transactions utilizing the traditional logarithmic scale, we would, no doubt, handle the decibels a little bit more cautiously than is sometimes done in practice. Provided that: 0 dB corresponds with $1, 30 dB would be equivalent to $1000 and 60 dB would mean that we would already be millionaires. But also trillions or quadrillions (Figure 3) in national debt expressed in the small figures 120 or 150 dB


Figure 1. Gradual assessment of the physical dimensions intensity, frequency and exposure time of noise for the development of an integral characteristic value.
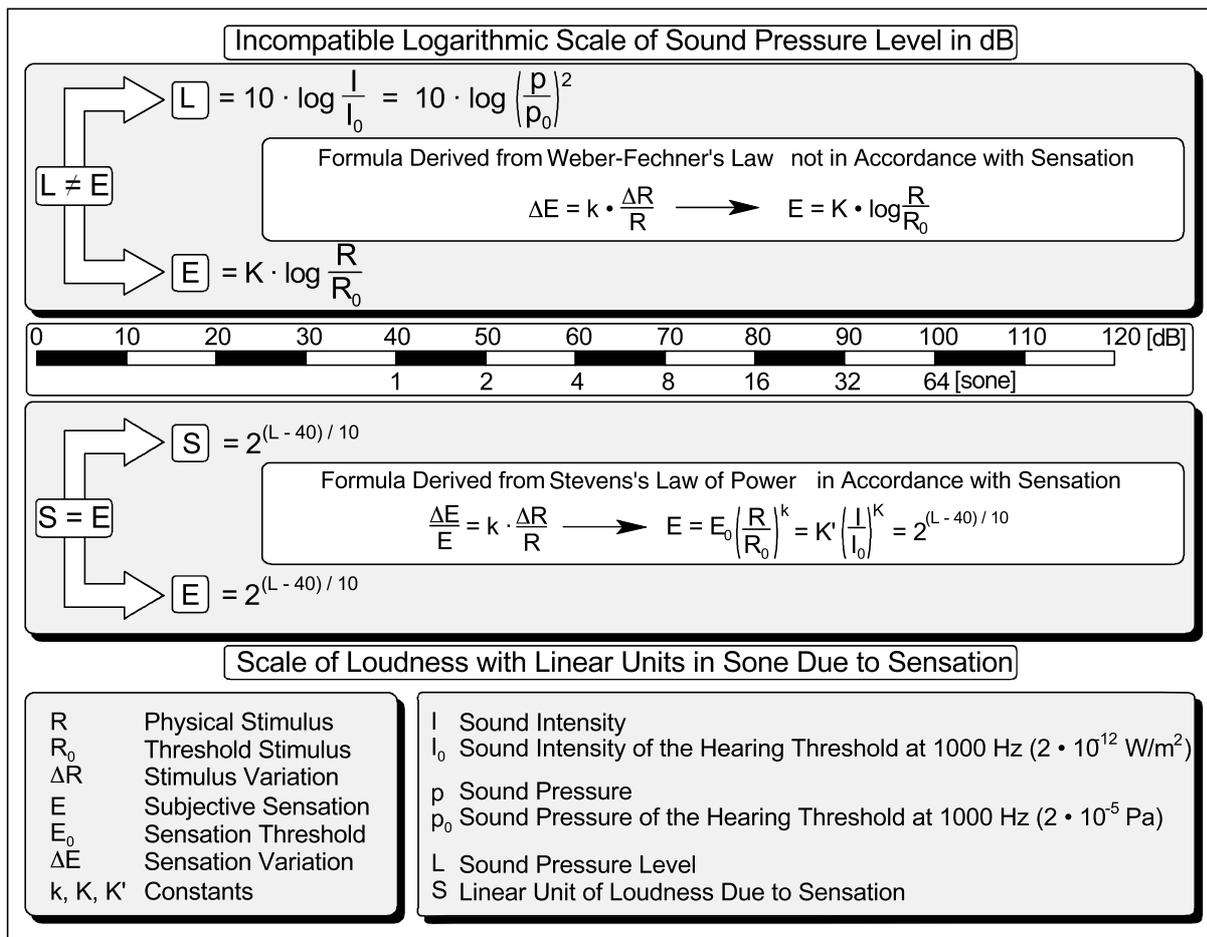

Figure 2. Incompatible logarithmic scale and scale of loudness according to Stevens (1957).

would seem to be not that tremendously much more than the money that "have-nots" have in their pockets.

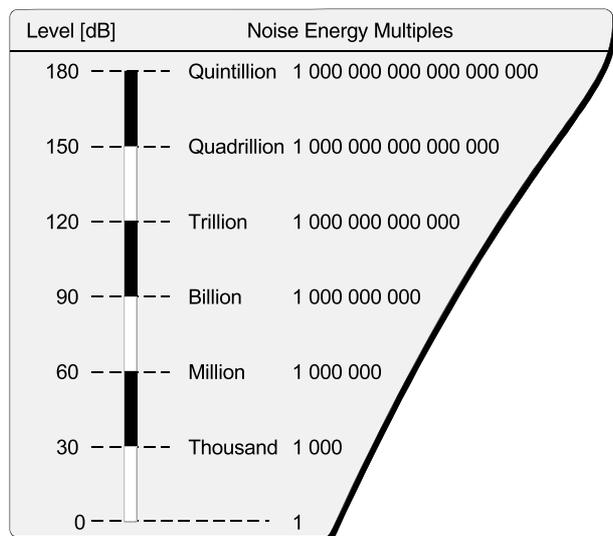
With the intention of specifying sound immission with regard to intensity and frequency in one single value — as shown in the middle row of Figure 1 — frequency-dependent filters A, B, C or D should take into account the physiological characteristics of hearing.


Figure 3. Noise energy multiples.

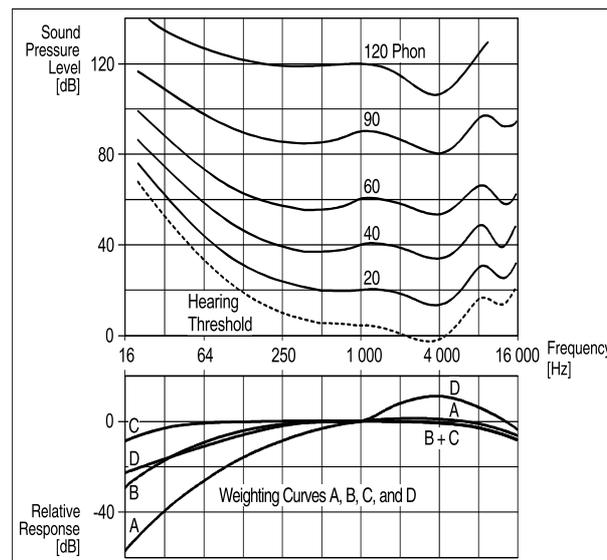
The filters A–D, however, as a reciprocal approximation of the phon curves in different volume ranges (Figure 4), are based


Figure 4. Curves of equal subjective sound level intensity (Phon) in the audible frequency range and dynamic area (upper) and frequency–response characteristics of the weighting networks A–D (lower).

517

on the subjective comparison of sequentially presented tones and, therefore, cannot lead to an adequate assessment of noise, which is normally a mixture of inharmonious sounds. Furthermore, in most cases today, only the A-weighting network is used for all volume ranges, although doing so conflicts with scientific knowledge. This discrepancy sometimes leads to the fact that, to the disadvantage of man, sound pressure levels of some noise sources do not represent the real sensations of man. A paradoxical contradiction sometimes results which can be expressed in the statement: lower dB(A) but higher loudness. This applies, for example, to some types of motorcycles, because the A-filter — which is strictly speaking only applicable to a dynamic range of up to 60 dB — reduces the sound pressure levels more than allowed when it is used to evaluate higher noise levels.

For noise control in particular, it is beneficial to obtain knowledge about the frequency ranges where noise is emitted from a source in order to select suitable protection measures. Therefore, frequency analysis or at least octave or third-octave band measurements of noise are more useful than the application of the weighting curves A, B, C, or D.

Sound pressure levels mentioned in ergonomics and in all legal regulations, standards, and prevention instructions (e.g. NN 1990, 1996, 1998, ISO DIS 1999) do not refer to a momentary sound event; they normally refer to the rating level L_r as an average value for the noise exposure associated with an 8-h working day.

3. RATING LEVEL AS AN INTEGRAL VALUE OF NOISE AND ITS DIVERGENT EFFECTS ON MAN

The energy equivalent calculation of the mean value — as shown in the lower row of Figure 1 — is, of course, applicable to a great many working situations. However, situations also exist where a purely formal calculation yields peculiar results that lead to a serious misinterpretation. This will be visualized and explained by the Figures 5 and 6.

When applying energy equivalence, 85 dB for 8 h are equivalent to 88 dB for 4 h, 91 dB/2 h or 94 dB/1 h.

This mutual settlement of noise level and exposure time (Figure 5) is correct as far as sound dose and sound energy are concerned. However, with regard to physiological and psychological aspects of work, inevitably some discrepancies result.

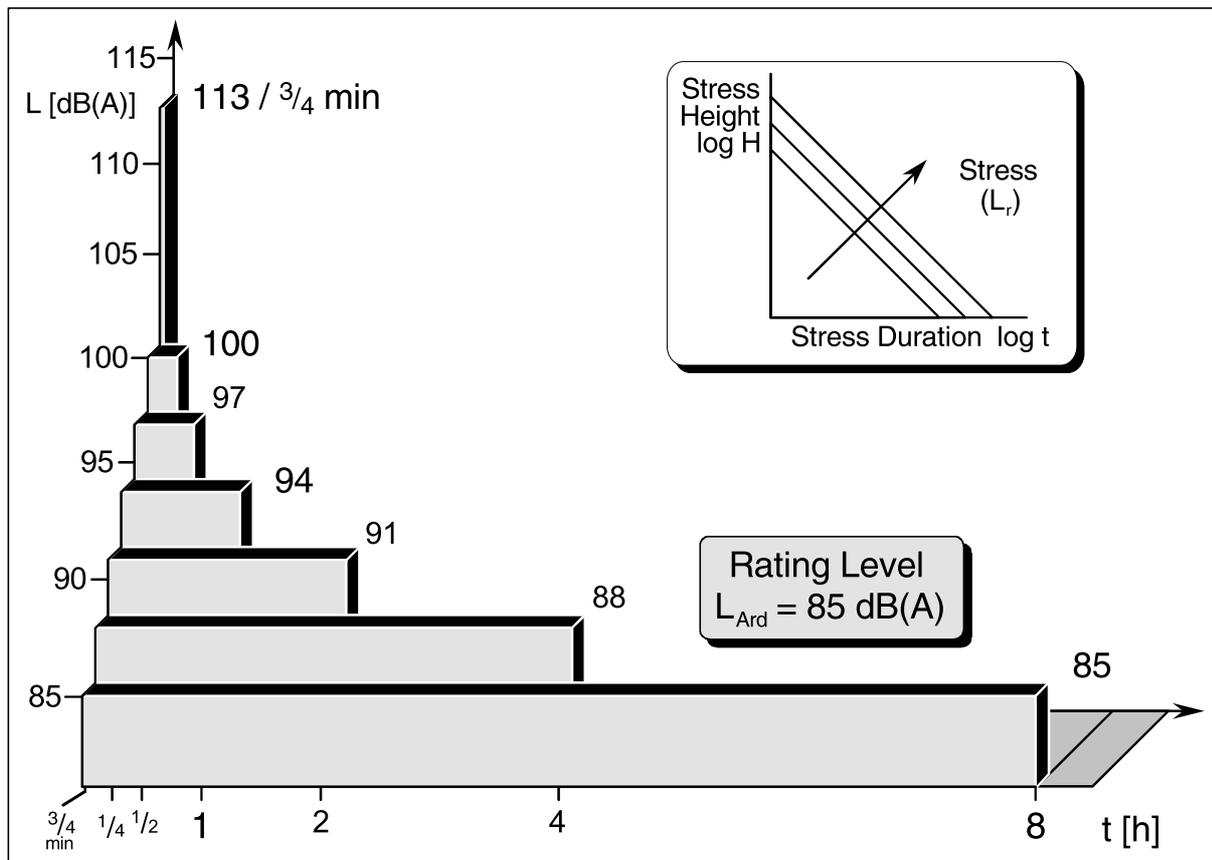
Ninety-four dB/1 h — as in the previous case — is energetically equivalent to 85 dB/8 h, i.e. it correspond to an $L_r =$ 85 dB. If only the energy, i.e. the sound dose, is considered, what is shown in the upper part of Figure 6 also holds true. In this case, 94 dB for 1 h and an additional 75 dB for the remaining 7 h also result in an $L_r =$ 85 dB. Physically seen, this is correct, but it is comparable with the situation of filling up quiet periods with noise, and from a psychological point of view it is likely that nobody would prefer a situation as described in the upper part of Figure 6. Provided that the noise distribution shown here would stem from two machines, strange effects would also result with respect to technical approaches of noise control. If an


Figure 5. Sound pressure levels of different durations leading to an equal rating level (in this case 85 dB(A)) when applying the "3-dB exchange rate."

Rating Level L_r for T = 8 h

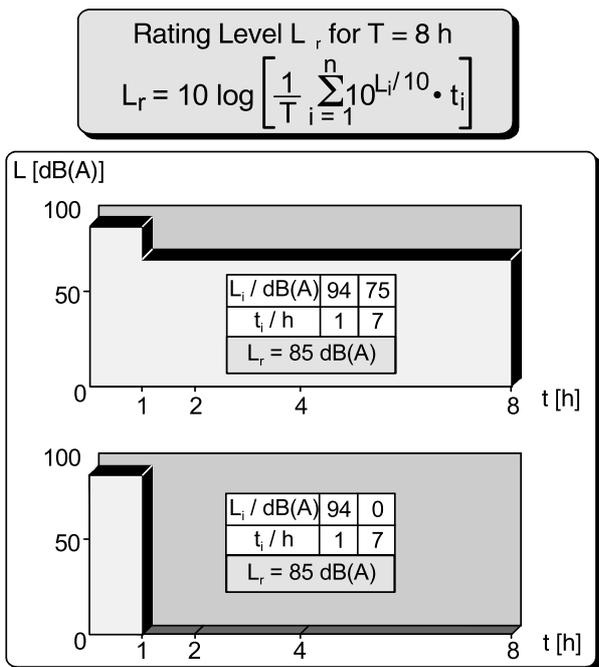
$$L_r = 10 \log \left[\frac{1}{T} \sum_{i=1}^{n} 10^{L_i/10} \cdot t_i \right]$$


Figure 6. Elucidation of discrepancies in rating noise via the 3-dB exchange rate.

engineer in this case would decide to completely insulate the machine which emits the lower level, the rating level would not be influenced at all. The application of the measure "rating level" consequently allows these curious ratings, as long as the lower

value of noise remains a certain amount below the peak levels. For an equal exposure time, a difference of only 10 dB between the two levels is already enough to neglect the lower level, which absolutely agrees with legal regulations, standards, and national or international guidelines.

When continuing to halve the exposure time and when applying the "3-dB exchange rate" — from a purely arithmetical point of view — even 15 min of dance music in a club at 100 dB would correspond to an 8-h working day at 85 dB (Figure 5). This exposure is still tolerated in the production sector according to almost all international standards (NN 1997). Nevertheless, physiologically seen, high sound levels for a short period, e.g. 100 dB over a 15 min or consequently 113 dB for 45 s have to be assessed much more advantageously than continuous noise. This can be demonstrated, for example, by temporary threshold shifts (TTS) resulting from different noise levels with corresponding exposure times in an energy equivalent arrangement (Irle *et al.* 2000).

4. EQUAL ENERGY PRINCIPLE AND THE CONVENTIONAL RATING OF CONTINUOUS AND IMPULSE NOISE

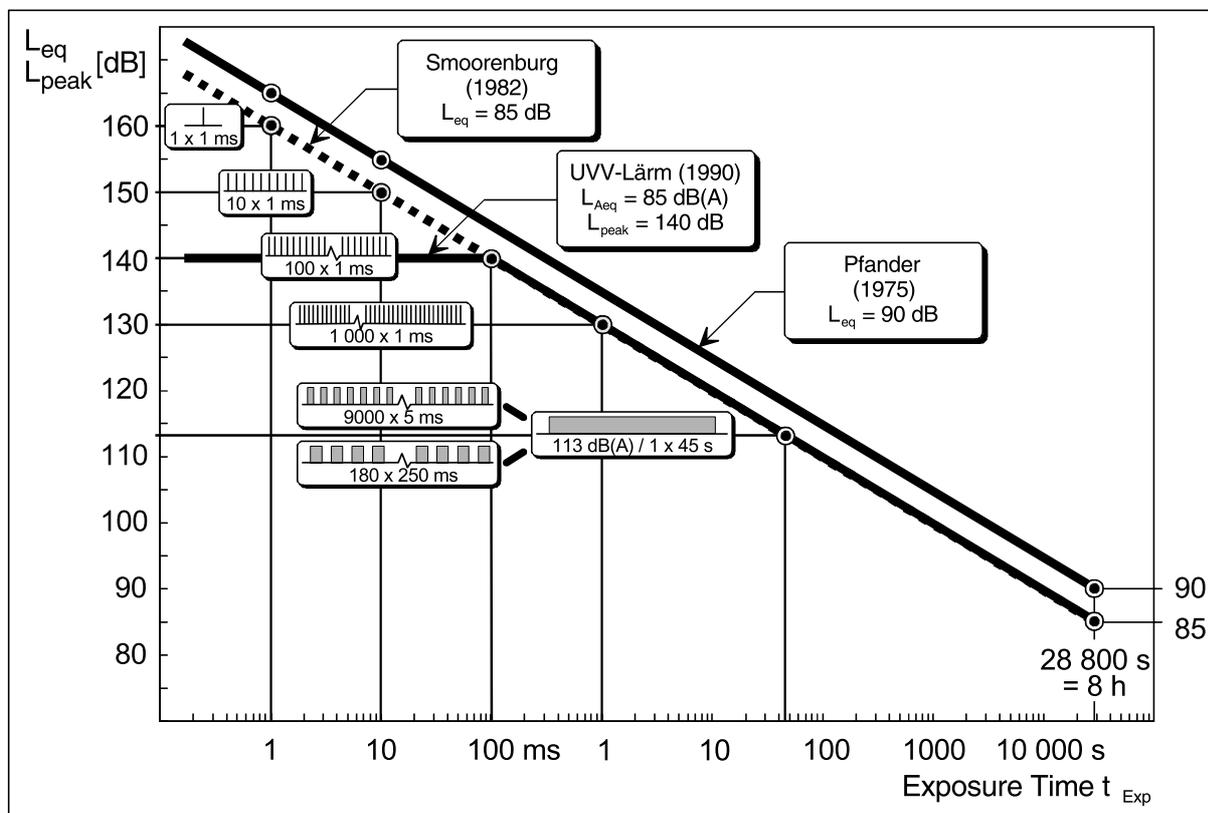
But may the mutual compensation of stress height and exposure time to the advantage of man be applied without limit? Can 120, 130, 140, 150 or even 160 dB at an adequately reduced exposure (of 10, 1, 0.1, 0.01 or 0.001 s) be assessed to be identical to or even more advantageous than, for example, the above-mentioned 113 dB/45 s? From a physiological point of view the answer must be 'no,' even though TTS may level off completely. Nevertheless, in the past, the energy equivalent compensation of a halving of


Figure 7. Comparison of various noise rating procedures.

the duration with a level increase by 3 dB and vice versa (or the factor 10 in duration versus level) has become the basis for cut-off level diagrams to avoid hearing impairment which are applied in civil as well as in military sectors (NN 1987).

In the case of impulse noise, exposure times even reach down into the range of ms. When establishing a logarithmic scale for the exposure time in addition to the already existing one for the noise level in dB, the lower straight line in Figure 7 illustrates the energy equivalence for the rating level of 85 dB, e.g.:

- 1 _ 1-ms impulse of 160 dB;
- 10 _ 1-ms impulses of 150 dB;
- 100 _ 1-ms impulses of 140 dB;
- 1000 _ 1-ms impulses of 130 dB;
- 9000 _ 5-ms impulses of 113 dB; and
- 85 dB for 8 h (28 800 s) respectively.

Although a rating level of only 85 dB(A) which has long been tolerated in civil sectors is now provided as limit in the military sector, too (contrary to the former tolerable rating level of 90 dB), and although the unevaluated noise level in industry may not exceed 140 dB according to revised noise regulations (e.g. NN 1990, 1997) due to the lower line in Figure 7, the varying time structures are not considered.

Figure 8 shows cut-off level diagrams that were used to avoid hearing impairment in case of bang noise. The lower limiting line was utilized (in the military sector) for assessing noise constellations, e.g. 165 dB for 1 ms or 90 dB for 8 h, which would still be tolerated without ear protectors. Assuming a 20-

or even a 40-dB noise insulation of an applied protective equipment, the "border line" can be moved upwards by 20 or 40 dB with the consequence that any acoustic stress is allowed, provided that the intersection points of peak sound pressure levels and the exposure times remain below the limit line in the diagram being considered.

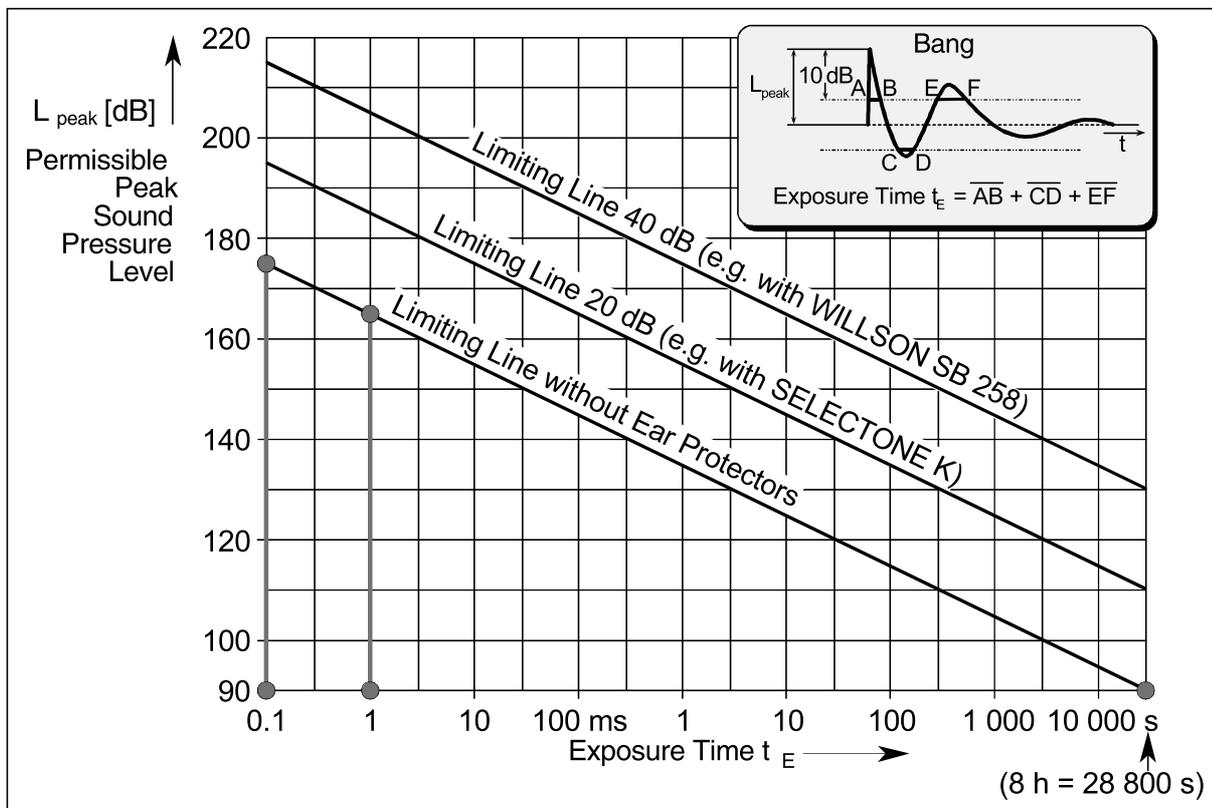
The following example will help to illustrate the conventional procedure of rating impulse noise. For details see Strasser (1990) and Strasser and Hesse (1993). When shooting live ammunition from a rifle, a peak level of ~160 dB during an exposure time of ~1 ms can be measured. Similar exposures can be found for policemen's target shooting or when using signal-cartridges or bolt setting guns in the building trade. According to the previous cut-off level diagram, without an ear protector, it can be calculated that two shots per day are the utmost to be allowed; three events would already be beyond the limit. In the case of a total exposure time of 2 ms from two impulse events, the measured peak level indeed leads to a peak-duration constellation (160 dB/2 _ 1 ms), which is just below the limit line. The use of practice ammunition with a peak level of ~140 dB, which is 20 dB less than when using live ammunition, should — from a purely mathematical point of view — allow ~100 times more noise events. That would correspond to ~200 shots per day. Since the exposure time is ~1.5 ms, "only" 186 tolerable impulse events per day have been calculated. Similarly, when using a subcalibre barrel with a peak level of 30 dB less than when using live ammunition, 1000 times more events (2000 events) would be allowable; the number of


Figure 8. Cut-off level diagram to avoid hearing impairment in case of bang noise. Valid for exposures per day with a following recovery of at least 8 h (Strasser 1990).

shots was finally reduced to 1250 because of the increased exposure time of 1.58 ms in this case.

5. EQUAL WORK OR ENERGY, A PRINCIPLE BEYOND ERGONOMICS LIMITS

But can these calculations, claiming a high level of exactness in the procedures of traditional occupational health and safety, really guarantee a safe degree of hearing protection? The answer is no, because they are based solely on the principle of equal energy, and this is a principle beyond ergonomics limits. Traditional cut-off level diagrams as well as the determination of the rating level can only represent an aid for the evaluation of the sound energy acting on man. But when stress is quantified only with regard to physical aspects, man and his physiological characteristics are principally not included in the approach of the assessment. The calculation of the total stress by a multiplication of intensity and duration indeed is a common procedure for the assessment of other kinds of the physical environment, too. However, if man is involved in work, which is, of course, unalterable in ergonomics, plausible limiting conditions may never be neglected in the domain of stress. This may be visualized in a simple, well-known example.

A performed output (physical work) can be calculated by the height and duration of work, e.g. the performance in Watts on a bicycle ergometer. However, this is only reasonable within physiological limits of the endurance level. A male worker may be able to perform about 50 Watts for extended periods of time. For instance, the product from 50 watts and 60 min working time (e.g. $B_3 = H_3 \_ T_3$ as seen in the front part of Figure 9) is identical to the work resulting from 100 W and a working time of 30 min or also 200 W performed for 15 min (analogous to $B_1 = H_1 \_ T_1$). Yet, can the strategy of mutual compensation be continued arbitrarily ad libitum? The answer must be no. At least in the limiting ranges, human nature does not play along. Nobody will comply with a demand of 500 W for 6 min or 1000 W for 3 min. The principle of equal work, i.e. the mutual compensation of intensity and time, cannot meet physiological laws.

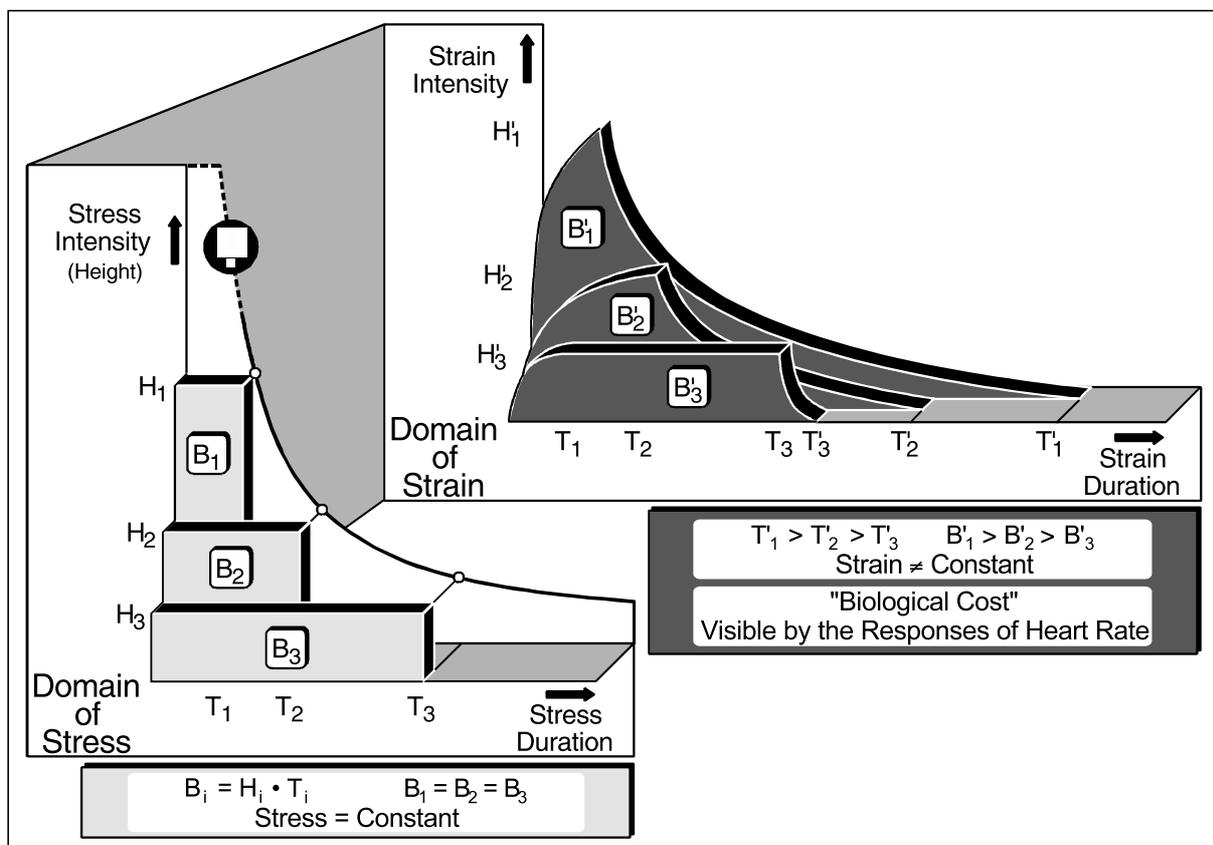
This can be shown via the general responses of the heart rate to the above-described workload constellations, which are identical with respect to the demanded output (upper part of Figure 9). The well-known course of a work-related increase of the heart rate during and after a physical workload representing the physiological costs which have to be paid for physical work by the organism in the domain of strain clearly shows that the "steady-state" during work is lost when exceeding the endurance level. Furthermore, the time after work needed for recovery processes increases over-proportionally. This well-known fact in ergonomics makes it necessary to allocate strain-based measures of recovery time. But, finally, overload cannot always be compensated by rest pauses and restitution periods. For physiological reasons, occupational situations must not occur which, e.g. result in critical heart rates of about 180 beats/min, even if this occurs for only a short time. In this case, the mutual settlement of high workload and short duration must reach an upper limit. But it is exactly this procedure — a procedure which is based solely on physics rather than ergonomics — which is practiced when applying the equal energy


Figure 9. Equal dynamic work, i.e. product of stress intensity and duration (lower frontal part) resulting in varying "biological cost," i.e. work-related increases of heart rate during and after stress (upper part behind).

principle, i.e. the 3-dB exchange rate, to assess short duration continuous and impulse noise.

6. RISKS IN OCCUPATIONAL SAFETY AND HEALTH BY THE APPLICATION OF THE EQUAL ENERGY HYPOTHESIS

Drawing inferences about all the reported theoretical considerations on the one hand (which are presented by Strasser 1995 in much more detail), and regarding the results of several experimental investigations into the physiological costs of noise on the other hand (Irle *et al.* 2000), it should become evident that real risks exist in occupational safety and health rules which are based on the equal energy hypothesis or the principle of equal work. Critical workload areas exist not only in the case of cardiovascular system loading or in the case of hearing; they also exist for most organs and senses. The following examples illustrate that the mutual balancing of the intensity and duration of stimuli is always a questionable procedure:

- Should not local burning be expected when skin temperature is increased, even if it is increased for only a very short period of time? The local increase in temperature resulting from touching the hot-plate of a cooking stove cannot be converted into a cozy warmth over the whole organism at that very moment.
- We should remember that a glaring light beam is always irritating, whereas a balanced optical environment in terms of luminance and illumination enhances visual perception.
- Is not the prick of a needle, e.g. into a finger, always one and only one singular event of a mechanical irritation that causes pain? This cannot be converted into the caressing of this very point over a longer period.

The above-mentioned rhetorical questions also raise the inevitable issue whether our sensory organ "ear" may represent an exception in the case of noise. Can the ear actually be expected to tolerate 160 dB for 1 ms or 100 noise events of 140 dB/1 ms in the same way as it tolerates continuous noise of 85 dB for 8 h, which is what the principle of equal energy suggests? When considering the density of energy acting on the ear, impulse noise simply cannot be compared with continuous noise. Equalizing 160 dB/1 ms or 1000 noise impulses with a level of 130 dB and a duration of 1 ms, each, with, e.g. 85 dB for 8 h according to the 3-dB exchange rate is in accordance with energy equivalence. However, this does not mean that the term 'dose' as a datum level is in fact acceptable in this case. During continuous noise, the sound energy acting on the ear is distributed over the 28 800 s of an 8-h working day. However, in the case of impulse noise, the total sound energy is forced on the human sensory organ in extremely high doses within a fraction of a second. Just as a drug which in a small dosage over a longer period can induce healing and one single "overdose" of that drug can be lethal, the impacts of impulse and continuous noise simply are not identical. An impulse noise event is comparable, for example, with a hurricane in the inner ear which can hardly pass the carpet of hair cells without any adverse effect, just as a short-time gust blowing over a cornfield or being caught in a sail cannot have the same effect as a light wind over a longer period of time.

7. CONCLUSIONS

In the context of the energy equivalence principle in rating the

physical environment (e.g. Martin 1976), one must not forget a mechanical analogue where deformations of materials are the intended aim of an energy concentration. Fast, energetic manufacturing operations, such as, e.g. beating, bumping, or punching, are the essential presuppositions for deformations of materials. Therefore, it is only a stringent consequence that short but intensive events of environmental stress must involve a greater potentiality of health hazards for man. Therefore, the validity of acceptable equivalences of environmental stress to guarantee health protection must be called into question. There should be no doubts that the effect of a dose which is dispensed within two different time intervals is more striking within the shorter one. Also, unquestionably, in the case of increasing density of energy or concentrations of harmful agents, the exceeding of physiological barriers with simultaneous intensifications of the effects becomes much more probable. This is especially true when the organism does not possess effective potentialities of temporal and/or spatial buffers. Therefore, the well-known endeavor for simplification and standardization which drives attempts to squeeze the rating of complex environmental situations into simple models or integrated measures as is done, e.g. also for ultraviolet radiation, mechanical vibrations, and carbon monoxide, cannot be adopted by ergonomics. Via this procedure, multidimensional connections get lost. In this context, a simple but slightly meditative comparison may be convincing for skeptics: The leveling of short lasting high intensity stress, based on physical rudiments, indeed seems to be as trustworthy as the statement that nobody can drown in a river with a statistical average depth of 50 cm.

Occupational Stress Mechanisms

B.M. Gwóźdz

Institute of Physiology, Silesian Medical University, 41-808 Zabrze, Poland

1. INTRODUCTION

The concept of stress has more than one interpretation (Hincle 1979). In physiology, stress means physical or mental tension when the organism is threatened or challenged. Stress is evoked by a variety of physical factors, extremely potent or damaging (injury), and psychological factors which pose a threat to a person's life situation (fear, anxiety, feeling of guilt) (Margolis *et al.* 1974).

There are many factors in the workstation that may provoke non-specific response of the organism involving hyperactivity of the central and peripheral nervous system with a subsequent increase in endocrine function. In this way, excitation causes changes in the organism's internal environment and disturbances in homeostasis.

Homeostasis is the ability to maintain a stable internal environment (plasma and interstitial fluid). Disrupted homeostasis is responsible for decreased work performance and efficiency, and has a negative effect on a person's well-being and state of health. Prolonged lack of homeostasis results in illness (Chrousos and Gold 1992).

2. STRESSORS

Factors which induce stress are known as stressors. There are different categories of stressors associated with occupational stress. Physical stressors include: cold, heat, noise, radiation, sounds and ultrasounds of high intensity, vibrations, mechanical injury, high and low barometric pressure, chemicals, toxins, air pollution, hypoxia and high-force exercise.

Social stressors related to an individual's interaction with the environment are, among others: poor workplace conditions, interpersonal relation problems, relations of domination and subordination, conflicts, loss of somebody or something significant (a person, job, home, money), retirement, loneliness, crowding, high responsibility, as well as unexpected success at work or substantial financial gain.

Psychological stressors form a significant group of job stressors. They are responsible for excitation of the central nervous system under real or imaginary threat accompanied by strong emotional states such as: anxiety, frustration, feeling of guilt, anger, hate, worry, love, and envy. Emotional excitation results in hyperactivity of the sympathetic nervous system and an increase in heart rate, arterial blood pressure, sweating, peristalsis, and metabolic rate.

Powerful job-related psychological stressors also include: inability to fulfill one's ambitions, lack of promotion, low self-esteem, lack of self-confidence, making mistakes, poorly defined role, ambiguous goals, work overload, time pressure, decision-making or exclusion from the process.

One of the most potent occupational stressors is differentiation, i.e. decision-making, particularly in unfavorable circumstances or when the nervous system is overloaded with signals from the rapidly changing work environment. This usually results in prolonged reaction time, which is of crucial importance in some jobs. In the complicated world of signals, the individual is faced with difficult choices, being at the same time aware of the unpleasant consequences of wrong decisions. This stress state is biologically threatening, especially when long-lasting and causing discomfort and neurosis. Therefore, differentiation requires some time and the individual acting under time pressure is at a higher risk of stress-related health problems.

3. STRESS EFFECTS

In the work place, numerous stressors may act simultaneously causing a more intense response which involves nearly all functional systems, i.e. the sensorimotor, vegetative, and endocrine systems. Excitation of the central nervous system leads to an increase in skeletal muscle tone and blood flow in the muscles, while the cardiovascular system responds with elevated stroke volume and cardiac output. The metabolic rate is enhanced to mobilize energy reserve. In response to a stimulus defined as energy unit of high intensity, the central nervous system becomes activated, which results in stimulation of the hypothalamic–pituitary–adrenal axis (Ganong *et al.* 1987) and, in consequence, elevated levels of stress hormones as well as hormones like adrenocorticotropic hormone (ACTH), glucocorticoids, epinephrine, norepinephrine, dopamine, endorphins and enkephalins. In such a state the organism is on the alert for fighting. When the energy reserve is utilized, e.g. during exercise, it is beneficial for the organism, but in sedentary jobs, the increased activity of many organs, including the heart and blood vessels, means unnecessary load for the organism.

In prolonged states of alertness, the system involved becomes exhausted and more susceptible to illness. In the majority of events, and regardless of the type stressor, the response is always manifested in hyperactivity of the functional organs, resulting in overloading of the organism and increased physiological cost.

However different the stressors, their mode of action is similar. Stress at work is evoked by excessive reaction to a stimulus. Therefore, not every factor related to the work process fulfills the stressor criteria. Assessment of stress threat also depends on the outside observer's negative emotions.

Over-excitation of the nervous system and the resulting motor and vegetative responses usually hinder the individual's adjustment to changes in the work environment. Conditioned reflexes are the most commonly inhibited responses in stress, both through external and internal inhibition.

Seemingly simple job tasks require integration of incoming information in the central nervous system as well as formation of action program. In many stress situations, this is not easy, particularly when the individual has to cope with a lot of information in a short time. In such cases, stress becomes more intense and work performance decreases.

4. PHYSIOLOGICAL EFFECTS

Excitation of the nervous system in stress contributes to an increase in skeletal muscle tone. The level of muscle tone regulation changes, manifesting itself in uncontrolled and usually uncomfortable position of the body and, in consequence, leading to central nervous system overload.

Increased stress-induced attention is accompanied not only by elevated skeletal muscle tone but also by higher heart rate

and intense sweating; this results in reduced work efficiency despite the individual's efforts.

Physiological changes accompanying the control processes of the central nervous system in individuals exposed to occupational stress are used to assess the overloading of organs or the nervous system, e.g. heart rate, arterial blood pressure, and the effect of the sympathetic system on heart rate. In stress, reduced work efficiency, ill-being, and health problems depend on a person's individual characteristics and the degree of reaction to factors associated with work itself and its environment. The same stressor may provoke a completely different response in individuals of the same or opposite sex. In some, it will cause stress, while others may experience pleasurable emotions. Prolonged acute stress may result in various diseases when the regulatory mechanisms become inefficient.

5. ADAPTIVE MECHANISM

In response to the same stimulus, some individuals may develop adaptive mechanisms of regulating homeostasis at a different level. The mechanism of response to stress involves the nervous and endocrine systems as well as the immune system. The latter largely determines the activity of cellular immune mechanisms (Dorian and Garfinkal 1987). During stress, the immune response is inhibited, while on cessation of stress the immune system is stimulated, unless the stress has been long term and intense. The response is possible due to the action of glucocorticosteroids, epinephrine, and norepinephrine which are released in stress and usually inhibit cellular immunity. Stimulation of cellular immunity in the post-stress period is a manifestation of the organism's adaptation and mobilization of immune defense forces under threat. Activation of the nervous, hormonal, and immune systems clearly differs and is related to the individual's age.

6. STRESS RESPONSE

Response to occupational stress largely depends on individual tolerance, i.e. a characteristic reaction to a given situation. Response to stress, irrespective of its health effects in individual cases, is particularly important in group work characterized by differences in individual work performance. The relationship between the efficiency of the best and the worst performers is 2:1, regardless of the tools, equipment, technology used.

Work performance and efficiency are biologically determined. In group work, the overall results depend on the performance of the individual most susceptible to stress. If it is impossible to exclude this individual from the group, the sources of occupational stress should be eliminated through ergonomic, technological, and organizational improvements to compensate for the individual's biological defects. It is essential, therefore, to eliminate the recognized stressors.

1. INTRODUCTION

Work content refers to those activities that constitute the nature of the job composition. The work context, the setting (i.e. physical, organizational, social, and individual growth) in which the work activities take place, and the work content characterize the spectrum of the work demands input to the worker. Work content can be subdivided into physical and mental demands components. The physical demands component describes the set of activities that require dynamic body movement and static exertion to maintain a given posture. The mental demands component describe the set of activities executed by the brain's perceptual and cognitive processes. Assessment of physical work is an essential component of the health and safety programs as well as job redesign and work improvement efforts. However, while overwhelmingly regarded as essential, detailed general purpose tools for the assessment of the entire spectrum of industrial physical demands do not exist.

2. PHYSICAL DEMANDS AND EVALUATION METHODS

Physical demands and evaluation methods can be categorized into three major classes: (1) mathematical models (i.e. statistical, empirical, biomechanical, fuzzy set); (2) tabular data; (3) rating methods (see Karwowski and Marras 1999).

2.1 Statistical Models

Statistical models use experimental data to formulate numerical models. Work factors and their interactions in these models are subject to conformance to certain statistical criteria such as the maximum value of multiple-squared correlation (i.e. R^2). Genaidy *et al.* (1988) provided a review of psychophysically based regression models that can be used in predicting human capacity for object handling work. On the basis of this kind of psychophysically based regression models, situations can be evaluated where the human object handling capacity is exceeded. Genaidy and Asfour (1987) reviewed physiological cost-based regression models for object handling work. These models predict the oxygen consumption and/or heart rate values associated with the handling of objects. The obtained values are then compared to physiological tolerance limits (Asfour *et al.* 1988). If these limits are exceeded, the job or task at hand will be a candidate for redesign. Recently, Marras *et al.* (1993, 1995) developed logistic regression models to predict the risk of lower back injuries as a function of trunk motion (e.g. average twisting velocity, maximum lateral velocity) and task variables (e.g. weight of load, frequency)

from lifting tasks. Trunk motion factors were measured using the Lumbar Motion Monitor (Marras *et al.* 1992).

2.2 Empirical Models

Empirical models postulate a certain form for equations and then fit data to them. They are used to predict worker capacity under various conditions. Examples of empirical models are the work of the US National Institute of Occupational Safety and Health (NIOSH 1981; Waters *et al.* 1993), Hidalgo *et al.* (1997), Shoaf *et al.* (1997), Karwowski and Marras (1997), and Karwowski *et al.* (1998). These equations were patterned after the Drury and Pfeil (1975) model which is multiplicative in nature (i.e. interactive work factors). It assumes that there is a maximum load to be handled under ideal conditions. When one deviates from the ideal conditions, discounting multipliers are applied to reduce the amount of load handled.

2.3 Biomechanical Models

In static and dynamic biomechanical models, the human body is treated as a mechanical system made up of various links. Forces and torques imposed upon various joints are estimated using biomechanical models, then compared with tolerance limits of the workforce (Genaidy *et al.* 1993). The job is considered hazardous if the imposed forces and torques exceed the specified biomechanical tolerance limit of either an individual or an agreed percentage of the working population. As an example, a simple static model was devised by Tichauer (1978) on the basis of the following prerequisite for biomechanical work tolerance: "minimize the moments acting upon the vertebral column". The model was expressed mathematically as: $M_E = \{[8 + (1/2) * L] * W\}$ where: (1) 8 is the approximate distance (in inches) from the joints of the lumbar spine to the front of the abdomen — a constant for each individual according to Tichauer; (2) L is the length (in inches) of one side of the object; (3) W is the weight (in pounds) of the object; (4) M_E is the biomechanical lifting equivalent (lb-in). If the moments around the lower back are 350 lb-in or less, the work is considered "light" and can be performed with ease by untrained individuals, either males or females, regardless of body build. Between 350 and 750 lb-in, the work can be classified as "medium-heavy" and requires good body structure as well as some training. Tasks resulting in moments between 750 and 1200 lb-in are considered "heavy", requiring selective recruiting of employees and attention to rest pauses. The work is considered "very heavy" when 1,200 lb-in is exceeded. Very heavy work cannot be performed on a continuous basis and requires great care in worker recruitment and training. A more thorough discussion of biomechanical models can be found in Chaffin and Andersson (1991).

2.4 Fuzzy Set Models

Karwowski *et al.* (1986) presented a detailed fuzzy set methodology to analyze lifting activities. According to this methodology, each variable was defined numerically and qualitatively. Distribution functions were then established to determine the degree of certainty with which the numerical variable belongs to the qualitative variable. For example, our certainty that a 50 lb load belongs to the class "moderate heavy" load is 0.8. Rules in an ''IF THEN'' format (*e.g. If A is low and B is high THEN C is moderate*) were then established on the basis of

approximate reasoning. The method developed by Karwowski *et al.* (1986) is an appropriate methodology which can be extended to analyze complex physical demands in industry. Such an approach allows the involvement of both users and engineers in the analysis of muscular work. On the one hand, users are usually the most knowledgeable about the work tasks in question. Although they are not formally trained in detailed quantitative methods as engineers, their knowledge will allow the quick analysis of work tasks through the use of linguistic descriptions (*e.g.* load is heavy). On the other hand, engineers, by virtue of their training, can transform these linguistic descriptions into numerical scores which can be used later for evaluation and design/redesign purposes.

2.5 Tabular Data

Several ergonomic databases have been detailed in the form of tables. Snook and Ciriello (1991) published detailed tables on the manual handling capacity of individuals for lifting, lowering, pushing, pulling, and carrying activities. Physiological outcome measures such as energy expenditure or oxygen consumption and heart rate have been summarized for various types of tasks, mostly object handling work (e.g. Asfour *et al.* 1986a, 1986b). Astrand and Rodahl (1986) reported that Passmore and Durnin (1955) published tables of daily energy expenditures for various types of activities. On the basis of their experience and review of prior findings, Astrand and Rodahl classified work into five categories on the basis of physiological responses:

(1) In terms of oxygen consumption (i.e. indirect measure of energy expenditure): light work (up to 0.5 liter/min), moderate work (0.5–1.0 liter/min), heavy work (1.0–1.5 liters/min), very heavy (1.5–2.0 liters/min), extremely heavy work (over 2.0 liters/min); and

(2) In terms of heart rate: light work (up to 90 beats/min), moderate work (90–110 beats/min), heavy work (110–130 beats/min), very heavy work (130—150 beats/min), and extremely heavy work (150–170 beats/min).

Webb Associates (1978a, 1978b) published extensive tables on anthropometric measures. These tables included body size and range of motion data for various percentages of the population. These measures were mostly obtained for military personnel and were primarily used for equipment design.

2.6 Rating Methods

Rating methods have ranged from being relatively simple to very complex. The checklist approach represents the simplest methods of evaluating muscular demands. Traditionally, this approach consists of a number of questions in which the answers are binary, i.e. "yes" or "no" answers. Similar to mathematical models (i.e. statistical, empirical, biomechanical), this approach has focused on analyzing selected individual activities. An example is the work of Lifshitz and Armstrong (1986) for evaluating repetitive upper extremity activities. Their checklist consisted of twenty questions requiring yes or no answers. They found good agreement between the evaluation scores obtained from the checklist and injury statistics. Another example is the PLIBEL checklist developed by the Swedish National Institute of Occupational Health (Kemmlert 1995). The checklist consisted of seventeen yes or no questions and was intended for general purpose use.

More elaborate rating methods attempted to analyze various physical activities. Examples are the "AET" (Rohmert and Landau, 1983) and "Job Profile" (Wagner 1985). These are among the most detailed rating methods found in the published literature. The AET method was designed to analyze any type of industrial activity and has been used extensively in Germany. The H-AET was added as a supplement to AET to enhance its level of details. The Job Profile method, on the other hand, was used to evaluate short-cycle activities at Renault plants in France. In contrast to the design of simple checklists, detailed rating methods included more work factor detail and assigned more than two values to each rated work factor. Some methods had more detail than others.

Many efforts, particularly European research, focused on the assessment of postural loading in industry. The Job Profile system, for example, provided a detailed account of postural loading (Wagner 1985). In general, each posture was ranked in terms of difficulty and its intensity was assessed using the time spent in a particular static posture. The RULA was recently devised as a method to analyze: the postures of the upper extremity joints (i.e. hand, lower arm, and upper arm), neck and trunk; the load on the musculoskeletal system caused by excessive static muscle work; repetitive motions; and the requirement to exert force or maintain an external load (McAtamney and Corlett 1993). The main advantage of the RULA system is its practicality for work posture analysis. A comprehensive review on assessment of postural loading in industry can be found in Genaidy *et al.* (1994).

3. CLASSIFICATION SYSTEM FOR PHYSICAL DEMANDS

To support assessment of physical work demands in industry, all activities must be classified and evaluated. A classification and evaluation systems are based on the physiological and epidemiological concepts.

3.1 Physiological Concepts

3.1.1 Dynamic and static work

Muscular work consists of combinations of dynamic and static contractions and releases. Dynamic work is characterized by a rhythmic alternation of contraction and extension, tension and relaxation (Grandjean 1988). Static work, on the other hand, consists of a prolonged state of muscular contraction lasting longer than four seconds (Rohmert and Landau 1983). Both dynamic and static components of muscular work must be analyzed to account for physical requirements.

3.1.2 Human limits: strength, endurance, and range of motion

In the study of muscular work, the following limits must be observed (Genaidy 1996):

- Endurance is a major requirement for continuous work. Repetition and work duration are important factors in the evaluation of continuous work.
- Strength governs the ability to perform infrequent work. Here, the maximum load handled or force exerted is one of the important factors.
- Range of motion and constrained postures resulting in prolonged static effort are determinants of static postural load. The angular deviation of a body part from neutral positions is an indicator of static postural load. The larger

the angular deviation, the higher the static postural load. The range of motion is the maximum angular deviation.

3.2 Epidemiological Concepts

Many studies have documented that overloading the musculoskeletal system at work can result in injuries. Statistics reported by the US Association of Schools of Public Health (1986) indicated that musculo-skeletal injuries are the leading cause of disability of people in their working years and rank first among health problems in the frequency with which they affect the quality of life. Moreover, the cost of musculo-skeletal injuries based on lost earnings and worker compensation exceed that of any other health disorder and they account for one-third of annual worker compensation claims. In general, musculo-skeletal injuries arise due to three primary activities: object handling, repetitive extremity, and prolonged static postural loading.

3.2.1 Object handling injuries

It is well established that manual handling of objects is the largest single subset of musculo-skeletal disorders — particularly the lower back disorders (CDC 1983). In 1993, back disorders accounted for 27% of all non-fatal occupational injuries and illnesses in the United States (NIOSH 1996). Estimates of the total cost of lower back pain to society in 1990 were between $50 billion and $100 billion per year with a significant share borne by the worker compensation system (NIOSH 1996). Troup and Edwards (1985) reported that, in the United Kingdom, object handling accidents were responsible for between 20% and 30% of all industrial accidents in the time period 1930–1977. According to the 1979 statistics, lifting, carrying, and throwing activities were responsible for almost 67% of all over-exertion injuries. An additional 19% resulted from pushing and pulling. The statistics associated with object handling has triggered extensive research over the past several decades. Lifting activities have been studied in depth because they have been reported as one of the principal causes of lower back disorders (e.g. NIOSH 1981; Chaffin and Andersson 1991; Snook 1978; Liles *et al.* 1984; Marras *et al.* 1993, 1995; Ayoub *et al.* 1997).

3.2.2 Repetitive extremity injuries

Although not an entirely new problem, repetitive extremity work, particularly in seated or standing positions, has emerged as a major cause of cumulative trauma disorders (CTD) or repetitive strain injury (RSI) in the past two decades. The magnitude of the problem has been documented by many researchers (e.g. Armstrong *et al.* 1986; Hagberg 1984; Ayoub and Wittels 1989; Burnette and Ayoub 1989; Wallace and Buckle 1987; Kilbom 1988, 1994; Karwowski and Marras 1999). More than $2.1 billion in worker compensation costs and $90 million in indirect costs are incurred annually for upper extremity cumulative trauma disorders (UECTD) (NIOSH 1996). The most frequently reported UECTD affect the wrist/hand region, with carpal tunnel syndrome (CTS) or entrapment median neuropathy occurring at a rate of 5.2 per 10 000 full-time workers.

3.2.3 Prolonged static postural problems

Prolonged static postures have also been linked to work-related musculo-skeletal disorders and productivity losses in the workplace. Punnett *et al.* (1987) and Fine *et al.* (1987) reported strong correlation between the angular deviation of non-neutral shoulder and back postures, and musculo-skeletal disorders. Ryan (1989) found that for standing postures employed in grocery stores, lower back and extremity problems started when the percentages of standing times were 25% and 45—50% of the shift duration, respectively.

On the basis of experience gained from several field studies and his own observation, Grandjean (1988) reported that static loads are associated with a higher risk of arthritis of the joints due to mechanical stress, inflammation of the tendon sheaths, symptoms of arthrosis, and intervertebral disc troubles. He argued that, according to van Wely (1970), persistent musculo-skeletal problems are commonly observed among operators who work all year around at the same machine where the manual controls are either too high or too low.

4. CLASSIFICATION OF PHYSICAL DEMANDS

4.1 Classification Description

Any physical activity can be described in terms of two general classes of muscular work: object handling and extremity postural. A general description of these classes of muscular work is given below.

4.1.1 Object handling classification

Object handling (OH) is an overall body activity which consists of moving objects with one or both hands and involves the use of upper and lower extremities including some action of the trunk. In this study, OH is defined for handling activities performed during standing (i.e. lifting and lowering, pushing and pulling) and walking (i.e. carrying, pushing, and pulling) positions. A typical example is loading and unloading trucks. Handling activities performed in positions other than standing and walking are analyzed under the extremity postural demand classification. An example of such activities is the moving of small parts while the body is in a seated position.

Traditionally, OH has been investigated using three approaches: (1) biomechanical criteria were used to examine non-repetitive (Chaffin and Park 1973; Chaffin *et al.* 1978; Keyserling *et al.* 1980) and repetitive (Marras *et al.* 1993, 1995); (2) physiological approaches were utilized for repetitive activities (Genaidy and Asfour 1989; Genaidy *et al.* 1990; Asfour *et al.* 1991a, 1991b); (3) psychophysical criteria were employed for both repetitive and non-repetitive activities (Snook 1978; Snook and Ciriello 1991; Ayoub *et al.* 1978, 1983, 1997; Liles *et al.* 1984; Mital 1984). Very recently, Karwowski *et al.* (1998) proposed a cognitive engineering approach to setting limits in manual handling tasks.

Karwowski (1983) and Karwowski and Ayoub (1984) demonstrated that psychophysical criteria integrate the acceptability of both biomechanical and physiological approaches for lifting activities. Recently, Hidalgo *et al.* (1997) and Shoaf *et al.* (1997) developed a comprehensive OHW capacity limits which take into account the acceptability of the aforementioned criteria.

Object handling is classified into lifting, lowering, carrying, pushing, pulling, and other types of activities. During lifting and lowering activities, a work object is moved vertically from a lower or a higher level to a higher or lower level. A carrying activity involves holding a load while the person is walking, climbing

stairs, climbing ladders/ramps, or crawling. A pushing or pulling activity involves pushing or pulling a work object either on flat surfaces and ramps (e.g. pushing hand carts) *or* on a work table (including conveyors). The other activity category includes other types of object handling work such as throwing bags and shoveling. For lifting and lowering, the weight of load, height of lift or lower, horizontal distance in front of the body, twisting angle, frequency and work duration are the essential set of variables to determine the physical demands (Waters *et al.* 1993; Hidalgo *et al.* 1997). For carrying, the weight of load, frequency, work duration, travel distance and dynamic posture are the relevant variables (Shoaf *et al.* 1997). For pushing or pulling, force, frequency, work duration, and travel distance are the necessary variables for analysis (ibid.).

4.1.2 Extremity postural classification

Extremity postural work deals with repetitive work in a fixed or dynamic lower body position (e.g. seated, walking) as well as prolonged static postural loading. Many of the variables affecting extremity-postural work have been documented by many researchers (e.g. Armstrong *et al.* 1986; Karwowski and Marras 1997; Hagberg 1984; Ayoub and Wittels 1989; Burnette and Ayoub 1989; Wallace and Buckle 1987; Genaidy *et al.* 1994).

The following fixed and dynamic lower body positions are defined in extremity postural work: (1) seated; (2) standing; (3) kneeling; (4) squatting; (5) one-legged; (6) crouching; (7) reclining; (8) walking; (9) climbing stairs; (10) climbing ladders/ramps; (11) crawling; (12) other postures. For each of these lower body positions, extremity postural work consists of repetitive extremity/head and static postural work.

Dynamic work, which describes the repetitive extremity/head work, can be classified according to the following categories:

- finger work — hand, lower and upper arms maintained in a fixed position (e.g. typing)
- hand work (including palm and fingers) around the wrist — lower and upper arms maintained in a fixed position (e.g. hand tool usage)
- lower arm work (including hand and fingers) around the elbow — upper arm maintained in a fixed position (e.g. hammering with the lower arm only)
- whole arm work around the shoulder (including the hand) — whole arm movement (e.g. hammering with the whole arm)
- head work around the neck — (e.g. driving a car)
- work around the hip or knee — (e.g. operating a floor pedal with the whole leg)
- foot work around the ankle — leg maintained in a fixed position (e.g. operating a floor pedal with the foot only)
- other repetitive work — (e.g. knee movement during carpet laying)

Static work involves two subclasses:

- continuous force exertion using the fingers, hands (assisted or unassisted by the arms), knees, feet (assisted or unassisted by the legs)
- static postural work of the hand, lower arm, upper arm, head *or* back

The frequency, force, travel distance, and work duration are the most important factors which affect repetitive extremity and head work (e.g. Drury and Wick 1984; Armstrong *et al.* 1986;

Silverstein *et al*, 1986; Tanaka and McGlothlin 1989; Burnette and Ayoub 1989; Snook *et al.* 1995). The above postural classification is based, to a large extent, on a recent review conducted by Genaidy *et al.* (1994) with some modifications.

4.2 Mathematical Models

The physical demand classification allows the hierarchical evaluation of muscular work at different levels where higher level demands (e.g. object handling) can be obtained as a function of lower level demands (e.g. lifting, lowering, carrying, pushing, pulling, other activity).

As pointed out before, work demands must be analyzed for strength and endurance requirements. Work factors for strength-related activities can be assessed in terms of the maximum load handled or force exerted with the corresponding work variables (excluding repetition and duration). Nevertheless, all work factors are included in the analysis of endurance-related activities.

The mathematical formulation of each variable in every layer of the hierarchical structure is presented below:

4.2.1 Overall physical demands

$$PD = f_1 (OHD, EPD) \tag{1}$$

where:
PD — overall physical demands
OHD — object handling demands
EPD — extremity postural demands

4.2.2 Object handling demands

$$OHD = f_2 (LID, LOD, CAD, PUD, PLD, OOHD) \tag{2}$$
$$LID = f_3 (WL, HD, F, WD, HD, TA) \tag{3}$$
$$LOD = f_4 (WL, HD, F, WD, HD, TA) \tag{4}$$
$$CAD = f_5 (WL, TD, F, WD, DP) \tag{5}$$
$$PUD = f_6 (WL, TD, F, WD) \tag{6}$$
$$PPD = f_7 (WL, TD, F, WD) \tag{7}$$
$$OOHD = f_8 (WL, TD, F, WD) \tag{8}$$

where:
LID — lifting demands
LOD — lowering demands
CAD — carrying demands
PUD — pushing demands
PLD — pulling demands
OOHD — other object handling demands
WL — weight of load or force
HD — horizontal distance in front of the body
F — frequency
WD — work duration
H — height of lift and lower
TA — twisting angle
TD — travel distance
DP — dynamic posture.

4.2.3 Extremity postural demands

$$EPD= f_9 (SED, STD, KD, SQD, OLD, CRD, RED,$$
$$WAD, CSD, CLD, CRD, OEPD) \tag{9}$$
$$AEPD = f_{10} (DD, SD) \tag{10}$$
$$DYD = f_{11} (FIMD, HMD, LAMD, WAMD, HEMD,$$
$$LMD, FOMD, OMD) \tag{11}$$

$$AMD = f_{12}(F, WL, WD) \tag{12}$$
$$HEMD = f_{13}(WD) \tag{13}$$
$$SD = f_{14}(CFED, SPD) \tag{14}$$
$$CFED = f_{15}(SFFD, SHAFD, SHUFD, SKFD, SFAFD, SFUFD) \tag{15}$$
$$ACFED = f_{16}(SF, WD) \tag{16}$$
$$SBPPD = f_{17}(SHD, SLAD, SWAD, SHED, SBD) \tag{17}$$
$$ASBPPD = f_{18}(WD) \tag{18}$$

where:

EPD — overall extremity postural demands;
SED — seated demands;
STD — standing demands;
KD — kneeling demands;
SQD — squatting demands;
OLD — one legged demands;
CRD — crouching demands;
RED — reclining demands;
WAD — walking demands;
CSD — climbing stairs demands;
CLD — climbing ladders and ramps demands;
CRD — crawling demands;
OEPD — other extremity postural demands;
AEPD — any extremity postural work demands such as seated (SED);
DD — dynamic demands;
SD — static demands;
FIMD — finger movement demands
HMD — hand movement demands
LAMD — lower arm movement demands

WAMD — whole arm movement demands
HEMD — head movement demands
LMD — leg movement demands
FOMD — foot movement demands
OMD — other movement demands
AMD — any movement demands such as finger demands (FIWD)
F — frequency
WL — force exerted during dynamic activities
WD — work duration
CFED — continuous force exertion demands
SFFD — static finger force demands
SHFAD — static hand force demands assisted by the arms
SHFUD — static hand force demands unassisted by the arms
SKFD — static knee force demands
SFFAD — static foot force demands assisted by the legs
SFFUD — static foot force demands unassisted by the legs
ACFED — any continuous force exerted demands such as static finger force demands (SFFD)
SF — static force exerted by the fingers, hands, knee, or feet
SBPPD — static body part postural demands
SHD — static hand postural demands
SLAD — static lower arm postural demands
SWAD — static whole arm postural demands
SHED — static head postural demands
SBD — static back postural demands
ASBPPD — any static body part postural demands such as static hand postural demands (SHD)

Table 1. Evaluation of infrequent object handling demands (i.e. evaluation of activities involving the maximum load or force exerted on an infrequent basis)

Lifting	weight of load	very light	light	moderate	heavy	very heavy			
	horizontal distance	very close	close	moderate	far	very far			
	height of lift	floor–knuckle		floor–shoulder		floor–reach	knuckle–shoulder	knuckle–reach	shoulder–reach
	twisting angle	very small	small	moderate	large	very large			
	lifting demands	very low	low	moderate	high	very high			
Lowering	weight of load	very light	light	moderate	heavy	very heavy			
	horizontal distance	very close	close	moderate	far	very far			
	height of lift	floor–knuckle		floor–shoulder		floor–reach	knuckle–shoulder	knuckle–reach	shoulder–reach
	twisting angle	very small	small	moderate	large	very large			
	lowering demands	very low	low	moderate	high	very high			
Carrying	weight of load	very light	light	moderate	heavy	very heavy			
	travel distance	very short	short	moderate	long	very long			
	dynamic posture	walking		climbing stairs/ladders	crawling				
	carrying demands	very low	low	moderate	high	very high			
Pushing	force	very light	light	moderate	heavy	very heavy			
	travel distance	very short	short	moderate	long	very long			
	pushing demands	very low	low	moderate	high	very h igh			
Pulling	force	very light	light	moderate	heavy	very heavy			
	travel distance	very short	short	moderate	long	very long			
	pulling demands	very low	low	moderate	high	very high			
Other	force	very low	low	moderate	high	very high			
	travel distance	very light	light	moderate	heavy	very heavy			
	other demands	very low	low	moderate	high	very high			
Object handling demands		very low	low	moderate	high	very high			

Table 2. Evaluation of frequent object handling demands (i.e. evaluation of activities involving the load handled or force exerted on a frequent basis)

Lifting	weight of load	very light	light	moderate	heavy	very heavy			
	horizontal distance	very close	close	moderate	far	very far			
	frequency	very low	low	moderate	high	very high			
	work duration	very short	short	moderate	long	very long			
	height of lift	floor–knuckle		floor–shoulder		floor–reach	knuckle–shoulder	knuckle–reach	shoulder–reach
	twisting angle	very small	small	moderate	large	very large			
	lifting demands	very low	low	moderate	high	very high			
Lowering	weight of load	very light	light	moderate	heavy	very heavy			
	horizontal distance	very close	close	moderate	far	very far			
	frequency	very low	low	moderate	high	very high			
	work duration	very short	short	moderate	long	very long			
	height of lift	floor–knuckle		floor–shoulder		floor–reach	knuckle–shoulder	knuckle–reach	shoulder–reach
	twisting angle	very small	small	moderate	large	very large			
	lowering demands	very low	low	moderate	high	very high			
Carrying	weight of load	very light	light	moderate	heavy	very heavy			
	travel distance	very short	short	moderate	long	very long			
	frequency	very low	low	moderate	high	very high			
	work duration	very short	short	moderate	long	very long			
	dynamic posture	walking		climbing stairs/ladders			crawling		
	carrying demands	very low	low	moderate	high	very high			
Pushing	force	very light	light	moderate	heavy	very heavy			
	frequency	very low	low	moderate	high	very high			
	work duration	very short	short	moderate	long	very long			
	travel distance	very short	short	moderate	long	very long			
	pushing demands	very low	low	moderate	high	very high			
Pulling	force	very light	light	moderate	heavy	very heavy			
	frequency	very low	low	moderate	high	very high			
	work duration	very short	short	moderate	long	very long			
	travel distance	very short	short	moderate	long	very long			
	pulling demands	very low	low	moderate	high	very high			
Other	force	very low	low	moderate	high	very high			
	frequency	very low	low	moderate	high	very high			
	work duration	very short	short	moderate	long	very long			
	travel distance	very light	light	moderate	heavy	very heavy			
	other demands	very low	low	moderate	high	very high			
Object handling demands		very low	low	moderate	high	very high			

5. THE LINGUISTIC CHECKLIST APPROACH

The simplest instrument that can be designed to implement the comprehensive physical demand evaluation is the linguistic checklist approach (Karwowski *et al.* 1999). Tables 1 through 6 illustrate the different forms which can used to evaluate the different activities classified under physical demands. The checklist approach employed here differs from traditional checklists in that variables and activity demands are evaluated using five levels rather than a binary (i.e. absent or present) indicator. An example of the linguistic descriptors used in the tables is: "very light", "light", "moderate", "heavy", and "very heavy". Based on experience with the work presented here, we found that three levels are not adequate to provide a linguistic description of the variables and activities evaluated in the workplace. Additionally, five levels and "does not apply" were used in the Position Analysis Questionnaire, a widely used job analysis instrument (McCormick *et al.* 1969).

Tables 1 and 2 are used to evaluate object handling activities for strength- and endurance-related requirements. In table 1, the assessment is on the evaluation of the variables associated with the maximum load handled or force exerted on the job. Frequency and work duration are considered negligible and are not part of Table 1. On the other hand, they are added to other variables in order to evaluate frequent activities or endurance-related requirements in table 2. Under these circumstances, the evaluation is performed with reference to the most common load handled or force exerted on the job during frequent activities.

The evaluation of extremity postural demands is performed for dynamic activities (Table 3), continuous static force exertion (Table 4), and static awkward postures (Tables 5 and 6). It should be noted that static postural loading is evaluated for the most common static posture (Table 5) and the most awkward posture (Table 6) for a given body part. Wagner (1985) reported the evaluation of the most common and awkward postures in the "Job Profile" work assessment instrument.

Because the physical demand model is designed for the evaluation of most muscular demands in industry, there is a need to assess the degree of importance of different activities in order to determine whether they should be included in the physical demand evaluation. Importance here refers to the "significance", "consequential", "critical", "momentous", and "value-added" aspects of work demands relative to job performance.

Table 3. Evaluation of dynamic extremity postural demands (specify body position_____)

Finger	not applicable	very low	low	moderate	high	very high	
	frequency		very low	low	moderate	high	very high
	force/weight of load		very light	light	moderate	heavy	very heavy
	travel distance		very short	short	moderate	long	very long
	work duration		very short	short	moderate	long	very long
	finger demands		very low	low	moderate	high	very high
Hand	not applicable	very low	low	moderate	high	very high	
	freuency		very low	low	moderate	high	very high
	force/weight of load		very light	light	moderate	heavy	very heavy
	travel distance		very short	short	moderate	long	very long
	work durtation		very short	short	moderate	long	very long
	hand demands		very low	low	moderate	high	very high
Lower arm	not applicable	very low	low	moderate	high	very high	
	frequency		very low	low	moderate	high	very high
	force/weight of load		very light	light	moderate	heavy	very heavy
	travel distance		very short	short	moderate	long	very long
	work duration		very short	short	moderate	long	very long
	lower arm demands		very low	low	moderate	high	very high
Whole arm	not applicable	very low	low	moderate	high	very high	
	frequency		very low	low	moderate	high	very high
	force/weight of load		very light	light	moderate	heavy	very heavy
	travel distance		very short	short	moderate	long	very long
	work duration		very short	short	moderate	long	very long
	whole arm demands		very low	low	moderate	high	very high
Head	not applicable	very low	low	moderate	high	very high	
	frequency		very low	low	moderate	high	very high
	force/weight of load		very light	light	moderate	heavy	very heavy
	travel distance		very short	short	moderate	long	very long
	work duration		very short	short	moderate	long	very long
	head demands		very low	low	moderate	high	very high
Leg	not applicable	very low	low	moderate	high	very high	
	frequency		very low	low	moderate	high	very high
	force/weight of load		very light	light	moderate	heavy	very heavy
	travel distance		very short	short	moderate	long	very long
	work duration		very short	short	moderate	long	very long
	leg demands		very low	low	moderate	high	very high
Foot	not applicable	very low	low	moderate	high	very high	
	frequency		very low	low	moderate	high	very high
	force/weight of load		very light	light	moderate	heavy	very heavy
	travel distance		very short	short	moderate	long	very long
	work duration		very short	short	moderate	long	very long
	foot demands		very low	low	moderate	high	very high
Other	not applicable	very low	low	moderate	high	very high	
	frequency		very low	low	moderate	high	very high
	force/weight of load		very light	light	moderate	heavy	very heavy
	travel distance		very short	short	moderate	long	very long
	work duration		very short	short	moderate	long	very long
	other demands		very low	low	moderate	high	very high
Demands of dynamic work	not applicable	very low	low	moderate	high	very high	

Table 4. Evaluation of continous force (i.e. lasting more than 4 sec) extremity postural demands (specify body position:_____)

Fingers	not applicable	very low	low	moderate	high	very high
	force	very light	light	moderate	heavy	very heavy
	work duration	very short	short	moderate	long	very long
	static finger force demands	very low	low	moderate	high	very high
Hand unassisted by arm	not applicable	very low	low	moderate	high	very high
	force	very light	light	moderate	heavy	very heavy
	work duration	very short	short	moderate	long	very long
	static hand force demands	very low	low	moderate	high	very high
Hand assisted by arm	not applicable	very low	low	moderate	high	very high
	force	very light	light	moderate	heavy	very heavy
	work duration	very short	short	moderate	long	very long
	static hand force demands	very low	low	moderate	high	very high
Knee	not applicable	very low	low	moderate	high	very high
	force	very light	light	moderate	heavy	very heavy
	work duration	very short	short	moderate	long	very long
	static knee force demands	very low	low	moderate	high	very high
Foot unassisted by leg	not applicable	very low	low	moderate	high	very high
	force	very light	light	moderate	heavy	very heavy
	work duration	very short	short	moderate	long	very long
	static foot force demands	very low	low	moderate	high	very high
Foot assisted by leg	not applicable	very low	low	moderate	high	very high
	force	very light	light	moderate	heavy	very heavy
	work duration	very short	short	moderate	long	very long
	static foot force demands	very low	low	moderate	high	very high
Other	not applicable	very low	low	moderate	high	very high
	force	very light	light	moderate	heavy	very heavy
	work duration	very short	short	moderate	long	very long
	static other force demands	very low	low	moderate	high	very high
Static continuous force demands		very low	low	moderate	high	very high

Table 5. Evaluation of the most common static postural demands for extremity postural work(specify body position:_____)

Back	posture	bent forward(BF)	bent backward(BB)	twisted(T)	side bent	combined BF & T	combined BB & T
	level of angular deviation	very small	small	moderate	large	very large	
	work duration	very short	short	moderate	long	very long

Psychophysical Risk Assessment in Manual Handling

P. G. Dempsey

Liberty Mutual Research Center for Safety & Health, 71 Frankland Road, Hopkinton, MA 01748, USA

1. INTRODUCTION

Psychophysics, biomechanics, and physiology represent the three primary approaches to the ergonomic design of manual handling tasks. All three approaches consider the acute responses of the human body. Physiology and biomechanics typically consider the responses of the cardiovascular and musculoskeletal systems, respectively. Psychophysics, on the other hand, considers the perceptions (or sensations) of humans in response to stimuli of different magnitudes (typically load weight or forces) while performing manual handling tasks.

The primary goals of psychophysical data are for design purposes and to assess manual handling tasks at the workplace. At the design stage, such data can be used for relative comparisons of alternative designs. Workplace assessments most often involve a determination of whether or not a particular task, or set of tasks, should be redesigned through alteration of task variables, workplace geometry, equipment, and work organization. This entry provides an overview of performing such assessments in conjunction with psychophysical data as risk assessments.

2. RISK ASSESSMENT

A clear definition is required to discuss risk assessment in the context of the psychophysical approach to manual handling. Risk assessment is comprised of several components. The National Research Council (1983) has defined these components as (a) hazard identification, (b) dose-response assessment, (c) exposure assessment, and (d) risk characterization.

Hazard identification involves determining whether the manual handling tasks performed at the workplace include risk factors for musculoskeletal disorders (particularly of the lower back), risk factors such as awkward postures and high forces or loads handled. This step of the assessment does not usually employ psychophysical data and can be accomplished through a variety of means, including checklists. In some cases, passive surveillance data may have indicated that musculoskeletal disorder hazards exist. Then the hazard identification is sometimes skipped and the analyst proceeds to a detailed assessment of exposure to manual handling tasks.

The dose-response assessment involves examining the results of previous epidemiological studies. The dose-response relationships provide an assessment of the expected value of the outcome of interest (e.g., lower back disorder incidence) for a given dose. Exposure is often used in place of dose, as most studies of musculoskeletal disorder risk examine exposure-response relationships. As will be discussed in the next section, the major barrier to performing risk assessments with psychophysical data is the lack of dose-response (or exposure-response) relationships.

Exposure assessment involves measuring the frequency, magnitude, and duration of exposure to manual handling. The approach using psychophysical data to assess exposure will be discussed in the next section.

The final step in the risk assessment is the risk characterization. By this stage, the exposure assessment has been completed. These results are then used in conjunction with the exposure-response relationships to characterize the risk potential.

3. PSYCHOPHYSICAL RISK ASSESSMENTS OF MANUAL HANDLING TASKS

Hazard identification is usually fairly straightforward for manual handling tasks. The observer will typically look for factors such as awkward trunk postures (bending, twisting), reaching while handling, the handling of heavy loads, or high force exertions required by pushing and pulling. To some extent, the method of hazard identification is independent of the manual handling approach. The analyst may choose to use a checklist or other available tools. At this stage, it is best to be conservative, and if a task or set of tasks appears to pose marginal risk, the analyst should choose to proceed with a more detailed analysis.

A critical aspect of risk assessments is the exposure-response relationship. Unfortunately, we have limited knowledge of exposure-response relationships when exposure is quantified with psychophysical data. The available literature will be briefly summarized.

The study by Snook *et al.* (1978) provided the first epidemiological investigation of the psychophysical approach. It used data on 191 compensable lower back cases. The jobs in which the injuries occurred were analyzed using psychophysical data (Snook 1978), and a determination was made regarding whether or not the manual handling tasks accommodated more or less than 75% of the population. Using this approach, Snook *et al.* (1978) concluded that workers were three times more likely to file a worker's compensation claim when the job accommodated less than 75% of the population than when the job accommodated more than 75% of the population.

The second relevant study had a very different design. Liles *et al.* (1984) did a field study to determine whether the job severity index (JSI) was predictive of future injury. JSI is a time- and frequency-weighted ratio of worker capacity to job demands. Worker capacity was predicted with the models developed by Ayoub *et al.* (1978), which predict individual psychophysical capacity from worker strength and anthropometry values. A total of 453 subjects was used. The results of the field study indicated that both incidence and severity of recordable lower back disorders rose rapidly at JSI values greater than 1.5. Liles *et al.* concluded that JSI is an effective screening method and job design aid. JSI can be reduced to a desirable level by increasing worker capacity (e.g., selecting a worker with higher capacity) or altering task and job parameters to reduce JSI to an acceptable level.

Herrin *et al.* (1986) investigated the relationships between the percentage of the population accommodated according to Snook's (1978) data (most stressful task within a job and average of all tasks) and medical dispensary visits. There was a fairly strong negative correlation between percentage of the population accommodated by the most stressful task and visits for overexertion injuries and contact injuries. There did not appear to be

enough "back" incidents to make a reliable conclusion, but the relationship was also a negative correlation.

The exposure assessment step requires measuring the manual handling task parameters required to apply the psychophysical data being used. The first step of the exposure assessment requires the analyst to perform a task description of the job, i.e., each individual manual handling task needs to be identified. Once all tasks have been identified, the critical parameters of each task need to be measured. Examples of parameters include task frequency, lifting range, vertical hand height, initial pull forces, and carry distance.

The final step is the risk characterization, which uses the exposure-response relationships and the exposure assessment. The studies discussed earlier do not provide explicit quantitative exposure-response relationships. The Snook *et al.* (1978) study used a qualitative exposure measure in the analyses (exposure was dichotomized as above or below 75% of the population being accommodated). Liles *et al.* (1984) presented quantitative analyses, but the JSI represents stress relative to psychophysical capacity for an individual, not in terms of the percentage of the worker population accommodated. The Herrin *et al.* (1986) study used visits to the medical dispensary as the response measure, which is fairly qualitative since this outcome encompasses a very wide range of outcomes, especially in terms of severity. Thus, the risk characterizations using the exposure assessment relationships from these studies must be performed with the limitations of the study designs in mind, i.e., the exposure assessment results need to be expressed in terms compatible with the results of the study or studies used.

4. CONCLUSIONS

Using the formal definition of risk assessment, it is arguable whether risk assessments can actually be conducted when using the psychophysical approach. This problem is not unique to psychophysics, but is pervasive in the field of manual handling (Dempsey 1998). Perhaps the problem is that the term "risk assessment" is used too often without careful consideration of its meaning.

Given the limitations in performing risk assessments, one possible alternative is to call assessments performed with psychophysical data (and other manual handling criteria) compliance assessments. That is, the assessment determines whether the tasks are in compliance with the criterion of interest.

Aside from compliance assessment, psychophysical criteria also provide valuable comparisons of different work designs. This use is too often overlooked when the manual handling criteria are discussed. Whether at the design stage, or when comparing alternate redesigns for existing tasks, psychophysical criteria can provide useful relative comparisons. These relative comparisons are not risk assessments, but provide guidance to help the designer select the best alternative with respect to the acute responses of the human body to the different designs.

Rating Scales for Perceived Physical Effort and Exertion

G. Borg

Department of Psychology, Stockholm University, Sweden.

1. INTRODUCTION

Interest in subjective aspects of physical work has increased during the last decades. One main reason for this is the improvement in rating methods designed to measure perceptual attributes. Another reason is the increased understanding of how important it is to listen to the worker who is doing the job. At the beginning of the last century, it was common to simply select individuals for a demanding task, instead of changing and adapting the task to the individual. This approach caused a lot of problems because individuals differ in terms of gender, age, and culture, and because educational and training opportunities are also variable. In the long run, it also led to risks for the individual and expensive medical care. Scaling subjective somatic symptoms and difficulty-of-work tasks are, therefore, important and necessary complements to physical and physiological measurements.

2. THE PURPOSE OF SCALING PERCEIVED EFFORT AND EXERTION

2.1. ''Psychophysical Scaling''

A main purpose of "psychophysical scaling" (meaning measuring perceptual magnitudes) is to complement objective measurements with subjective estimates. Valid physiological measurements are not always easy to obtain in field situations. This is especially true of certain short-term work carried out using bad postures. An advantage in using a rating scale to estimate physical work load is that a direct and individualized measure is immediately obtained.

2.2. Perceptual Estimates

Perceptual estimates integrate many cues from the peripheral musculoskeletal system and the cardiovascular and respiratory organs into a kind of "Gestalt" — a representation of the exertion as a whole. The human sensory system is an important information system that integrates the cues and give weights to those that are most important. Still it is possible to focus on separate aspects, such as local muscular effort and fatigue, breathlessness, or joint pain.

2.3. Subjective Evaluation

A subjective evaluation is, however, not merely a complement to "objective" measures. It has a significance and value in itself, since all individuals act according to what they perceive, how they evaluate a work task, and according to how motivated they are to learn, perform and cooperate. By adding subjective estimations one more "information channel" is added.

3. REQUIREMENTS OF A SCALING METHOD

3.1. Basic Demands

Basic demands on a rating method are that it must be reliable and valid to be useful for analyses and predictions. It should be simple to be practical in most situations. But more than a good scale is needed. The total methodology is very important, including good administration and instruction, both to the test leader and to the person making the ratings.

3.2. Classification of Scales

S.S. Stevens at Harvard University made a great contribution to the field when he classified scales according to their metric properties. Ordinal scales can only measure responses arranged in rank order. Interval scales have scale steps distributed at equal intervals, but no absolute zero. Ratio scales have the best metric properties, that is they have an absolute zero and scale values are at equal intervals. Only ratio scales allow for most kinds of mathematical calculations.

3.3. Scale Properties

It is important to distinguish between mathematical requirements and abstract scale properties, and the actual scaling and its purpose. Stevens' goal was to construct a method that could generate responses along a ratio scale. This goal was never reached, mainly because of cognitive difficulties and "response biases". However, if most people use numbers in a similar way, that is, if there is a high degree of intersubjectivity in number conceptions and usages, then reliable invariances and valid predictions may be obtained.

4. DIFFERENT KINDS OF SCALING METHODS

4.1. Ordinal Rating Methods

The ordinal scales are often called category scales or just simple rating scales. A typical category scale has numbers from, for example, one to five, with verbal anchors such as "very weak", "weak", "medium", "heavy", and "very heavy". To evaluate the effort and exertion of a work task, ordinal methods are mainly used to give very rough evaluations of intensity levels, not to scale relations between work tasks. The different scale values serve primarily as alternatives, such as in a multiple choice task.

4.2. Acceptability and Preference Scaling

In many work tasks it is important to obtain individualized measurements of preferred or acceptable workloads. There is a range of subjective intensities and workloads within which an experienced worker can adapt his or her level and work comfortably and efficiently for a long time-period. In contrast to most scaling methods in which stimuli are rated, with acceptability/preference scaling individuals are asked to adjust or produce a physical intensity until it is perceived to be just right according to the instruction. These methods are very useful in many situations, especially when it is desirable to obtain a certain level or short range of intensities (see Mital *et al.* 1993).

4.3. Equidistant Partition Scaling

4.3.1 The visual analogue scale (VAS)

A visual analogue scale usually consists of a simple line, often ten centimeters long, anchored at one end with the word "Minimum" and at the other with "Maximum". The subject is asked to make a mark on the line that shows the intensity of the perception. Sometimes the lowest end is named "Nothing at all" or "None at all" and the highest "Worst exertion (or pain)

imaginable". If a VAS is anchored in this way, it may be inappropriate for making interpersonal comparisons, since people can imagine so many different things, and from many different points of view. With appropriate administration VAS may be a useful instrument.

4.3.2 Paired comparisons

The method of paired comparisons may be classified into this group of equidistant scales. If the distribution of perceptual estimates is well known, e.g. a normal distribution, results from a comparison task may be placed on an interval scale based on standard deviations. However, such a scale is not a direct scaling method (as dealt with in this article), but an indirect one belonging to the set of discrimination scaling procedures. It is time consuming, but in some situations very useful (see Gescheider 1997).

4.3.3 The Borg RPE scaling

Very few category scales belong to the class of interval scales. If people are instructed well and can understand the concept of equisection, a scale of interval character may be obtained. The "Borg RPE scale", or just simply the "RPE scale" (from Ratings (R) of Perceived (P) Exertion (E), sometimes also called the "Borg

1 9   **Extremely hard**

2 0   **Maximal exertion**

Figure 1: The Borg RPE scale, the 15-grade scale for ratings of perceived exertion

scale") is commonly used in ergonomic evaluations of perceived workloads. Constructed by Borg in the 1960s and slightly modified later (see Borg 1998), it may be characterized as an interval scale. The RPE scale differs from the old rating scales and also from the "ratio scales" (see S.S. Stevens 1975) with regard to determinations of levels of intensity and their interrelations. A numerical scale from 6 to 20 was selected, to cover a roughly similar number range as that of heart rate (HR), from 60 to 200 bpm (divided by 10). Verbal expressions were placed on the scale such that a linear growth function was obtained between given numerical ratings and workloads for exercise on a bicycle ergometer. In this way, RPE values were also made to increase linearly with HR and oxygen consumption.

High reliability coefficients have been obtained, especially if a whole range of intensities is used in the evaluation. When expressed as correlation coefficients from data obtained with parallel testing or re-testing, most coefficients are above 0.90. Also, very good validity coefficients are obtained, e.g. correlations between HR and RPE, between 0.70 and 0.90. Good predictive power to performances has also been obtained, similar to that of HR.

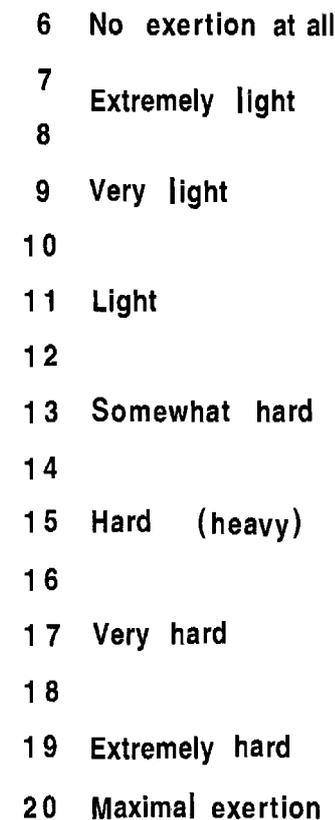
4.4. Relative Ratio Scaling

S.S. Stevens developed the "ratio scaling" methods in psychophysics (see Stevens 1975). In analogy with scaling in the natural sciences, an arbitrary unit was used on a ratio scale. Several methods were developed, the most common being "magnitude estimation" (ME). In ME a physical standard is chosen and a certain number is assigned as the "modulus", e.g. ten (10) or hundred (100). Subjects assign numbers to each stimulus in relation to the standard such that the numbers reported represent the relative perceptual magnitudes. In "absolute magnitude estimation" (AME) no standard and modulus are given, and subjects report the magnitudes according to some "absolute" inner feeling. The aim was to improve estimates of "absolute" intensity levels. However, AME does not function much better than ME in this respect.

Stevens' "ratio scaling" methods were not as good as he had hoped. This is because human beings, when estimating intensities with numbers, are using their own number conceptions and ideas instead of abstract concepts. However, the methods functioned — and still do — well enough to make possible reliable descriptions of relative growth functions for different sensory modalities. For perception of effort and exertion, positively accelerating functions have been found. This is true of the perception of weight in lifting tasks, of subjective force of handgrip or pedal resistance, and of subjective exertion in short- and long-duration work on an ergometer. These functions can be described by power functions with exponents between 1.3 and 1.8. The differences depend both upon kind of work and scaling methods.

4.5. Level-anchored Ratio Scaling

4.5.1 Basic principles

The latest generation of direct scaling methods are the category (C)-ratio (R)-scaling methods. That a rating scale, such as ME, has properties of a ratio scale may be a necessary condition, but it is not a sufficient one. The CR scales constructed by Borg incorporate the best properties of category scales and those of ratio scales. They are constructed for measuring most kinds of perceptual attributes.


An advantage with "ratio scaling" is that it permits rough descriptions of relative growth functions. However, a main drawback is that valid determination of direct intensity levels is not possible. (That one weight is perceived to be twice as heavy as another does not tell us if the weight is heavy or light). The old category-rating methods, however, were to get estimates of intensity levels.

There are several fundamental principles behind the development of the CR scales. They were constructed according to internal psychophysical criteria, without considering any special relations to physiological correlates. A basic starting point was the results obtained using "ratio scaling", and a new method should give a similar growth function as obtained with these methods. The range principle was another fundamental principle, implying that the whole perceptual range from zero to maximum should be covered. Simple verbal expressions showing a high degree of inter-individual agreement were then chosen. The expressions were positioned on a ratio scale so that a congruent relation was obtained between the meaning of the numbers and the meaning of the expressions. Possibilities were also opened up to give subjects the opportunity to go above the highest scale value and below the lowest one, thus encompassing extreme situations — for example, if a person experiences exertion that is greater than ever previously experienced. A special dot was therefore placed above the scale to encourage people to give higher ratings if necessary.

4.5.2 The Borg CR10 scale

The first CR scale commonly used internationally is the CR10 scale. It has a numerical range from 0 to 10, with the first verbal anchor above 0 set to 0.5. In this way a suitable numerical range

0	Nothing at all	"No P"
0.3		
0.5	Extremely weak	Just noticeable
0.7		
1	Very weak	
1.5		
2	Weak	Light
2.5		
3	Moderate	
4		
5	Strong	Heavy
6		
7	Very strong	
8		
9		
10	Extremely strong	"Max P"
11		
⚡		
●	Absolute maximum	Highest possible

Figure 2: The Borg CR10 scale, a category (C) scale with ratio (R) properties

of 1:20 was obtained (see Borg 1998 and figure 2 below). The dot above 10 means that people may use 11 or 12, or an even greater number. There is usually no need to go above 12 in ratings of physical exertion. If higher ratings are given, they usually depend upon special personality characteristics and rating behavior, or pathological circumstances, such as extreme pain, and should be further investigated.

The reliability and validity of the CR10 scale is as good as that of the RPE scale. However, one special advantage is that the CR10 scale allows determinations of relative growth functions of a more absolute character than the RPE scale.

4.5.3 The cM scale

In some special cases, a more finely graded scale may be needed. A hundred point scale, the cM scale (centi-Max scale, also called CR100), has therefore been constructed by Borg and Borg in 1994; (see also Borg 1998). The responses obtained with this scale closely follow percentage ratings when tested with subjects that have a good ability to perform percentage estimates. To help individuals with difficulties in this respect, and to ensure a high degree of interpersonal agreement, numbers are anchored with verbal expressions. These are placed at about the same positions as on the CR10 scale. Of special interest is that physiological and performance measurements may also be transformed to one and the same CR scale.

5. BASIC FACTORS "BEHIND" RPE RESPONSES AND INDIVIDUAL DIFFERENCES

5.1. Variance Factors

Most of the differences in RPE responses ("RPE" here used independent of kind of scale) can be attributed to physiological factors. In homogeneous groups of healthy individuals as much as 60–70% of the variance can be "explained" by factors such as oxygen uptake and HR, ventilation and respiration rate, EMG measures, perspiration rate, blood lactate, blood pH, monoamines, and catecholamines, among others. A very difficult problem, then, is how to integrate and give weight to all factors for different kinds of work. An advantage with the perceptual system is that it can integrate information related to most of these factors.

5.2. Psychological Factors

A rather large part of the variance in RPE responses may, however, be attributed to psychological factors. In normal cases, one major factor influencing ratings is personality and rating behavior. Emotional and motivational factors may also play an important role.

5.3. Working Capacity Factor

Because of the strong dependence on physiological "causes", one main factor explaining the level of a given rating is the individual's working capacity. A given RPE-rating thus decreases systematically with increasing capacity. However, when the capacity is adjusted there is no real difference in obtained ratings. The same is also true when ratings are plotted against HR. In those cases there is no gender difference. When RPE values are studied as a function of age, they increase with decreasing working capacity. However, since maximal HR also decreases with age, relative HRs have to be calculated for different age groups. The relation is then the same as in age homogeneous groups.

5.4. Individual Differences and External Factors

Differences between individuals are found depending upon kind and duration of work, and the influence of external factors, such as temperature and altitude, and also upon actual somatic factors related to food intake, liquid and medication. Various somatic problems, such as musculoskeletal and cardiovascular diseases, may have a strong influence on RPE values and the profile of different symptoms (e.g. muscle ache, breathlessness and joint pain).

6. DIFFERENT APPLICATIONS

6.1. Physical Workload Evaluation

In order to evaluate the exertion and difficulty of a work task in manual materials handling, RPE-values are often registered. The purpose may be to compare different performance techniques, such as lifting according to the squat or the stoop technique, cleaning the floor by mopping or swabbing, or to evaluate the "absolute" magnitude of effort and exertion. Of special interest are gender differences. It is, of course, of utmost importance that all ergonomic improvement be carried out so as to avoid gender discrimination. Another target group is the elderly or handicapped, who need help with better managing their daily activities and improving well-being.

6.2. Mental Workload Evaluation

Another field of application of the CR10 scale is in human factors studies of mental workload. The difficulty of tasks involving fast and correct perceptual identification of signals and symbols, or psychomotor performance is, thus, analogous to physical work load. Simple evaluations of traffic noise, electric lighting, bad air, etc. may also be made using the CR-scaling technique. Still another field of application concerns determinations of the intensities of moods and emotions, such as the discomfort of traffic noise.

6.3. Risk Assessments

Because ratings give important information about actual strain, they are also used in risk assessments. No regular exertion should be "strong" and "heavy". "When it's hard it's too hard", meaning that RPE values should be less than 15, or CR10 values less than 5. A "moderate" (CR10 "3") level may often be just right (see Colombini *et al.* datum). Because there may be "silent symptoms", a medical examination is always necessary. Subjective ratings can never guarantee that no risks are involved in a certain performance. The sensory system is far from perfect, nor do physiological signs always provide enough information. Work considered to be risky includes low intensity but long-lasting repetitive activities of a "monotonous" kind as, for example, work in the fast check-out line or with steady computer work. For this kind of work, even "light work" may be too hard in the long run. Ratings are often utilized in clinical diagnostics, and in training and rehabilitation.

CONCLUSION

In most situations, ratings of effort and exertion give important information. They are valuable complements to physiological and biomechanical measurements, and are also important in themselves, since people act according to their perceptions of work activities. It is necessary to use a rating scale with good metric properties. This is, however, not a sufficient condition. If a method is to provide valid results, correct instruction and administration are essential.

Signal Detection Theory

J. D. Balakrishnan and J. A. MacDonald

Department of Psychological Sciences, Purdue University, West Lafayette, IN 47907, USA

1. INTRODUCTION

Many of the jobs carried out by human operators in the workplace have a "detection" component to them. Various kinds of watchkeeping tasks (e.g. radar monitoring, airport security, product quality control) are some of the more obvious examples. Other seemingly more complicated tasks, such as medical diagnosis and personnel evaluation, can also be reduced in many instances to a set of all-or-none decisions about the need for an intervention of some kind. In virtually all of these cases, the potential for human error exists, and a critical question for the human factors specialist is whether some or all of these errors can be attributed to operator training, system design, or other aspects of the job that could be retooled in some way.

To answer this question, many researchers prefer to use well-controlled experiments and objective performance indices, if they are feasible. In addition to a rigorous measure of the difficulty of an operator's task and a numerical scale for comparing different approaches to a problem, these indices make it possible for the researcher to examine how factors such as attention and strategy may interact with system design or other factors to determine the overall performance pattern of the operator. Unfortunately, none of the performance indices currently available to researchers are "theory-independent." Essentially, they are byproducts of a relatively simple, skeletal model of the operator's behavior in a goal-directed setting. To be used appropriately, therefore, their assumptions and limitations need to be properly understood. Here we briefly review the several measures and experimental techniques that originated with one of the most successful performance theories in psychology, the so-called Theory of Signal Detection (or, Signal Detection Theory; e.g. Green and Swets, 1966). Elsewhere we consider some alternatives to signal detection theory and some recent empirical results that may fundamentally change the way operator performance is assessed in the future.

2. FORMAL MODELS OF DETECTION

In most real world tasks, the operator can and will make different kinds of errors, with different consequences, and the rate at which some kinds of errors are committed will often be inversely related to the rate of other kinds of errors, presumably because of attention shifts or other changes in the operator's approach to the task. In other words, there will be trade-offs. Changes in the environment or system design presumably can affect the decision-making strategy of the operator, exclusively or in addition to their effects on the quality of the information exchange between humans and machines. Formal models such as signal detection theory represent attempts to provide measures of information processing capacity that are not confounded by the operator's decision-making biases.

The first step in the development of such a model is to analyze the logical structure of the operator's task. With few exceptions, human errors in the workplace are incorrect decisions about the state of a system or real world event, or about the best possible course of action in response to a situation. Signal detection theory encompasses both kinds of errors by dividing the decision-making process into two discrete, non-overlapping stages. In the first stage, the operator collects information from the outside world, and in the second stage the operator applies a decision-making strategy or rule to the information state to arrive at a decision about the nature of the circumstances and/or the best course of action. Of course, in most workplace environments, the situations faced by the operator are constantly changing and so this encoding/decision-making sequence must continuously repeat itself. The absence of any overt action on the part of the operator at any given point in time presumably represents a decision (conscious or otherwise) not to react on the basis of current information about the environment.

The terms "collect information" and "apply a rule" are very general, which is one reason why signal detection theory can be so widely used. Any kind of information processing task will involve information collection of some kind followed by the selection of an appropriate action. Errors can be due to poor information (encoding errors) or faulty decision-making (response selection) strategies. The main objective of the signal detection theory analysis is to separate and quantify these two kinds of errors so that their relative frequencies and their dependence on the properties of the system can be studied.

To do this, the theory borrows some fundamental concepts from the statistical decision-making literature. First, the information that reaches the decision-maker is assumed to be ambiguous or "noisy": the same information state can be produced by more than one of the physical events that need to be discriminated. The decision-maker's problem is, therefore, to determine which event is more likely to have produced this information state and from this the action that is most likely to be correct. In this way, the decision-making process is analogous to a statistical hypothesis test. The operator makes an error when the information output of his/her encoding process is sufficiently misleading, or when the statistical decision rule is misconstrued.

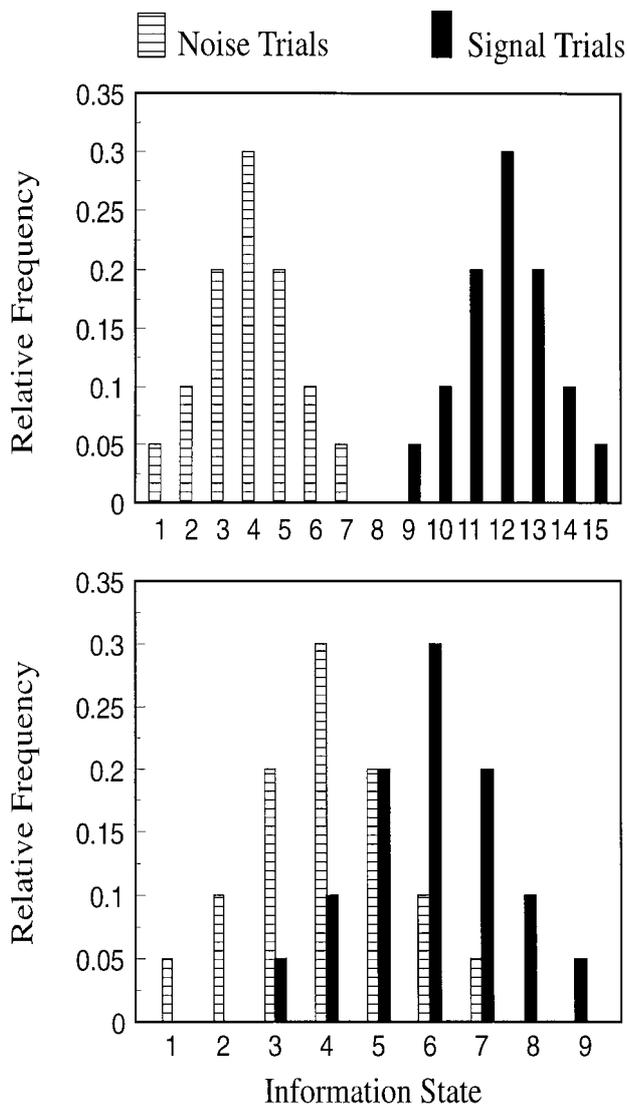
At least in principle, this theoretical framework can be adapted to arbitrarily complex decision-making tasks, involving many different situations and many possible decisions that might need to be taken (and to some extent, Thurstonian Scaling is an example of this; Torgerson 1958). However, most of the efforts to develop the theory have concentrated on relatively simple decision-making tasks in which there are only two possible states and, therefore, two possible classification responses. In this two-choice classification (or discrimination) task, the two possible states of the world can be arbitrarily labeled "noise" and "signal," and there are two possible correct responses (correct signal responses or "hits" and correct "noise" responses, or "correct rejections") and two kinds of errors (incorrect "signal" responses to noise or "false alarms" and incorrect "noise" responses to signals, or "misses"). Signal detection theory assumes that the information state of the operator can be represented by a point on a one-dimensional, bipolar continuum or "decision axis." Values on the one end of this continuum represent instances during the experiment in which the operator is highly certain that the correct response decision should be "noise," and values the other end represent high confidence "signal" responses. Somewhere between


Figure 1. Concept of sensitivity in signal detection theory. (upper) The presentation of a signal puts the operator into one of seven states (9–15 on the abscissa). Noise alone never causes any of these information states, but instead may cause one of a different set (1–7). In this case, the operator can (with an appropriate decision rule) perfectly discriminate between the two events. (lower) Some of the information states (3–7) are caused by both signal and by noise alone (i.e. the distributions overlap), making discrimination errors inevitable for all possible decision rules.

these two extremes is the "complete uncertainty" or "indifference" point.

2.1. Encoding Distributions and Detection Criteria

If the presentation of a signal (or noise alone) does not always have the same effect on the operator, then it follows that the information state of the operator has some univariate probability (relative frequency) distribution. The difference between this distribution of states on noise trials from its distribution on signal trials presumably depends on the physical differences between

the two events and the "sensitivity" of the operator to these differences. In fact, the degree overlap of these two distributions would be the degree to which the noise and signal stimuli are confusable when they are presented equally often. This property is illustrated in Figure 1. In the upper panel, the distributions are completely non-overlapping. In this case, the decision-maker can always correctly identify the stimulus because the information states caused by the noise stimulus are never caused by the signal stimulus, and vice versa. In the lower panel, the distributions overlap. In this case, information states lying close to the middle of the continuum have similar relative frequencies under the two stimulus conditions, and perfectly equivalent relative frequencies for one value (information state "5"). No matter which response is assigned to information states "3" through "7," the operator's decision will sometimes be incorrect.

Using a probability distribution to describe the effect a stimulus on the operator was standard practice long before signal detection theory was developed. The new contribution of this theory was in its emphasis on the sophisticated decision-making processes that should be (and presumably are) applied by human operators to minimize the problems caused by noisy encoding. In addition to the relative frequency of a state on signal trials (or on noise trials), the statistical decision-maker would also consider the relative frequencies, or "base rates," of the signal and noise events during the experiment, the relative costs of the two possible errors (false alarms and misses), and the rewards for the two possible correct decisions (hits and correct rejections). For example, if the signal occurs very infrequently (i.e. its base rate is low), then a state that occurs with moderate frequency on signal trials and moderator frequency on noise trials would actually constitute fairly strong evidence in favor of a "noise" response. Presumably, the operator combines knowledge about the probability distributions with the base rates and payoffs to select an appropriate "criterion" or "decision boundary" to divide the information state continuum into two response regions. As the base rate of the signal event increases, for example, the operator presumably shifts the criterion to the left, increasing the size of the signal response region and hence the relative frequency of the signal response.

3. PERFORMANCE INDICES

Different assumptions about the shapes of the information state distributions partition signal detection theory into several different detection models. The most popular of these assumes that the distributions are normal with equal variance. In this case, the distance between the means of the two distributions in standard deviation units, or d', is a suitable index of the degree to which the distributions overlap ("sensitivity"), and the ratio of the two distributions at the criterion (b) is an index of preference for one of the two responses ("response bias"). Thus, b < 1 would indicate a bias towards the signal response and > 1 would indicate a bias towards the noise response. The decision rule is unbiased (b = 1) when the criterion is set at the point of intersection between the two distributions, which occurs at the midpoint between their means. Both d' and b can be calculated from the hit and false alarm rates of the operator.

If the distributions are normal but have different variances, then an additional parameter is needed to fix the sensitivity scale. Unfortunately, these indices cannot be obtained from a single

pair of hit and false alarm rates, which presumably explains why they are not widely used, despite the fact that the equal variance assumption is generally untenable. To fit the unequal variance normal model to data, estimates of the hit and false alarm rates must be obtained for several different values of the decision criterion.

3.1. Criterion Shifts and the ROC Curve

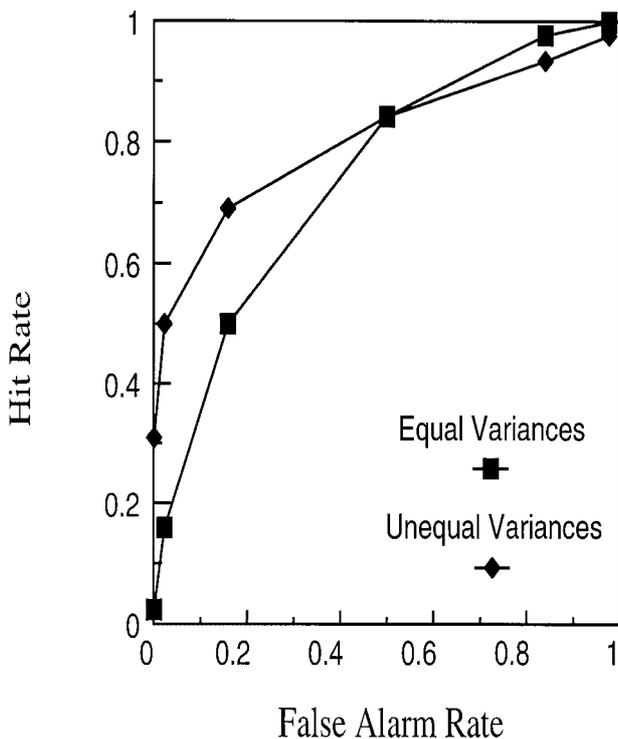
Running the same experiment under several different base rate or payoff conditions is one way to obtain the extra data needed to allow for unequal variance. Another method is simply to instruct the operator to favor one type of response over the other to some degree. Each manipulation should cause the operator to shift the detection criterion. The different pairs of hit and false alarm rates can then be graphed together in a single parametric plot (or scatterplot) called the "receiver operating characteristic" (ROC) curve. The points on the graph are the hit rates (on the ordinate) corresponding to each observed false alarm rate (on the abscissa). Two examples are shown in Figure 2. For several reasons the shape of the ROC curve is the most powerful diagnostic from the point of view of signal detection theory. The area under the curve, for example, increases as the sensitivity of


Figure 2. Two possible ROC curves when the distributions are normal with equal variance (squares) or with larger variance in the signal distribution (diamonds). Each of the six different points on the curve corresponds to a different placement of the detection criterion. Area under the complete ROC curve (when the hit and false alarm rate are calculated for every possible location of the detection criterion) can be estimated by computing the area under the these incomplete functions. In this case, however, the operators' placement of the criteria will have some effect on the measure.
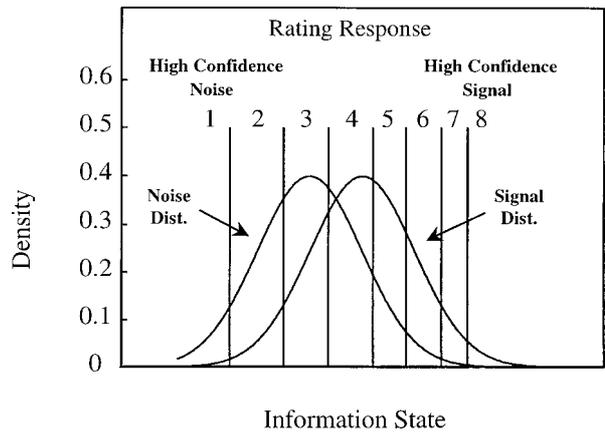

Figure 3. Signal detection theory representation of confidence rating data when there are eight possible rating responses on a single bipolar rating scale. Small values on the scale (e.g. "1") are high confidence "noise" responses and large values (e.g. "8") are high confidence "signal" responses. Each of the seven criteria is a possible value of the detection criterion, making it possible to calculate seven different points on the ROC curve from the operator's ratings data. For example, the proportion of rating responses > 3 on noise trials and the proportion of rating responses > 3 on signal trials are the false alarm and hit rates respectively when the detection criterion is placed at the same location as the upper bound on a "3" response.

the operator increases. Unequal variance in the distributions causes the function to be skewed with respect to the negative diagonal (the diagonal line connecting the upper left corner of the graph to the lower right corner), and the direction of the skew indicates which distribution variance is larger (assuming that the distributions are normal). Alternatively, the researcher can plot the z-transform of the false alarm rate against the z-transform of the corresponding hit rate and observe the shape of this "z-ROC" scatterplot. If the normality assumption is satisfied, this function will be linear with a slope equal to the ratio of the standard deviation of the noise distribution to the standard deviation of the signal distribution.

3.2. Ratings Method

Empirical studies of the shape of a ROC curve can be time consuming and expensive if each point of the curve must be estimated from a different experimental condition. An alternative approach that is perfectly consistent with the signal detection theory assumptions, and at the same time considerably more efficient in terms of costs, is to elicit confidence rating responses from the operator. According to signal detection theory, the operator's information is "graded" and stochastic, varying from strong and reliable on some occasions to weak and uncertain on others. Asking the operators to choose one of two responses is equivalent to asking them to separate their confidence states into two "response bins": "more confident signal" and "more confident noise." Asking them to also rate their confidence in their detection judgment is equivalent to asking them to separate their confidence states into more than two confidence bins. The results are illustrated in Figure 3. The proportion of rating responses larger

than a given value, k, on the rating scale is equal to the proportion of times that the confidence state fell above the upper bound of response bin k. Separating the data into signal and noise trials, these proportions are equal to the hit and false alarm rates that would be observed if the detection criterion were placed at the same location as this upper bound. Thus, a number of points along the ROC curve can be estimated from a single experimental condition. An estimate of the area under the ROC curve is easily obtained from these "incomplete" curves by connecting the points and calculating the areas under each segment.

4. RECENT APPLICATIONS

Watchkeeping (or vigilance) is one of the most natural applications of signal detection theory and probably the most common one. In the laboratory vigilance task, subjects follow a sequence of stimulus presentations and after each one of these they decide whether or not to sound an alarm (detect a signal). A great deal of effort has been extended to understand how biases and sensitivity change over the course of the watch (e.g. See *et al.* 1995, Parasuraman *et al.* 1987 for reviews). Many other variables affecting vigilance performance have also been examined using the signal detection theory approach. For example, Matthews (1996) used d' and b to examine the effects of signal rates on vigilance in high workload (fast presentation rate) conditions. The results suggested that sensitivity declined with time on task, and more precipitously when the signal rate was high (i.e. when the operator must explicitly respond more often). Response biases, on the other hand, apparently remained constant across different signal rates. Results of this kind are not uncommon and seem very plausible. In fact, few researchers take the trouble to qualify their inferences about decision-making strategies in vigilance even though they ultimately depend on the validity of the signal detection theory indices.

Another illustration of the wide range of potential applications of signal detection theory is its routine use as an arbitrator when two relatively informal theories or hypotheses make different predictions about the effects of a factor on the operator's performance. If one theory predicts that there should be no effect of this factor or the opposite kind of effect, then the d' measure is typically recruited to verify that observed differences in overall percent correct or in the hit and false alarm rates are not merely due to effects of the factor on response bias. The direction and size of the operator's response bias are not usually specifically predicted by theories of operator performance (response biases are, by definition, "subject-controlled" factors) and so the d' statistic is usually the measure of most interest. Patterns of bias, however, can sometimes inform the researcher about variables such as cognitive style or motivation. For example, in a recent study on aircraft recognition and recognition training, Goettl (1996) looked at two memory models and their predictions about aircraft recognition under different learning conditions. Recognizing whether an aircraft is or is not a member of a predefined class (e.g. commercial versus noncommercial) is a two-response discrimination task, making it possible to apply a signal detection theory analysis. The signal detection theory measures were used to estimate memory strength (sensitivity) and the results indicated that for male subjects, there was a

difference between two different types of learning schedules on memory strength and not merely on bias, but for the females,the differences between the two schedules could be attributed to bias effects alone.

Another natural application for signal detection theory has been in the various kinds of expert decision-making problems involved in medical and clinical diagnosis. ROC curves are used fairly routinely in these areas to characterize the extent to which some quantifiable property of a medical image informs the physician about the presence or absence of a pathology. Researchers also make use of these measures to compare experienced and inexperienced diagnosticians and to show how new imaging technologies can combine with or replace traditional methods of diagnosis (e.g. Jiang *et al.* 1999, Tsuda *et al.* 1999). Quite often, new approaches to diagnosis do not increase both the "hit" and "correct rejection" rates, making bias effects a very important factor to consider.

In each of these examples, and in many others, some interesting and important discoveries about human performance, including losses of sensitivity with time on task, idiosyncratic response biases, and other well-documented phenomena, would not be possible without the benefit of a formal measurement system. However, these discoveries are only "conditional" statements of fact because of their dependence on the specific assumptions of signal detection theory. Other interpretations of the data are possible, and occasionally other indices are adopted in addition to or in place of the signal detection theory measures. In the next chapter, we look at the evidence in support of signal detection theory and then discuss some of the alternatives and their motivations.

Signal Detection Theory – Alternatives

J.D. Balakrishnan and J. A. MacDonald

Department of Psychological Sciences, Purdue University, West Lafayette, IN 47907, USA

1. INTRODUCTION

In *Signal Detection Theory*, we discussed the rational and the basic concepts behind the "formal model" approach to human performance assessment and then briefly sketched out the assumptions and methods associated with the field's most popular formal measurement system, signal detection theory. Over the past several decades, the experimental methods and statistics associated with the signal detection theory framework have become so deeply ensconced in the measurement literature that relatively few theorists would see any serious reason to question them. Competing views have also been developed, however, and should not be ignored merely because they are less familiar. After all, the validity of signal detection theory has never been established, and from time to time some cracks in its foundation have been discovered. In fact, here we review some very recent empirical results that purportedly show that the signal detection theory measures have actually grossly misled human factors researchers about the nature and limits of human performance. First we review the experimental data that make signal detection theory seem so compelling and then consider the strength of this evidence and some alternative interpretations.

2. EVIDENCE IN SUPPORT OF SIGNAL DETECTION THEORY

For most human performance researchers, the important question about signal detection theory is not whether it is a valid theory or not, but whether it is valid enough for their purposes. Typically, the performance statistics are recruited to identify changes in sensitivity and response bias, not their absolute values. The signal detection theory measures are trusted in this role because the way they change under different experimental conditions is usually predictable and consistent with the theory. Most importantly, perhaps, the theory correctly predicts the effects of changing the base rates or payoffs in a yes–no detection task: increasing the frequency of the signal trials almost invariably increases both the hit and the false alarm rates. Stronger manipulations lead to stronger effects of the same kind. Similarly, the sensitivity indices (e.g. d' and area under the ROC curve) seem relatively unaffected by base rates and payoffs, while the bias measure b is not: it increases and decreases appropriately when the base rates or payoffs are manipulated, indicating that the operator's decision-making strategy is rational. Other kinds of evidence seem to justify the 'technical" assumptions of the theory while rejecting the underlying assumptions of many other statistics (Swets 1986b). Empirical *z*-ROC curves, for example, usually are almost perfectly linear, consistent with the distributional assumptions (normality) of signal detection theory.

Using these statistics for more fine-grained analyses of operator performance also leads to a plausible and cohesive account of human behavior. For example, studies have consistently shown

that the operator shifts the detection criterion when the base rates are changed, but the size of the shift is presumably insufficient to cause the decision process to be "optimal" (i.e. to maximize the percentage of correct decisions). In other words, the decision process is "conservative" (e.g. Creelman and Donaldson 1968, Macmillan and Creelman 1990). In laboratory studies of watchkeeping (i.e. the vigilance paradigm), the measures have been used to "establish" that changes in the detection rate are due to changes in the operator's willingness to make a detection response under some conditions (e.g. relatively slow paced detection tasks) and losses of sensitivity under others (e.g. relatively fast paced detection tasks with a memory load; Parasuraman 1979). These accounts are interesting and plausible, and certainly do not raise any special concerns about the validity of the model that gives rise to them, even though it could easily have been otherwise. If the model was untenable, one might expect a more inconsistent or a more confusing pattern of results.

3. ALTERNATIVE INTERPRETATIONS OF THE DATA

Although the classical findings undoubtedly do tell us something important about human performance, they can also be interpreted in other ways, some of which are at least as plausible as the signal detection theory explanation. Response time models, for example, can reproduce all of these properties of the data, even though they represent the decision-making processes in a profoundly different manner (e.g. Townsend and Ashby 1983, Luce 1986). Instead of adjusting a detection criterion, these models assume that the operator accumulates information until enough evidence has been collected to justify one of the two possible responses. Because the decision is reached only after the accumulated information crosses a boundary, the number of samples (the encoding time) will depend on the quality or strength of the evidence as it is collected. If the operator receives weak information early on, for example, s/he will wait longer before responding so that additional information can be obtained. In signal detection theory, the decision-making process only plays a role after the encoding process is completed. Thus, this "static" model assumes that the amount of information collected is entirely independent of the information quality.

In some circumstances, such as clinical or medical diagnoses, the "fixed sample" assumption of signal detection theory is reasonable, or perhaps even necessarily true if the amount of physical evidence available to the decision-maker is not under the decision-maker's control. In many other situations, however, the decision to stop collecting new information and formulate a response is a crucial aspect of the operator's decision-making process, which may itself be biased in some way. In the real world detection problems associated with watchkeeping, for example, the operator must respond quickly as well as accurately to changes in the status of the system. Attempting to decide more quickly whether a signal or a non-signal event has taken place will generally increase both the false alarm and the miss rate (the so-called "speed–accuracy trade-off"), causing d' to decrease. Such biases might show up in mean response times of the operator or in the estimates of the parameters of a dynamic model, but would be invisible to signal detection theory. The difference between tasks that lend themselves to a signal detection theory analysis and those that do not is not always recognized: many researchers

Double Exponential

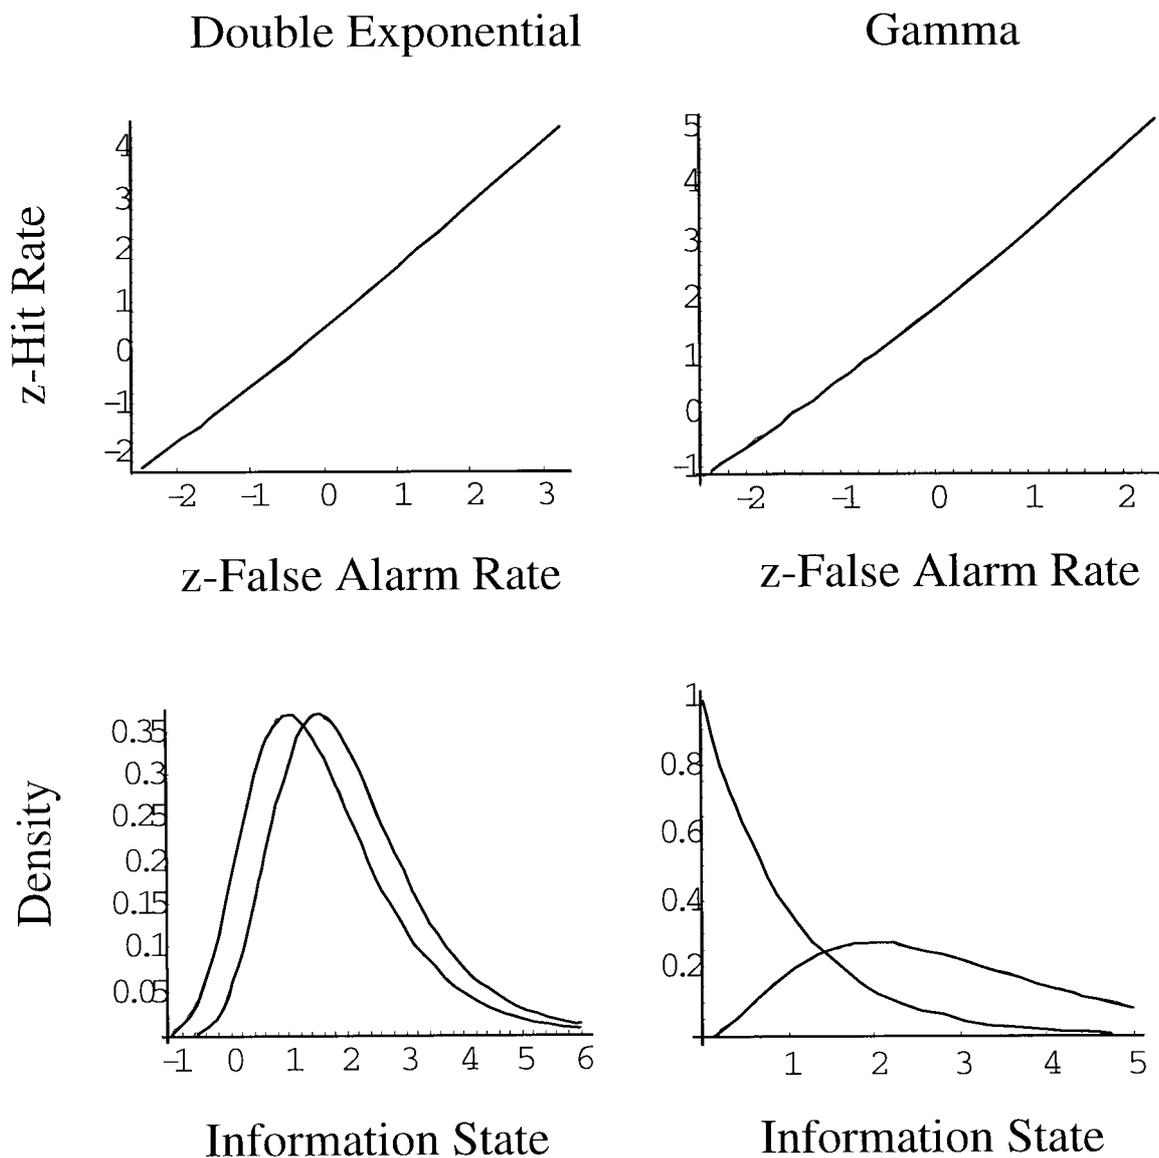
Gamma


Figure 1. z-ROC curves obtained when pairs of hit and false alarms rate from non-normal distributions are converted to z scores from the standard normal distribution. The two "double exponential" distributions in the lower left panel have equal variance but are positively skewed (e.g. Luce 1986: 508). The "gamma" distributions are unequal variance and positively skewed (e.g. Luce 1986: 507). Many other distributions also predict quasi-linear z-ROC curves.

use d' or similar measures even when the operators are under time pressure.

The evidence purportedly supporting the normality assumptions of the signal detection theory model — i.e. the shape of the empirical ROC curve — is also very weak. Many other distribution models predict a virtually linear z-ROC curve. In fact, the small deviations from linearity in empirical z-ROC curves are actually larger than the deviations predicted by these alternative distributions. Examples of the z-ROC curve predictions of two other distributions, vastly different from the normal (and not "transformable to the normal"), are shown in Figure 2.

4. OTHER APPROACHES

Apart from the response time models, very few of the alternatives to signal detection theory were specifically developed to repair any specific or known deficiencies of d'. Instead, they were proposed as

alternatives that might be more reliable if complete list of these alternative indices would be quite long (>20). Fourteen sensitivity indices are reviewed in Balakrishnan (1998a). Five different bias measures were recently compared by See *et al.* (1997). Not all of these measures were derived from an explicit description of the decision-making process, making it more difficult to evaluate them. However, the supposedly non-parametric indices make some testable predictions about the shape of the ROC curve and other predictions related to the effects of base rates and payoffs (e.g. Swets 1986a, Macmillan and Creelman 1996). In his review of 10 different sensitivity indices, Swets (1986a) concluded that a variable criterion measure that assumes normal distributions with different variance (area under the normal ROC curve) was the most viable index. Similarly, See *et al.* (1997) recommended a variant of the criterion value from signal detection theory over several supposedly non-parametric bias indices.

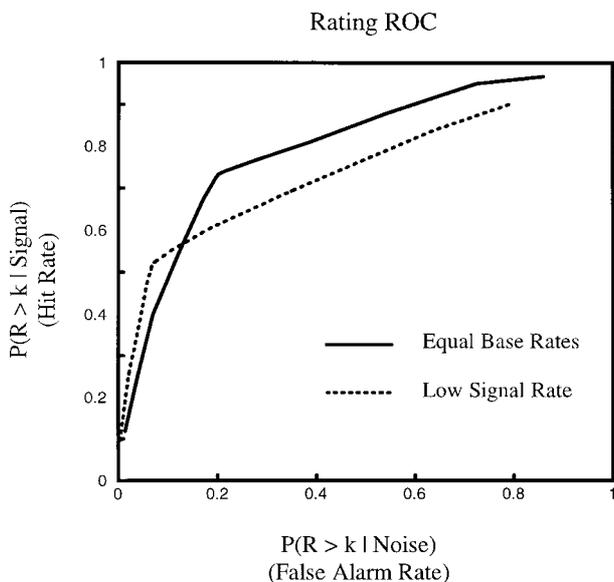
Rating ROC


Figure 2. Empirical ROC curves from a vigilance experiment with two different signal rates. When the signal rate is low, the curve is sharply skewed with respect to the negative diagonal (the line connecting the upper left to the lower right corner), consistent with larger variance in the signal distribution. According to signal detection theory, the two curves should be identical. For Figures 2–5 are revised versions reprinted with permission from *Human Factors*, 40(4). Evidence against the signal detection theory approach is somewhat hard to come by. However, a significant part of the success of this theory may be due to the lack of strong empirical tests of its basic assumptions. Recently, some new methods developed by Balakrishnan (1998a, b, 1999) have made it possible to directly test, in an assumption-free manner, the fundamental principles of signal detection theory and other two stage detection models, including the assumption that (1) response biases exist, (2) the decision process tends to be conservative and (3) the encoding and decision-making processes are independent. To avoid the assumptions required by *d'* and *b*, these tests make use of some extra information about encoding and decision-making contained in confidence ratings data. In many respects, these new methods are a relatively straightforward extension of the ratings paradigm developed earlier by signal detection theorists. However, they differ from the traditional signal detection theory methods in three ways:

- A cutoff between the "noise" and "signal" responses must be explicitly defined on a bipolar confidence rating scale. For example, if the rating scale has 10 values numbered from 1 to 10, rating responses five and six would be labeled "lowest confidence noise" and "lowest confidence signal" responses respectively. The two extremes of the scale (responses 1 and 10) would represent "highest confidence noise" and "highest confidence signal" responses respectively. Alternatively, the researcher may elicit first the yes–no detection response and then a "confidence level" response. For each confidence level in this two-response method, there is a corresponding confidence rating in the one-response method (e.g. five levels of confidence in the two-response method would be

equivalent to 10 rating responses on the bipolar scale in the one-response method). For purposes of data analyses, the confidence levels should be transformed into confidence ratings on a single bipolar scale (e.g. confidence level "2" in a "noise" response would become confidence rating "4" on a 10-point bipolar scale with a cutoff between responses five and six).

- To test the assumptions of signal detection theory, the signal rate or some other factor presumably tied exclusively to the decision process should be set in such a way as to induce a response bias.
- The operators should be instructed to limit their use of the extremes of the rating scale (i.e. the two lowest confidence responses on a bipolar scale) to situations in which they are extremely uncertain. If the operator uses these responses frequently, the new measures will not misrepresent the decision-making process, but they will be uninformative.

5. DISTRIBUTION-FREE MEASURES OF BIAS

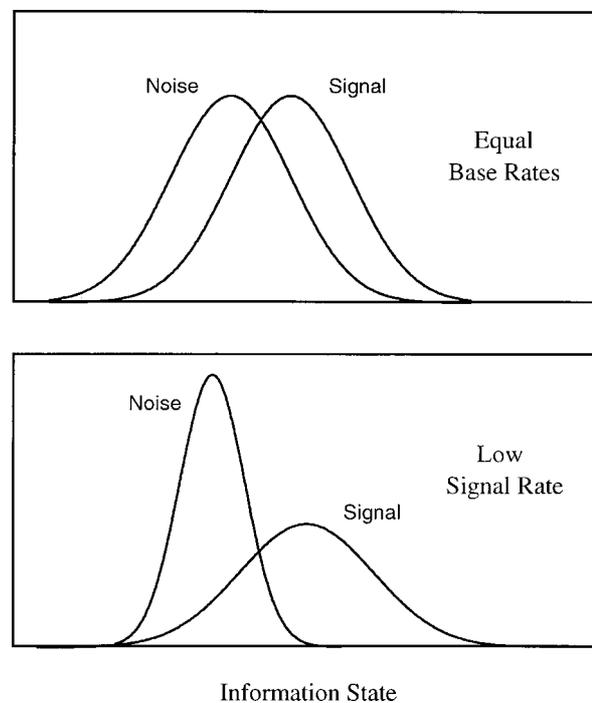
The utility of signal detection theory as a data interpretation tool rests on two fundamental precepts. First, the location of the decision criterion should be strongly dependent on the base rates or payoffs, shifting away from the "unbiased" location (i.e. the point at which the two distributions intersect). Second, the encoding distributions should be independent of the base rates. Both assumptions appear to be incorrect. Figure 3 shows the ROC curves from two different base rate conditions of a vigilance experiment (Balakrishnan 1998b) in which the operators were asked to discriminate between two patterns varying in overall size. The larger of the two patterns was the "signal" and occurred on half of the trials in one condition (Equal Base Rates) and on


Figure 3. One possible distribution model that could account for the ROC curve data in Figure 2. Decreasing the signal rate increases the variance of the signal distribution while decreasing the variance of the noise distribution.
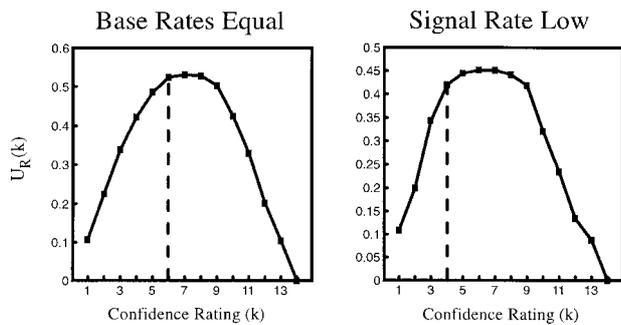

Figure 4. Empirical estimates of the bias test function, $U_R(k)$, in two base rate conditions of a vigilance experiment. The maximum of the function occurs at the value 7 in both conditions, indicating that the detection criterion is set at the intersection of the two encoding distributions, regardless of the base rates. The dashed vertical lines indicate the point at which the function would have reached its peak if the distributional assumptions of signal detection theory were satisfied.

only 10% of the trials in another (Low Signal Rate). Confidence rating data were elicited using a 14-point bipolar rating scale with a cutoff between responses seven and eight. If the encoding distributions do not depend on the base rates, the empirical ROC curves obtained under different signal rate conditions should fall along a single curve. Instead, the two curves clearly map out two very different functions. Their shapes are consistent with the assumption that the variances of the distributions depend on the base rates of the stimuli (Figure 4). When the signal is infrequent, the variance of the signal distribution is relatively large compared with the noise distribution. When the two events are equally frequent, the variances of the distributions are equal.

Clearly, the distributions in this experiment were not independent of the base rates. The next question is therefore whether base rates affect both the distributions and the decision criterion, or just the distributions. Confidence rating data can also be used to determine whether there is any shift of the criterion, without involving any assumptions about the shapes of the encoding distributions. The test is based on the difference between the cumulative relative frequency histograms of the operator's confidence rating responses,

$$U_R(k) = F_N(k) - F_S(k),$$

where $F_N(k)$ and $F_S(k)$ are the proportions of rating responses less than or equal to k on noise and on signal trials respectively, and the argument k is the rating value on a bipolar scale with a cutoff at k^*. If this function is decreasing for any k associated with a noise response ($k \pounds k^*$), or increasing for any k associated with a signal response ($k > k^*$), then the decision rule is biased (i.e. the criterion is not set at the point where the two encoding distributions intersect). The total proportion of these "biased rating responses" in the data, or W_p, is an estimate of the proportion of times the participant makes a biased response. For example, if the rating scale has 10 values with a cutoff between responses five and six, and $U_R(k)$ reaches it maximum value at rating response three, then the total proportion of four and five responses during the experiment is the (estimated) proportion

of trials on which the operator's decision differed from the unbiased decision rule. According to signal detection theory, this value should increase as the signal and noise base rates diverge.

If the peak of $U_R(k)$ occurs at the cutoff (and hence $W_p = 0$), the decision rule could still be biased to some degree. However, in this case, the proportions of the two lowest confidence responses (e.g. responses "4" and "5" on a 10-point bipolar scale) provide upper bounds on the probability of a biased response (e.g. the proportion of "4" responses is an upper bound on the bias towards the noise response, and the proportion of "5" responses is an upper bound on the bias towards the signal response). Instructions to the operator to be conservative in the use of extreme values on the rating scale are intended to keep this upper bound to a minimum. If it is large when $W_p = 0$, then the test will be relatively uninformative (but not misleading).

Illustrative results from the vigilance study described above are shown in Figure 5. In these examples and in many other experiments in our laboratory, the peak of the $U_R(k)$ function occurs at the cutoff value (response "7"), causing $W_p = 0$ when the base rates were equal and when they were unequal. The proportion of lowest confidence "noise" responses was < 0.01 in both conditions. Thus, even when the signal occurred on only 10% of the trials, the subjects' decision rules were not biased towards the noise response.

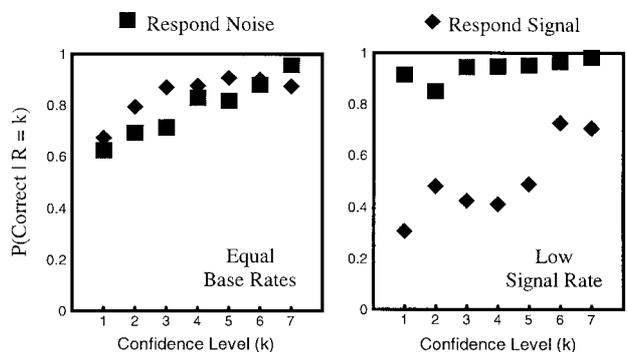
The absence of bias in the decision rule implies that the subject's decision-making strategy is suboptimal (i.e. does not maximize the percentage correct decisions). Suboptimality was already implied by the supposed "conservatism" of the decision rule that was uncovered by classical signal detection theory studies. However, it is also possible to test for suboptimality without making any assumptions about the structure of the discrimination process or the encoding distributions. To do this, the researcher calculates the proportion of correct responses associated with each rating response given by the operator. If the decision rule is optimal (maximizes % correct), then all of these correct response proportions will be greater than one half, regardless of the base rates. If any are less than one-half, then the decision rule is suboptimal. For example, considering only the trials of the experiment on which the operator chose rating response "2" on the 10-point bipolar rating scale (i.e. the "noise


Figure 5. Proportion correct conditioned on the discrimination response and confidence level for two base rate conditions of a vigilance experiment. Any value < 0.5 indicates that overall proportion correct could be improved by changing the decision rule (i.e. the decision rule is suboptimal).

responses" given at confidence level 4), more than half of these responses should have occurred on "noise" trials. If this is not true, then the operator could improve his/her performance by simply switching from a "noise" to a "signal" response whenever s/he would normally make this "2" response.

Examples of this optimality test are shown in Figure 6. Notice that for several of the lower confidence "signal" responses, the subjects are more often incorrect than correct. Reversing these "suboptimal" responses to "noise" responses "corrects" for the suboptimality of the decision rule, providing a measure of the performance level that the subjects could have achieved if their decision rules were optimal. This *post-hoc* correction process has some important potential applications in the workplace: in principle, a trainer can make use of this information to give the trainees focused feedback that will allow them to optimize their decision-making strategies.

6. IMPLICATIONS FOR PERFORMANCE ASSESSMENT

Unless and until some other interpretation of these new empirical tests can be found that is consistent with the basic tenets of signal detection theory, the legitimacy of the *d'* and b analysis of discrimination performance is seriously open to question. Apparently, correcting for the effects of bias on the performance of a human operator is not merely a matter of adjusting for the value of a decision criterion, but instead involves explaining how and why biases affect the two distributions that describe the operator's information states. Area under the ROC curve, *d'* and other indices associated with signal detection theory may still provide some useful information about the operator's behavior, but it is not clear how this information should be interpreted. Similarly, most of the other indices developed to complement or replace the signal detection theory measures also rely heavily on the assumption (implicitly or explicitly stated) that the two encoding distributions are not affected by response bias.

Correcting for any suboptimality in the decision rule using the methods described above will make it possible to compare different operators or systems without the results being confounded by biases in the operator's decision rule. However, this method does not control for biases in the decision processes that influence other aspects of behavior, including how much information is collected before a decision is reached. If the encoding time is operator controlled, then biases can easily mimic the effects of sensitivity changes in signal detection theory. In such a case, the relationship between the operator's accuracy and response time may be the best source of information about the contribution of biases to overall performance. Fitting a response time model to the data is one way to quantify these effects, but of course there is no guarantee that the assumptions of a dynamic model will be any more accurate than those of signal detection theory. If accuracy (hit and correct rejection rate) is increasing and response time is decreasing under the two conditions being compared, than it would be difficult to find any formal model, static or dynamic, that would not attribute this effect to a change in sensitivity. However, if accuracy increases but response times also increase, then the result could be attributed to biases in the data collection process, even though *d'* and other performance indices are likely to suggest a change in sensitivity. Until more facts are known about the effects of bias on operator performance, strong inferences about relative sensitivity levels or the effects of a factor on sensitivity should probably be limited to situations in which response accuracy and response speed are either independent or positively covarying.

Situation Awareness

M. R. Endsley

SA Technologies, Inc., 4731 East Forest Peak, Marietta, GA 30066 USA

1. INTRODUCTION

Situation awareness (SA) is important for effective decision-making and performance in many domains, including aviation, nuclear power and chemical processing, automobiles, air traffic control, medical and health systems, tele-operations, trains, space operations, maintenance and advanced manufacturing systems. In these complex and dynamic environments, human decision-making is highly dependent on SA — a constantly evolving picture of the state of the environment. Situation awareness can be described broadly as people's state of knowledge or mental model of the situation around them.

Many definitions of SA have been developed, some very closely tied to the aircraft domain and some more general (Dominguez 1994 for a review). A general, widely applicable definition describes SA as "the perception of the elements in the environment within a volume of time and space, the comprehension of their meaning and the projection of their status in the near future" (Endsley 1988). SA involves perceiving critical factors in the environment (Level 1 SA), understanding what those factors mean, particularly when integrated together in relation to the decision maker's goals (Level 2), and at the highest level, an understanding of what will happen with the system in the near future (Level 3). These higher levels of SA allow operators to function in a timely and effective manner.

An operator's understanding and classification of the situation he or she is in forms the basis for all subsequent decision-making and performance. Even the best-trained operators will perform poorly if their SA is incorrect. One study of aircraft accidents found that as much as 88% of all accidents attributed to human error had an underlying problem with SA (Endsley 1995c).

1.1. Level 1 SA — Perception

The first step in achieving SA is to perceive the status, attributes and dynamics of relevant elements in the environment. This includes relevant system parameters, characteristics and actions of other individuals, and features of the external environment. In many systems, the basic information needed may not be present or may be obscured. In other cases, the information is clearly present; however, it is not attended to due to omission from the scan pattern, attentional narrowing, directing attention to other tasks or information or outside distractions. Failures in SA at this level have also been found to occur due to memory errors (where information is initially detected and then forgotten), and initial misperception of information (often due to distractions of other tasks or falsely succumbing to expectations) (Jones and Endsley 1996). Thus system designs which leave human operators susceptible to such errors may encourage low levels of SA.

Just knowing the value of system parameters is not sufficient, however. Data perceived also must be integrated and compared with operational goals to provide an understanding of what it really means, forming the second level of SA.

1.2. Level 2 SA — Comprehension of the Current Situation

Comprehension of the situation is based on a synthesis of disjointed Level 1 elements. Level 2 SA goes beyond simply being aware of the elements which are present, to include an understanding of the significance of those elements in light of one's goals. The decision-maker puts together level 1 data to form a holistic picture of the environment, including a comprehension of the significance of objects and events. Level 2 SA is developed over time based on the observed dynamics of the system (how variables are changing in relation to each other). It is furthermore highly goal-oriented. The values perceived are only meaningful as a function of the operator's goals.

Failures in comprehension of perceived information (Level 2 SA) have been found to be due to poor mental models for combining and interpreting information, use of the wrong mental model, and over-reliance on default values (normal expectations) in the mental model (Jones and Endsley 1996).

1.3. Level 3 SA — Projection of Future Status

It is the ability to project the future actions of the elements in the environment, at least in the very near term, that forms the third and highest level of situation awareness. This is achieved through knowledge of the status and dynamics of the elements and a comprehension of the situation (both levels 1 and 2 SA). This ability to predict what will be happening with the system, at least in the near term, allows them to behave proactively instead of reactively in dealing with the system. A high level of expertise may be needed to develop Level 3 SA. Failures in projection have been found to occur due to poor mental models and over-projection of current trends (Jones and Endsley 1996).

2. MODELS OF SA

Several researchers have put forth theoretical models depicting the role of numerous cognitive processes in the development of SA (Endsley 1988, 1994, 1995b, Fracker 1988, Taylor 1990, Taylor and Selcon 1994, Adams *et al.* 1995, Smith and Hancock 1995). There are many commonalties in these efforts that point to key mechanisms that are important for SA.

Endsley (1988, 1994, 1995d) proposed a framework model based on information processing theory. SA is regarded as a stage separate from decision-making and performance. SA is the main precursor to decision-making, however, many other factors can come into play in turning good SA into successful performance, including individual strategies, decision-making, training, and features of the environment (such as workload and system capabilities).

Several factors relevant to the individual and to the system/environment effect the accuracy and completeness of SA that operators derive from their environment. First, humans are limited by working memory and attention. The way in which operator attention is employed in complex environments that are often full of multiple competing cues is essential in determining which aspects of the situation will be processed to form SA. Once taken in, information must be integrated with other information, compared with goal states and projected into the future — all heavily demanding on working memory. Thus, limited attention and working memory can negatively effect the completeness and accuracy of SA.

Long-term memory stores in the form of mental models or schemtaa are described as playing a major role in overcoming these limitations. With experience operators develop internal models of the systems they operate, the individuals they work with (or against), and the environments they operate in. These models serve to help direct limited attention in efficient ways, provide a means of integrating information without loading working memory, and provide a mechanism for generating projection of future system states. Associated with these models may be schemata of prototypical system states. Critical cues in the environment may be matched to such schemata to indicate prototypical situations that provide instant situation classification and comprehension. Scripts of the proper actions to take may be attached to these situation prototypes, simplifying decision-making as well. Schemata of prototypical situations are incorporated in this process and in many instances may also be associated with scripts to produce single-step retrieval of actions from memory, thus providing for very rapid decision-making such as has been noted by Klein (1989). The use of mental models and schemata in achieving SA is considered to be dependent on the ability of the individual to pattern match between critical cues in the environment and elements in the mental model.

Goals are also shown in the model as being highly important for SA. SA is seen as resulting from dynamic alternating between data driven (bottom-up) and goal driven (top-down) processing. In goal driven processing, attention is directed across the environment based on current operator goals. The operator actively seeks information needed for goal attainment and the goals simultaneously act as a filter in interpreting the information that is perceived. In data driven processing, perceived environmental cues may indicate new goals that need to be active. Dynamic switching between these two processing modes is important for successful achievement of good SA.

In addition, preconceptions or expectations are shown to influence the formation of SA. These expectations may be formed based on mental models, prior experiences, instructions or other communications. These expectations influence how attention is deployed and the actual perception of information taken in.

Finally, automaticity is another mechanism developed with experience that is shown to influence SA in this model. With experience, the pattern-recognition/action-selection sequence can become highly routinized and developed to a level of automaticity. This provides good performance with a very low level of attention demand in certain well-understood environments. Thus, automaticity can positively effect SA by reducing demands on limited attention resources. SA can also be negatively effected by automaticity due to a reduction in responsiveness to novel stimuli, however.

Fracker (1988) similarly discusses the importance of both working memory and schemata in long-term memory for SA. He points out that while schemata may be very useful for facilitating situation assessment by providing a reduction in working memory demands, they can also lead to significant problems with biasing in the selection and interpretation of information which may create errors in SA. Jones (1997) showed that these biases can be very difficult to overcome, despite very overt cues indicating the erroneousness of the initial schemata.

Adams *et al.* (1995) stress the importance of the inter-relationship between one's state of knowledge, or SA, and the processes used to achieve that knowledge. Framed in terms of Neisser's (1976) model of perception and cognition, they make the point that one's current knowledge effects the process of acquiring and interpreting new knowledge in an ongoing cycle. This agrees with Sarter and Woods (1991) statement that SA is "the accessibility of a comprehensive and coherent situation representation which is continuously being updated in accordance with the results of recurrent situation assessments."

Smith and Hancock (1995) further support this proposition by stating that "SA is up-to-the-minute comprehension of task relevant information that enables appropriate decision-making under stress. As cognition-in-action, SA fashions behavior in anticipation of the task-specific consequences of alternative actions." In defining SA as "adaptive, externally directed consciousness," they take the view that SA is purposeful behavior that is directed toward achieving a goal in a specific task environment. They point-out that SA is therefore dependent on a normative definition of task performance and goals that are appropriate in the specific environment.

Several features of the external environment are also extremely important to SA (Endsley 1995d). First the capabilities of the system's sensors and other aids for detecting and presenting critical situational information to the operator is fundamental. The design of the operator interface for managing and presenting this information in a meaningful, easy to process and timely format is also evident. Other system features, such as automation and complexity, have also been found to significantly effect SA (Endsley and Kiris 1995, Endsley and Kaber 1999). Stress and workload are other external factors that relate to SA.

The relationship between SA and workload has been theorized to be important. Taylor (1990) includes a consideration of supply and demand of resources as central to situation awareness. Adams *et al.* (1995) also discuss the task management problem, involving prioritizing, updating task status, and servicing tasks in a queue, as central to SA. Endsley (1993), however, shows that for a large range of the spectrum, SA and workload can vary independently, diverging on the basis of numerous factors. Only when workload demands exceed maximum human capacity is SA necessarily at risk. SA problems may also occur under low workload (due to vigilance problems) or when workload is in some moderate region.

3. SITUATION AWARENESS MEASUREMENT

As SA has become a major design and training goal in many systems, the direct measurement of SA during system evaluation has become important. Several methods have been established for the measurement of situation awareness. (For a complete review see Endsley 1996 and Endsley and Garland 1999.) The impact of a particular design concept on SA can be measured directly through either objective or subjective means, or it can be inferred through less direct performance measures.

3.1. Objective Measurement

The most commonly used means of objectively evaluating a design concept's impact on SA involves directly questioning operators as to their perceptions of critical aspects of the system they are operating. The Situation Awareness Global Assessment Technique (SAGAT) (Endsley 1988, 1995b) is a technique in which an operator-in-the-loop real-time simulation of the system of interest

is frozen at randomly selected times, the system displays blanked and the simulation suspended while operators quickly answer questions about their current perceptions of the situation. A number of these "snap-shots" are collected across a range of operational conditions and events. Operator perceptions are then compared with the real situation based on simulation computer databases to provide an objective measure of SA with that particular design concept.

SAGAT includes queries about all operator SA requirements, including Level 1 (perception of data), Level 2 (comprehension of meaning) and Level 3 (projection of the near future) components. This includes a consideration of system functioning and status as well as relevant features of the external environment. SAGAT provides an objective, unbiased assessment of operator SA that overcomes memory problems incurred when collecting data after the fact, yet minimizes biasing of operator SA due to secondary task loading (from asking questions during system operation for instance). Empirical, predictive and content validity has been demonstrated for this technique (Endsley 1990a, b, 1995a). A certain degree of measurement reliability has been demonstrated in a study that found high reliability of SAGAT scores for four individuals who participated in two sets of simulation trials (Endsley and Bolstad 1994). SAGAT has been used successfully in a wide variety of domains, including cockpits, air traffic control, medicine, driving and power plant operations.

3.2. Subjective Measurement

Subjective measures of SA are easier and less expensive to administer than objective measures, but may lack the same degree of accuracy and diagnosticity. The most commonly used method is to have operators provide ratings of their SA with system concepts along a designated scale.

Taylor (1990) developed the Situational Awareness Rating Technique (SART) which has operators rate system designs on the amount of demand on attentional resources, supply of attentional resources and understanding of the situation provided. As such, it considers operators' perceived workload (supply and demand on attentional resources) in addition to their perceived understanding of the situation. While SART has been shown to be correlated with performance measures (Selcon and Taylor 1990), it is unclear whether this is due to the workload or the understanding components. SART and SAGAT have been found to have low correlation and are most like measuring very different aspects of the construct (Endsley *et al.* 1998).

3.3. Performance Measurement

In general, performance measures provide the advantage of being objective and are usually non-intrusive. Simulation computers can be programmed to record specified performance data automatically, making the required data relatively easy to collect. As many other factors can act to influence performance measures, however, such as individual strategy differences, variations in decision-making, and inability to carry out desired actions, performance measures can be limited for inferring SA by themselves. In addition, finding sensitive and diagnostic performance measures may be difficult in many systems.

Another limitation of this approach stems from the interactive nature of SA subcomponents. A new system or training technique-enhancing SA on one factor may simultaneously reduce SA on

another, unmeasured, factor (Wickens 1995). One way of dealing with these issues has been the careful development of scenarios that incorporate a "testable response" (Pritchett *et al.* 1995). This approach assumes very specific measurable performance outcomes that can be predetermined to be correct, given a particular level of SA. Researchers must be prepared for anomalous outcomes, however, because individuals may not react as expected to events and interpretation of their actions can sometimes be ambiguous. Performance measures can be used to augment the information provided by other SA measures, subject to these limitations.

4. SUMMARY

Following a structured approach from analysis to design to testing, SA can be incorporated as a significant and attainable design goal. Models of SA can be used to guide the design of systems and training programs to support operator SA. While not all human error is preventable, a significant portion of those problems that are currently labeled as human error can be addressed proactively and successfully by tackling the major design factors that lead to SA problems.

1. SITUATION AWARENESS

The term "situation awareness" came from the aviation operational environment where it has a personal meaning for crew members of all experience levels. In crew members' informal definitions, situation awareness (SA) equates to knowing what is going on with all relevant elements in the flight. For human factors research and theory, definitions of SA have been developed primarily for aviation. In general, definitions emphasize "awareness" over "situation". Perhaps the most quoted definition is that of Endsley (1995a): "the perception of the elements in the environment within a volume of time and space, the comprehension of their meaning, and the projection of their status in the near future."

Endsley (1995a) used an information processing model as a base for her framework, building an explanation for SA that centers on the use of mental models and pattern matching. She characterized SA as a "snapshot" of the crew member's awareness of the situation or situation model. Endsley and other researchers have explained that SA leads to the state of awareness and emphasized the temporal aspect in a dynamic situation (Endsley 1995a, Salas et al. 1995). In a different view, SA has been explained as an accessible situation representation that results from ongoing SAs (Sarter and Woods 1995). That is, a person's state of awareness is based on integrating and updating the knowledge which comes from multiple SAs. This view emphasizes SA as an ongoing cognitive process (Sarter and Woods 1995), as opposed to a state (Endsley 1995a).

Another position was proposed by Adams et al. (1995), who suggested that, because they are interdependent, it is difficult in practice to differentiate between the process and the product (or state). Adams et al. used Neisser's (1976) perceptual cycle to explain SA at the most basic level. In this view, exploratory activities directed by the individual's existing knowledge result in new information. That information is incorporated into the individual's existing knowledge, subsequently helping to direct further exploration. So this position views SA as an iterative process. In summarizing definitions and explanations of SA, Salas et al. (1995: 125) concluded that it "occurs as a consequence of an interaction of an individual's pre-existing relevant knowledge and expectations; the information available from the environment; and cognitive processing skills that include attention allocation, perception, data extraction, comprehension, and projection."

2. TEAM SITUATION AWARENESS

Although explanations of SA have focused on the individual, most aviators fly as part of a crew or team. The impact of the team on each crew member's SA is acknowledged in crew resource management (CRM) programs, where SA is regularly included as a topic. There is evidence that SA is an important aspect of performance in nonaviation teams as well (Salas et al. 1995). Team SA is considered sufficiently relevant to have research projects dedicated to its study and to have published guidelines for its training (Prince 1998).

Despite its recognized importance, there is not a defined scope for team SA. Definitions of team SA have been similar to those for individual SA, with the addition of some team interaction elements as part of team awareness (Salas et al. 1995). There are some who describe team SA as the sum of the awareness of all the crew members; others who consider team SA as only the state of awareness of crew members that are similar; and still others who define team SA as the awareness of each crew member necessary for accomplishing their tasks (Salas et al. 1995).

Each of these positions, as well as information from other relevant literature, was reviewed and considered by Stout et al. (1996) to propose a theoretical framework that explained how cognitive mechanisms facilitate the development of SA in teams performing in dynamic environments (e.g., aviation teams). They suggested that team SA is composed of each team member's SA (based on preexisting knowledge bases and cue and pattern assessment) and the degree of shared understanding (developed via compatible mental models and team interaction behaviors).

The state of team SA at any given time was proposed to be affected by a number of factors, including the situational context (e.g., mission to be performed, aircraft type), environmental elements (e.g., terrain and/or weather conditions), and temporal elements (e.g., time pressure, team being ahead or behind the game plan). This theoretical framework also considers the dynamic quality of team SA by suggesting that it can change instantaneously, based upon how the situation context and environmental and temporal factors affect team processes and the achievement and quality of shared understanding present in the team at any point in time.

3. RESEARCH EFFORTS

As theorists have explained, SA and team SA are primarily cognitive processes, and therefore research is arduous, deficient, and complex. Despite the difficulties, researchers have taken on the challenge of developing conceptual frameworks and conducting empirical investigations that generally have one of three major goals: to increase understanding of the construct, to develop SA instructional strategies, and to enhance SA measurement. Some of these research efforts and their implications are presented below.

3.1. Research to Understand the SA Construct

Several techniques have been used to identify the cognitive activities required for performing highly complex tasks, e.g., knowledge elicitation interviews, multidimensional scaling, concept mapping (Cooke 1994). These techniques, known collectively as cognitive task analysis (CTA), are used to identify task-related knowledge (e.g., concepts, rules, strategies, plans) and cognitive processes (e.g., recognize, anticipate, interpret). Information derived from this approach can have various applications, such as theory evaluation, expert/novice differences, human performance modeling, interface design, and instructional design.

Also CTA would be beneficial for learning about cognitive activities required for effective SA. For example, the ability to recognize relevant cue sets and patterns that facilitate the rapid assessment of a given task situation is critical for effective SA (Stout *et al.* 1999). Based on this notion, Stout and colleagues used knowledge elicitation interviews to uncover cue sets critical for naval aviators to achieve SA (Stout *et al.* 1999). These techniques were successful in identifying trends in the use of common and divergent cue patterns which aviators would attend to while performing a given task. So this data could become the basis for designing and delivering training.

3.2. Research to Develop SA Instructional Strategies

Information derived from a CTA can have implications for designing training strategies to instruct operators so they develop effective cue and pattern assessment that will enhance their SA. One approach that has emerged is cue recognition training, which involves prompting trainees to attend to relevant information in the task environment to increase the probability they will be aware of these cues in the future (Stout *et al.* 1999). Cue sets can be pointed out by using one of several subsets of cueing instructional strategies: passive system prompting, active prompting, behavioral coaching, and instructor-guided practice.

For passive system prompting, cue demonstration can occur via a static system demonstration that prompts relevant information. With active system prompting, cues are pointed out online as the individual or team is practising tasks. Behavioral coaching is a strategy in which a passive demonstration system is used for an instructor to verbalize cues they attend to in accomplishing a task, the relevant processes, and necessary steps taken. Instructor-guided practice is used to demonstrate cues online as the trainee is practising the task. This information is provided with instructor comments on what cues to attend to, the processes to attend to, and the necessary steps to accomplish the tasks. Each of these methods directs the trainee to relevant information in their task environment, and each is believed to enhance SA. Given that these strategies are still at a conceptual stage and have not been empirically evaluated, the choice of one method over another is probably best made by considering available resources.

3.3. Research to Enhance SA Measurement

The strategies, such as training, designed to enhance SA need to be evaluated for their effectiveness. This requires tools to assess individual SA and team SA. Researchers have proposed assessing cognitive processes and behavioral manifestations that indicate presence or absence of SA. Several strategies have been developed to capture a component of SA, but the effectiveness of each one has been criticized. It seems SA is difficult to measure.

SA measures have typically been clustered by several researchers into three categories: subjective measures, implicit measures, and explicit measures (Fracker 1991). Subjective measures are used to obtain an operator's impressions of their own SA or their impressions of another person's SA. An example is the situation awareness rating technique (SART), which requires individuals to rate statements based on the perceived demands of attention to different resources and perceived understanding of specific situations experienced during a given scenario (Taylor 1989). These measures have been critiqued as being ambiguous about whether individuals actually used or integrated information to understand the dynamics of a situation, so it is difficult to determine what these ratings actually capture (Fracker 1991). Despite these criticisms, SART type measures are commonly employed because they are easy to use and to document.

A second cluster of measures are the explicit measures, designed for individuals to self-report information from conscious memory. One of the most popular is the situation awareness global assessment technique (SAGAT); a "freeze" measurement technique, it was developed to assess the awareness of a pilot at various times during a scenario (Endsley 1995b). SAGAT stops a pilot as they fly a scenario, blanks all instruments, and asks a number of questions that relate to awareness (e.g., current heading, altitude, winds at destination). Answers to these questions are used to indicate the pilot's level of awareness. However, this technique has been criticized for intruding into the scenario. Not only is the pilot "removed" from the scenario's actions during questioning, but the questions asked may influence the information to which they are attending. On the other hand, prompting individuals to attend to specific information is believed to have potential as a training strategy for making individuals aware of the extent to which they missed relevant information in the situation.

The third cluster, implicit measures, attempt to use aspects of performance as an index of SA. One example is SALIANT, an event-based methodology whose acronym stands for situation awareness linked instances adapted to novel tasks. This approach uses a number of theoretically derived, predetermined markers; the markers are associated with specific events and they indicate the awareness of an individual or crew (Muñiz *et al.* 1998, Bowers *et al.* 1998). SALIANT was developed to be applicable in a variety of operational settings. The utility and validity of SALIANT have been evaluated with teams performing simulated aviation scenarios. Results of two preliminary validation studies indicated that SALIANT was related to measures of team communications and indices of performance, as suggested by theory (Muñiz *et al.* 1998, Bowers *et al.* 1998). A main criticism of this technique is it assumes a direct link between SA and performance. This problem may be addressed in part by generating indicators of SA based on theory and different from performance indices. A main advantage of the implicit methodology is that it facilitates online assessment of SA without disrupting an individual's behavior.

In general, a major criticism for SA measures is that each of them appears to have the potential to evaluate a component of SA while remaining insufficient to capture the construct as a whole. This suggests that SA should be measured using multiple evaluation instruments to capture its various dimensions.

4. PRINCIPLES OF INDIVIDUAL AND TEAM SA

SA has become important in various operational settings, therefore much research is dedicated to this topic. These efforts have generated a great deal of relevant information, and we can use it to extract principles or fundamentals about the current state of our knowledge.

SA is primarily a cognitive construct

At a high level there are several cognitive elements involved in the formation of SA, such as memory, perception, and action (Neisser 1976, Adams *et al.* 1995). Specifically, knowledge about

a particular situation guides exploratory and perceptual activities used to increase the interpretation about available information. But this is shaped by an individual's preexisting knowledge and expectations and basic familiarity with the current situation. This results in an update in the individual's knowledge, a modification in expectations, and another cycle of information.

SA is not a process but a state

SA is the *state* of knowledge for any given situation at some point in time, whereas the *process* is the cognitive activities that allow the situation to be assessed (Sarter and Woods 1995, Endsley 1995a, Adams *et al.* 1995). Although there are many useful motivations for establishing this distinction, e.g., clarification of the construct, measurement, and system design, remember there is no clear division at the cognitive level. This suggests an interdependence between the processes and the resultant state (Adams *et al.* 1995).

SA in teams involves individual SA and team-shared knowledge

A recent theoretical framework suggests that SA in teams has two main components: individual SA and shared knowledge. Stout and her colleagues have noted how each team member forms SA based on preexisting knowledge along with cue and pattern assessment. Team members also achieve a level of shared knowledge about a given situation and this is developed using compatible mental models and team interaction behaviors.

SA must be measured with multiple methods

Although there are now many measurement methodologies, they share the same problem of capturing only one element of SA. In this respect, they are *all* considered insufficient. There is no single measure that gives a complete index of SA. This means that we need more than one type of measurement to capture the various dimensions of SA so we can obtain a true sense of its level in an individual or team.

SA measures must be construct valid

Many critics have noted that SA measures are not clear about what they capture. To address this problem, it is important to derive SA components as suggested by theory; this ensures the measures actually assess the relevant construct. According to Muñiz *et al.* (1998) and Bowers *et al.* (1998), to demonstrate its effectiveness, each measure should be compared with other SA measures and with measures of other theoretical constructs which modify or influence SA (e.g., communication, performance, mental models).

SA must be trained in context

Cue recognition training has recently emerged as a way of training individuals to attend to relevant cues delineated a priori with CTA (Stout *et al.* 1999). This makes it critical to determine which cues are more relevant and when they are most relevant, given the specific mission at hand. This information is crucial in determining how the cues are important within a given context, hence it affects how to incorporate appropriate learning activities to make them salient during training. With proper training, an individual can derive why the cues are meaningful in context, and can go on to build appropriate knowledge structures for future situations that require attention to these cues.

Overall there is a great deal of information derived from SA research, suggesting that some strides have been made in this area. Progress in SA-related research is helping us to formulate some principles. The future of SA research seems bright. There is still much more to be learned and many more questions to be answered. But our knowledge about this domain is undergoing continual advancement.

1. INTRODUCTION

The performance of a skill is influenced, and often determined, by the information provided as feedback from an external source, such as a supervisor, or expert. One class of such information is augmented feedback — movement-related information about the task, which supplements a performer's intrinsic feedback. Over the past century or so researchers have examined the various aspects associated with the informational content of augmented feedback, the schedules to present this information, the temporal placement of this feedback, and plausible theoretical explanations that describe how feedback affects skilled performance (for a review, see Schmidt and Lee 1999). In this chapter we discuss the various classes and experimental methods used to study augmented feedback, then present some of the primary laws regarding how augmented feedback influences performance and learning, and end with a description of some explanations that serve as a basis for applying feedback to human performance.

2. CLASSES OF AUGMENTED FEEDBACK

Of the various classes of information that are received and processed as feedback, several distinctions and characteristics are of importance for defining augmented feedback. First, augmented feedback is concerned with the control of movement, such as the direction of the error that a movement has produced. Second, the information is generated as a consequence of the movement; hence, it is not available before the execution of a movement. Several other important distinctions are presented next.

2.1. Extrinsic Feedback

The information provided about the movement by an external source (e.g. instructor, computer, etc.) is defined as extrinsic feedback. In contrast, the sensation or feel that is inherently provided by our sensory receptors in the normal course of a movement is classified as intrinsic feedback. Often, this information, which includes tactile, auditory, and visual feedback, can provide a sufficiently clear representation of the necessary cues relevant for performance (e.g. turning a potentiometer to move the hands on a watch to the appropriate time). However, there are many instances where additional information is needed for performance (e.g. the information provided by a speedometer to indicate the speed of vehicle) or to adequately learn how to perform skill. In this way, extrinsic feedback supplements or augments the information beyond that which is available from the performer's own intrinsic sources.

2.2. Concurrent Feedback

Augmented feedback, although generated as a consequence of movement, can be provided to a performer during a movement. When delivered during the course of a movement, the information is referred to as concurrent feedback. The information feedback about the glide path that occurs when landing a plane is one such example. Generally, performers can utilize concurrent feedback to minimize errors in continuous tasks that exceed several hundred milliseconds. Although concurrent feedback has obvious benefits for performance, it can be detrimental to the relatively long-term beneficial effects associated with learning (Schmidt and Wulf 1997). One potential problem with the provision of augmented concurrent feedback is that it can be used as a substitute for sensory information — when feedback is not available, as in a later test condition, performance suffers (see Section 3).

2.3. Terminal Feedback

When augmented feedback is delayed until the completion of a movement, it is referred to as terminal or post-movement feedback. Often, feedback is delayed to provide the complete set of information about the entire response or its outcome. The vast majority of research has manipulated some aspect of terminal feedback that is not coincident with the movement. This body of research provides the basis for the principles and laws that govern when, how, and what augmented feedback should be provided.

2.4. Informational Content

There are various classes of augmented feedback that provide different sources of information to a performer. Two of the more important sources of information for both performance and retention of skilled performance are given as outcome information (knowledge of results) and movement-pattern information (knowledge of performance).

2.4.1. Knowledge of results

Information about extent to which the performer achieved the outcome in terms of the environmental goal is typically referred to as knowledge of results (KR). This type of feedback provides information about the success of the movement, but not about the movement pattern or characteristics that led to the outcome. KR can augment intrinsic feedback, but also can be redundant with the information the performer normally receives during the course of a movement (e.g. receiving auditory information from a buzzer about entering a building and visually detecting the same information).

2.4.2. Knowledge of performance

In contrast to KR, which provides information about goal success, feedback concerned with the movement pattern itself or some aspect the human system that leads to the movement is referred to as knowledge of performance (KP). In the broadest sense, this feedback includes information about movement pattern kinematics, the forces that produced the movement (or kinetics), and other aspects of the physiological system that are not easily perceived by a performer.

Videotaped feedback of a performer's action is now a common method used to display KP of limb and/or body kinematics. Although there often is a delay associated with the playback of this augmented feedback, performers can observe their overall movement pattern to gain an enhanced perspective of the spatio-temporal aspects of the action and coordination pattern. One

critical aspect in the provision of videotaped feedback involves directing a performer's attention to specific aspects of the movement that require modification or correction. In this way, a performer is less likely to be distracted by irrelevant features of the movement or environmental stimuli, and can focus on those characteristics of the movement pattern that are critical in achieving the desired behavioral outcomes. Failure to direct a performer's attention to specific aspects of the videotape can diminish the beneficial effects of this presentation method and make KP ineffective for learning.

3. AUGMENTED FEEDBACK RESEARCH METHODOLOGY

Two experimental approaches have played an important role in understanding how feedback influences performance. Each has ramifications for training procedures as well as retention and transfer performance.

3.1. Knowledge of Results Paradigm

Much of what is known about how augmented feedback functions to alter human performance and skill acquisition has been derived from one basic experimental paradigm. Typically, this methodology requires subjects to control a very simple, single-degree-of-freedom task (e.g. pointing), where the outcome is masked from the performer's intrinsic feedback sources. In this way, augmented feedback — typically given as information about the movement's success or KR — becomes a necessity for performance and learning. In this movement environment, albeit a very artificial and contrived situation, manipulations of the precision, schedule and temporal placement of feedback can be made to determine how feedback influences performance. Hopefully, the findings from these experiments generalize to other, more complex movement settings, where some type of augmented feedback is provided to a performer. This body of research serves as the basis for our formulation of laws of augmented feedback.

3.2. Transfer Designs

Another important empirical consideration in the study of augmented feedback includes the utilization of a transfer design. This method for studying the influence of some feedback variable (e.g. precision of feedback) consists of an acquisition phase and a retention or transfer phase that are separated by a rest interval that varies from a few minutes to a week or more. The purpose of using this experimental method is to distinguish the temporary effects of feedback, which are associated with performance in acquisition, from the more permanent effects of feedback that would be displayed in performance during the retention test. Other advantages of this method are presented in the section on practice (see Skill Learning: Conditions of Training, Chapter xxx).

4. LAWS OF PRECISION

The accuracy, in terms of the correctness or specificity, of feedback has been of interest to scientists because of its implications for information processing theory. However, an understanding of the laws of precision will also provide a reliable method for administering feedback in training situations.

4.1. Correct and Erroneous Feedback

Early research on feedback established that correct feedback reduced errors in performance, and was responsible for gains in retention over nonsense or no feedback. Subsequent research further established the powerful influence of feedback with manipulations of incorrect or erroneous feedback. In these studies, incorrect feedback was found to impair performance and learning in tasks where subjects could evaluate their performance via intrinsic feedback mechanisms. Hence, subjects used the inaccurate feedback, instead of their own more accurate internally generated sensory feedback, as a basis for acquiring a new skill. These findings are of particular relevance for the provision of KP, as the incorrect information about the pattern of actions could result in negative or reduced learning.

4.2. Specificity of Feedback

The consideration of how specific the feedback should be provided has typically been separated into two classes: qualitative and quantitative. Qualitative feedback is general information about goal success can be provided in forms that merely indicate the correctness ("right" or "wrong"), direction ("short" or "long), or along some other dimension ("high force" or "low force"). In contrast, to qualitative feedback, specific information or quantitative feedback about the accuracy of the response can be provided with exact deviations from target-goals (e.g. "2 mm too short of the target"). This specific feedback, when compared with qualitative feedback, is generally more effective for both performance and learning. However, studies have shown that extremely precise information about errors is ignored and, therefore, unnecessary. Generally, the evidence suggests that information about the direction and magnitude of the error is most beneficial.

Another variant of feedback precision, bandwidth feedback, provides specific information about the accuracy of a movement only when performance exceeds a specified boundary or tolerance for error. In this method of providing feedback, learning is significantly improved in retention with 10% bandwidth (i.e. providing feedback when the errors are less than 90% correct) when compared with a 0% bandwidth (i.e. providing feedback after every trial). As discussed below, this method for providing feedback may be effective because of the precision of the information provided, but also due to the reduced frequency that the information is given to the performer.

5. TEMPORAL LOCUS PRINCIPLES

The provision of augmented feedback between trials of training, i.e., during the inter-trial interval, has created two additional intervals of importance for performance and learning. Unfortunately, the research is somewhat unclear as to how some of the associated temporal-locus variables influence movement control. Nevertheless, this section provides an overview of the general understanding in this area.

5.1. Feedback–Delay Interval

The first is the feedback-delay interval, representing the time that the feedback is delayed after the movement. It has long been believed that increasing the feedback-delay interval would degrade learning for two reasons. First, a long delay would be similar to the degraded learning effects found in the delaying a

reinforcement or reward in animal learning studies. Second, a lengthened feedback-delay interval would weaken the possibility that the performer could associate the movement commands with the outcome or intrinsic feedback consequences thought to be critical for learning (Adams 1971). These notions, however, are no longer considered correct as empirical research has indicated that increased feedback-delay intervals have not affected learning of human skills. In fact, the opposite effect has been shown — no delay or instantaneous presentation of feedback after the movement degrades learning, and, to some extent, performance as well.

Further research that has involved the completion of interpolated activities has provided support for the notion that subjects process intrinsic information about their movement during this interval. Research has shown that interfering with these processes by "filling" the interval with a non-related, attention-demanding task degrades learning. In other research, which has required subjects to verbally estimate their movement errors during this interval, skill learning is facilitated. Together, these findings provide strong evidence that the intrinsic error-detection processes associated with movement control are important in the learning process.

5.2. Post-Feedback-Delay Interval

In contrast to the feedback-delay interval, the temporal interval following the provision of feedback has not been as thoroughly investigated. Some data support the presumption that two important activities occur here. First, a comparison of intrinsic and extrinsic feedback is completed, which is then followed by a development of a plan for the subsequent movement. Unfortunately, support for these propositions is sparse and potentially related to variations in the inter-trial interval. Nevertheless, there is no evidence to suggest that important processes do not occur here.

6. SCHEDULING FEEDBACK

There are a variety of ways in which one could present feedback over the course of an training session. In this section, we present several of the more well-known and studied methods.

6.1. Frequency of Feedback

Studies have evaluated the "amount" or number of trials for which feedback is presented through absolute and relative frequency manipulations. Absolute frequency is the number of feedback presentations received over the course of an acquisition phase, while relative frequency refers to the proportion of trials on which feedback is provided. Research consistently reports that more feedback in the acquisition phase facilitates performance over lower absolute and relative frequencies. However, contrary to these findings, the effects in retention are very different. The vast majority of research indicates that relative frequencies, some as low as 10%, are more beneficial for retention performance than every-trial or 100% feedback conditions.

6.2. Fading Schedules

The effects of relative frequency are more pronounced when provided in a "fading" schedule, which provides feedback relatively often during the initial stages of practice and systematically withdraws feedback as practice progresses. When

compared with a 100% feedback condition, the fading of feedback generates similar effects to those discussed above: the lower relative frequency reduces acquisition performance, relative to an every-trial feedback condition, but facilitates retention performance.

6.3. Trials Delay

Another method for providing feedback to a performer involves the delay of this information for more than a trial. That is, the feedback for a given trial would not be verbalized or provided to a performer until after a number of intervening trials have been completed. On the surface, this trials-delay procedure would appear to be extremely disruptive to performance as a learner would have difficulty in linking or associating a particular feedback result with a movement responsible for producing it, since several other trials could potentially intervene. Early literature in this area confirms these negative effects on acquisition performance. However, more recent research that has examined the effect of a trials-delay procedure in both acquisition and retention report counter-intuitive results. Instead of lower performance relative to an every-trial schedule, a trials-delay of feedback given in a summary format — where feedback about each trial in a sequence was provided after all trials in that set had been completed — resulted in greater retention performance (e.g. Schmidt et al. 1989). These general "reversal" effects are shown in Figure 1. Similar effects have been found for an average format, which involves providing an average value for a set of trials at the completion of the set.

One aspect of subsequent work on summary feedback has attempted to determine an optimal summary length. This effort was based on the assumption that an extremely long summary length would be of little use to a performer, yet every-trial feedback would be detrimental to learning. Although no particular summary length appears to optimal for learning, there is strong evidence to indicate that summary length is related to task complexity, where longer summary lengths are appropriate for simple tasks and shorter lengths for more complex tasks.

7. THEORETICAL EXPLANATIONS

Over the course of the last century or so, there have been numerous explanations for how augmented feedback is used in the control and acquisition of skills (see Adams 1987, for a historical review). In this section, we present the theoretical explanations that have substantial empirical support and represent the current thinking about how feedback works.

7.1. Augmented Feedback Provides Information about Response Errors

Whereas augmented feedback has long been believed to function primarily as a reward, augmented feedback also can be used to determine the nature of their errors. This information is critical in planning what do change and how to make subsequent movements more accurate. Feedback may also serve to develop accurate error detection and correction mechanisms, where performers evaluate intrinsic feedback and compare it with extrinsic feedback.

7.2. Augmented Feedback can Motivate Performers

Augmented feedback has a strong energizing role for performers. It can make a task seem more interesting, enjoyable, and often results in individuals setting higher performance goals. As a result, performers are more inclined to practice longer, more often, and with more effort. These motivation effects appear to be performance phenomena, which can be expected to subside after the practice or training period has completed. However, given that learning is significantly influenced by practice and the conditions associated with it, the motivational qualities of feedback can be thought to indirectly influence learning as well.

7.3. Augmented Feedback Works like Guidance

Whereas older ideas suggested that augmented feedback helps to develop associations between movements and their outcomes, more recent evidence suggest that feedback has guidance-type properties (Salmoni *et al.* 1984). First, feedback directs performers about how movements are erroneous and helps to reduce these errors. Second, too-frequent or immediate feedback may prevent the development of important information processing activities. Third, too much information may force performers into developing corrective behaviors that are beneficial for immediate performance, but detrimental for long-term performance. These "short-term maladaptive corrections" occur when performers constantly adjust or change their movements after feedback is received. Finally, as with physical guidance, performers may develop a reliance on augmented feedback, process it as part of the task, and have difficulty with performance on the task later when feedback is not available.

1. INTRODUCTION

The acquisition of new skills is critical for operators who are required to adapt activities to workplaces that are new or which have been updated with different equipment, tasks, or procedures. For situations in which it is not cost-effective or safe for the operator to acquire these skills on the job, special training conditions may be organized so that the operator may acquire these behaviors before entering (or reentering) the workplace. These training conditions are designed to provide the operator with an opportunity to practice the skills that will be necessary for safe and effective performance in the workplace. The purpose of this chapter is to describe how training conditions can be organized to have a significant impact on the effectiveness of performance when the employee enters the workplace.

Applied research, involving specific workplace training conditions in specific job situations, has rarely been conducted or reported in the literature (for an exception, see, for example, Baddeley and Longman 1978). However, a significant amount of research has been conducted regarding the acquisition of skills that are novel to the learner and require practice in order to be learned. We discuss training *conditions* under two general sections: (1) involving hands-on practice (termed *on-task* training conditions), and (2) involving practice away from the actual task (*off-task* training conditions). Before we begin this discussion, however, we describe the important issue regarding how learning is assessed, and distinguish between situations in which training conditions primarily impact temporary changes in performance from the conditions that influence the more permanent changes associated with *learning*.

2. THE LEARNING/PERFORMANCE DISTINCTION

Some training conditions are effective in providing an immediate, short-term benefit to performance. In learning a new procedure, for example, guidance conditions can be arranged that are specifically designed to minimize the amount of error that can occur while practicing a task. However, even though performance may be enhanced while the guidance training condition is in effect, this temporary boost often fails to satisfy the overall training goal, which is to influence *learning* of the skills. By definition, learning involves the relatively permanent change in the capability to perform a skill (Schmidt and Lee 1999). Assessments of learning during the time when a guidance training condition is being implemented can be misleading because of the temporary elevation in performance that is provided by these conditions. A better way to assess learning is to evaluate *retention* or *transfer* of the skills following a period in which the skills have not been specifically practiced, and where the training conditions are no longer providing a temporary benefit to performance.

Performance in retention and transfer tests is used, retroactively, to assess the effectiveness of the different conditions that had used during the training interval.

In this paper, we refer to *effectiveness* in terms of whether a type of training condition results in retention or transfer performance that is qualitatively and/or quantitatively superior to one or more comparison training condition(s). But, training conditions are also concerned with *efficiency*, defined in terms of the amount of training time that is required to produce equivalent amounts of learning under different conditions. In our review of training conditions we will be concerned with both effectiveness and efficiency when discussing the relative merits of specific conditions of training.

3. ON-TASK TRAINING

Physical interaction with the materials, equipment, tools, etc. to acquire new skills is the most critical condition of learning. Below we describe conditions in which the organization of physical interactions with a task during training session(s) has been assessed.

3.1. Distribution of Work and Rest Periods

Practice *distribution* refers to the amount of time spent in training (periods of "work") relative to the amount of time spent not in training (e.g. resting). Experiments of this type often include conditions of *massed* and *spaced* practice, which represent two points on a practice distribution continuum. No rest at all during practice on the task would represent an extreme form of massed practice, and an infinite time between on-task practice would represent the hypothetical extreme of spaced practice. Many types of tasks have been used in this research and the vast majority of them can be classified as *continuous* tasks, in which the work activity continues uninterrupted for an extended period of time (e.g. 20 or 30 s duration). The results of this research are very clear: spaced practice conditions produce very large performance benefits during the training period in comparison with massed practice conditions (reviewed in Lee and Genovese 1988). A similar finding occurs in retention — spaced practice results in better retention performance (and, hence, better *learning*) than massed practice (although the size of the learning effect is usually not as large or dramatic as the performance effect).

Thus, for practice distribution *effectiveness*, the general conclusion is that it is better to provide significant rest periods between periods of work during practice than to provide little or no rest at all. Note however, that longer rest periods will reduce the *efficiency* of the training protocol in terms of the overall time spent in the training regime, due to the increased rest required for effectively spaced practice. Although this could pose a dilemma for deciding on the relative merits of spaced versus massed training, we discuss below a training condition in which practice on other tasks can be substituted in the "rest" interval to improve both learning effectiveness *and* efficiency.

3.2. Task Variability

In many job-related situations there is wide variation in the specific design of the workplace, the tools to be used, and the actions required of the operator. For example, parking lot attendants must be able to adapt to a variety of driver cockpit dimensions, using pedals, knobs, levers and other manipulanda

that vary widely in size, shape, action, etc., and they must perform these actions with varying amounts of movement amplitudes, forces, and accuracy tolerances. How can an effective training regime prepare the operator to adapt to these changing demands in the workplace?

Research on this issue has focused specifically on *transfer* as the main criterion for learning. Typically, studies have contrasted two types of training conditions. In one condition (*low* variability) the operator practices only one version of the task to be learned. In another training condition (*high* variability) the operator practices the same number of total practice trials as in the low variability condition, but disperses these trials across several or more variations of the task to be learned. The assessment for learning effectiveness is a transfer test in which individuals in both experimental conditions are required to perform a novel version of the task. Using our original analogy, such a transfer test might involve an employee parking a completely unfamiliar car for the first time.

As one might expect, performing *n* trials on one version of a task results in better overall performance than practicing the same number of trials spread out over several task variations (see Shapiro and Schmidt, 1982, for a review of this literature). In contrast, transfer to a novel task variation almost always favors the operator who has practiced multiple variations of the task. These findings are consistent with the view that skills are learned as a *schema* — an abstract form of memory representation for the motor skill that allows the operator to generalize beyond the subsets of skills that have been specifically practiced (Schmidt 1975). Development of the schema will be more effective if the practice regime promotes a breadth of task variation experience. It should also be noted that training efficiency will also be facilitated by variability in practice. Not only will training time on new task variations be reduced by variable practice, but evidence also suggests that retention of the specific tasks that have been practiced is also facilitated by variable practice (for details, see Schmidt and Lee 1999).

3.3. Contextual Interference

Above we presented evidence that training several versions of a task facilitates retention and transfer. One additional issue about this research pertains specifically to *how* the training is conducted. If *n* training trials are conducted on each of *x* tasks or skills, then a critical question remains as to how to *structure* the training order of the tasks. A traditional view of skill training advocates concentrated, drill-type practice sequences (termed *blocked* training) in which all of the practice attempts on any one task are practiced in isolation; training trials on another task are introduced into the practice sequence only when considerable mastery of performance has been demonstrated for the current task. More recently, however, researchers have examined the effectiveness of a practice sequence in which practice trials are conducted concurrently on all of the task versions to be trained. In this practice sequence (termed *random* training) there is no concern that a certain level of performance must be achieved before practice on a new task is introduced. In fact, the random ordering of practice trials suppresses the overall level of performance that can be achieved during the training session. This suppression in performance, however, is only an artifact of the training regime. When learning is assessed later, in retention

and transfer, there is overwhelming evidence to suggest that random practice has resulted in far superior learning effectiveness than blocked practice. Although differing views exist for the reasons why random practice is so effective, there is considerable evidence to suggest that it relates to the *cognitive effort* that operators must exert when faced with the difficulties of practicing in such a highly performance-debilitating task order (reviewed in Schmidt and Lee 1999).

The blocked versus random practice issue, termed the *contextual interference effect* (Shea and Morgan 1979), represents a fundamental paradox regarding the performance of operators during training as compared with their later performance in retention and transfer. By its very nature, blocked practice results in superior performance during the training session(s) than random practice, and might therefore be considered the better training order in terms of both effectiveness and efficiency. The paradox is that blocked practice is actually very *ineffective* for learning because much of the improvement in performance vanishes quickly, and *inefficient* because retraining on the same skills will be necessary. This basic finding has been replicated for a large number of motor skills, as well as various perceptual, verbal, and problem-solving skills (for a review, see Schmidt and Lee 1999).

Random practice conditions also represent a potential solution to the problem of inefficiency when practice distributions are spaced, as discussed above. Recall that, in spaced practice, the interval of time between practice attempts is spent resting or otherwise not engaged in practice. Compared with massed practice, this more effective practice schedule is not very efficient because it lengthens the overall total training time. The contextual interference evidence, however, would suggest that both efficiency and effectiveness would be facilitated if, rather than resting, the operator spent this time engaged in practice on a different task or a variation of the task.

3.4. Part- and Whole-task Practice

When introducing a new skill to be learned, a frequent question is whether the operator should practice the task in its entirety (termed *whole-task* training) or break down the task and practice it in its component parts (termed *part-task* training). The issue is primarily one involving transfer, as eventually the operator will be required to practice the whole task, and whether transfer from part-task training will be more effective and/or efficient than practice of the entire task.

The research evidence on this question varies depending on the type of task that is practiced. In some tasks, the operator's goal is to perform a brief action that involves the coordination of various body segments. Shifting while operating a vehicle is a good example as the actions of all four limbs must be timed precisely in order to achieve a smooth shift. In these tasks (termed *discrete* tasks), the whole action of each of the limbs must be learned, but successful completion cannot occur unless they can be performed together, with the correct timing of their sequence, including their mutual (dynamic) interactions. For discrete (and continuous) tasks, the research suggests that training the whole task is more effective and efficient than part-task training; and part-task training has even been shown to produce negative transfer to the whole.

In a different type of task (termed *serial* tasks), any one discrete

component of the task can be considered a unique entity of the whole task to be performed. In serial tasks, the whole task actually is comprised of a series of individual, discrete component tasks. For example, swiping a card with a magnetic stripe through a card reader represents a component task that initiates an automated human–computer sequence. In this situation, it is not critical that the component task be learned as part of any specific whole task. Indeed, for most serial tasks the individual discrete components represent parts of other serial tasks as well (e.g. swiping the card for initiating a purchase, to identify oneself, to enter a secure area, etc.). Research suggests that part-practice is as effective for whole-task transfer and is more efficient due to the transferability of the individual components of the task to the performance of other serial tasks.

4. OFF–TASK TRAINING

Although the effects are not as large as when physically interacting with a task, considerable learning can be gained from different types of training conducted away from the task. Below we describe how training can continue when the operator does not physically perform the task.

4.1. Observational Learning

Cognition, although overshadowed by the dominance of the active, physical component in many tasks, plays a very important role in learning new skills. In fact, most learning theories acknowledge that the cognitive stage is the initial step in the acquisition of any new skill. The operator must understand the goal of the task and the regulatory environmental information that is important to attend to, and be capable of verbalizing some rudimentary plan about how to structure the action prior to performance. In other words, knowledge that is verbalizable and which can be imaged serves a critical role in the acquisition, retention, and transfer of any skill.

Acquisition of the cognitive components of skill can be facilitated through observation. Some of this research has been directed at learning sport skills. An example is the use of videotapes of skilled athletes to model correct or desirable performance. However, research suggests that simply watching a skilled performer has limited benefits. For example, an equivalent benefit to learning can be achieved from observing the performance of a cohort who is at about the same stage of learning as the observer, to ascertain what the cohort has done and how attempts are made to improve performance. In a sense, the observer is drawn into the same problem-solving process as the cohort, but without actually performing the task.

There are many other research issues pertaining to the effectiveness of the observational learning situation that are of obvious importance to human factors, but are beyond the scope of this review (McCullagh 1993 is a good source for further information). Perhaps of most importance however, is the potential for observational learning to improve the efficiency in the training of new skills, especially so when the cost of "hands-on" training with expensive equipment is a factor (e.g. learning to fly an airplane).

4.2. Mental Practice

As the term suggests, mental practice involves the "performance" of a skill in the absence of overt, physical activity. Various forms of mental practice have been investigated, although the most common involves the use of *imagery*. Above we discussed the role that cognition plays in the early stages of learning, and why observational learning is effective. The same logic applies for mental practice. The verbalizable components of skills can be rehearsed through subvocalizations, the visualizable components can be imagined (from either an internalized viewpoint or from a "bird's-eye" viewpoint), and the nature of the action can be subjected to a form of mental rehearsal that runs through both the motor and sensory components of the movement.

Mental practice is quite effective in learning a wide number of tasks. In fact, some studies have shown that, when combined with trials involving physical practice, mental practice is as effective as an equivalent number of additional physical practice trials. Many other factors, such as individual differences, schedules of mental practice, and the like, were reviewed by Feltz and Landers (1983; also Schmidt and Lee 1999). Similar to observational learning, the role of mental practice to human factors has important implications for the efficiency of training programs. If some of the learning benefits from expensive physical interactions with a piece of equipment can be generated by mental rehearsing the task elsewhere, then the overall cost of training could be reduced substantially.

5. SUMMARY COMMENTS

In the foregoing discussion we have presented evidence of a number of situations in which learning can occur in the *absence* of observable physical improvements in performance (e.g. in mental practice and observation). As well, situations occur where performance during practice completely misrepresents how learning is proceeding (e.g. variable versus constant training conditions; random versus blocked training conditions). In these and other instances feelings about the effectiveness and efficiency of a training condition may be an *illusion* if based on subjective evaluations or short-term changes in performance (Bjork 1998). Thus, we feel that it is important not only for the instructor or evaluator of training conditions to be aware of the distinction between performance and learning, but also that the learner be made aware of this distinction as well. Illusions of competence in learning can be potentially dangerous if performance improvements vanish quickly or do not transfer well beyond the training regime.

Sleeping Systems: Current Status

B. Haex and R. van Haute

Biomechanics and Engineering Design, Celestijnenlaan 200 A, B-3001 Leuven, Belgium

1. INTRODUCTION

In the Western world, people did not think about sleeping on a well-supported structures until recently: they slept on a sagged, worn down mattress placed on a declined spring base. In the late 1950s a firm bed was promoted for the prevention of low back pain, and many people started to put a wood board under the mattress, it being a typical solution that insufficiently corrects the supporting properties and may cause ventilation problems. Today the definition of a correct sleeping system is much more differentiated, as is discussed in Chapter XX. Nowadays a bed generally consists of a mattress, a mattress support, a frame, a head cushion and a blanket. This Chapter discusses how these different parts can be designed and combined to obtain an adequate sleeping system.

Section 2 discusses different mattress varieties (both core and top layers) and how their material properties influence general characteristics; section 3 illustrates different supporting structures, and explains which kinds of supports can be combined with each of the different mattress classes; finally section 4 briefly discusses head cushions. The bed frame should be strong enough, but apart from esthetical aspects it has no further influence on sleeping comfort, and it will, therefore, not be discussed. Nor will the variety of blankets, because they only affects heat and moisture transportation, which is of secondary importance compared with mechanical properties (especially back supporting qualities) when concentrating on the development of sleeping systems for normal healthy people and thus on the prevention of eventual back problems and discomfort.

2. MATTRESSES

A mattress consists of a core with one or more top layers, surrounded by a cover. Depending on the kind of mattress the cover may be stretchable or detachable. Generally four kinds of mattresses are produced: foam (e.g. polyurethane), latex (e.g. nature latex), spring (e.g. bi-conical-spring mattress) and fluidum-based beds (e.g. waterbeds). Wool, silk and cotton are common top layer materials. Futon or straw mattresses will not be discussed.

2.1. Core

2.1.1. Polyurethane foam mattresses

Polyurethane is a synthetic material that obtains its flexibility through foaming; the material can be applied to perform different functions, e.g. isolation, bedding, coating. Foam mattresses consist of a cellular network giving the material a specific density, elasticity and air permeability. Mattress density measures the weight per unit of volume, and defines the fatigue resistance of mattresses. In principle, foams with higher densities should have a higher stiffness; the fact that one can achieve a wide variety of stiffness characteristics for a given density is one of the main advantages of polyurethane. New chemical procedures (e.g. high-resilient foam) allow producing mattresses with a high density without a stiffness that is too high. A foam mattress core should have a thickness of at least 0.12 m and a density of at least 35 kg/m^3 brut to obtain a reliable fatigue resistance.

Normal polyurethane cells have a homogeneous, non-isotropic, open structure. These mattress cores give a reasonable

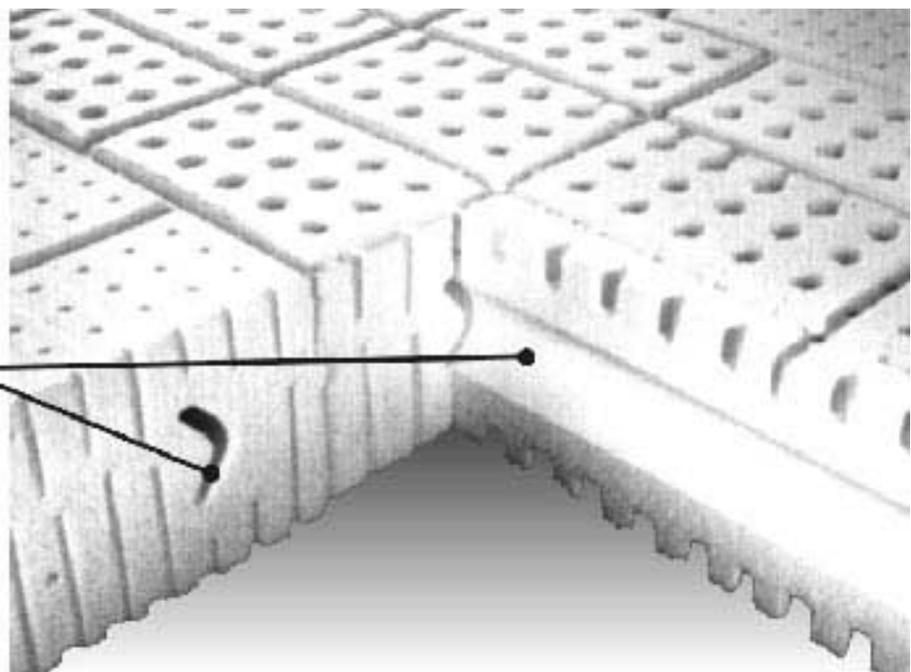
Soft zone indentation


Figure 1. Latex mattress with different stiffness zones.

body support thanks to a small hysteresis and a good elastic behavior. Further, they give good heat isolation, reasonable moisture permeability and they are light and, therefore, easy to manipulate. High-resilient foam cells have a differentiated, isotropic and open structure; material density is much higher. A minimal hysteresis and a perfect elasticity give these mattresses very good supporting qualities; fatigue resistance and moisture transportation are optimal; heat isolation is very good, as is the case for most foams.

2.1.2. Latex foam mattresses

Latex mattresses consist of a block of foamed rubber particles and, therefore, sometimes are called rubber foam mattresses. Rubber particles are of synthetic or natural origin — combinations are possible — and can be foamed firmly or softly. Nature latex mattresses contain ~80% natural latex, completed with synthetic additives, which are necessary to process rubber to latex and to obtain the required elastic properties. Latex is further formed by molding and vulcanized to be dimensionally stable and resistant to temperature fluctuations. As opposed to polyurethane, latex foams show a rather strict relation between density and hardness.

Latex is especially suited for the fabrication of mattresses with different stiffness zones: thanks to adequate mould design a material cut-away obtains a softer elastic behavior when requested. Each zone with well-defined elastic properties can deform independently from other zones: when indenting the hip zone, it only deforms locally without exerting influence on either the shoulder zone or leg zone. Latex, therefore, presents perfect supporting qualities in case the mattress is conceived well; an air chamber with an adjustable volume can even improve the support in the lumbar area. Further, latex is supple, heavy and consequently difficult to manipulate; it has a low air permeability, but offers a very good heat isolation.

2.1.3. Spring mattresses

Spring mattresses exist in all kinds of shapes, dimensions, springs and spring connections. Only the spring core and the top and bottom comfort layers — both synthetic and natural foams — are common. The design of the springs, notably the wire thickness, is mainly responsible for the elastic properties of this kind of mattresses. Their main advantage is that spring stiffness

can be adjusted generally (to suit different population classes) or locally (to combine different comfort zones, e.g. a softer shoulder zone with a firmer pelvic zone). Sometimes springs and foam are combined over the entire volume to combine spring advantages (good ventilation) with foam benefits (heat isolation and good elastic behavior).

Bi-conical-springs — also called "Bonell springs" — have a smaller diameter in the middle (D_2 on figure 2) compared with the extremities (D_1). Spring stiffness is high compared with other types of springs and is constant in the usual range of deformation, resulting in an enlarged resistance against increased loading. Springs are mounted independently next to each other and linked by spiral wires on both sides.

Endless-spring cores consist of one single woven steel wire linking small cylindrical springs together, which guarantees a large flexibility. Pocket springs are mostly cylindrical or tun-shaped (larger diameter in the middle compared with the extremities) and are individually wrapped up into pockets. Pocket springs are mounted into rows — perpendicularly to the cranio-caudal direction — and can deform almost independently from each other, so that they can be used to create different stiffness zones in a mattress. Generally spring mattresses offer a rather low heat isolation and reasonable body support; pocket springs offer a good body support and a slightly better heat isolation (15%) compared with normal springs, but still 50% less than standard foam mattress.

2.1.4. Fluidum-based beds

When sleeping on a too firm surface, body weight will not be distributed homogeneously and the contact area will be reduced, which results in increased pressure (Clark and Cullum 1992) and shear forces (Goossens and Snijders 1995) (parallel to mattress surface) on the skin and the underlying soft tissues, e.g. blood vessels. Sophisticated beds for hospital applications (e.g. alternating pressure or fiber-filled mattresses) generally achieve a good contact pressure distribution to improve the blood and oxygen supply to prevent skin damage and eventual decubitus ulcers. Ordinary waterbeds offer a similar or worse pressure distribution compared with a standard foam mattress.

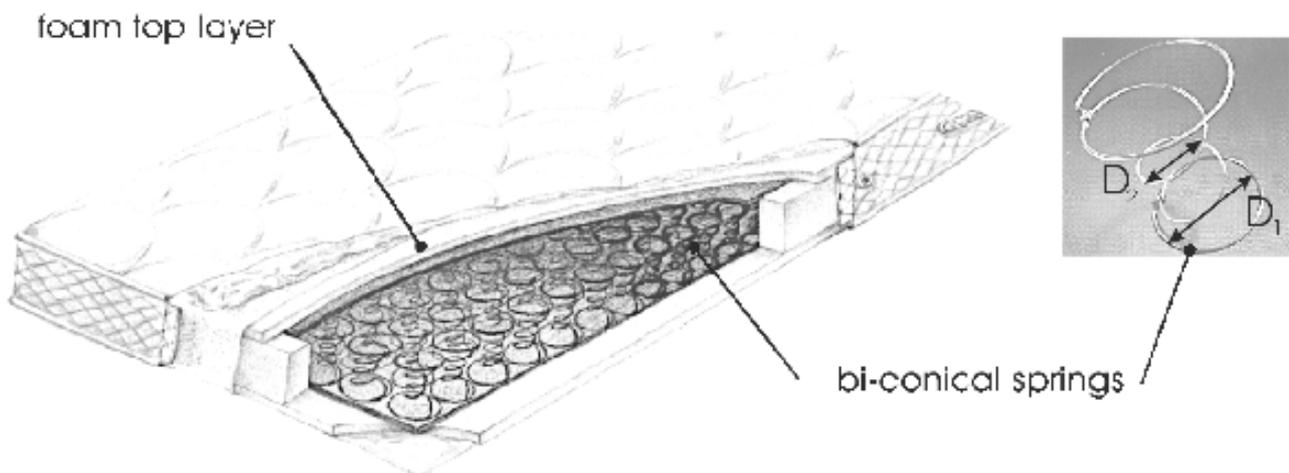
At the other hand pressure-relieving mattresses do not necessarily support the spine correctly: places where weight is concentrated will sink deep into the mattress resulting in other


Figure 2. Bi-conical-spring mattress with firmer pelvic zone (left) and single bi-conical spring (right).
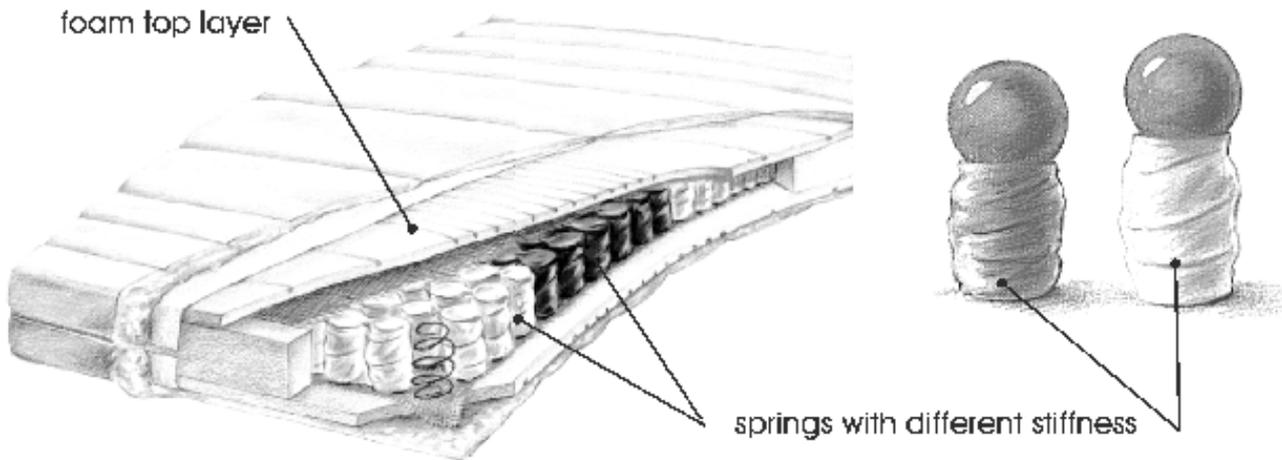

Figure 3. Pocket spring mattress with different stiffness zones (left) and pocket springs with different stiffness (right).

zones to raise. The heavy pelvic zone consequently will cause the mattress to sag, while the lifted shoulder zone will be loaded asymmetrically. Further, the large contact surface will limit mobility — due to the body sagging into the mattress — while water oscillations obstruct stability in case only one fluid chamber is employed. Finally impermeable beds generate a microclimate with much higher temperature and relative humidity (60–70%) compared with a normal mattress (37%); an adequate top layer that is ventilated regularly may prevent humidity transportation problems.

2.2. Top Layer

The humidity regulation of a sleeping system is mainly depending on the top layer of the mattress; the core of the mattress plays a negligible role. Top layers further have isolation and protecting purposes, and are mostly treated against bacteria and mildew formation. Most layers distribute the contact pressure in between the mattress and the human body; some are stretchable to avoid shear forces. Top layers generally can be subdivided into top layers that are stitched to the tick and core covers.

Wool can absorb wet vapor up to 33% of its own weight, without feeling clammy: moisture is first diffused and then slowly evaporated to the environment. Thanks to this absorption quality wool fiber avoids sudden cooling off in case of large temperature changes. Further, it can hold a lot of air for heat isolation purposes, and has a good flexibility to recuperate during daytime.

Silk can absorb moisture up to 40% of its own weight, evaporating it fast to the environment, making it especially suited for people who emit lots of moisture. It cannot hold air within its structure for heat isolation purposes, but has an anti-allergic activity.

Cotton can only absorb moisture up to 8% of its own weight without feeling clammy. It has poor heat isolation properties, which makes it only suited for summer, but it is extremely anti-bacterial and is supported well by allergic people. The use of a top layer — synthetic or natural — that can be stretched off and can be washed > 60°C, is the best prevention of allergy to the house dust mite.

3. MATTRESS SUPPORTS

Generally four kinds of supporting structures can be defined: board bases, spiral bases, box springs and slatted bases. In the Western world slats are becoming more and more common, resulting in an increased research, development and individualized variety for this kind of support. First different supporting structures will be illustrated; further it will be explained how different kinds of supports can be combined with different mattress classes.

3.1. Varieties

3.1.1. Board base

A board base mostly consists of a wooden frame on which perforated plates are mounted at both sides. This kind of mattress support has poor ventilation properties and is very hard. Consequently it offers an inferior support to the human spine, especially when combined with a hard mattress.

3.1.2. Slatted base

A slatted base is composed of a wooden or metal frame on which slats are fixed horizontally and perpendicularly to the cranio-caudal direction. These slats are fabricated in wood, plastic or glassfibre, and are mostly fixed separately onto the frame, comparable to a plank that is cut in pieces. In some cases slats can bend and to cant, to improve the supporting qualities.

Wooden slats are mostly layered and are mounted pre-stressed on the frame. Their number (14–30) and their thickness varies depending on the manufacturer; sometimes diversified slats, e.g. with different thickness, radius, or stiffness, are combined in one single base to optimize general bending properties: heavier slats are used in the pelvic zone where more weight has to be carried; softer slats are applied in the shoulder zone too allow a larger displacement. The same effect is obtained by limiting directly or indirectly the bending of the slats in the pelvic zone, e.g. via a strip or clips linking several slats together.

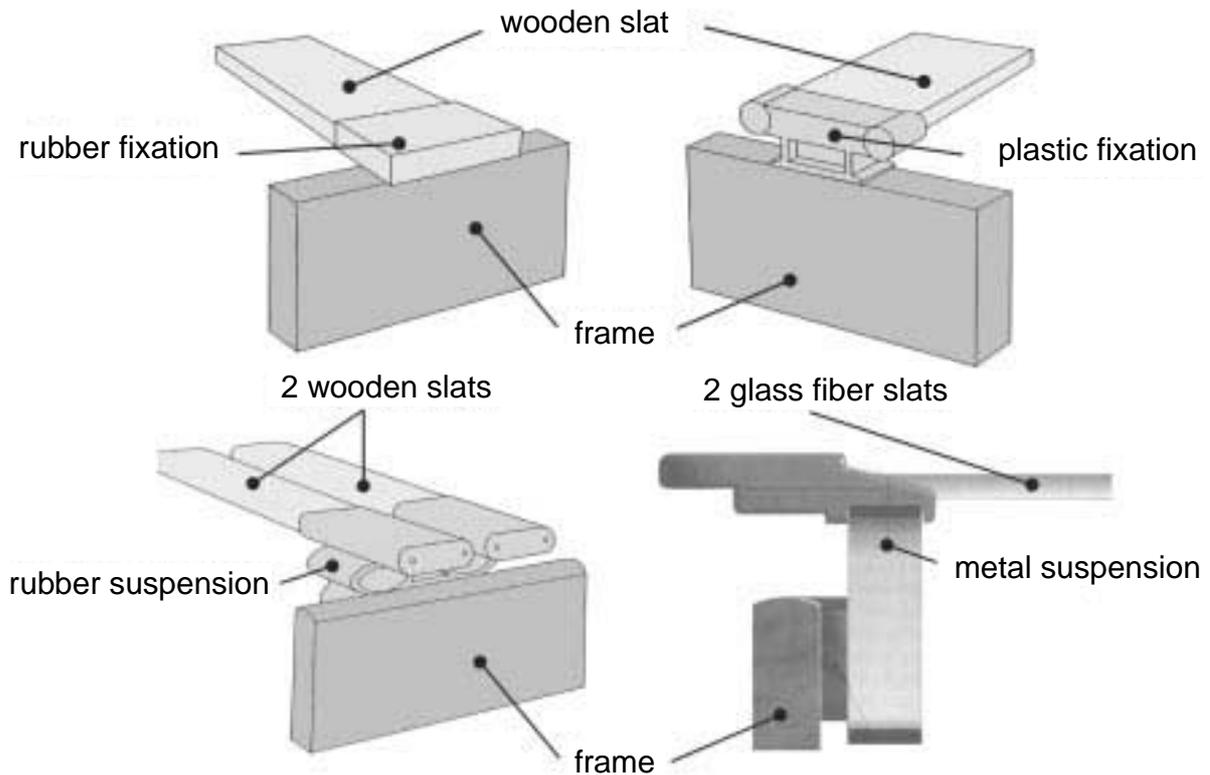
Recently mechanical properties are optimized by a proper design of the suspension of the slats in the frame: flexible slat supports made of rubber, plastic or steel can now bend and to cant. Canting slats that are mounted in pairs allow a better adjustment to the contours of the human body, especially in case of lateral recumbency; this adjustment can be even improved by adapting the height of the slat suspension. The main part of the flexibility now comes from the suspension, resulting in a mattress


Figure 4. Separate slat fixation (up left) or slat suspension (up right) on the base frame; twin slats (wood) on a rubber suspension (bottom left) and twin slats (glass-fiber) on a steel suspension (bottom right).

support not only bending in the middle, which is especially useful when placing two supporting structures next to each other for a double bed. When glassfiber slats are used, the entire flexibility comes from the suspension (e.g. steel clips or rubber), guaranteeing the same elastic characteristics over the entire width. Steel suspension clips can be fabricated with different material or geometrical properties, which allows to combine several clip classes (e.g. soft pelvic zone) to optimize the supporting qualities over the entire width.

3.1.3. Spiral base

A spiral bed base consists of a metal frame on which ~400 springs are horizontally stretched and weaved into each other. Mostly springs are stretched perpendicularly to the cranio-caudal direction to avoid sagging by spanning only 1 m instead of 2 m. A spiral bed base has perfect ventilation properties and offers reasonable supporting qualities, especially when different body zones are equipped with an adapted spring tension.

3.1.4. Box springs

Box springs generally consist of the same components as a bi-conical-spring mattress (see above), but have different material properties to offer a much firmer support to serve as a mattress supporting structure. Bi-conical springs are linked and mounted vertically, as is the case in a bi-conical-spring mattress, but they are mounted on a stiff wooden or metal base frame. The elastic foam on top and around the springs gives rise to the box springs being softer than other kinds of supports.

3.2. Combination with Mattress Classes

When choosing an optimal combination mattress-supporting structure, several anthropological characteristics are relevant to make a correct combination of different sleeping system qualities. Especially supporting qualities should be measured or modeled adequately before assigning a mattress to a person. Only most significant personal requirements will be discussed here to avoid a large elaboration. Further, not every mattress can be combined with any kind of supporting structure: both evident and unsound combinations will be reviewed.

Body weight is an objective criterion to determine whether a mattress has to be soft or firm: heavier persons need a firmer support, but extreme properties should be avoided. When people have a personal preference, supporting qualities should remain primordial, keeping in mind that it mostly takes only 2 weeks to get used to a new bed. People with perspiration or allergic problems should choose an adequate combination (e.g. spring mattress + slat support). People with pronounced contours (e.g. large shoulder or hip width) are helped with different comfort zones: pocket spring or latex mattresses are perfectly suited here, especially when people sleep in lateral recumbency. In spite of the fact that the mattress is responsible for 60–80% of the support, it can be improved significantly by using an adjusted base, e.g. a canting slat suspension combined with a latex mattress.

A board base only can be combined with a spring mattress to avoid ventilation problems: the combination of a foam or latex mattress with a board base can cause mildew formation. For the same reason a box spring is best combined with a spring mattress. A spiral base has no ventilation or stability problems, and can be combined with any kind of mattress. When combining a slat

base with a spring mattress, the stability of the springs is the prime issue: slats should be wide enough (at least 4.5 cm), they should not cant, and their number should be sufficiently large. Pocket springs can be combined with a slat base if a stretchable layer on the slats prevents the springs from slipping through.

The good supporting qualities of a slat base are best expressed in combination with a supple latex of foam mattress. Latex is less firm in comparison to foam, which makes it more suited to be mixed with an adjustable slat base. Especially twin slat bases with a canting and bending suspension are best combined with latex mattresses to make use of the entire slat flexibility.

4. HEAD CUSHIONS

To support the cervical spine correctly also the head cushion should be designed properly. In case of lateral recumbency the entire spinal column should be a straight line when projected in a frontal plane (Pheasant 1991). This objective can be reached both by correctly positioning and shaping normal deformable cushions (e.g. feather cushions) and by correctly designing less deformable structures (e.g. latex cushions).

Cushions filled with down and feathers are easy to shake up, to sustain the head and the neck in a proper way; they also have a better moisture permeability than polyurethane pillows. Latex cushions offer a good heat isolation and supporting qualities when conceived well: sometimes they are pre-shaped to support the neck, but it can take some time (2–3 weeks) to get used to it. An air chamber with an adjustable volume can even improve the support in the neck area.

5. RECOMMENDATIONS

- Back supporting qualities are of primary importance when assigning a sleeping system to a healthy person.
- People with perspiration or allergic problems should choose adequate materials. By defining material properties correctly (springs, latex, polyurethane) one can obtain correct supporting qualities for different kinds of mattresses.
- By combining different stiffness zones one can optimize supporting properties. Care should be taken in assigning a mattress with comfort zones to an individual: in principle each person needs different zone subdivisions, so an incorrect assignment will do more harm than good.
- Keep in mind that not every mattress can be combined with any supporting structure.

Sleeping Systems: Design Requirements

B. Haex and R. van Audekercke

Biomechanics and Engineering Design, Celestijnenlaan 200 A, B-3001 Leuven, Belgium

1. INTRODUCTION

One spends about one-third of our life asleep in bed, while our inactive body is given over to the sleeping system (i.e. mattress + supporting structure) we are lying and relying on. The quality of body support during bed rest not only affects the mental quality of sleep, but also has a major influence on physical condition. Low back pain — one of the most compelling problems in the industrialized world — is often caused or worsened by an incorrect body support, which justifies the need to search for an objective and science-based method to determine the right sleeping system for each individual, by guiding the factory design and production of mattresses.

A well-qualified sleeping system has to fulfil many needs depending on personal requirements, and has to be reliable for different sleeping postures. Most authors consider a resting-place being ergonomically justified when the entire musculoskeletal system can recuperate well: muscles have to relax while the unloaded intervertebral disks are rehydrating. Unfortunately this is not the case for many chairs, couches and beds that are available on the market: despite a growing consciousness towards back problems the vertebral column is often supported insufficiently. We discuss below the mechanical properties of a sleeping system that largely determine these supporting qualities.

Although it is influenced by various mattress characteristics, the comfort of sleep is a factor that is often referred to as "subjective." Indeed, specific limitations are easily overlooked when assigning an appropriate sleeping system to a person: next to a house dust mite or latex allergy, other limiting constituents — like respiratory problems or excessive sweating — make it virtually impossible to ignore them while defining sleeping systems. These properties are also discussed below.

The best mattress finally has to be chosen by assigning different weight factors to its qualities, depending on the objectives to be fulfilled, and keeping in mind that most of its properties are not designed for eternity: even a fatigue-resistant mattress looses 10–15% of its elasticity after 10 years.

2. MECHANICAL CHARACTERISTICS

When concentrating on the development of sleeping systems for normal healthy people and, thus, on the prevention of eventual back problems, one will focus rather on mechanical properties (especially back supporting qualities) than on non-mechanical characteristics (e.g. heat transport). Within mechanical objectives back-supporting qualities are primary while all other purposes are secondary, keeping in mind that peak values (e.g. pressure peaks) should be avoided. Only in case of applications involving injured people other issues come first: pressure-relieving qualities become of prime importance in case of hospital applications.

At first sight mattress stiffness seems to be a question of personal preference; in reality mattress properties should be adjusted objectively to personal needs. It is clear that heavier persons need a firmer mattress to avoid the pelvic girdle from sinking too deep into the mattress. Materials have to be developed and combined to optimize general sleeping system characteristics. While the material density mainly affects fatigue resistance, the material elasticity — and the combination of materials with different elasticity — guarantee a correct support of the human body. In fact one can obtain the required characteristics with any material by defining it correctly. Latex mattress elasticity can be adapted by changing mould specifications (e.g. use of indentations); designing spring dimensions enables the modification of pocket spring mattresses; polyurethane mattress elasticity can be adjusted by the use of different kinds of foam (e.g. different densities).

Standardized compression and tensile tests can describe most mechanical properties. Displacement controlled benches measure force at a fixed interval, resulting in a force-displacement characteristic consisting of a loading and a relaxation phase, which can be recalculated to a stress–strain characteristic. Elasticity further can be calculated as the ratio of stress to strain: the more force is needed to reach a certain indentation, the stiffer the mattress will be. In case of a perfectly elastic material, elasticity will be constant; in case of a visco-elastic material (e.g. polyurethane) elasticity is deformation velocity-dependent.

When building a mattress with different elastic properties (e.g. a softer shoulder zone or a harder pelvic zone) it is important that different zones — each with its well-defined elastic behavior — deform independently: when indenting the hip zone, it should only deform locally without exerting too much influence on either the shoulder zone or leg zone. For example this kind of "local elasticity" can be obtained by placing pocket springs with different properties in a matrix, allowing them to deform independently.

Mattress hysteresis can be determined by calculating the area in between the load curve and the relaxation curve. It measures the energy that is dissipated in the mattress and should be minimized to avoid exaggerated energy consumption while moving.

Mattress density measures the weight per unit of volume, and defines the fatigue resistance of mattresses. In principle, foams with higher densities should have a higher stiffness; nevertheless new chemical procedures (e.g. bultex foam) allow the production of mattresses with a high density without a stiffness that is too high.

Of course, the dimensions of a sleeping system and the ability to adjust the mattress support noticeably improve sleep comfort. Bed width should be at least shoulder width plus 0.40 m; length should be at least body length plus 0.20 m; bed height should be at least 0.45 m (for ventilation purposes, see below) while high beds (> 0.55 m) make it more easy to get in or out. When staying in bed for other activities (e.g. reading) a supporting structure can add a considerable surplus when it is large enough and when it guarantees a correct back support in these changed positions.

2.1. Spine Support

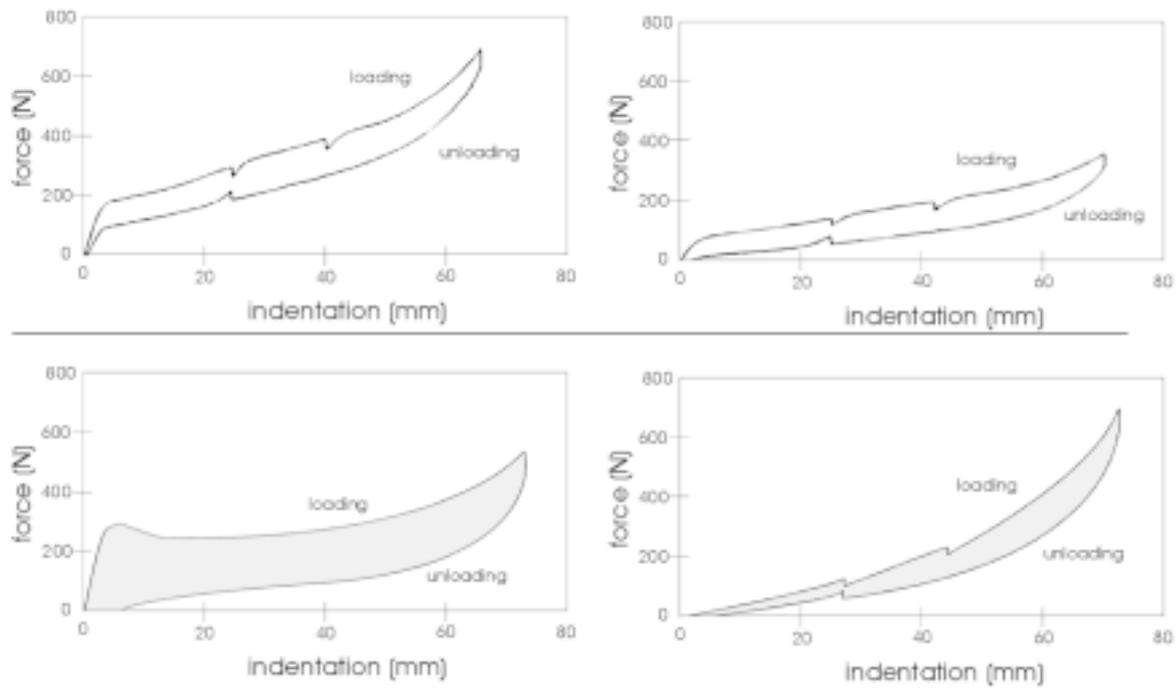
It is justified to consider back injuries being a social problem: only a few people (20%) are never confronted with it. Many back problems are induced by posture or movements: an incorrect


Figure 1. Force-indentation characteristics of a soft (top left) and firm (top right) polyurethane mattress. Unacceptable hysteresis (bottom left) on a visco-elastic foam and agreeable hysteresis (bottom right) on a latex mattress.

support of the spinal column during sitting, working or sleeping often causes or aggravates low back pain. Most authors pose that in a correct sleeping posture natural physiological curves have to be maintained; others emphasize that the lumbar lordosis has to be flattened. When concentrating on the optimal sleeping system for normal healthy people — as it is suggested by most ergonomic

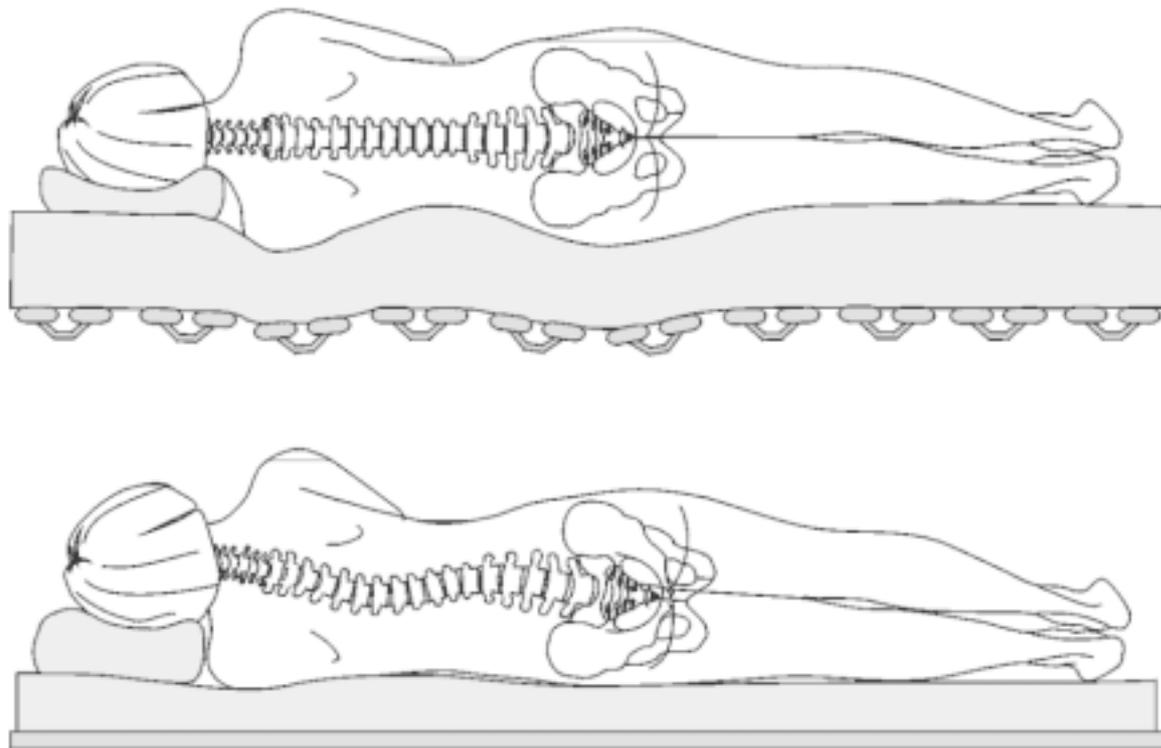
specialists — it has to support the human spine such that it adopts its natural position, which is assumed to be the same as it takes in the upright position (Adams and Hutton 1985). If this thesis is presupposed then an optimal body support for lateral recumbency gives rise to the spinal column being a straight line when projected in a frontal plane. For posterior recumbency an


Figure 2. Correct back support (top) and too firm support (bottom) in case of lateral recumbency.

optimal support gives the spinal column the same thoracic kyfosis and lumbar lordosis as in the upright position, yet slightly smoothened by the loss of body weight working in longitudinal direction on the spinal column. Consequently a small prolongation of the spine occurs, as during weightlessness. The incapability of the human body to control actively the spinal column when sleeping justifies the definition of correct sleeping system for each individual, by defining and combining different materials correctly. A perfect support can be realized when different zones of the sleeping system can deform more or less independently.

Intervertebral disk injuries and the way they act on the surrounding soft tissues are responsible for the main part of posture-dependent low back pain; facet joint or ligamentous impairments are of rather secondary importance. Especially the lumbar region is very sensitive to disorders due to the fact that pressure and tension forces mount up under load. During sleep pressure in the intervertebral disks will decrease allowing them to rehydrate, resulting in a prolongation of the vertebral column which is mainly responsible for the increase at night of the body length by 1%. Also muscle relaxation can be obtained on a well-conditioned sleeping system which is the case when mobility and stability are promoted (see below).

When a sleeping system is too soft, places where body weight is concentrated (e.g. the hip zone) will sink deeply into the mattress. Some muscles may be well relaxed in this position, but the spine certainly will not: when lying in posterior recumbency the pelvis will cant backward resulting in a complete and unnatural smoothening of the lumbar lordosis. At the anterior side intervertebral disks will be compressed while soft tissues (e.g. ligaments) will be under tension at the posterior side. When sleeping in lateral position the spine will be loaded asymmetrically as shown on the figure below. Most mattresses that are worn down have the characteristic to sag in the middle; a typical solution is to put a stiff wood board under the mattress, which insufficiently corrects the supporting properties and may cause ventilation problems (see below).

When sleeping too firm the spinal column will be supported incorrectly: in case of lateral recumbency only places with a large body width — the shoulders and the hip zone — will be supported, while the lumbar region will bend down, especially with people who have a more pronounced contour e.g. women. In posterior recumbency the pelvis is first canting forward under influence of tension in the m. illipsoas; after muscle relaxation it will cant backwards as is the case on soft mattresses. The consequent flattening of the lordosis is less pronounced and harmful compared with a mattress that is too soft. Further it is clear that people with major spinal disorders (e.g. people with a spinal injury) need a special treatment: although a hard mattress induces increased pressure peaks and stress at some places by flexing the spine laterally, it can however yield a temporary stress relief at the level of injury.

In order to support the cervical spine correctly also the head cushion should be designed properly. In case of lateral recumbency the entire spinal column should be a straight line when projected in a frontal plane. This objective can be reached both by correctly positioning and shaping normal deformable cushions (e.g. kapok cushions) and by correctly designing less deformable structures (e.g. latex cushions).

As opposed to what some manufacturers of sleeping systems claim, pressure-relieving mattresses do not necessarily support the spine correctly: places where weight is concentrated will sink deep into the mattress resulting in other zones to raise up. The heavy pelvic zone consequently will cause the mattress to fag, while the lifted shoulder zone will be loaded asymmetrically. A correct support of the spine consequently can not be measured with equipment picturing the pressure distribution. Video-raster-stereography (Haex *et al.* 1999) is a possible technique to measure spinal deformations in order to evaluate sleeping systems. It can quantify the spine in any sleeping position in between a prone and a lateral position; for posterior recumbency other equipment was developed (Geelkerken *et al.* 1994).

2.2. Weight Distribution

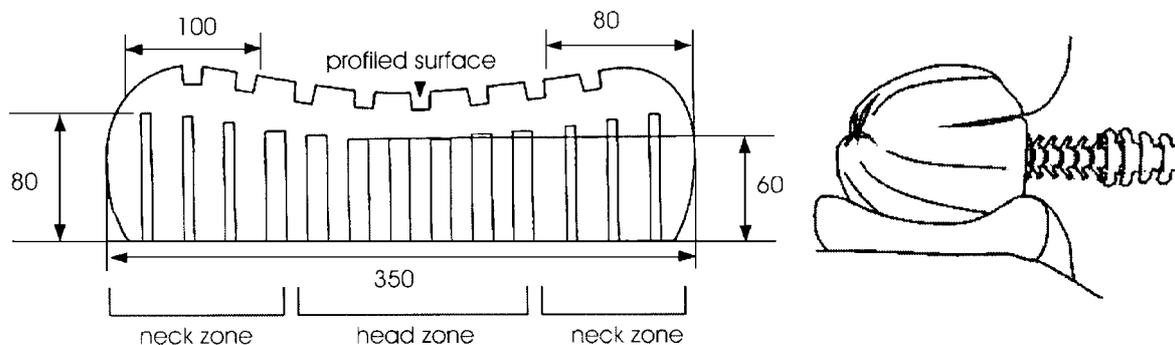
During sleep a local ischemy will arise in body zones that are in contact with the sleeping system. This ischemy generates metabolic substances that stimulate the sensible nerve extremities, which will cause the person to change his posture before it gets painful (see below). When sleeping on a too hard surface, body weight will not be distributed homogeneously and the contact area will be reduced, which results in increased pressure (Allen *et al.* 1993) and shear forces (Frobin and Hierholzer 1981) (parallel to mattress surface) on the skin and the underlying soft tissues e.g. blood vessels. Blood supply will be attenuated (or even stopped) due to the deformation of these tissues. Normal capillary arteriolar pressure should vary in between 3.3 and 4.6


Figure 3. Correct cushion design (left; in mm) and neck support in case of lateral recumbency (right).

kPa (25 and 35 mmHg); pressure in the venules should ~1.6 kPa (12 mmHg) while critical pressure is considered to be 4 kPa (35 mmHg). The combined effect of loading time and intensity may result in the development of decubitus ulcers. Hence, most decubitus ulcers occur with people that stay in bed for a long time, especially when the patient can not be moved because of injuries. Pressure relieving qualities of a sleeping system, therefore, become primordial in case of hospital applications to prevent these ulcers. Also people with symptoms of fybromyalgy, e.g. tender points in bony areas, require an enhanced sleep comfort by optimizing contact pressure.

Many authors analyzed the relation between body posture, the kind of sleeping system, body characteristics and decubitus ulcers. Most of them describe mattress evaluations based on pressure measurements that are easy to perform by means of a mapping system that consists of a blanket containing a matrix of (capacitive) pressure sensors. The general conclusion is that the duration and the level of contact pressure have to be limited to improve the blood and oxygen supply to prevent skin damage and consequent decubitus ulcers. Next to the decreased supplies of nutrients, the reduced removal of waste is a component to reckon with. An increasing number of authors also mention the importance of shear forces to be minimized to prevent stretching and angulation causing thromboses of the blood vessels. Most vulnerable to both phenomena are places where the skin is pinched in between bed and bone, especially because these areas have no fat tissue or muscles to distribute the contact forces. The scapula, the elbow, the sacrum and the heel are, therefore, risk areas in case of posterior recumbency; for lateral recumbency the ankle, the knee, the big trochanter region and the shoulder (acromion) are zones to pay attention to. Women generally have a lower risk to develop decubitus ulcers.

2.3. Mobility and Stability Promotion

Frequent posture changes during sleep require a sufficient mobility: when a mattress is too soft and nearly surrounds the human body, turning around requires lots of energy or even becomes impossible; also the mattress hysteresis (see above) should be minimized to avoid exaggerated energy consumption while moving. At the other hand a stable body support is required to sleep relaxed: when a mattress is too firm, the body is insufficiently surrounded and may roll down uncontrolled. Conclusively a bed guarantees sufficient rest (1) when changing posture is easy and (2) when each adopted posture is stable.

2.3.1. Mobility

Posture changes are necessary to avoid a pressure overloading of soft tissues (see above) and to prevent muscle stiffness; a regular position shift — ~20 times a night — should be sufficient. On some kinds of waterbeds, pressure distributors or too soft mattresses, the pelvic girdle sinks too deep into the mattress. Owing to the fact that a permanent muscle force application is impossible during sleep, the person will roll back in the cavity when trying to change his posture. The consequent extensive periods of immobility are harmful.

Although necessary, posture changes have to be limited: switching back and forth too frequently, e.g. when sleeping on a mattress that is too hard, will increase physical restlessness and the tense to sweat (see below) during sleep. Further a consequent

unsatisfactory muscle relaxation will impede intervertebral disk rehydration, thus, causing back pain indirectly.

In addition, position shifts have to be limited because they influence the consecutive sleeping stadia. Sleep cycles are strongly related to episodes of immobility, which occur mainly during non-REM sleep: immobility mostly starts in stadium 2 and ends in stadium 3 or 4 of the same sleep cycle. Suddenly induced position shifts may cause these stadia — which can be characterized as "deep" sleep — to end prematurely, causing the person not being fit in the morning.

2.3.2. Stability

A stable body position is not guaranteed at all when a sleeping system reacts on body movements by oscillating. In that case the sleeping person will need to apply continuous muscle force in order to stabilize his sleeping posture adequately, resulting in some muscle groups being under permanent stress.

In the event of acute back pain the affected area is protected against sudden body movements — which could provoke pain — by an increased tension of the back muscles. Mattress oscillations might interrupt this stable, back supporting posture, and, therefore, should be prevented.

2.4. Contact Area Optimization

In fact the optimization of the contact area implies several primary objectives which have been — or will be — discussed and, therefore, it can not be considered as an aim on itself. On one hand the contact area should not be too small: when sleeping on a too firm surface, body weight will not be distributed homogeneously, which results in increased pressure and shear forces, giving rise to the symptoms mentioned earlier. It will also be difficult to adopt a stable posture (see above).

At the other hand a too large contact area — which is often pursued in order to prevent blood circulation disorders — causes the person to sink deeply into the mattress and, therefore, limits body mobility (see above). Further a large contact will restrain the skin from breathing and, thus, increases the tense to sweat and the inconvenient feeling to sleep on a clammy surface.

3. NON-MECHANICAL CHARACTERISTICS

3.1. Microclimate Regulation

3.1.1. Humidity

Fluid absorption and fluid transport to the environment (= ventilation) are the main humidity-related mattress characteristics. The human body emits 200–300 ml (up to 1 liter) body moisture each night. One-third is emitted through breathing; the remaining two-thirds is transmitted through the body surface and has to be absorbed by the mattress (25%), the sheets, blankets and head cushion (together 75%). This moisture excretion is not to be confused with perspiration, in which case much more body fluid is lost (e.g. at the time of a fever).

Moisture further has to be transported to the environment to avoid a clammy feeling at the mattress surface, to avert mildew formation at the mattress bottom, and to prevent decubitus ulcers, since a moist skin is rough and, therefore, more sensitive to shear forces (see above). The relative humidity measured between the skin and the blanket or bed should stabilize after 20 min and should not > 65%.

The humidity regulation of a sleeping system is mainly

depending on the top layer of the mattress (80%). The core of the mattress plays a negligible role; even body movements during sleep do not improve its ventilation capability significantly. Both synthetic and natural latex cores have an impenetrable skin, which gives them poor ventilation properties compared with spring mattresses. In case of dry weather room ventilation can be improved by opening a window. Further warm humid air has to be prevented from floating into colder rooms (e.g. bed rooms) where it might condense, thus, obstructing mattress ventilation and creating a seed-bed for house dust mites (see below). Of course, mattress maintenance is a capital issue for the preservation of its ventilation properties; mattresses should, therefore, be easy to manipulate to prevent back problems when turning them around.

3.1.2. Temperature

The main part of the temperature regulation takes place by evaporating water through breathing; the remaining warmth produced by the human body is given out through the skin. Body temperature should stay constant during sleep: when heat isolation is too low, the body will cool off resulting in muscle stiffness and sleep disorders; when heat isolation is too high, transpiration will increase resulting in a too high relative humidity (see above) and consequent sleep disturbances. An optimally isolating sleeping system ensures a bed temperature between 28 and 32°C, allowing the contact temperature to stabilize between 30 and 35°C.

The isolating capabilities of a bed are mainly depending on the core of the mattress and on its top layer(s). A core consisting of natural latex or polyurethane gives a higher isolation than springs (e.g. pocket springs). Further most people prefer warm contact, which largely depends on the capability of the top layer (e.g. wool) to hold air.

Extreme low (–9°C) and extreme high room temperatures (25°C) must be avoided because they affect the duration of REM sleep. It is hypothesized that thermal regulation of the body is suppressed during this phase, resulting in the body temperature varying with the environment. A consequent body temperature variation can act as a stimulus to wake up. Further, the optimal room temperature depends on the sleeping system, the kind of bed textile and the person (e.g. age); generally low temperatures are better supported by most people, but the lower temperatures are, the higher the risk for mildew formation and the better ventilation should be.

3.2. Prevention of House Dust Mite Allergy

House dust mites are minuscule spiders (0.1–0.5 mm) that populate mattresses, carpets, curtains and head cushions, and in large quantities. A house dust mite allergy is not originated by dust nor by the mites themselves; the real cause lies in the allergen "Der PI," which is produced in the intestinal canal of the mites when degrading organic dirt — especially human skin peels — biologically. The mites' desiccated excrements carrying allergen can be assimilated in the breathing air of man and may, thus, penetrate into the cavity of the mouth and the lungs causing allergic reactions (asthma, coughing spells, irritated eyes) which manifest themselves during the night.

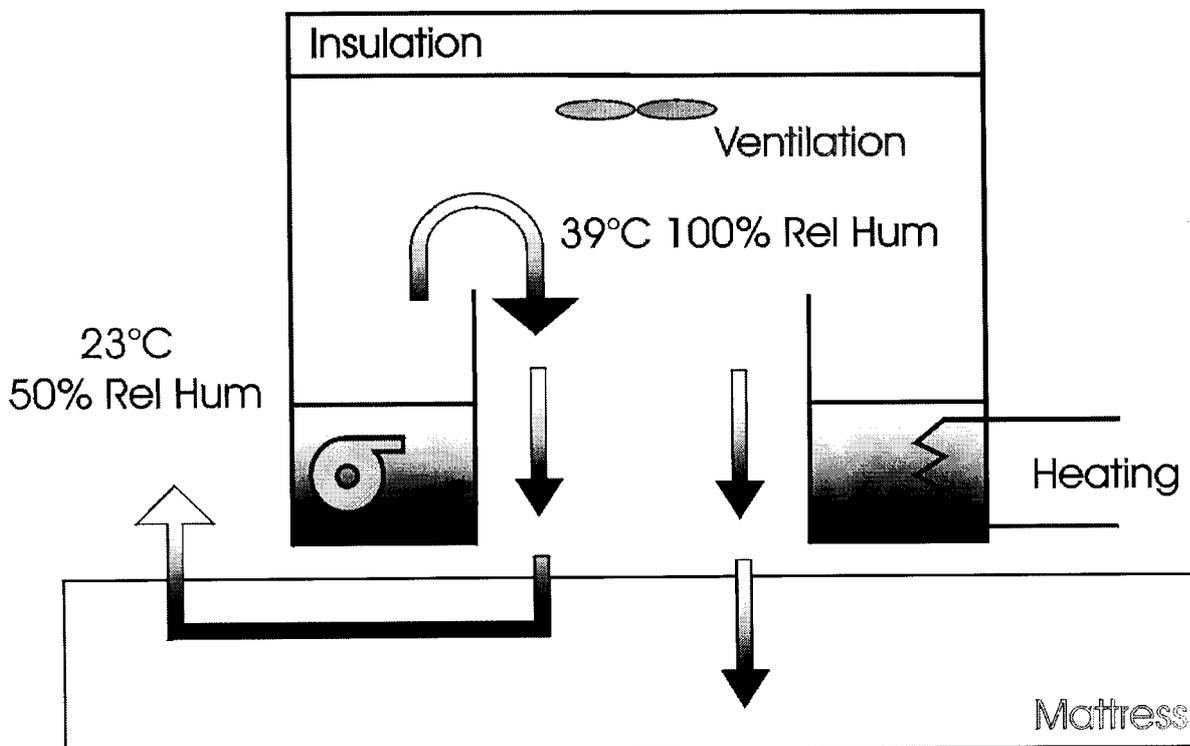
The mites prefer a temperature between 20 and 25°C and a relative air humidity between 70 and 75%. A complete extinction of the mites is virtually impossible, but allergic symptoms can


Figure 4. Cross-section view of moisture transportation measurements.

decrease by keeping the air humidity < 55% or by limiting the exposure to the excrements by a correct and thorough sanitation: allergen-proof polyurethane coating around the mattress core and a synthetic top layer that can be stretched off and can be washed > 60°C. Mattresses should, therefore, be easy to maintain.

4. RECOMMENDATIONS

- When concentrating on normal healthy people and, thus, on the prevention of eventual disorders, back supporting qualities are of primary importance.
- The optimal supporting sleeping system has to support the human spine such that it adopts its natural position, which is assumed to be the same as it takes in the upright position, yet slightly smoothened by the loss of weightlessness working in longitudinal direction.
- All other purposes are secondary, keeping in mind that peak values (e.g. pressure peaks) should be avoided.
- Only in case of applications involving injured people other issues come first, e.g. pressure-relieving qualities become primordial in case of hospital applications.
- By defining material properties correctly (springs, latex, polyurethane) one can obtain the same required mechanical characteristics for different kinds of mattresses. By combining different zones one can optimize general sleeping system properties.
- Not every mattress can be combined with any kind of supporting structure.

Standing Work

S. Konz

Department of Industrial and Manufacturing Systems Engineering, Kansas State University, Manhattan, KS 66506 USA

1. INTRODUCTION

Prolonged standing is common in many jobs; some examples are sales clerks, bank tellers, retail checkout operators, barbers/hairdressers and many factory jobs. Generally, they do not stand with "rooted" feet but occasionally move around a limited area. The problems are pain (feet, legs, back) and venous pooling of blood in the legs.

2. BACK/LEG/FOOT

2.1. Anatomy

The mean distance between the inside of the two feet, when standing, is ~100 mm, between foot centerlines is ~200 mm and between outside edges is ~300 mm (Rys and Konz 1994). Yet mean height for males is 1750 mm. Thus, there is a base of only 200–300 mm for a structure of 1750 mm. When standing, the center of gravity passes from the ear opening forward of the spine (even L4–L5) so the body normally has a forward bending moment, counteracted by forces of ligament and back muscle and soleus muscles of the calf.

In supporting the body, the calcaneus (heel) supports 50% of the weight, the 1st and 2nd metatarsals 25% and the 3rd, 4th and 5th metatarsals 25%. Underneath the heel is the heel pad (~18 mm thick). The bottom of the calcaneus is not spherical but has two small "mountains" (upside down!); the pad reduces the pressure on these mountains, and, thus, on the ankle, knee and back.

Sometimes one forgets that everyone does not have a perfect body. The spine is concave backwards in two areas (cervical and lumbar) and concave forwards in one area (thoracic). Lordosis is an increase in lumbar curvature — a swayback posture, with the stomach protruding. (Pregnancy gives a temporary increase in lordosis.) Kyphosis is an increase in thoracic curvature – shoulders roll forward, the person slouches, becomes a hunchback. Scoliosis is a bending of the spine to the side (i.e. from a front view).

Leg length discrepancy (LLD) is the technical name for differences in leg length in the same person. Contreras *et al.* (1993), summarizing studies with $n = 2377$, reported that 40% of people had LLD < 5 mm, 30% had < 9 mm, 20% had < 11 mm and 10% had < 14 mm.

Other imperfections (due to injuries, aging, disease) also can affect posture.

2.2. Physiology

If the legs do not move, the blood from the heart tends to go down to the legs and stay there (venous pooling). Venous pooling causes more work for the heart, as, for a constant supply of blood, when there are lower milliliters of blood/beat, then there must be more beats. In addition, venous pooling causes swelling of the legs (edema) and varicose veins.

Pollack and Wood (1949) give mean ankle venous pressure while standing as 87 mmHg; Nodeland *et al.* (1983) give 80.

Walking ~10 steps drops ankle venous pressure to ~22 mmHg. Nodeland *et al.* (1983) reported standing bench work, with occasional steps around the area, had ankle pressure (48 mmHg) approximately equal to sitting at a desk.

2.3. Dimensions

Weight of leg segments (as % body weight) are: 1.47% for foot, 4.35% for calf, and 10.27% for thigh; a total leg is 16.1% and both legs are 32.2%. For example, the weight of both legs for a 70 kg person would average 70 (0.322) = 22.5 kg.

Mean and SD (cm) of nude US adult female civilians are 162.9 (6.4) for stature height, 74.1 (4.4) for crotch height, 51.5 (2.6) for knee height, 24.4 (1.2) for foot length and 9.0 (0.5) for foot breadth; the corresponding male values are 175.6 (6.7), 83.7 (4.4), 55.9 (2.6), 27.0 (1.2) and 10.1 (0.5). As a rule of thumb, female dimensions are 93% of the corresponding male dimensions. A large proportion of the variation in human stature is in leg length; the torso is relatively constant in height.

3. WORKSTATION DESIGN

3.1. Vision

The viewing angle depends not only on the line of sight of the eyes but also the inclination of the head (usually downward).

Location of a work object is a compromise between visual requirements (seeing object comfortably) and hand requirements (work at elbow height). Reduce the visual requirements by (1) improving lighting, (2) using optical aids (magnification mounted on a worksurface or the head or even using video pictures) or (3) modifying the task (improving size such as use of 12 point text rather than 10-point text, improving contrast such as printing on white paper instead of tinted paper, or increasing viewing time (shooting sitting ducks)).

3.2. Reach

Operator position and object position affect reach distance.

3.2.1. Operator position

While standing, horizontal reach distance is affected by foot position. A barrier extending down to the floor may restrict foot position and, thus, require a bent back while reaching for/manipulating an object. Provide a space of 150 x 150 x 500 mm wide for the feet. (Note that conveyors for seated operators need to have space for the knees and thighs.)

Reduce vertical reach distance by adjusting height of the operator by using platforms; usually it would be a simple wooden structure but it could be motorized to go up and down.

3.2.2. Object position

Minimize horizontal reach distance to reduce forward bending and, thus, stress on the back. For example, when working at a conveyor, keep objects on the closer side of the conveyor; this may require a plow (diverter) on the conveyor.

Minimize vertical reach distance by keeping object position at waist height. Thus, objects on the floor are not acceptable. A simple technique is to stack a loaded pallet onto several empty pallets — thus raising the package heights. Conveyor heights are easy to modify for single operators (adjust conveyor support heights); the situation is more complex if multiple operators use the workstation or there are multiple workstations along the con-

veyor. For gravity conveyors, short sections of belt conveyors may be needed to elevate the load. However, conveyors should be convenient for those working with them, not necessarily easy for engineers to design.

4. POSTURE PROBLEMS WHILE STANDING

As discussed above, not every body is perfect. But even if the body is "perfect," the work activity can cause stress.

Swat and Krzychowicz (1996) assumed that the "free comfort boundaries" are trunk forward < 20°, to the sides < 10°, backward < 5° and twisting < 5°. They calculated force moments from trunk, knee and ankle bending and got five zones. Zone 3 (zero force moments) is the best; it has the trunk bending forward < 20°, the knees straight and the hands below the shoulder. Zones 2 and 4 (2.3 force moments) are next; in zone 2, the hands are above the shoulder; in zone 4, the hands can be as low as knee height (with knees straight). In zone 1 (4.2 force moments), the worker is standing on tiptoe, reaching above the shoulders. In zone 5 (the worst with 7.0 force moments), the hand is below the knees.

Table 1 is another approach to quantifying postural stress while standing; it differentiates neck, trunk and general body as well as combines joint deviations with exposure time.

Table 1. Posture checklist for neck, trunk and legs (Keyserling *et al*. 1992). A zero indicates insignificant risk. An X indicates a potential risk. A star indicates a significant risk.

Job Studied _____	PERCENT TIME POSTURE USED IN JOB		
	Never	<1/3	>1/3
Neck			
1. Mild forward bending (>20°)	0	0	X
2. Severe forward bending (>45°)	0	X	*
3. Backward bending (>20°)	0	X	*
4. Twisting or lateral bending (>20°)	0	X	*
Trunk			
5. Mild forward bending (>20°)	0	X	*
6. Severe forward bending (>45°)	0	*	*
7. Backward bending (>20°)	0	X	*
8. Twisting or lateral bending (>20°)	0	X	*
General body/legs			
9. Standing stationary (no walking or leaning)	0	0	X
10. Standing, using footpedal	0	X	*
11. Knees bent or squatting	0	X	*
12. Kneeling	0	X	*
13. Lying on back or side	0	X	*

Total X = ___ Total * = ___

Comments:

5. SOLUTIONS FOR STANDING

5.1. Changes from Standing

Two basic changes are sitting and walking. The optimum job design will have some sitting, some standing and some walking – not 100% of just one. If a job requires 100% standing (very few do), consider job rotation within the shift.

5.1.1. Sitting

Sitting reduces the load that is exerted on the feet and legs. Thus, there is less energy consumption and less biomechanical loading on the leg/foot joints. However, the person may become a "couch potato," giving inadequate nutrition to the spinal discs (which depend on movement for nutrition) and overadequate nutrition to the flesh, yielding a weight gain.

As pointed out above, the legs are ~32% of body weight. A stool (i.e. no arm or back support) means only 68% of the body weight must be supported by the human structure. It is difficult to quantify the benefits of a chair back support but common experience indicates they are beneficial. Supporting both hands/arms is ~10% of body weight but the percent decreases as the hands are used (e.g. keyboarding, assembly).

Biomechanically, sitting provides a stable support (chair seat) that is closer to the hands than the feet; this reduces sway and tremor. Yet standing permits movement of the legs and feet (not just the torso) so reach distances are improved and ability to twist the torso is improved.

5.1.2. Walking

Some of the problems of standing can be reduced by movement. Occasional walking (say > 10 steps) improves blood flow in the legs, decreasing ankle blood pressure ~60 mmHg. The movement of walking also improves disc nutrition. Walking also improves reach ability over standing.

5.2. External Aids

Two divisions are aids on the body and aids off the body.

5.2.1. Aids on the Body

Body aids are divided into back belts, support hose and shoes.

For such a popular product as back belts, there has been relatively little theoretical analysis or experimental study (Rys and Konz 1995). Back belts come in an amazing variety of designs with an equally amazing lack of theoretical support for the design. Back belts generally are tested on healthy male students doing lifting for short periods (often < 1 h); the results are extrapolated to male and female workers doing a wide variety of tasks for 2000/h year for multiple years. Much more (and better) research needs to be done. However, for simple standing tasks (with no material handling), it is hard to visualize benefits from back belts.

Support hose reduce venous pooling by constricting leg diameter and, thus, not permitting space for the blood to pool.

Shoes also come in an amazing variety of types and styles. Athletic shoes are divided into running shoes (designed for forward movement) and court shoes (designed for quick side-to-side movement); neither would seem applicable to prolonged standing.

Ankle support from boots normally would only be needed in outdoor activities with varied terrain.

A good shoe will have a good innersole that molds itself to the foot, giving support over a relatively large area and, thus, minimizing pressure on the sole. The outer sole of the shoe should be cushioned (either by material such as crepe or by form such as ripple soles). A good coefficient of friction combined with a design allowing liquid to escape from the floor–sole interface should reduce slipping. Shoes worn for standing should be purchased half to one size too large as feet will swell during the

day. Shoe laces permit adjustability; four-lace-hole shoes adjust better than three-lace-hole shoes.

5.2.2. Aids off the body

Two possibilities are standing aids and mats/carpets.

A standing aid allows the person to vary posture and/or support some of the body weight. Can the person lean on a counter or table? Bars have used leaning plus a bar rail for the foot for many years. In an occupational setting, Rys and Konz (1994) recommend, instead of a cylindrical rail, a 100 mm-high platform, either flat or angled 15°. Another alternative is a sit/stand stool; the adjustable height seat should have a forward slope of 10–15°. Nijboer and Dul (1987) reported they were useful in upholstery work even when they could be used for only 15% of the working time.

Cushioning the floor can be done everywhere (carpets) or locally (mats). Carpets/mats also act as a frictional surface (reducing slips).

6. SUMMARIZING

- Avoid surfaces with a low ratio of surface to holes (e.g. grating) as you are standing on "knives."
- Mats/carpets improve comfort over hard-surfaced floors. Comfort may increase in the back as well as the legs/feet.
- Mats/carpets should compress but not too much. Optimum is ~6% under the shoes of a 70 kg adult. Steel and concrete surfaces (i.e. no compressibility) are the worst surfaces for standing.
- Mats should have beveled edges to reduce tripping.

- Mats should be non-slip (both versus the sole and versus the floor).
- Mats that have to be cleaned periodically (e.g. in food service environments) should be smaller for ease of handling.

Static Load

B. Kapitanik

1. STATIC WORK ARDUOUSNESS

The assessment of work arduousness connected with static efforts becomes more and more significant in the general assessment of work stations. It is due to a widespread introduction of mechanization and automation in modern industry. It leads to an important reduction of dynamic efforts, but also to the appearance of static efforts caused by a still position at work, or by operating self-propelled tools. Such efforts create workloads stemming from both their intensity and duration. A train driver, for instance, has to keep still during a long period of time in order to watch his way ahead and to check the switchboard reading. Similar workloads are experienced by truck drivers, aircraft pilots or operators of huge, multipurpose machines such as excavators, combine harvesters or gantries.

Another kind of workload, which could be called the active static workload, is connected with the use of semi-automatic tools. It is well illustrated by the welder's job, especially in shipbuilding or in erecting steel constructions, presenting on the one hand a very uncomfortable, untypical, still position at work, and on the other hand the necessity to keep the burner fixed. Similar workloads can be found in foundries, where the stamping of the molding mass, the cleaning of the casts, the sand-blasting and the polishing are accomplished with tools, mainly pneumatic, which the worker holds and keeps still in his arms. The same type of active static load is experienced by a woodcutter operating a chainsaw weighing up to some 14 kg, which he has to keep stable. The operators of drifters, graders, grinders, and similar hand tools are often found in many branches of industry.

The terms "workload" and "work arduousness" are often left ambiguous thus leading to misunderstanding and confusion. Therefore, in this article, workload will mean the value of the external strain factor affecting the body, so that it represents the value of the force exerted and the duration of its action as far as the static workloads are concerned, whereas in the case of dynamic workloads, it is the magnitude of the power generated by the body and its duration. This workload can be related to the maximal capacities of a single organism and will then be called relative load; for the static workloads it can be expressed as the percentage of the maximal muscular force which can be exerted by a loaded muscular group (%MVC — maximal voluntary contraction). The workload produces a temporary disturbance in the functional balance of the body, which is compensated by mechanisms of adaptation. Triggering these mechanisms is connected, on the one hand, with the physical capacity (physiological strain) and, on the other hand, with a feeling of discomfort (psychological strain). An objective assessment of the latter is made difficult by its subjective nature. The sum of both physiological and psychological strains will be called work arduousness. Therefore, for the sake of practice, the following simplified assumption can be adopted: the value of the individual physiological response of the body to the workload can constitute an objective measure of work arduousness. Yet, in the present state of knowledge, the physiological assessment of work arduousness based on the appraisal of the value of the individual physiological response of the body to the workload seems to be of paramount importance in ergonomics.

The response of the cardiovascular system is particularly interesting as far as the assessment of work stations is concerned. The parameters characterizing the state of that system are easily accessible for a study with non-invasive techniques, and can be observed unceasingly without interrupting the tasks that the examined person is performing on the workstation.

2. APPROACHES TO ASSESSMENT OF STATIC LOAD

The first scientific recording concerning the physiological response of man's organism to static efforts was made by Beclard in 1861. He studied the changes of temperature in a muscle charged with an intermittent static load, while Tapie published in 1886 a vast monograph on the muscular thermoregulation during static and the dynamic efforts. In 1896, Chauveau presented the results of his research on the energy expenditure of the static work, considering for the first time the practical aspect of his research. Atzler, one of the first researchers to study the possibility of an appraisal of work arduousness connected with the static effort, worked out a method of such an assessment through measuring the energy expenditure for the static effort.

Simonson (1971) proposed a method of assessing the arduousness caused by a static load, basing it on the definition of a so-called "restitution constant", which would testify to the rate of evacuating the oxygen debt after the static work. Thus, he used Linhard's phenomenon described in 1913 consisting of the increase of oxygen consumption after the static work has stopped in relation to the duration of that work. However, the studies by Monod (1956), Rohmert (1961), Laville (1961), Lind (1966) and Wald and Harrisson (1975) showed that this phenomenon is independent of the load value.

Borsky and Hubac (1967) elaborated a nomogram whose construction was based on observing that during static efforts the increase of the heart rate is accompanied by a much lesser oxygen consumption than during the dynamic efforts. The same phenomenon was used by Klotzbucher (1975) to elaborate an index figure which was the quotient of the increase of the heart rate and the net energy consumption. My own research (1980) on work stations in which both general and local static loads were encountered, has proved that Klotzbucher's index figure only allows assessment of work arduousness connected with a general static load, but is unpractical in case of a local load.

The observation made by many authors that, during a static effort, the arterial blood pressure, both systolic and diastolic, grows in proportion to the value of the relative load has led to no practical application as yet. The difficulties of making measurements and a significant individual variability result in a reluctance to use the arterial blood pressure as a parameter in the studies on workstations.

To sum up, it can be said that the present state of research on the cardiovascular response to the static efforts has not laid the foundations for the elaboration of a method of assessing the arduousness caused by the static loads that could suit the needs of ergonomics. The proposed methods allow a haphazard appraisal of the arduousness caused by the static loads and only

within an incomplete range of those loads. Moreover, the first series of methods requires the measurement of oxygen consumption, which causes a certain inconvenience for the subject and cannot be performed continuously. There is a need, therefore, for a method of assessing the arduousness connected with the subcritical static efforts (i.e. involving less than 20%MVC) lasting for a long period of time.

3. STRESS EVALUATION

Since static work generates no visible movement, the static stress (constraint) cannot be measured with physical units of work. Therefore the intensity of work is assessed by the level of the exerted force and the time of the exercise in the case of a continuous task, or the number of repetitions in the case of an intermittent task.

3.1. Application of Force Measurements

During professional work the postural constraints generate neither high levels of force nor high energy expenditure. Conversely, the handling of manual tools (screwdriver, pliers, etc.) or portable tools (drills, saws, etc.) often generates a relatively important percentage of the maximal force.

The most relevant assessment of static stress is done by measuring the forces involved and comparing them with the maximal forces. The measurements are made with a strain gauge placed in a direction of force exercise. Figure 1 presents the measurement of the force of pressing on the pedal of a hospital trolley. The strain gauge (SG) is pressed against the pedal and held in the work position. The same kind of setting allows easy measurement of the forces involved in pushing the trolley, holding a parcel or pulling an object. The measured forces are compared with the maximal forces by using two different methods.

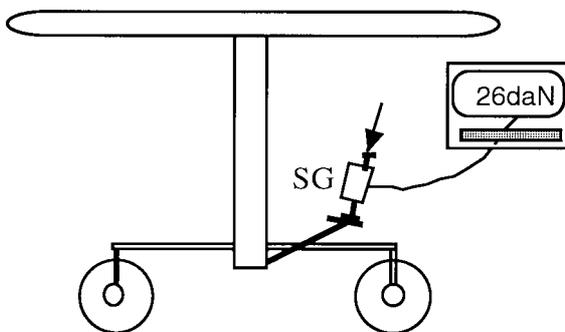
The first method consists in measuring the operators' maximal forces in the same position as at work with the same strain gauge. The advantage of such a procedure is that it gives the real maximal forces of those directly using the machine. The main drawback is that those forces are measured on a small sample and could be altered by measuring conditions which are impossible to standardize. Therefore, a second parallel procedure must always be applied in order to check the normative data. In France, the norm NF X35-105 indicates the limits of forces acceptable for static work. Similar recommendations have been set by NIOSH in the USA and are currently being converted into a European norm EN1005-3 and an international norm ISO11228-2.


Figure 1. Measurement of the force of pressing on a pedal of a hospital trolley

By applying these procedures we were able to assess the hospital trolley with variable height (see figure 1) and observe that the forces necessary to push it are acceptable for 95% of the female population, whereas the forces necessary to press the pedal are beyond acceptable limits even for the male population.

3.2. Repetivity Calculation

In industrial conditions static work for driving a machine or operating a manual tool is often intermittent. It is crucial in the assessment of workload to have a reliable way of assessing the ratio of static exercise time in relation to rest time. For this purpose it is vital to observe the activity directly with precise time control. In cases of repetitive work, it is advisable to use video recordings which allow precise study later on. Currently, there are several video-processing software packages which facilitate analysis and make results readily available. Some software packages aim mainly at postures (OWAS), others are more general (KRONOS). It is likely that this technology will be considerably improved in the near future.

4. STRAIN ASSESSMENT

4.1. EMG Application

Surface electromyography (EMG) is a totally non-invasive technique which permits the quantification of muscular activity due to portable devices becoming more and more sophisticated and miniaturized. This technology is beginning to be used in ergonomics especially in the case of predominantly static muscular constraints.

With electrodes attached to the skin, the surface EMG permits the recording of bioelectric activity of the part of the muscle close to the electrodes and concomitant with their mechanic activity. The spectral analysis and the integration of the EMG signal allow the quantitative analysis of this activity and comparisons to be made during different exercises of the muscles; integrated EMG (iEMG) represents the intensity of the isometric contraction of muscles. Median frequency (MF), which is among the most common parameters of spectral analysis, is directly proportional to the speed of intramuscular conduction and the mean power frequency (MPF); the two allow the dynamics of muscular recruitment to be seen.

The application of surface EMG during static effort allows the extent of the muscular mass involved in the effort, the intensity of the muscular effort, and the apparition of fatigue to be assessed.

4.1.1. Identification of active muscles

This is important during complex activities, such as using a keyboard. The identification of the muscles involved in this task allows optimization of the keyboard so that the local work of different muscles is minimized and not taken over the threshold of 15% of their maximal force. Similarly, a correct identification of the muscles involved in lifting loads provides a basis for the training of packers and thus contributes to the prevention of musculoskeletal disorders.

4.1.2. Intensity of contraction

During static maintenance, there is a linear relation between the exerted force and the amplitude of electric activity. This relationship becomes slightly exponential when the maintained force reaches values higher than 50%MVC. The EMG increases

more rapidly beyond those values, according to the mobilization of rapid fibers, whose activation threshold is higher. However, for ergonomic applications it is possible to adopt a simplified linear relation because the static efforts exerted during professional tasks are situated in a section lower than 50%, and even for those whose intensity is higher the error is relatively low.

The measurements of the iEMG can only be interpreted in relation to a reference corresponding to the exercise of the maximal force because the recorded electrical intensities depend on the impedance of the electrodes and of the tissue, and on the placing of electrodes. Indeed, it was the evolution of EMG that indicated the intensity of the contraction, not the absolute values recorded.

With this technique we were able to observe that the static effort exerted by a professional violinist in keeping the left hand still during a concert reaches 23% of the maximal activity recorded during the exercise of the maximal force in the same position of the arm (see figure 2).

4.1.3. Effect of fatigue

For a given level of maintained force, the amplitude of the EMG increases with time when the isometric contraction is prolonged. When muscular exhaustion in close, potential of great amplitude and big activity outbursts appear and electrical signals fall to low frequencies because there is a progressive increase in the number of active motor units occurring at the end of the time limit. This muscular fatigue is characterized by an increase of the iEMG and a decrease of MF and MPF.

Muscular fatigue also provokes the apparent emphasis of physiological trembling at 2.5–30 Hz (12 Hz on average), easily detectable in EMG recordings.

4.2. Cardio–circulatory Adaptation

During static exercise the cardiac output remains unchanged initially, and slightly increases later as the isometric contraction of the muscles provokes an important increase of peripheral resistance, which beyond 75%MVC may result in an interruption of the local flow in the contracted muscle. The stroke volume decreases and the heart rate increases because of a reflex of muscular chemoreceptors. This increase is much more important in relation to the increase of oxygen consumption than during a dynamic exercise at a corresponding level of relative load.

By comparing the dynamics of increase for the heart rate and for oxygen consumption, one can assess the influence of the static load. This comparison requires knowledge of the subject's physical capacity. For an average subject (with a VO2 max. at 3 1/min.) the consumption of 110 2/min. during a dynamic exercise generates a heart rate of 120 bpm. During static effort at the same heart rate of 120 bpm the oxygen consumption is approximately 0.6 10 2/min. Yet attempts to establish a practical index of static load have been unsuccessful because of important individual variability and the fact that, although the cardiac reflex does not depend on the muscular mass involved, the oxygen consumption does.

The limit that is proposed for cardiac acceleration during static effort is the absolute value of the cardiac cost of 25 bpm above the rest value. In terms of relative cardiac cost, it is dangerous to go beyond 20% of the maximal cost.

Static Work Capacity

B. Kapitaniak

Ergonome, Maître de conférences à l'université Pierre et Marie Curie, faculté de médecine Pitié-Salpêtrière. Paris

1. STATIC WORK DEFINITION

The term "work" is used in physiology in the context of static work in a slightly different way from physics because the shifting occurs only within the muscle with no visible movement outside. The increase of the muscular tension is obtained thanks to the work of the contractile muscular fibers which, in the precise case of an isometric contraction in which the muscle cannot change its length, work against the whole of muscular elastic structures. The work is accomplished by the contractile part of the muscle by stretching the elastic part. In order to characterize this work on must therefore consider the force developed by the muscle during its isometric contraction, the duration of this contraction and the conditions that guarantee the energy supply in the muscle. The product of the maintained force by the time of maintaining is therefore a measurement of static work widely applied in ergonomics.

2. MUSCULAR STRENGTH MEASUREMENT

Since the developed force depends on the length of the muscle, the measurements of the maximal force are made only during isometric contraction when the length is fixed arbitrarily. The maximal voluntary contraction (MVC) of a muscle group involved in a static contraction is a reference to assess the relative forces in terms of %MVC.

MVC depends on physiological, psychological and metrological factors. Above all, it is determined by the quality of the muscles involved in the contraction, characterized by the number of myofibrils per unit of section surface, by the orientation of muscular fibers in the muscle and by the type of fibers dominating in the muscle (at equal force, a rapid muscle exerts a force higher than a slow muscle). It also depends on the quality of the motor command and the nervous transmission, as well as the motor coordination especially in the case of complex contractions.

Beside the quality of the muscles, the MVC depends a lot on the subject's motivation; at equal muscular mass an athletic subject exerts an MVC higher that an untrained subject.

Finally, MVC is subject to an influence of the contention system that allows it to exert a force that can more or less limit the supplementary contractions. This factor may be mastered when measuring the MVC in laboratory conditions, but it is more difficult to realize in the field. When measuring the forces exerted on a workstation one must take all the precautions to define measuring conditions as stable as possible.

The level of the exerted force is expressed either in absolute values (Newtons) or in relative values (%MVC), which allows a fair assessment of the constraint in the case of static work.

During spontaneous activity the static contractions are frequent: the postural bearing, holding or carrying a load, or pressing a pedal. In most of these activities the forces involved may easily be measured with dynamometers and compared with the maximal forces exerted in the same conditions.

3. TIME LIMIT OF STATIC MAINTAINING

The time of the static exercise is expressed either in absolute values (seconds) or in relative values (the percentage of the maximal time of upholding a force called the "time limit"). A quasi-exponential relation was established between the relative force and time limit by Monod (1956) and confirmed by Rohmert (1958).

The time limit of maintaining a given level of force characterizes the capacity of static work. The hyperbolic relation between the force (%MVC) and the time limit of maintaining is presented on figure 1. The origin of the curve situated on the axis of forces corresponds to 100%MVC, the time limit for 50%MVC is ~1 min, and the asymptote of the curve is between 15 and 20%MVC. The critical force corresponding to a theoretically infinite time of maintaining is therefore situated at ~15%MVC. Any contraction realized at a level higher than the critical force leads to local exhaustion, whereas at a lower level it could theoretically be carried on without any time limit. However the prolonged exercise of forces lower but close to the critical force leads to important discomfort, yet without any objective sign of muscular fatigue. On the practical level it would be better to adopt a critical force of 10%MVC for the recommendations concerning the efforts exerted on machinery commands (norm prEN 1005-3).

The time of static exercise determines the intensity of physiological reactions. For forces higher than the critical force reactions increasing proportionally to the time of exercise may be observed. The reactions become intense after 50% of the maximal time limit of maintaining.

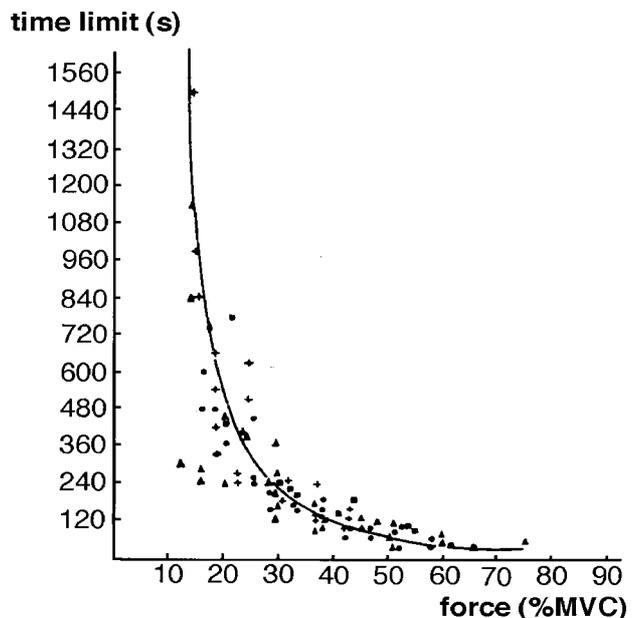
4. CHARACTERISTICS OF STATIC WORK CONDITIONS


Figure 1. Relation between force (%MVC) and time limit of maintaining (Monod 1956).

4.1. Bioenergetic Consequences of Static Work

The static work of an intensity higher than the critical force is often accomplished in the muscles with an important participation of anaerobic metabolism. This participation depends on the level of relative load and of exercise time which determine the local blood flow in the active muscles. The local flow increases up to 20%MVC, whereas above the increase in no longer appropriate to the energetic needs. It is low at 50 and 70%MVC the flow almost stops.

The low load exercises, < 10%MVC may be realized in aerobic. Those > 20%MVC have an important anaerobic participation and < 70%MVC the exercises are accomplished solely in anaerobic. The work realized during static exercise is there very costly because it carries an important oxygen debt in relation to the mechanical work realized. For intense static exercises low oxygen consumption is observed during the exercise, whereas it significantly increases once the exercise has stopped (Lindhard's phenomenon).

4.2. Cardiac Consequences of Static Work

The mechanical pressure of muscular fibers which is exerted on the vascular compartment and which is clearly reduced as soon as the force is > 25%MVC, provokes an increase of peripheral resistance with heavy hemodynamic consequences. Unlike dynamic work, the vasodilatation generated by the muscular work is impeded by this mechanical pressure which results in an important increase of the systolic and diastolic blood pressure as well as of the heart rate.

The current concept of mechanism concerning cardiovascular response to sustained isometric contraction assumes that the heart rate increases initially by central command via vagal withdrawal and may be modified later by activation of sympathetic nerve activity. On the other hand, the rise in blood pressure at the beginning of isometric exercise is due to increased peripheral resistance and cardiac output, whereas the further increase in blood pressure is due to activation of sympathetic drive originating from muscle chemoreflex. In fact the significant increase in HR associated with a moderate increase in cardiac output and the decrease of stroke volume depending on the decrease of the venous return are commonly observed during different modes of isometric contractions.

Cardiovascular response to sustained static exercise is dominated by the relative workload because the mechanism is essentially reflex. However, it may also be influenced by the mass of muscle involved that can be responsible for a moderate increase of oxygen consumption in the cases of moderate static load.

4.3. Vegetative Modifications on Static Load

The vegetative modifications appear quite early, even for forces scarcely higher than the value of the critical force. They arise as an increase of the plasmatic noradrenaline rate. They seem independent from the muscular mass involved but related to the relative force used. The effect of this "pressure reflex" of muscular origin is to delay the hypoxy due to contraction. Thus, the values of the heart rate noted during static work and resulting from this reflex do not have the same significance as those observed during dynamic work, for purely energetic reasons.

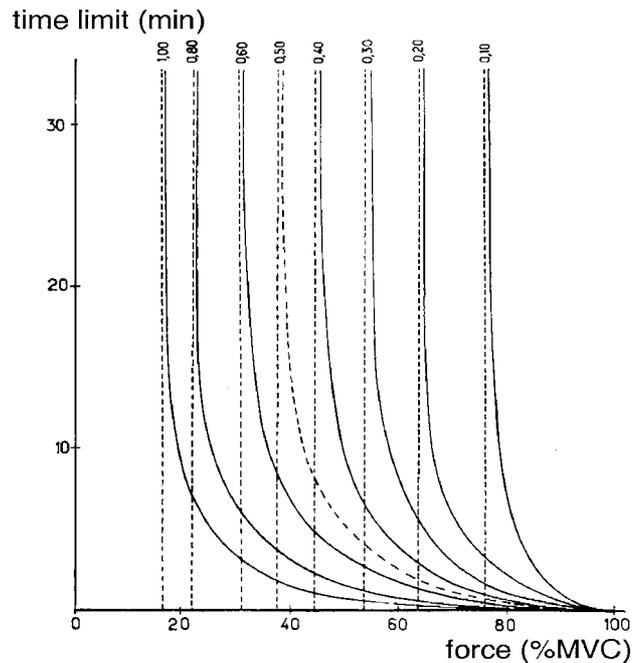
5. INTERMITTENT STATIC EXERCISE


Figure 2. Relation between force (%MVC) and time limit of maintaining in the cases of intermittent static work (Pottier 1969).

The introduction of pauses during which the blood flow is free (intermittent static work) enables the muscle to work longer with higher levels of force. There is a shift of the value of critical force all the more important as the relations between rest period and contraction period are bigger (figure 2).

Intermittent static work is close to dynamic work when the pauses are important because of the liberation of local circulation. On the other hand, repetitive dynamic work may generate the same effects as static work when the frequency of repetition of movements becomes so high that the muscle has no longer the time to restore the local circulation during the pause.

6. LOCAL AND GENERAL STATIC LOAD

In physical professional activities two types of exercises are the most frequent : the use of segmentary force at high levels (holding loads at arms' length, effort on a lever or on a motorized tool) or tasks involving the whole body (lifting and holding heavy loads, pushing a trolley with the whole body). These two aspects correspond to a physiological distinction based on the muscular mass used during the task and which allows to separate local work involving less than a third of the total muscular mass from general work involving more than one-half.

If the intensity of the reflex of muscular chemoreceptors depends mainly on the relative intensity of the isometric contraction, the adaptive reactions also take into account the muscular mass involved. The oxygen consumption increases more during general than during local static work, at equal relative intensity. Similarly, the increase of the breathing output is more important during general work.

7. MIXED WORK

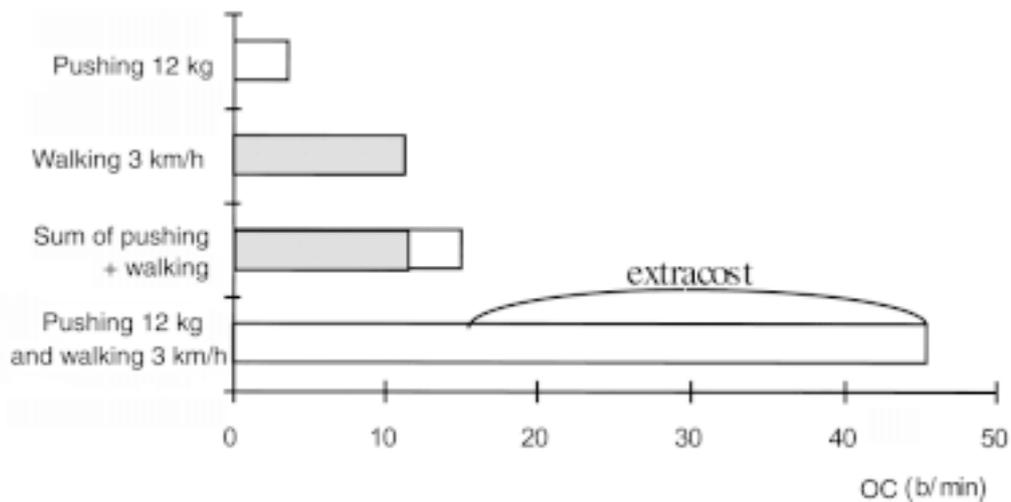
In industrial practice the static load is very often accompanied by dynamic load. Manual handling of loads includes a static load of holding an object and a dynamic load of walking. The result


Figure 3. Multiplying effect of mixed load for cardiac cost (CC). The sum of CC from pushing only and walking only is widely under the CC observed for both tasks exerted together (Sanchez 1977).

of this simultaneous double load on the cardiovascular plane is a multiplying effect. Indeed, the reaction observed during mixed load is stronger than the sum of the reactions due to the two separate loads. These multiplying effects were noticed during pushing trolleys experience (figure 3).

8. DETERMINATION OF STATIC WORK CAPACITY

Unlike dynamic work there are no commonly accepted indices of capacity for static work. This is due to the important variability of the tested indices, which does not allow one to reach relevant practical conclusions. The maximal time limit may be considered as the only practically applied index.

There is no correlation between the muscular force and the maximal time limit. Comparing the sex differences, one may observe that women have a maximal time limit higher than men, whereas their maximal voluntary force is ~66% of mens'.

Several studies have been devoted to anisotonic isometric contractions, consisting in maintaining a decreasing level of force.

It seems that the reduction of the maintained force depends on the nature of muscular fibers involved, as well as on the maximal time limit. The studies carried out on trained sportsmen do not systematically bear out this hypothesis. No single proposition of a global index has ever been retained due to the lack of necessary coherence.

Stimulus–Response Compatibility

R. W. Proctor

Department of Psychological Sciences, Purdue University, West Lafayette, IN 47907-1364, USA

1. INTRODUCTION

Stimulus–response (S-R) compatibility effects are differences in speed and accuracy of responding as a function of the relation or mapping between stimulus and response sets. Such effects are neither perceptual nor motoric in nature. Rather, they are due to response-selection processes that intervene between stimulus identification and response execution. When the mapping of display elements to controls is highly compatible, an operator can respond faster and more accurately than is possible when the mapping is incompatible.

Compatibility effects have been investigated extensively since classic studies conducted by Paul Fitts *et al.* in the 1950s. Many issues that are fundamental to human cognition, including the nature of spatial coding, the role of attention in coding, and the influence of irrelevant information on performance, have been addressed in compatibility research. The following sections summarize current knowledge regarding the determinants of compatibility effects and discuss the implications for display-control design.

2. PAUL FITTS'S CLASSIC STUDIES

Fitts and Seeger (1953) first demonstrated S-R compatibility effects. Subjects performed an eight-choice reaction task in which three arrangements of stimulus locations were paired in all combinations with three arrangements of response locations. Responses were made by moving a stylus from a centered home location to the response location signified by the stimulus, using the most compatible mappings of the individual stimuli to responses. Although the number of S-R alternatives was identical in all cases, responses were faster and more accurate when the stimulus and response arrangements corresponded than when they did not. A second experiment showed that the compatibility effects persisted across many sessions of practice, a finding that has been replicated in a variety of other task situations. The fact that compatibility effects are resistant to practice implies that the negative consequences of a design that is low in S-R compatibility cannot be overcome simply by providing operators training and experience.

Fitts and Deininger (1954) used one of the spatially corresponding combinations of S-R sets examined by Fitts and Seeger (1953), circular stimulus and response arrays, but varied the mapping of individual stimulus locations to response locations. Responses were much faster and more accurate for a spatially compatible mapping in which each stimulus location was mapped to the corresponding response location than for a mapping in which the relation between stimulus and response locations was random. Although responses with a mirrored S-R mapping (respond at the mirror opposite location) were slower than those with the spatially compatible mapping, they were still

much faster than those with the random mapping. This study illustrates two major points about S-R mappings: responses are fastest when spatial compatibility of display and control elements is maintained, and responding benefits from systematic relationships when the mapping is not spatially compatible.

Through the remainder of the 1950s and 1960s much of the research on S-R compatibility had the goal of discovering the situations under which compatibility effects occur and was relatively atheoretical (Alluisi and Warm). In the 1970s and 1980s, theoretical issues regarding S-R compatibility became of increasing concern in a variety of disparate research areas, including attention and performance, cognitive neuropsychology, motor control, and human engineering, among others. These research efforts culminated in two influential publications in 1990, Proctor and Reeve's edited book that integrated the different strands of research, and Kornblum *et al.*'s dimensional overlap model and taxonomy. In the 1990s there has been a concerted effort by many researchers to examine fundamental theoretical issues pertaining to S-R compatibility. Much of this research is described in the 1997 book edited by Hommel and Prinz.

3. SPATIAL CODING

3.1. Coding of S-R Locations

Most accounts of S-R compatibility rely on the concept of coding in response selection. In the case of spatial compatibility effects, the emphasis is on spatial codes that mediate between stimuli and responses. Much of the basic research on compatibility effects has used two-choice tasks. The standard finding is that responses are faster and more accurate with a spatially direct mapping in which a left stimulus is mapped to a left keypress and a right stimulus to a right keypress than with the opposite mapping. Although most such studies have used horizontally arrayed locations, similar compatibility effects occur if the stimulus and response locations are arranged vertically. Evidence for spatial codes is apparent in the widely replicated finding that the spatially direct mapping is faster than the opposite mapping, even when the hands are crossed so that the left key is pressed by the right hand and the right key by the left hand. Crossing the hands slows response time overall, but this effect is additive with that of spatial compatibility. This finding implies that the response is first determined on the basis of spatial location, and then the appropriate effector is specified to execute the movement at the desired location.

Stimulus location also affects performance when it is irrelevant to the task. Thus, a designer cannot ignore spatial compatibility even when the relevant stimulus information is non-spatial. For example, if a left response is to be made to a red stimulus and a right response to a green stimulus, responses are faster when the red stimulus occurs to the left and the green stimulus to the right. This phenomenon, first observed by J. R. Simon in the late 1960s, is now called the Simon effect (Lu and Proctor 1995, for reviews Simon 1990, Umiltà and Nicoletti 1990). The Simon effect indicates that a spatial code corresponding to the stimulus location is formed automatically and produces response activation when not intended. Because the issue of why spatial codes are formed when location is irrelevant is of theoretical interest, the Simon effect has been the focus of much of the recent research on compatibility effects (Hommel and Prinz 1997).

3.2. Relative Location

Whether stimulus location is relevant or irrelevant to a task, the spatial codes are based on relative location. That is, even if either the display elements or the response keys are both located to one side of the performer in the same hemispace, the mapping of left stimulus to left response and right stimulus to right response is superior to the reversed mapping. Compatibility effects also occur when the spatial information is conveyed by words (e.g. LEFT), symbols (e.g. a left-pointing arrow), or direction of motion (e.g. leftward movement). They occur as well as for vocal responses with spatial content (e.g. the utterances LEFT and RIGHT), movements of a joystick to the left or right, etc. However, the relative advantage for a compatible S-R mapping (e.g. left-to-left and right-to-right) is larger when verbal stimuli are paired with verbal, vocal responses and when non-verbal stimuli are paired with manual responses (Proctor and Wang 1997).

The coding of relative location depends on task goals and the performer's intentions, and not simply the locus or direction of the effector. In one study, subjects performed a two-choice task using sticks to operate the keys, with the sticks crossed such that a press of the left key required movement of the right hand on the right side, etc. Responses were fastest for the mapping in which the key location corresponded to the stimulus location, even though this meant there was no correspondence between the location of effector movement and stimulus location. Another study used a Simon task for which the pitch of a tone (high or low) was relevant and tone location (left or right) irrelevant. The unique aspect of this study was that the keypress response lit a light on the opposite side. When subjects were told to trigger the left light to the low pitch tone and the right light to the high pitch tone, or vice versa, responses were faster when stimulus location and light location corresponded than when they did not, even though the location of the keypress did not correspond with that of the tone. The important point from these studies for system designers is that very different spatial compatibility effects can be obtained as a function of the task goals of the performers.

3.3. Multiple Reference Frames

The results from several studies imply that spatial codes are formed with respect to multiple frames of reference when more than one is present. This point is illustrated by studies that used displays with eight locations, four in the left hemispace and four in the right hemispace. The relevant stimulus attribute was non-spatial, for example, a red stimulus signified a left keypress and a green stimulus a right keypress. On each trial a fixation cross, presented in the left or right hemispace, restricted the possible stimulus locations to the four in that hemispace. This was followed by presentation of two boxes to the left or right of the fixation point (i.e. in the left or right hemifield), one of which contained the stimulus to which a keypress response was to be made. The relative position of the stimulus in the two boxes defined the third frame of reference. Spatial correspondence effects were evident for all three reference frames, hemifield, relative position and hemispace. In other words, responses were fastest when the spatial codes with respect to all frames of reference corresponded to the response that was to be made and slowest when they all conflicted. Conflict between multiple spatial codes can have serious consequences, with such conflict apparently being the primary cause of the crash of a British Midland Airways Boeing

737-400 aircraft in January 1989 in which the pilot shut down the wrong engine following fan-blade failure.

The findings indicative of coding with respect to multiple frames of reference are in accord with the view that spatial codes are generated automatically with respect to referent objects or frames (Hommel 1997). An alternative proposal is that the formation of spatial stimulus codes is linked to shifts of attention involved in the control of saccadic eye movements (Stoffer and Umiltà 1997). Although there is considerable evidence to suggest that attention shifts may play a role in spatial coding, the exact nature of that role has yet to be determined.

It is possible to have stimuli and responses vary along both vertical and horizontal dimensions. That is, with four locations arranged in a square, each location can be characterized as a combination of up or down and left or right. If a two-choice task is used in which stimuli on one diagonal are mapped to responses on the other diagonal, responses are fast if the mapping is compatible on both dimensions and slow if it is incompatible on both. Of interest is what happens when there is compatibility on one dimension and incompatibility on the other. Several studies have suggested a form of what is called right–left prevalence. Performance is often better when there is compatibility on the horizontal dimension than when there is compatibility on the vertical dimension. Current evidence suggests that this prevalence is a function of a strategy that is adopted when either instructions emphasize the horizontal dimension or practice is sufficient to lead the performer to discover the benefit of coding the relations in terms of left and right.

4. SYMBOLIC S–R COMPATIBILITY EFFECTS

Compatibility effects are not restricted to spatial dimensions. Symbolic compatibility effects can be obtained when, for example, stimuli are colors and response keys are visibly labeled with the same colors. Responses will be faster when the assigned response color corresponds to the stimulus color than when it differs. Similarly, verbal responses to alphanumeric stimuli will be faster and more accurate when they are the typical names of the letter, number or word than when they are reassigned. Also, the mapping of an ordered stimulus set, say, the digits 1–4 to four linear response locations is more compatible if the ordering is increasing digit magnitude going from left-to-right than if some other mapping is used. According to Kornblum *et al.* (1990), dimensional overlap between the stimulus and response dimensions, that is, physical or conceptual similarity, is necessary to produce mapping effects.

Even stimulus and response sets that seemingly have no dimensional overlap can produce S-R compatibility effects if the structure of the stimulus set is mapped onto the structure of the response set. According to the salient features coding principle proposed by Proctor and Reeve (1990), when the members of the stimulus set and the members of the response set are distinguished in terms of salient features, performance is best for mappings in which the salient features of the two sets correspond. For example, if four stimuli vary along two dimensions, size (small or large) and letter identity, and letter identity is salient, then performance is better with a mapping in which letter identity corresponds to the salient left–right distinction for a row of four response keys than when it does not. The salient features coding principle has fared well in predicting the relative compatibility

of alternative mappings for numerous stimulus and response sets that vary along two dimensions. In sum, when there is similarity between the dimensions along which the stimulus and response sets vary or structure to the two sets, mappings that maintain the similarity or structure will typically lead to better performance than ones that do not.

5. COMPATIBILITY EFFECTS FOR ORTHOGONAL ORIENTATIONS

One of the more interesting findings in recent years is the occurrence of spatial compatibility effects for orthogonal spatial dimensions. When stimuli vary along a vertical dimension (up and down locations) and responses along a horizontal dimension (left and right responses), the mapping up-right/down-left typically yields better performance than the mapping up-left/down-right. The advantage for the up-right/down-left mapping is obtained for a variety of stimulus types (physical locations, words, arrows) and response sets (aimed movements, keypresses, vocal words). Compatibility effects for orthogonal dimensions are important because there are many situations in which controls and displays are orthogonal, either explicitly or implicitly. For example, the volume control on a car radio may require pressing a right button marked with a right pointing arrow to increase loudness and a left button marked with a left pointing arrow to decrease loudness.

One possible explanation for the orthogonal compatibility effects, based on the notion of salient features coding, is that "up" and "right" are the salient polar referents for the two dimensions and that less translation is required when the salient referents correspond than when they do not. Some authors have suggested that this salient features coding account may apply only to situations in which a person codes the stimuli verbally. The extent to which asymmetric coding is limited to verbal codes or is a more general characteristic of coding is a matter of debate at this time.

A finding with considerable design implications is that when making unimanual left–right switch or finger movements, the preferred mapping varies as a function of where the switch is placed relative to the body midline. If the switch is in the right hemispace, a pronounced up-right/down-left advantage is evident. However, if the switch is in the left hemispace, the advantage shifts in favor of the up-left/down-right mapping. A modified version of the salient features hypothesis says that the relative salience of left versus right is influenced by the relative location of the response switch, such that when the switch is to the person's left, left becomes the polar referent. Evidence has also been presented that the effect can be attributed at least in part to use of the hand as a frame of reference with respect to which the horizontally arrayed response locations can be coded vertically, thus rendering the coding of stimulus and response locations parallel.

Use of frames of reference to align orthogonally oriented stimulus and response arrays has been demonstrated for visual reference frames as well. Specifically, when two vertically oriented stimulus locations coincide with the locations of the eyes of a face rotated 90° to the left or right, responses are faster and more accurate if the location corresponding to the right eye, as viewed by the observer, is mapped to the right response and that

corresponding to the left eye to the left response. The implication is that frames of reference may provide a basis for coding orthogonal dimensions in a parallel manner, allowing a mapping that maintains spatial correspondence to be used.

There has not been much research with orthogonal stimulus and response arrays composed of more than two alternatives, but the limited results that are available suggest that in this case one of the arrays, most likely the response array, is mentally rotated to be aligned with the other array. A recent suggestion is that the effects of response eccentricity on the mapping preference for up and down stimuli mapped to left–right responses in two-choice tasks may be a consequence of changes in preferred direction of rotation. The extent to which mental rotation is involved in performance with orthogonally oriented arrays remains to be determined.

6. ONE OR TWO RESPONSE–SELECTION ROUTES?

Beginning with Fitts, compatibility effects have been attributed in part or whole to a response–selection route that usually is characterized as involving "translation" of the stimulus information into a response based on the instructions given the performer. Translation is considered to be fastest when an identity rule is applicable, for example, respond with the spatially corresponding response, and slowest when a search or look-up process must be used, as when there is no systematic relation between stimuli and their assigned responses. Translation also benefits from other rule-based relations, such as respond with the mirror opposite location.

During the 1990s, the most widely accepted view has been that there is a second response–selection route, characterized as "direct" or "automatic," that contributes to compatibility effects. The general idea is that a stimulus will automatically activate its natural, corresponding response via this route. Kornblum *et al.*'s (1990) dimensional overlap model is a dual-route model of this type. A major reason for proposing an automatic activation route in addition to the translation route is that, as described earlier, stimulus location affects performance even when it is irrelevant to the task. The basic idea is that the irrelevant location information affects performance because the stimulus activates the corresponding response via the automatic route. Measurements of the lateralized readiness potential, an event-related brain potential that shows differential activation of the motor areas in the two cortical hemispheres, in fact show an initial tendency to prepare the spatially corresponding response even when the relevant information specifies the non-corresponding response. As would be expected on the basis of automaticity, the response activation produced by irrelevant stimulus location tends to occur quickly and then, because it is irrelevant, to decay. Thus, the effects of irrelevant location on performance often will be larger when the relevant information can be processed quickly than when it takes longer to do so.

This automatic activation of the corresponding response is frequently characterized as due to links that are hardwired genetically or learned through a lifetime of experience with spatially compatible relations (Umiltà and Zorzi 1997). However, which response is activated can be altered with relatively little experience. Lu and I recently gave subjects given ~1000 trials of

practice with a spatially incompatible mapping of stimulus locations to response locations in a two-choice task. When stimulus location was subsequently made irrelevant, the Simon effect was reversed, that is, responses were faster when stimulus location and response location did not correspond than when they did. This reversal of the typical Simon effect persisted > 600 trials, so it was not extremely short-lived. The point is that the tendency to make the spatially corresponding response can be modified by task instructions that were in effect previously. It is also possible to reverse the effects by using a mapping rule for the relevant stimulus dimension (e.g. color) that allows an "opposite" transformation to be applied (e.g. press the red key if the stimulus is green and vice versa). In this case, the re-coding rule apparently gets misapplied to the location dimension, producing an advantage when stimulus and response locations do not correspond.

There has been less agreement about whether and how this automatic activation route contributes to compatibility effects for relevant stimulus information. Kornblum *et al.* (1990), for example, assume that it is a factor contributing to such compatibility effects whenever the relevant stimulus dimension overlaps with the response dimension. Another view is that the automatic route only comes into play when all of the possible stimuli are mapped compatibly to responses. The finding on which this view is based is that when compatible and incompatible mappings are mixed, the compatible responses are slowed substantially relative to a pure compatible block, but the incompatible responses are not affected much. It has been suggested that the automatic route is inhibited and the slower translation route used when only some of the S-R relations are known to be compatible. The important point for designers is that the benefit of compatible mappings may be lost if other information in the environment is mapped incompatibly.

7. IMPLICATIONS FOR HUMAN FACTORS

1. S-R compatibility effects are pervasive and persistent. They occur whenever there is physical, conceptual, or structural similarity between stimulus and response sets. A good interface must have a high degree of compatibility and allow fast and accurate response selection.
2. With spatially arrayed displays and controls, correspondence in terms of relative spatial locations should be maintained whenever possible. If multiple reference frames exist, compatibility with respect to all frames must be considered.
3. Spatial compatibility effects can occur even when the stimulus location does not provide relevant information.
4. Compatibility effects often occur when displays and controls are oriented orthogonally. These orthogonal compatibility effects

may vary as a function of alternative frames of reference that are available and the location of the controls relative to the operator.
5. Much of the advantage of compatible S-R mappings may be lost when they are mixed with incompatible S-R mappings.

The Substance of Cognitive Modeling

E. Hollnagel

Linköpings Universitet, S-581, 83 Linköping, Sweden

1. INTRODUCTION

One of the hard problems in the study of human cognition is how it should be modeled. While it is taken for granted that models are necessary in the study of cognition, just as in every other field of science, there are two issues of the model problem that need to be addressed. One concerns *what* should be modeled; this is the issue of the substance of modeling. The other concerns *how* the models should be expressed, i.e. the language of modeling, or the technical issue. This article only discusses the former.

The interest in the modeling of cognition goes beyond the common use of models as a tool of science, and can probably best be understood as a backlash to the positivistic view of classical behaviorism. The modern study of cognition is intrinsically linked to the invention of the digital computer and the emergence of scientific disciplines such as cybernetics and information theory, and in large parts derives its legitimacy from those. Within this tradition it has long been the accepted norm that the modeling of human performance requires the modeling of the inner, mental processes and knowledge of the user — in the shape of the ubiquitous user model. The merits of this view notwithstanding, during the 1990s it has been questioned whether cognition should be described primarily as a mental process, and in particular whether it can be considered as a context-free mental process. The aim of this article is to investigate this view, as well as its more recent alternative, and propose a basis for resolving the substance issue.

2. COGNITION WITHOUT CONTEXT

The notion that cognition could be modeled as specific processes or functions without raising the specter of mentalism goes back to the very beginning of the time when computers started to become commonly known. In a seminal paper, Edwin Boring (1946) described a five-step program for how the functions of the human mind could be accounted for in a seemingly objective manner. First, the functional capacities of the human should be analyzed, e.g. by listing the essential functions. Second, the functional capacities should be translated into properties of the organism by providing a description of the input-output characteristics (essentially a black-box approach). Third, these functions should be reformulated as properties of a hypothetical artifact, which in modern terms means expressing them as operational descriptions for a computer system, e.g. in the form of flow charts or programs. The fourth step was to design and construct actual artifacts, which is equivalent to programming the functions in detail and running a simulation. The fifth and final step was to explain the workings of the artifact by known physical principles. This would serve finally to weed out any mentalistic terms and capacities.

Boring believed that the ultimate explanation should be given in terms of psychophysiology, so that "an image is nothing other than a neural event, and object constancy is obviously just something that happens in the brain". Although written more

than 50 years ago, the approach is in all essentials identical to the principles of information-processing psychology, as it became popular in the mid-1970s. The essence of this view was that cognition should be studied and understood as an inner — mental — process rather than as action. More particularly, cognition was explained in terms of more fundamental processes, hence in all essence treated as an epiphenomenon of human information processing. This idea of context free cognition was promoted by people such as Herbert A. Simon, who argued very convincingly for the notion of a set of elementary information processes in the mind. One consequence of this assumption was that the complexity of human behavior was due to the complexity of the environment, rather than the complexity of human cognition (Simon 1972). This made it legitimate to attempt to model human cognition independently of the context, which effectively was reduced to a set of inputs. In the same manner, actions were reduced to a set of outputs, and the inputs and outputs together represented the direct interaction with the context.

As the main interest of human information processing was to model cognition per se, the chosen approach corresponded well to the purpose. Cognitive ergonomics and cognitive systems engineering, on the other hand, are rather more interested in developing better ways of analyzing and predicting human performance. This purpose cannot be achieved by the information processing types of models, and therefore requires an alternative approach.

3. THE LANGUAGE OF COGNITION

The language of cognition, as the term is used here, does not refer to descriptions of how cognition is assumed to take place in the mind or the brain, i.e. the neurophysiological or computational processes to which cognition allegedly can be reduced. It refers rather to the terminology that is used to describe cognition and its role in human behavior. The language of cognition is important because the terms and concepts that are used determine both which phenomena come into focus and what an acceptable explanation is. This is illustrated by the classical work in the study of cognition (e.g. Newell and Simon 1972), which used astute introspection in well-controlled conditions to try to understand what went on in people's heads, predicated on the notion of information processes. While many of the features of cognition that have been found in this way are undeniably correct on the phenomenological level, their description often implies assumptions about the nature of cognition that are ambiguous, incorrect, or unverifiable. This can be illustrated by a small example.

In the daily use of the language of cognition these assumptions are easily forgotten, and the reality of the underlying mechanisms or concepts, such as human information processing, is taken for granted and hence rarely questioned. Consider, for instance, the fact that it is sometimes difficult to recognize people that one knows. In one situation a face may be recognized as familiar, yet it may be impossible to recall the context. In another, a person may be fully recognized, yet the name cannot be recalled. On the other hand, it rarely happens that someone is recognized as familiar and that the name can be recalled, but that nothing else is about the person comes to mind.

The language of cognition determines how this phenomenon is explained. In one case it can be described as a failure to retrieve

the name of the person from long-term memory, and the explanation is that the brain stores information about people's names separately from all other information about them. This explanation implies that there are a number of separate memories, and that the recognition of a person goes through a number of steps, starting by seeing the face and ending by retrieving the name. In another case the phenomenon can be described as the difficulty in remembering people's names. The explanation is, in this case, that names are hard to remember because they are generally meaningless. This explanation does not require an elaborate theory about human information processing, nor a mental model, but simply states a fact (although it also requires an independent definition of what "meaningless" is).

4. COGNITION IN CONTEXT

Since the late 1980s the scientific disciplines that study cognition — predominantly cognitive science, cognitive psychology, and cognitive engineering — have increasingly emphasized the relation between context and cognition. This has been expressed in a number of books, such as Hutchins (1995) and Klein *et al.* (1993). The essence of this "new look", which has been referred to by terms such as "situated cognition", "natural cognition", and "cognition in the wild", is:

(1) that cognition is not confined to a single individual, but is rather distributed across multiple natural and artificial cognitive systems;

(2) that cognitive activity is not confined to a short moment as a response to an event, but is rather as a part of a stream of activity;

(3) that sets of active cognitive systems are embedded in a social environment or context which constrains their activities and provides resources;

(4) that the level of activity is not constant but has transitions and evolutions; and

(5) that almost all activity is aided by something or someone beyond the unit of the individual cognitive agent, i.e. by a tool.

Many people have seen this development as a significant step forward, although the enthusiasm has not been the same on both sides of the Atlantic. Yet while it is praiseworthy that the study of cognition at long last acknowledges that cognition and context are inseparable, it should not be forgotten that "situated cognition" is far from being something new. As long ago as 1976, Ulrich Neisser (1976: 8) wrote that:

(w)e may have been lavishing too much effort on hypothetical models of the mind and not enough on analyzing the environment that the mind has been shaped to meet.

And a few years later Donald Broadbent (1980: 117) echoed the same view when writing that:

one should (not) start with a model of man and then investigate those areas in which the model predicts particular results. I believe one should start from practical problems, which at any one time will point us towards some part of human life.

After many years of gradually moving down a cul-de-sac of human information processing, it is easy to see the shortcomings of this approach to the study of cognition. It is less easy to see what the problems are in the alternative, since its power to solve — or rather dissolve — many of the difficult problems is deceptive. Although it was a mistake to assume that cognition

could be studied without considering the context, it is equally a mistake to assume that there is a difference between cognition in context, i.e. in natural situations whatever they may be, and context-free cognition. The methods of investigation may be widely different in the two cases, but this does not warrant the assumption that the object of study — cognition — is different as well.

The hypothetico-deductive approach preferred by academic psychology emphasizes the importance of controlled conditions, where independent parameters can be varied to observe the effect of predefined dependent variables. This classical approach is often contrasted to the so-called naturalistic studies, which put the emphasis on less controlled but (supposedly) more realistic studies in the field or in near-natural working environments. It is assumed that the naturalistic type of study is inherently more valid, and that the controlled experiments run the risk of introducing artifacts and of studying the artifacts rather than the "real" phenomena.

Many of the claims for naturalistic studies are, however, inflated in a misguided, but understandable, attempt to juxtapose one paradigm (the "new") against the other (the "old") and to support the conclusion that the "new" is better than the "old". Quite apart from the fact that the "new" paradigm is not new at all (e.g. Brunswik 1956), the juxtaposition disregards the essential reality that all human performance is constrained, regardless of whether it takes place under controlled or naturalistic conditions. Given any set of conditions, whatever they may be, some activities are more likely than others – and indeed some may be impossible under given circumstances. In the study of firefighters during actual fires, the goals (e.g. to put out the fire as quickly as possible) and the constraints (resources, working conditions, command and control paths, roles and responsibilities, experience, etc.) will, to a large extent, determine what the firefighters are likely to do, and how they will respond to challenges and events. In the study of firefighters using, for instance, a forest fire simulation game, there will be other goals and constraints, hence a different performance. The difference between the controlled and the naturalistic situations is not the existence or the reality of the constraints, but rather the degree to which the constraints are predefined and controllable. In both cases the performance will be representative for the situation, but the two situations may not be representative of each other.

The hypothetico-deductive approach requires the conditions of a controlled experiment in order to succeed and the *ceteris paribus* principle reigns supreme, although it is well known that this is a strong assumption that rarely is fulfilled. The degree of control is often less than assumed, which may lead to problems in data analysis and interpretation. The important point is, however, to realize that all human performance is constrained by the conditions under which it takes place, and that this principle holds for "natural" performance as well as controlled experiments. For the naturalistic situation it is therefore important to find the constraints by prior analysis. If that is done, then we have achieved a degree of understanding of the situation that is similar to our understanding of the controlled experiment, although we may not be able to establish the same degree of absolute control of specific conditions (e.g. how an event begins and develops). Conversely, there is nothing that prevents a "naturalistic" approach to controlled studies, as long as the term

is understood to mean only that the constraints are revealed by analyzing the situation rather than by specifying it in minute detail. Possibly the only thing that cannot be achieved in a controlled setting are the long-term effects and developments that are found in real life.

5. MENTAL MODELS AND THE LAW OF REQUISITE VARIETY

One answer to the substance issue is provided by the Law of Requisite Variety, which was formulated in cybernetics in the 1940s, and 1950s (Ashby 1956). This law is concerned with the problem of regulation or control and expresses the principle that the variety of a controller should match the variety of the system to be controlled. The latter usually is described in terms of a process plus a source of disturbance. The Law of Requisite Variety states that the variety of the outcomes (of a system) can only be decreased by increasing the variety in the controller of that system. Effective control is therefore not possible if the controller has less variety than the system.

It is consistent with the interests of cognitive ergonomics and cognitive systems engineering, that the study of cognition should focus on problems which are representative of human performance, i.e. which constitute the core of the observed variety. The implication is that the outcome of the regularity of the environment is a set of representative ways of functioning, and that these should be investigated rather than performances that are derived only from theoretical predictions or from impoverished experimental conditions. With regard to the modeling of cognition the substance should thus be the variety of human performance as it can be ascertained from experience and empirical studies — but, emphatically, not from theoretical studies. The requirement to the model is therefore that model variety is sufficient to match the observed variety of human performance. The model must, in essence, be able to predict the actual performance of the user to a given set of events under given conditions.

The difference between the observed variety and the theoretically possible variety is essential. The theoretically possible variety is an artifact, which mirrors those assumptions about human behavior and human cognition that are inherent in the theory. The theoretically possible variety may therefore include types of performance that will not occur in practice — because the theory may be inadequate or because of the influence of the working conditions. (It follows that if the working conditions are very restricted, then only a very simple model is needed. This principle has been demonstrated by innumerable experimental studies.) If research is rooted in a very detailed theory or model we may at best achieve no more than reinforcing our belief in the theory. The model may fail to match the observed variety and may very likely also be more complex than strictly needed, i.e. the model is an artifact rather than a veridical model in the sense of being based on observable phenomena.

The requirements to modeling of human cognition should be derived from the observed variety, since there is clearly no reason to have more variety in the model than needed to account for the observed variety. The decision about how much is needed can therefore be based on the simple principle that if the predicted performance sufficiently well matches the actual performance, then the model has sufficient variety. This furthermore eliminates the affliction of model validation. The catch is, of course, in the meaning of "sufficiently" which, in any given context and for any given purpose, must be replaced by a well-defined expression. Yet even if this problem may sometimes be difficult to solve, the answer to the substance issue should definitely be found by asking what cognition *does*, rather than what cognition *is*.

Tolerance to Shiftwork

I. Iskra–Golec

Institute of Management, 13 Pilsudski Street, Jagiellonian University, 31–110 Krakow, Poland

1. INTRODUCTION

Humans seem to be the only diurnal species requested to be active at night and to sleep during the day at certain circumstances, i.e. when they work shifts including night work. Humans evolved in the rhythmic environment resulting from planetary movements (e.g. light/dark cycles). This lead to the development of internal mechanism (a body clock) producing biological rhythms of body processes and behavior (e.g. circadian rhythms) to prepare and enable humans to function in the rhythmically changing environment. The social environment exhibits rhythms structured according to daytime working hours and night time rest. How shift working people react to the displacement of natural sleep–wake pattern in the day oriented pattern of activity and rest of the society and what are the factors which determine their reaction?

2. MODELS OF SHIFTWORK–SHIFTWORKER RELATIONSHIP

There have been developed two groups of models explaining the relationship between shiftwork and working individual; simple, linear ones founded in stimulus based stress theory and more complex models stemming from transactional framework of stress (Colquhoun *et al.* 1996; Härmä 1993).

The first models focus on environmental factors considering the worker as a passive recipient of stress. They regard shiftwork as disturbing environmental factor (exposure to phase shifting of sleep–wake cycle relative to its natural phase) which causes strain in the worker manifesting itself in complaints and health problems. Between stress and strain mediate intervening variables including working conditions, housing, family situation, and personality moderating the strain.

The models of second group take into account apart of biological clock, sleep and social factors also more environmental variables and shiftworker's cognition and behavior emphasizing multi-directional links between them. The most advanced transactional model regards shiftworker as active agent engaged in two-way relationship with the environment. Environmental demands and the workers' capabilities to deal with or manage are cognitively appraised with stress appearing when the demands burden or surpass the capabilities of the worker. Then coping strategies are adopted in response to the judgements that can alter the environment directly and/or can change appraisal process to alter the stressfulness of the situation.

3. CONCEPT OF TOLERANCE TO SHIFTWORK

In the literature an understanding of tolerance to shiftwork is founded on stimulus-based theories of stress. The notion of shiftwork tolerance is often used without any explicit explanation. Judging from the measures used tolerance to shiftwork is assessed according to self-reported complaints concerning ill-health and sleep disturbances (Taylor *et al.* 1997). The only definition of tolerance to shiftwork explains the concept by its reverse, i.e. clinical intolerance to shiftwork, which refers to existence and intensity of a set of following medical complaints: sleep disturbances, persisting fatigue, alteration of mood, digestive troubles and regular use of sleeping pills (Rainberg and Smolensky 1994: 246). Such a conceptualization has been called "biologically restricted perspective of tolerance" and criticized for neglecting psychosocial consequences of shiftwork, and their relations to and interactions with biological shiftwork effects (Nachreiner 1998).

Intolerance to shiftwork has been suggested to be a process following a certain temporal pattern. It is assumed to develop in interactions between health and other factors (biological clock, working and family situations) through four phases from "adaptation" through "sensitization" and "accumulation" to "manifestation" when the diseases and disorders appear.

4. FACTORS INFLUENCING TOLERANCE TO SHIFTWORK

4.1. Shift Systems Parameters and Tolerance to Shiftwork

The shift systems in operation seem to comfort the technological and economical needs of organizations rather than well-being of the workers employed. There is a body of evidence showing a potential of different ways of work scheduling for facilitating tolerance to shiftwork. It should be noted, however, that there is no ideal solution in designing shift systems (apart from excluding night shift) since systems facilitating tolerance in one sphere at the same time neglect the other.

4.1.1. Shift rotation

From chronobiological perspective the best, i.e. the least disruptive for circadian rhythms, is shift system that maximizes or minimizes circadian adjustment. Permanent night shift systems have been assumed to maximize circadian adjustment but when the worker can keep night orientation of circadian rhythms (sleep during the day and be active at night) also during the days off. This, however, would isolate him from the rest of the day-oriented society and this way would be disruptive for his family and social life.

4.1.1.2. *Speed of rotation*

Rapidly rotating shift systems (one, two or three shifts of the same kind in a row) allow circadian rhythms to remain day oriented. This way a continuous state of partial circadian adjustment to and from night work characteristic of slower rotating systems (resulting from insufficient time for the body clock to adjust) is avoided. However, low night time alertness and poor day time sleep are the disadvantages of circadian rhythms day orientation. The poor day time sleep adds to the average sleep loss per day which is the largest in rapidly rotating systems but a short period of night shifts prevents from accumulation of sleep deficit which tends to increase with a number of consecutive night shifts. Rapid shift rotation is also less disruptive for social life since a few free evenings in such systems allow for frequent and regular contacts with family and friends.

4.1.1.3. *Direction of rotation*

There is some support from the research that forward rotating shift systems (order of shifts: morning, evening, night) are

associated with fewer sleep problems, lower fatigue and less social disruption than backward rotating ones (order of shifts: night, evening, morning). Some chronobiologists explain that by a natural tendency of the body clock to run slow (in the absence of time cues its period is > 24 h) what makes people adjust better to delayed hours of sleep induced by forward rotation than to advanced what induces backward rotation. The others argue that backward rotation provides good opportunity to prepare for and to recover from the night shift and that not the work schedule limitations but social demands tend to determine shiftworker's sleep. It has been recently suggested that not the direction of rotation *per se* but "quick returns" (short breaks, e.g. 8 h between the end of one shift and start of the next) common for many backward rotating systems might be responsible for problems reported by shiftworkers.

4.1.2. Duration of work periods

There are not consistent research findings on the effect of extended shift duration (9–12 h) but the opinion that longer shifts are associated with accumulation of fatigue and reduced alertness especially on night shift in difficult working conditions predominates. On the other hand longer shifts are usually followed by longer time spans off providing an opportunity for recovery, social contacts and leisure pursuits so they are popular among shiftworkers. The number of consecutive working shifts in succession seems to be important due to accumulation of fatigue especially among the older workers so 5–7 working days before days off has been suggested as optimal.

4.1.3. Timing of shifts

Early start of morning shift seems not to facilitate shiftwork tolerance since it is associated with reduced sleep (early waking up time) and increased fatigue. In contrast, an early start of morning shift means an early end of night shift allowing earlier onset of day time sleep and its longer duration. The best solution regarding timing of shifts seems to be flexible working time arrangements allowing individual choice of starting and finishing shifts in "time autonomous groups" that experimental implementing has been found to reduce fatigue and complaints about social and family life among shiftworkers.

4.1.4. Distribution of leisure time within the shift system

It has been evidenced that not only the amount but also the positioning of free time within the week is important for shift work tolerance. Short intervals between two consecutive shifts (e.g. 8 h) reduce sleep substantially and increases the fatigue of shiftworkers. Days off during weekends has been suggested to facilitate social life of shiftworkers due to traditional concentration of social events on weekends and 2 days in succession have been advised for recovery from the effects of socializing (e.g. reduced sleep).

4.2. Tolerance to Shiftwork and the Individual

People differ in their ability to cope with shiftwork. It is assumed that relatively stable individual differences between shift workers (e.g. in age, personality) may modify shift work consequences they experience. At present there is not enough knowledge to predict what individual characteristics would make people better

tolerating shift work. Instead there is some evidence on associative relationships between individual difference measures and the amount of problems individuals have in dealing with shift work.

4.2.1. Age

Aging is associated with decreasing tolerance to shiftwork with the critical age being ~40–50 years. Sleep complaints predominate all shift work related problems that tend to increase with age. There also has been found slower adjustment of circadian rhythms, sleep–wake pattern and performance to shift work among middle-aged (> 40 years) shift workers when compared with younger ones.

Decrease in shift work tolerance may result from the aging effect on the body clock that induces changes in sleep–wake pattern (e.g. frequent waking episodes, early morning awakenings) and in the other circadian rhythms (e.g. shortened periods, decreased amplitude) what may hinder adjustment to shift work. Usually a variety of health complains appears with age and adds to the difficulty of coping with shiftwork.

4.2.2. Gender

The opinion that any differences between genders in tolerance to shiftwork result from differences in domestic workload rather than from inherent differences in biology seems to be supported by research findings. There have not been found differences between shiftworking men and women in health complaints but in domestic duties and leisure time activities. Excessive household responsibilities not only shorten women's leisure time but first of all their sleep duration. Female night workers with two children have been found to sleep ~9 h per week shorter than unmarried ones. The amount of symptoms of intolerance among shiftworking women is larger than among men up to 50 years of age. After that age, i.e. when children left home and the amount of duties decreased, the amount of symptoms reported by women decreases and is equal to those reported by men.

4.2.3. Circadian factors

It is assumed that ability to cope with shift work may depend on the circadian adjustment to disruption caused by work schedules. Circadian adjustment to shift work has been found to be associated with changes in circadian rhythms parameters including partial phase shift and decrease of rhythms amplitude which vary within the population.

4.2.3.1. Circadian phase

People differ in phasing of their body and behavioral rhythms. Morning people (morning types or larks) have earlier peaking of body temperature and other body circadian rhythms, wake up early in the morning, feel more alert in the morning and fall asleep earlier that does the population as a whole. The opposite is true for evening people (evening types or owls) who get up late, fall asleep late at night and feel more alert later during the day. Definite morning and definite evening types represent a small percentage (5% each) of the population most of which shows such differences to much less extent. There have been found associations between morningness and indices of shift work intolerance but the correlations achieved were low and inconsistent and with no validity to predict shift work tolerance.

Morningness/eveningness may exert its influence on factors associated with shift work tolerance i.e. on the amount of sleep achieved on different shifts. Natural tendency of morning types to wake up and fall asleep early makes them able to get enough sleep before morning shift but at the same time shortens their day sleep after night shift. The reverse is true for evening types. Neither of these types is advantaged in rotating shift systems.

4.2.3.2. Circadian amplitude

People differ with regard to amplitude between maximum and minimum of their daily body temperatures. There is some evidence suggesting that people with wider body temperature range are better able to tolerate shift work but there are also contradictory research findings. Tested in predictive context the circadian amplitude has not shown validity to predict tolerance. Low circadian amplitude has been found in quite healthy subjects without any clinical complaints so it is not recommended a reliable index of tolerance to shift work.

4.2.4. Personality characteristics

There have been found some association between personality characteristics and individual differences in circadian rhythm phasing so attempts have been made to relate the former to the shiftwork tolerance.

4.2.4.1. Introversion/extroversion and neuroticism

The studies focused on personality dimensions of introversion/extroversion and emotional stability/instability (neuroticism). Introverts (subjects not prone to communicate or socialize) when compared with extroverts tend to have an earlier phase position with regard to the circadian rhythms of body temperature, sleepiness and waking and performance. It is probably why circadian adjustment to night work is slightly faster in extroverts than in introverts. Neurotic extroverts exhibit a greater phase adjustment of body temperature in shiftwork situations than neurotic introverts. There has been found a relationship between extroversion and neuroticism with indices of shiftwork tolerance but the correlations were mainly low and inconsistent. Nether their power to predict tolerance have been demonstrated. Moreover, it has been found in longitudinal studies that neuroticism tends to increase with the shiftwork experience. It is why this is no longer considered a determinant of shiftwork tolerance but rather a symptom of intolerance.

4.2.4.2. Flexibility/rigidity of sleeping habits and ability to overcome drowsiness

A concept of circadian type has been developed to find factors determining adjustment to shiftwork. Two main dimensions were established flexibility/rigidity of sleeping habits referring to ease in changing sleep times and ability/inability to overcome drowsiness concerning the ease in throwing off feeling of drowsiness. There are contradictory results on whether these factors are associated with better circadian adjustment but it has been found their relationship with better long term tolerance to shiftwork. When tested for predictive power in controlled longitudinal studies they both exhibited low but reliable and consistent positive correlations with indices of subjective health.

4.2.5. Behavioral factors

The amount of problems in dealing with shiftwork seems to be associated to greater extent with worker's behavior and cognition (e.g. life style, coping strategies) than with relatively stable individual traits. More research both cross-sectional and longitudinal is needed before any firm conclusions can be drawn.

4.2.5.1. Commitment to shiftwork

Shiftworkers willingness and/or ability to structure their life around working hours has been reflected in better adjustment of both sleep and circadian rhythms (e.g. body temperature, alertness) to shiftwork. It is suggested that it can even overweight the eventual unfavorable for shiftwork tolerance effect of personality and circadian characteristics.

Regularity of behavior in some areas (e.g. eating habits, social behavior) has also been suggested to increase adaptation to shiftwork.

4.2.5.2. Physical conditioning

Physical fitness has been found to facilitate ability to cope with shiftwork. Regular exercising has been associated with increased general fitness, longer self-reported sleep, higher alertness and lower general fatigue during night work but not with better circadian adjustment to shiftwork. Such an influence of physical conditioning may stem from the sleep inducing and improving effect of exercise and/or increase in general strength.

4.2.5.3. Coping strategies

Ineffective strategies i.e. disengagement coping strategies (attempting to avoid or ignore sources of stress) and passive style of coping have been found to be associated to worsening of well-being.

4.3. Tolerance to Shiftwork and Family, Social and Situational Circumstances

4.3.1. Family

Spouses and children tend to both facilitate and hinder tolerance to shiftwork. Existence of spouse or partner seems to facilitate shiftwork tolerance by satisfaction from family interactions. Family acceptance of shiftworking is important for worker's well-being. Wives brought up in families with shiftworking parents tend to accept this work better than others. However, shiftworking seems to hinder fulfilling roles of a partner and a parent since higher divorce rate and lower children school achievements have been found in shiftworkers when compared with dayworkers. Children can make coping with shiftwork more difficult especially for women but also for men. The day sleep after night shift of shiftworking women has been shown to be of the shortest duration among women with small children and of the longest among women without children. The noise made by shiftworkers' own children is one of the most common reasons of day sleep interruptions.

4.3.2. Community

Shiftworkers living in areas where there is a tradition of working shifts seem to tolerate it better than those living in areas where shiftworking is an exception. Working hours of local community members may have an influence of shiftworkers social life since they tend to interact socially with one another rather than with others.

4.3.3. Living conditions and other situational factors

Shiftworkers living in unfavorable living conditions (e.g. unisolated sleeping accommodation, near roads with heavy traffic) complain more about lowering of well-being than those in more favorable ones. In developing countries the health effect of night work tend to be aggravated by bad working conditions, tiring climate conditions, poor and cramped housing and insufficient food.

5. DIRECTIONS OF INTERVENTIONS FACILITATING TOLERANCE TO SHIFTWORK

A number of factors with multidimensional links between them influencing tolerance to shiftwork implies a necessity of complex and multifaceted interventions aimed at its promotion. Research results founded on stimulus based approach to shiftwork stress show one direction of intervention. Emphasizing a potential in proper environment shaping they provide premises for designing shift systems facilitating tolerance to shiftwork. They also recommend regular medical checks and medical criteria for shiftworkers selection. Focus on relatively stable individual traits of this approach proved not to be fruitful at least at the present state of knowledge. Lack of predictive relationship between almost all relatively stable individual traits with indices of tolerance to shiftwork makes impossible any effective strategy of selecting suitable for shiftwork individuals. Transactional approach emphasizing shiftworkers' behavior and cognition suggest second direction of interventions providing premises for facilitating tolerance via enhancing worker's coping strategies by education programs and counseling.

1. DEFINITION OF AN AGING WORKER

Aging refers to the manner in which the functions, morphology and other features of living organisms change over time. The period of the process extends from birth through growth to decline and death. The World Health Organization's Study Group on Aging and Work Capacity (WHO 1993) defines the range of chronological age in an "aging worker" as 45 years and older. Similarly, Japan's Ministry of Labor defines persons 45 years or older as middle- to older-aged workers, and persons 55 years and older as older-aged workers, based on a special law to promote the employment of middle- to older-aged persons.

2. PRINCIPLE OF AGING AT THE WORKPLACE

In investigating the aging phenomenon among middle- to older-aged people active in the workplace, remember that the aging worker has two distinct aspects that work in a negative way, and a synergistic capacity that works in a positive way. When evaluating work ability as a person ages, note that synergistic capacity has a large influence in the workplace, whereas the negative aspects may be minimized depending on the type of job and circumstances involved. General remarks about the aging worker fall into three broad categories:

1. Physiological functions enter decline earlier than mental faculties. A general decline in physiological functions begins in the 30s age bracket, accelerating rapidly in the 40s.
2. The decline in muscular strength begins in the legs then proceeds to the upper body via the hips, arms and hands.
3. Artificially acquired capabilities and functions do not wane even after the decline of vital functions with aging. In addition, the more one uses these acquired capabilities — skills, knowledge, judgment, etc. — that have been cultivated through job experience, the more one can continue to use them into old age.

3. EFFECTS OF VDT–BASED WORK ON THE OPERATOR

The effect of visual display terminals (VDTs) on the health of operators has been under study from various angles since the mid-1970s. The findings of this research have brought to light the following six problems related to VDT-based work:

1. Impact on visual function: irritated eyes, blurred vision, burning eyes, and eye strain.
2. Musculoskeletal impact: painful or stiff neck and/or shoulders, and back pain.
3. Mental fatigue, stress and psychosomatic symptoms.
4. Nonionizing and ionizing radiation emissions.
5. Skin disorders linked to the combined effect of airborne chemical contaminants indoors and static electricity generated by low humidity and VDTs.
6. Health risks from the electromagnetic radiation emitted by many VDTs or large-screen VDT equipment in the workplace.

There are a number of methods that can relatively easily resolve the problems related to the effects of VDTs on the human body (items 1, 2, 4, 5) by improving the work environment, redesigning a workstation, and providing an appropriate schedule of work and rest breaks.

However, the effect on the psychoneurotic system — the problem of computerized work and mental stress—remains difficult to resolve.

Furthermore, studies into the effect of electromagnetic radiation on health have yet to establish clearly defined standards of exposure, leaving serious questions that remain to be answered.

4. VISUAL FUNCTION MOST IMPACTED BY AGING

The key feature of computer-based work is the act of viewing the display screen. Cathode ray tubes (CRTs) and flat panel displays (FPDs) are now in widespread use, and the viewing of luminous light is common to both. This is the most significant cause underlying the increasing frequency of subjective symptoms of the eye.

Close observation of an image requires the accommodating ability of the eye to focus light on the retina. However, this is difficult if the characters (letters) or symbols are either luminous themselves or displayed on a luminous background: this is the most significant cause of eye fatigue. Furthermore, it is believed that the eye blinks less frequently during close-range viewing, thereby drying the cornea and causing eye pain. An attempt was therefore made to identify the characteristic features of visual function unique to aged persons.

Earlier work indicates that aged individuals develop an impaired pupillary reflex and opacity of the optic media (Carter 1982, Pitts 1982, Reading 1968), thereby experiencing degradation of light sense, image focusing on the retina, color perception, and glare tolerance, which further impairs the capacity for far vision (Weale 1982), contrast sensitivity (Owsly *et al.* 1983), visual search (Plude and Hoyer 1981), and graphic recognition (Snellen and Sterings, 1924).

Table 1 shows a general overview of aging and changes in visual function from the standpoint of operational efficiency based

Table 1. Changes in visual function closely linked to the aging process

Phenomenon 1	Decline of visual acuity: although both static and kinetic visual acuity are in decline, the deterioration in kinetic visual is especially prominent; night vision also declines
Phenomenon 2	Decline in peripheral vision functions (kinetic field of vision): aging has little effect of the static field of vision
Phenomenon 3	Decline in focusing functions: lengthened focal distances, longer time for focusing
Phenomenon 4	Decline in ocular motion capacity: decline in the speed of ocular tracking motion, difficulty in moving focus

Table 2. Countering the degenerative effects of aging on visual function.

Countermeasure 1	The vision of older persons under bright lighting conditions is good compared with that of younger persons, and the rate of improvement of vision is also superior — adjustment of lighting conditions recommended
Countermeasure 2	Under static vision conditions, improvement is possible with corrective lenses
Countermeasure 3	Limit the field of vision of each eye to within 120° laterally
Countermeasure 4	Adjust the working vision distance

on this knowledge and Table 2 shows a basic set of counter-measures (Kumashiro 1997).

5. AGED PERSONS AND VDT–BASED TASKS USING A LARGE SCREEN

A large screen is useful in presenting a large amount of information at once, and it also has the advantage of facilitating viewing by aging workers. Yet large screens do have drawbacks regarding their effect on the health of users.

Some recent findings related to workloads were obtained from an experiment in which older and younger subjects performed a VDT-based simulation of an instrument monitoring operation and a fuel-control operation representing work within a human–computer system. This task required the dual capacity to input and to sense an external input stimulation largely through visual processes, as well as the ability to make an instantaneous evaluation as a psychophysiological reaction.

5.1. Speed and Accuracy

The response time was affected markedly by aging. Compared to the young group, the aging group required a significantly prolonged response time for an instrument resetting operation, and the incidence of overlooking malfunctioning instruments increased significantly. However, compared with a work setting using 17-inch video displays, functional differences between age groups were less evident when using 110-inch displays, which suggests that increasing the display screen size for VDT-based operations might reduce the burden of work on aging persons and contribute to improved work safety.

5.2. Physiological Effects

In order to predict the effect of aging on cardiac autonomic function, heart rate variation (HRV) was used as a guideline, and this showed a distinct difference between the aging group and the young group. In addition, compared to the young group, the aging group exhibited an apparent reduction in heart rate reactivity to the loaded task. More specifically, for either HRV parameter, the rest-hour value was significantly small in the aging group compared to the young group, and no marked change was observed between the rest-hour value and the value measured during the task. Such heart rate reactive reduction with aging suggests impaired homeostatic control in response to the load of a mental task. In that regard, an aging person may be more susceptible than a young person to the risk of cardiovascular disease in response to the load of a mental task.

Next, an apparent difference was found between the two age groups in the ability of accommodation. Furthermore, no change was observed in the ability to accommodate in response to shifts in optical status in the aging group. Deterioration in the ability of an aging person's eyes to accommodate may not only lead to work safety concerns — stemming from difficulty in alternately viewing far and near objects and more frequent incidences of visual oversight or outright visual error — but also to an increase in the work burden. Therefore, the ergonomic guidelines for VDT-based tasks, which are highly dependent on the sense of vision, should be reviewed in light of the changes in visual function that naturally occur with aging.

Visual Measurement: Modern Methods

T. Takeda

Faculty of Engineering, University of Tokyo, 7-3-1 Hongo, Bunkyo, Tokyo, 113-8656, and Core Research for Evolutional Science and Technology (CREST), Japan Science and Technology Corporation (JST), Japan

1. INTRODUCTION

The importance of visual information has been steadily increasing with the progress of the modern computer information revolution. Hence, simultaneous measurement of three major ocular functions — accommodation, eye movement and pupil diameter — in a real working environments, is being demanded in many fields such as ergonomics, ophthalmology, physiology and psychology. The evaluation of visual fatigue induced by prolonged VDT (visual display terminal) work is one such example. Although researchers have tried to achieve this goal, few have fully succeeded.

US researchers O'Neill and Stark tried to accomplish this task by measuring the deformation of lens curvature under accommodation, the diameter of the pupil of the same eye and the convergence of the other eye. But the measured eye was required to remain fixed on a viewing axis. US researcher Crane *et al.* developed eyetrackers using Purkinje images. Though the eye could rotate several degrees when measuring accommodation, it was not stated how the rotation influenced the accommodation measurement, nor how much rotation was permitted. Hence, the instruments were primarily suited for measurement of eye movement. Japanese researcher K. Kasai developed an optometer that used a spherical mirror to measure accommodation while the eye was moving horizontally, but vertical eye movement was not permitted.

In an initial attempt, Takeda *et al.* developed a refractometer that could measure dynamic accommodation easily by modifying a commercially available auto-refractometer. However, it required subjects to fix their eye direction to coincide with the optical axis. Next, a three-dimensional optometer (TDO) was developed. This new optometer eliminates the mechanical chopper used in the older models (Campbell and Robson 1959) and, hence, is much more reliable. The TDO is based on the principle of Kasai's device, but it also allows the eye to move freely for 40° horizontally and 30° vertically. This feature is achieved by using a light relay system that consists of two spherical mirrors and two servo-controlled mirrors that permit the infrared light used for measurement to enter perpendicular to the cornea. The area of the eye's pupil is computed by using a TV monitor image for alignment. The TDO is remarkably easy to operate: the time for alignment is several minutes for most new subjects, normal lighting is allowed and no drug is required for subjects with a pupil diameter of > 2.9 mm. It has proven its usefulness in measuring the accommodation induced by apparent depth sensation while looking at pictures.

The TDO still has one major restriction in that it requires subjects to hold their head still on a chin rest. It was pointed out that this posture restriction might have some influence on visual fatigue during TDO measurement. Takeda *et al.* have since developed an apparatus, called a three-dimensional optometerIII (TDOIII), which allows free head movement as well as free eye movement. The TDOIII is designed to combine the light relay system of the TDO and the optical component of an auto-refractometer into a single compact system. The optical system is mounted on the subject's head, with its weight counter-balanced so that subjects feel no weight and can move their head smoothly. Head movement is measured by a magnetic measurement device.

It is indispensable to have a visual stimulator that can change each visual function independently and combine them arbitrarily. As there was no such stimulator, Takeda *et al.* (1995) developed a three-dimensional visual stimulator (TVS) that can move targets within a 15° x 16° (height x width) rectangular visual field while changing their distance, direction and size with the aid of a relay lens system.

Recently, several new non-invasive measurement methods for human brain functions have been developed, such as PET (positron emission tomography), fMRI (functional magnetic resonance imaging) and MEG (magneto-encephalography). The MEG system is the most promising for investigating dynamic features of the processing of visual information in the brain because it has high temporal resolution. This chapter explains how a 64-channel whole-cortex MEG system is used to deal with visual response. The combination of an optometer with the MEG system allows a more in-depth study of accommodation by analyzing both ocular responses and brain activity. To carry out such research, a special relay lens system was developed to deliver visual stimuli while measuring the accommodation responses with a dynamic refractometer from outside of a magnetically shielded room. With these apparatuses, MEG and accommodation responses have been recorded simultaneously for the first time. This new approach should be highly effective for acquiring new insights into cerebral visual functions.

2. OPTICAL METHODS

2.1. TDOIII (Three-dimensional OptometerIII)

As the principles of TDO and TDOIII are similar, the principle of the TDOIII will be explained here. Subjects can move their head and eyes freely while head movement and the response of the three major ocular functions are being measured simultaneously. The measurement of accommodation is performed by a Campbell type auto-refractometer (Campbell 1959). Two infrared measurement beams are emitted by IR light-emitting diodes (LED). As their central frequency is 880 nm, the subjects sense no measurement light. The reflected images of the beams on the retina make conjugate images on photo detectors. An inner lens is moved to match the images of the two beams. The amplitude of accommodation is calculated from the distance of the lens displacement. Although the subjects are required to gaze into the apparatus and fix their eye position with an ordinary auto-refractometer, in the TDO they are allowed to move their eyes freely to observe objects by the aid of a relay lens system.

In the TDO, an X–Y tracker in a percept Scope (the first function of C3160, Hamamatsu Photonics) measures eye movement, and galvano-mirrors are driven to maintain the

Table 1.   Characteristics of the TDOIII.

Range: Accommodation −12.7D?+26.6D
Eye movement Horizontal ±20? Vertical −25?? +5? Pupil diameter 0 ? 100 %
Speed: Accommodation 4.7 Hz
Eye movement 6.4 Hz Pupil diameter 6.4 Hz
Resolution: Accommodation ±0.02D
Eye movement Horizontal ±0.18? Vertical ±0.25? Pupil diameter ±0.11 mm
Accuracy: Accommodation ±0.25 D
Eye movement ±0.5? Pupil diameter ±0.3 mm

DC offset reduction

monitored eye in the center of a CRT by a servo controller in the TDOIII. Thus, the infrared measurement light is guaranteed to be injected into the eye with the aid of the servo control mechanism, irrespective of eye movement. Pupil diameter is measured by the second function of the percept scope (area analyzer). It analyzes the image of the eye on a CRT, and counts pixels brighter than a threshold level. Then the pupil diameter is calculated using the assumption that the pupil is a circle. A microcomputer controls a measurement timing, and takes in the data of the three ocular functions and head movement.

Alignment is easily performed with a three-axis movable chin rest that is driven by small motors. The alignment can be done within several minutes with the aid of a CCD camera located on the optical axis and a CCD camera located just below the eye. It can be performed within 10 s for an immediate repetition on the same subject. The final characteristics of the TDOIII are summarized in Table 1.

2.2. TVS (Three-dimensional Visual Stimulator)
The TVS can change the directions, distances, sizes, luminance and varieties of two sets of targets for both eyes independently (Takeda *et al*. 1995). The optical system of the TVS consists of (1) liquid crystal projectors (LCP) that generate flexible visual targets for both eyes, (2) Badal optometers that change target distances while maintaining constant visual angles and (3) an optical relay lens system whose principle is the same as the one in the TDOIII. The ranges of stimulation are as follows: distances 0–20 D; directions ±16° horizontally and ±15° vertically; sizes 0–2° of visual angle and luminance 10^{-2}–10^2 cd/m². The target images are refreshed at 60 Hz and the speed of smooth change of the target (ramp stimuli) are as follows; distance 5 D/s, direction 30°/s, size 10°/s. Some applications of the TODIII and the TVS are explained elsewhere in this volume.

3. BIOMAGNETIC METHODS
3.1. MEG (Magneto-encephalography)
In the MEG system, the sensor coils have a 5 cm baseline distance and are equally distributed over the head with a mean distance of 4 cm. There are reference coils to measure environmental noise and reduce its influence, which is the most important characteristic of the system (Vrba *et al*. 1982). The whole system

is kept cold constantly with liquid helium. The measured data are pre-amplified and digitized by hardware and stored into a microcomputer. A phantom head (diameter 75 mm) evaluated the noise rejection algorithm. It was evaluated in two conditions varying the number of recordings. The door of the shielded room was closed in condition C and was left open with an active CRT placed at the entrance of the magnetically shielded room in condition O. The results revealed that the noise rejection algorithm was effective in condition O, especially for fewer trials in the average. The data confirm that the noise was reduced to an acceptable level with the door open after averaging 30 recordings or more (Takeda *et al*. 1996). The main characteristics of the whole-head MEG system are shown in Table 2.

3.2. Visual Stimulator
To measure accommodation together with MEG, a special relay lens system was developed that optically transferred the subject's eye image to the outside of the magnetically shielded room. It consisted of four identical spherical lenses with 400 mm focal lengths, moving the eye by 3200 mm to form a real image just in front of the dynamic refractometer where the subject's eye was placed in normal measurements. The accommodation measurement was done with the real image of the eye. The dynamic changes of the eye's focus point were measured by the dynamic refractometer.

4. A MEASUREMENT EXAMPLE
4.1. Subjects and Procedure
Subjects were three right-handed volunteers with adequate accommodative power and no ocular problems other than myopia. The accommodative power was measured with the dynamic refractometer by moving the target from a position located farther than the far point (the farthest point which the subject could focus) to another position nearer than the near point. The amplitude of the stepwise stimuli were set to be ~60% of each subject's accommodative power to prevent excessive visual fatigue. Subjects were instructed to try to watch the target as clearly as possible. The target was changed stepwise with a random time interval of 5 ± 0.5 s.

The measurements were done on the right eye, occluding the left eye with an eye patch. The experiments consisted of > 64 recordings; the collected data were averaged after discarding those contaminated by eye blinks. The sampling rate was set to 250 Hz. The recording was started 1.5 s before the onset of the stimulus and lasted 2.5 s. The evoked fields, the accommodation response and the target position were simultaneously recorded by a personal computer. The trigger signal for the MEG measurements was made at a predetermined threshold of the target position. The MEG signals were band-pass filtered between 0.5 and 40 Hz and the DC offset was removed using a 1.5-s pre-recording.

4.2. Results

The accommodation target was moved between –5 and –8 D, because the subject used was –5 D myopic. Figure 1 shows the accommodation and superimposed MEG responses for the same stimulus together with the target movement (Takeda *et al.* 1996). The time lag of the accommodative response was 288±50 ms. It was calculated by averaging the time lags of the 64 records. An arrow in Figure 1 indicates the beginning of accommodative responses. Though the amplitudes do not match with the stimulus, this is natural and is called the accommodation lag. The mean time lag and the shape of the accommodation responses are in good agreement with the literature.

Superimposed MEG responses indicated well-synchronized activation of the brain ~100 and 200 ms. Both peaks showed a phase reversal phenomenon. On the other hand, the brain signal was rather quiet ~300 ms when the average accommodative response began to rise. Several additional control experiments strongly infer that the second synchronized activity in the MEG comes from brain activity which controls accommodation.

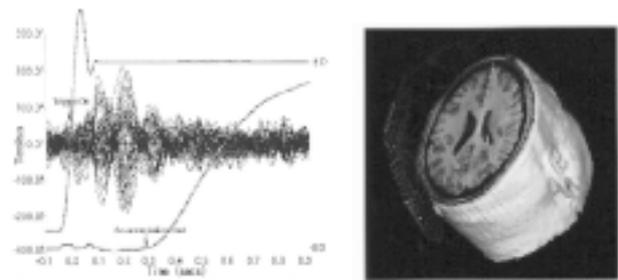
The iso-magnetic field map was a very simple pattern which showed outflow of magnetic field from right hemisphere and inflow in the left hemisphere. From a theoretical and biological consideration, a two-dipole model was adopted and the dipole fit was performed by the Nelder Mead Simplex Method. Consequently, it was found that the control center for accommodation, which had not been identified clearly even in electrophysiological studies with mammals, has been


Figure 1. (a) Typical MEG responses, accommodation responses and target change. There were two peculiar synchronized MEG responses ware found before the accommodation response. Visual Perception Under Night Driving Conditions

I. Noy

Transport Canada, Road Safety and Motor Vehicle Regulation — Ergonomics Division, 330 Sparks St, Ottawa, ON K1A 0N5, Canada

1. INTRODUCTION

Driving is a complex task, requiring several different processes, vision being the main source of information needed to operate a vehicle. The driver must continuously monitor and respond to the road, traffic, pedestrians, and environment to maintain safe automobile operation. Vision is used to obtain basic information from the driving environment such as where the road is going, one's position on the road, obstacles encountered along the way, and the location and actions of pedestrians and other vehicles. The human eye functions best under high levels of illumination. However, since driving at night is often accompanied by poor illumination, the ability to see is often inadequate.

2. VISUAL PERCEPTION IN NIGHT DRIVING

While a variety of visual factors can affect perception, *luminance contrast* is the principal visual cue at night since colors, surface textures, surface details, and contours are not discernible at low luminance levels. Luminance contrast is the contrast between the brightness of an object and that of its background. It can be positive (bright object on dark background), negative (dark object on bright background) or null. All three types are possible under normal roadway lighting conditions. It is generally preferred to provide positive contrast in busy urban environments as this type of contrast facilitates object recognition.

Luminance is a photometric measure of the amount of light perceived by an observer. It depends on the absolute amount of light energy transmitted, reflected or emitted from the object, the location of the observer in relation to the object, and the relative spectral sensitivity of the eyes. In addition, the sensitivity of the eyes to light energy depends on the level of ambient illumination and their state of adaptation to ambient conditions. (Different light-receptor cells in the retina, rods and cones, are used for day, or photopic vision, and night, or scotopic vision, conditions. A combination of rods and cones is used under dawn or dusk conditions, or mesopic vision.)

The amount of light reflected from an object, such as a pedestrian, depends on the amount of light falling on the object and the reflectance coefficient of the object. The photometric measure of the amount of light falling on an object from all sources is *illuminance*. The amount of light reflected depends on the material and color of the object. Steady-state sources of illumination include luminaries and the moon; erratic sources include headlights from traffic. For a typical pedestrian wearing conventional clothing, a reflectance coefficient of 18% is used.

3. PROCESSING VISUAL INFORMATION

At any given moment a great deal of information is available to the driver. The driver must process the information quickly and make the necessary decisions about which way to proceed. The information detected by drivers is virtually processed automatically, with little conscious awareness or effort. In general the human eyes are attracted to objects of larger size, to bright color, to movement, to objects that differ greatly from their background in terms of color, brightness and size, and to large concentrations of people, signs, lights, cars, etc.

Humans process information in two ways: serially and in parallel. Serial processing refers to dealing with one task at a time. Humans are generally serial processors of information, however, certain overlearned tasks such as eating can be done in parallel with other tasks. Generally, humans are capable of being aware of multiple things at once, yet able to act upon only one thing at a time (Olson 1996). During nighttime conditions, the driver receives and processes information at an even slower rate due to poor visibility and low contrast. Inadequate illumination can also decrease the detection of objects, hence, decrease processing and reaction time. The serial nature of information processing means that an unexpected event must compete with information already being processed to gain the individual's attention. The likelihood of the novel object being processed successfully depends largely on the object conspicuity.

Conspicuity refers to the characteristics of an object or condition that determine the likelihood that the object or condition will capture the observer's attention. Some objects may be present in the visual field but fail to be detected by the observer because it may have less conspicuity than other surrounding features. This is especially true at night, since illumination and contrast of objects is decreased. Nighttime conspicuity of road signs is highly dependent on brightness. When operating a motor vehicle at night, generally only brightness contrast is available. Nighttime conspicuity will increase as sign brightness increases for highly complex backgrounds but not for low complexity backgrounds (Schieber 1998). Headlights and fixed lighting installations solve some of the visibility problems encountered while driving at night; they provide illumination and enhance contrast at night by making the target object appear brighter than its background. In addition, fixed lighting systems may also brighten up the background so that the observer can see the target object in silhouette (Olson 1996).

4. DRIVER SELECTIVE VISUAL DEGRADATION AT NIGHT

Research has shown that most road users, drivers and pedestrians alike, are unaware of the devastating perceptual effects of reduced illumination, low contrast, restricted field of view, and glare. The phenomenon of selective visual degradation at night relates to natural limitations of perception and learning that are not well recognized by road users. For example, at night, drivers can easily see most road signs, road markings, vehicles and dashboard instruments. As a result, they are unaware of visual deficiencies that selectively impair their ability to detect low-contrast objects. Because such hazards are relatively infrequent, drivers have little opportunity to learn of their limitations and, consequently, may not be prepared for a dangerous encounter.

4.1. Factors that Degrade Visual Performance at Night

While many factors can affect visibility while driving at night, fixed lighting installations and vehicle headlights provide much of the illumination. However, the level of illumination provided

by the vehicle's headlights is often insufficient to detect obstacles on the road, especially ones having low reflectance. Fixed lighting installations can also provide adequate illumination especially in conjunction with headlights. However, many streets and highways do not have fixed lighting installations. As a result, the driver is often solely dependent on the vehicle headlamps to provide illumination. There are many factors that degrade visual performance at night, thereby further reducing visibility. Such factors can arise from the environment, the vehicle or the driver.

The atmosphere can greatly affect the driver's ability to detect road obstacles, other vehicles and pedestrians. The most common environmental problems are rain, dust, fog and snow. The result is that light is absorbed and scattered causing less of the light reflected by the object to reach the driver's eyes; and less light from the vehicle's headlamps to reach the target object. In addition, some of the scattered illumination is reflected back into the driver's eyes, causing the atmosphere to appear to light up and target contrast to diminish.

A second type of factor degrading visual performance at night arises from the vehicle and includes the vehicle's windshield and headlamps. The windshield could become badly scratched and pitted with use, reducing visibility and increasing the effects of glare. Headlamps can also be a frequent source of poor nighttime visibility. Out of aim headlamps can increase glare that reduces visibility and can cause discomfort to the driver. In addition, even moderate amounts of dirt on headlamps affect visibility, causing illumination to be scattered and absorbed, often increasing glare to oncoming drivers.

The final factor that can degrade visual performance at night involves problems arising from the vehicle operator. The problems can be temporary, such as fatigue, psychological distress, drugs and alcohol, or permanent, such as aging or night myopia. Nearly every aspects of visual function decreases with age. As a result, driving a night serves as an additional obstacle that can impede safe driving for the elderly.

5. DRIVER EXPECTATION

Driver expectancy relates to the driver's predisposition and readiness to respond to events, situations and information in predictable ways. Driver expectation is a key factor in visibility. When an observer knows what object (i.e. a pedestrian) is up ahead and where it will be encountered, the object can be detected at twice the distance that it will when the observer has no information about the type of object or its location on the road. For example, the key function of road signs is to set driver expectation. When a sign is posted, warning drivers of construction up ahead, the driver can pay close attention to persons working on the road. Hence, adjusting his or her driving and expectations of the road accordingly. Drivers also have preexisting notions of how pedestrians and bicyclist should behave on the road. It is safe to assume that people are generally rational and will not deliberately put their lives in danger. For instance, drivers expect that pedestrians will obey traffic laws, such as walking on sidewalks or crossing the street on a green light, which in turn will largely influence how drivers attend to the road. The importance of preconceived stereotypes and driver expectancy is even more pertinent for drivers under nighttime conditions since visibility is largely reduced.

Much of the emphasis with regard to night driving has been on the physical variables such as headlights, roadways, signs, road marking and delineators. However, psychological variables such as expectancy can have a tremendous impact on visibility. For example, retroreflective tags can provide an improvement in nighttime visibility of pedestrians when drivers expect to see retroreflective tags on pedestrians (Shinar 1985). Retroreflective tags, as safety devices, can be attached to any piece of clothing, thereby increasing the visibility of pedestrians. It is also more likely that pedestrians will wear tags rather than whole clothing pieces to increase their visibility at night since tags can be easily attached and detached from clothing. However, in order for retroreflective tags to serve as safety devices, vehicle operators and pedestrians must be properly informed of the tags purpose and come to associate their presence with that of a pedestrian.

Work Ability

M. Välimaa

Tampere University of Technology, Occupational Safety Engineering, BOX 541, Fin-33101 Tampere, Finland

1. INTRODUCTION

Work ability defines an employee's ability to do his work. As a definition work ability is complicated because its character is very individual. It is also not a constant concept but all the time it is changing depending on a close interaction between personal capacities, for example, health, professional skills, motivation and commitment to work, and external factors, like created necessary conditions to do the work and social circumstances.

2. DEFINITION OF WORK ABILITY

Work ability can be considered focusing on the effects of work on employee health or concentrating on an employee's fitness for work. Here questions have been asked about employees' ability to carry out their work in a manner without risk or harm to themselves or others. Such questions have been posed largely within the contexts of medical screening for work, health monitoring of workers in work and rehabilitation (Cox and Cox 1992)

Work ability can also be defined concerning the situation where it has been used. According to Mäkitalo and Palonen (1994) there are three different definitions for work ability, the medical concept, the balanced concept and the integrated concept of work ability.

3. MEDICAL CONCEPT OF WORK ABILITY

Medical concept defines work ability as health, precisely the lack of diseases and injuries. The basis of the medical concept is in the biomedical concept of sickness. Health has been used to refer only to physical health and lack of physical disease, injury or disablement. The degree of work ability and the degree of disability are defined based on that by clinically determined state of psychophysical disorder. According to this concept it is thought that when an individual is healthy (without diseases) he is completely able to work and when sick (without health) partly or completely unable to work. In practice work ability is often defined purely on the basis of clinical examination (injury–disability basis) without information of the demands or possibilities of the employee's environment (Urponen *et al.* 1991).

With regard to work ability in relation to legitimacy for social benefits, for example, disability pensions and sick leave, work ability has traditionally been defined from a very medical point of view (Stone 1984). This is very often true in the assessment of an individual's fitness for work, too.

The assessment of an individual's ability to work is also often done to help the administrative decision-making. Then the measures used and so the contents of work ability are defined by the basis of the administrative and legislative definitions for disability to work. In this connection work ability is strictly a characteristic of individual and the diseases and injuries are considered to be the essential factors affecting work ability (Mäkitalo and Palonen 1994).

The medical concept of work ability does not include the concept of work or the relationship of the individual and his environment. For that reason in the context of the prevention of disability, promotion of work ability and rehabilitation, as well as for assessment of an individual's ability to work, the purely medical concept of work ability is too narrow.

4. BALANCED CONCEPT OF WORK ABILITY

The balanced model of work ability defines work ability as a relationship or balanced state between the recourses of individual workers and the demands of work (Ilmarinen and Tuomi 1992, Järvisalo 1992). This concept is based on the definition of professional disability to work and includes medicine, physiology, psychology and ergonomics. According to the balanced concept of work ability the emphasis is on the capacity of the individual, which is divided into physical, psychic and social capacities (Ilmarinen and Tuomi 1992). Work ability is considered as a pure relationship between adequacy and suitability of these individual capacities and the demands of work. Individual factors affecting work ability go beyond health and are composed of educational ability, skills, experience, motivation to work, work environmental issues such as ergonomics, safety and work hygiene, and organizational factors such as developmental, psychosocial and management issues.

5. INTEGRATED CONCEPT OF WORK ABILITY

Even wider work ability is defined by the integrated concept of work ability. In this concept work ability is a means to describe how an individual copes with work. It forms the concept of work ability for the basis of assessment and adjustment of an individual's competence for work and the promotion of work ability instead of the incomplete fitness for work concept.

Integrated concept of work ability prescribes the contents of work ability by the factors that really are prescribing it in each situation and time. Instead of pure work–need dilemma, work ability is considered as an interaction and entirety formed of individual, community and environment. Besides disabilities also the possibilities and resources of individual, community and environment are taken into consideration. Backgrounds of the integrated concept are in the biopsychosocial human concept as well as in the system theoretic model in which several factors, activities and environmental factors are in a continuous interaction with each other (Mäkitalo and Palonen 1994)

According to the integrated concept, individual resources (like ability to act, professional skills, motivation) or problems related to them are considered necessary to develop and be meaningful in relationship to the structure of an organization, the activities of superiors and fellow workers and the employer's labor and educational policy (Järvikoski *et al.* 1991). Factors of community not only affect work ability but are a part of it (Mäkitalo and Palonen 1994). In this aspect there is also the emphasis on the individual taking an active part in improving his possibilities.

6. DISCUSSION

All factors of work ability act simultaneously and influence each other continuously. Some support it, others weaken it and the current work ability is a state balanced between all these. For that reason the wide aspect of work ability should be considered in order to assess an individual's ability to work properly and to understand disability and the factors behind it.

Individual factors affecting work ability are, for example:

- Health (physical, psychological and social).
- Physical, psychic and social resources.
- Professional skills, education and experience.
- Social and economic situation.
- Motivation and commitment to work.
- Environmental factors include as.
- Organizational culture.
- Management.
- Employer's labor and educational policy.
- Healthiness of the organization, possibilities to develop work community and efficiency, atmosphere and human relationships of work community.
- As well as the values and attitudes of society in relation to a willingness to work, a policy of social benefits.

Work and work environment-related matters are, for example:

- Organizing of work.
- Physical, mental and social strain at work.
- Condition of tools, instruments and environment.
- Safety and health at work and work hygiene.

All these factors are also naturally affected by the economic situation of both the enterprise and the society.

Problem of work ability always includes the question of those who cannot work and those who will not. Ability to work is related to an individual's personal habits and moral choice, how he manages his own life and how it is balanced in relation to all its parts and environmental factors.

The emphasis on work ability issues has traditionally been a little different when concerned with, e.g. society, insurance systems, and the employer and individual worker. Good work ability is a benefit to each part. To achieve this goal the common concept of work ability is significant. Essential is how, based on this common, wide concept, society, insurance systems, employers, as well as individual workers, support the concept of willingness to work and understand that it is possible to create safe and healthy work as a natural precursor of productive work.

Work Design: Age-Related Policies

R. Cremer

TNO Work & Employment, PO Box 78, 2130 AS Hoofddorp, Netherlands

1. INTRODUCTION

Over the past decades the workforce has been steadily aging in a large variety of countries. The increase in the average age of workers runs at different speeds in different sectors of work. This demographic trend can be considered from two perspectives: on the one hand that there will be more older workers and on the other hand there will be fewer younger workers. Making use of these facts requires knowledge about the concept of workability in various work sectors and for various age cohorts.

Apart from this knowledge, awareness in policy making is required on several levels of action. In this sense it is important that responsible organizations know how to make best use of both ends of the age spectrum, without under- or overloading their workforce. In this context the word "organizations" means not only employers but also other layers of work-responsible organizations. It is obvious that different actors are involved with a different focus of interest.

This state-of-the-art review uses a number of recent publications on work and age-related policies, mostly published in the context of progression in European work organizations. I have selected literature on policies aimed at maintaining a working life, not on redundancy schemes and the provisions of beneficial pensions. I look at the question of which parties are needed to bring about the changes in work society in order to prolong the working life of aging workers in good health.

2. AGING IN DIFFERENT EPOCHS

Aging carries different significance for different age cohorts. In other words, the process of aging is associated with changes which are typical for age cohorts. In this respect, it involves not just changes in health care and dietary habits but also the influence of historical and cultural determinants. Taking into consideration the cohorts outlined below, it can be imagined how life and work style in various time periods can be affected (epochs are suggestive and bound to the European situation).

- *Born in the epoch 1925–35*: the crisis generation. Nothing is guaranteed, making a daily living is not a self-evident process; it takes a lot of effort to survive and to establish a position in society; people are obedient and conventional; one should be pleased with whatever work is available.
- *Born in the epoch 1936–46*: the (European) war generation, later the profit generation. A privileged generation which believes chances are created and effort is rewarded and for whom many jobs were available; in their youth this generation was still poor but material growth came soon, prosperity grew rapidly, and a lifelong career was often guaranteed.
- *Born in the epoch 1947–57*: the protest generation, also the baby-boom generation. Everything is possible, many positions are available, and it is rather easy to establish a position.

- *Born in the epoch 1958–70*: the lost generation. Most positions in society have been filled in; an economic depression means economic shrinkage and even a halt to growth.

This illustrates that the effects of aging are in a sense also cohort-related. Whatever may be the exact effects of those cohorts on the process of aging, it is clear that (un)used capacities, health and well-being, values and beliefs towards aging are different. Note that cohort effects should be accounted for along with other individual differences.

3. AGE-RELATED POLICIES AND PARTIES INVOLVED

When market mechanisms outsource certain groups of employees, e.g., the disabled but also aging workers to a certain extent, a change in attitude or policy is relevant for various actors. In a review at least four groups of actors can be appointed with their specific focus and responsibility:

- At the governmental level (national or continental), conditions can be ordered by laws and regulations.
- On the level of society at large, changes in attitudes, expectations, and prejudices are usually lively and prevalent (opinions of elderly people, what they can do and how they should behave).
- The people in the older cohorts — the aging workers — can affect their situation by becoming self-aware and improving their positions; at work this may mean that workers' interests are promoted by employee unions or works councils in work organizations.
- On the level of work organizations, the employers' concrete actions can be developed and taken in order to better anticipate for change in workability in employees; employers' interests may also be promoted by trade unions.

Adequate adaptation to change can best be achieved in concerted action by all these actors. Actions can be based on various motives depending on the level of management. For example, at the governmental level, the number of pension claims increases and adds to social security expenses. This generally recognized development becomes too expensive and demands appropriate actions aimed at maintaining work for elderly workers. Similarly, due to poor adaptations in work conditions and provisions, elderly workers are more prone to sickness leave or work incapacity schedules.

Society at large is expected to become more tolerant towards senior citizens. Senior citizens form a major share in residential communities. The modern older person is well aware of their position, knows what to do, and knows how to spend their time. Self-awareness and self-esteem are no longer the exclusive preserves of the young developing person. But most important is the situation in work organizations. This is where age awareness should be better developed and action should be taken. In a World Health Organzation study group on aging and working capacity (WHO 1993) recommendations were given to employers, trade unions, and regulatory agencies. The following issues were addressed:

- Work capability, not age, should be the criterion for hiring and retaining employees.
- Employers should maintain sufficient flexibility in the design of jobs and the work environment to ensure appropriate working conditions for the markedly heteroge-

neous older population. Workers should be given the opportunity to participate in decisions or actions that affect their jobs.

- Work arrangements should be flexible to allow for job sharing, part-time work, and time off for family responsibilities. There should be incentives to encourage part-time work during the years traditionally dedicated to retirement in order to maximize older people's participation in the workforce.
- Every worker should be provided with appropriate education and vocational training as a basic component of work. This education should anticipate technical changes in the workplace, anticipate the redesigning of work as workers age, and allow employees to maintain and increase their skills and achieve job satisfaction.

These guidelines are the result of applied research and they may be useful. Also important are people's experiences in projects dealing with the problems of elderly workers.

4. PROJECTS IN EU MEMBER STATES

A state-of-the-art report published by the European Commission (1998) reviews projects in a large number of member states. In all, 123 examples of initiatives were given, representing activities of 13 EU member states. The study was meant to allow transferability of findings. All projects appeared to have the potential to be applied in other member states. Conclusions and recommendations are summarized below.

The initiatives in EU member states are considered to be at the vanguard of new policies for older workers. Projects serve several purposes, not only to employ older workers but also to overcome negative attitudes towards older workers among employers and the general public. Generally, projects offer considerable additions. Here are some areas mentioned in the EC (1991) report:

- Providing targeted services which generally do not exist elsewhere.
- Providing tailored solutions for both older workers and employers.
- Programs aimed at motivating older people to undertake further education and training.
- Methods of recording and systematizing the knowledge and work experience of older workers.
- Use of motivation and teaching methods which consider the age of participants.
- In-company career planning for older workers.
- Involvement of older people in the delivery of services; older people have a greater understanding of clients' needs.
- Helping people who have retired to reenter employment and to find useful work in the community.
- Providing employers with information about the employment of older workers and examples of best practice.
- Raising awareness about the needs of older workers among policy makers, employers, and the general public.
- Developing long-term relationships with groups of employers.
- Establishing good practice networks in member states.

5. RESEARCH OPPORTUNITIES

Apart from the conditions summarized in Section 4, the EC report concludes that substantial knowledge is missing. It has therefore proposed evaluation studies in which a variety of topics should be examined:

- Tracking of older workers over a period of several months in order to look at the longer-term effects of initiatives.
- Sustainability of jobs found by older workers.
- A detailed look at workplace attitudes following age awareness training — not only among managers but among younger and older workers — searching for concrete evidence of changes in workplace practices.
- Additionality, displacement of younger workers by older workers (particularly in projects providing incentives to recruit older workers) and deadweight.
- Relationships and networking between older workers initiatives and other organizations operating in the labor market, in particular to examine additionality and problems of referral between agencies.
- Take-up of places on initiatives by subgroups of older jobseekers (e.g., long-term unemployed people and disabled people).
- Benefits to employers of recruiting older workers.
- The process of adaptation to a working environment by older workers coming from projects, and the problems encountered by them and by employers.

6. GUIDELINES FOR CHANGE IN THE WORK ORGANIZATION

Recently Walker (1998) compiled a set of four guidelines that are intended to introduce good practice into work organizations in general. The guidelines were based on 22 in-depth case studies in seven European countries. They entail the following issues.

6.1. Backing from Senior Management

Good practice in age management is only possible by support from management.

6.2. A Supportive Human Resources Environment

All of the workplace case studies benefited from a supportive human resources environment. Sometimes sound business reasons meant that older workers were highly valued. Traditional cultures and traditional management styles may create an age-supportive human resources environment.

6.3. Commitment from the Aging Workers Involved

Workplace initiatives with respect to aging workers are mainly the result of top-down policy decisions. However, there is no doubt that the support of the older workers concerned is a vital key to successful age-related policy. In some organizations older workers had to be persuaded to accept and own the initiative.

6.4. Careful and Flexible Implementation

The implementation process is vulnerable and requires a number of steps that should be carefully followed. Here are some of them:

- Careful preparation, including research in recruitment trends and age profiles of employees and labor market projections.

- Open communication both with staff generally and with the target group about the objectives of the initiatives, including appropriate use of seminars, workshops, and newsletters.
- Early involvement of trade unions, works councils, and staff associations.
- Early involvement of workers themselves.
- Education and awareness-raising among line managers.
- Staged implementation, including a pilot phase both to test the initiative and to demonstrate to any doubter that it can be effective; provide regular monitoring and feedback with any required adjustments to the initiative.
- Periodic assessment of impact and feedback.
- Constant communication with all employees in order to avoid stigma and feelings of inferiority among older workers or the development of "them and us" attitudes.
- Attention to other aspects of the working environment, such as arduous tasks and conditions, which may inhibit the good practice initiative from achieving its intended goal.

7. SUGGESTIONS FOR GOOD PRACTICE

Here is an overview given by Walker (1999); it offers guidelines for good practice and it addresses all parties involved in changing the general attitude towards the aging worker.

7.1. National and European policy

7.1.1. European Union

Eliminate age barriers from the European Commission's own recruitment practices. Ensure that the new European Social Fund makes older workers a priority group. Ensure that the needs of older workers are adequately reflected in employment guidelines and equal opportunities policies. Introduce a new European Code of Good Practice covering employment of older workers.

7.1.2. Governments

- *Education*: promote public education to counteract negative images of older workers and the promotion of lifelong learning.
- *Employment policy*: active labor market policies should be designed to enable older workers to remain in employment or return to employment, and they should promote quality employment for this group and other groups.
- *Pensions and social security policies*: eliminate incentives to employers to make older workers redundant.
- *Inclusion of older workers*: encourage employers to establish comprehensive action programs on age and employment by publishing good practice guides and disseminating age awareness literature.

7.1.3. Trade unions (national)

Disseminate examples of good practice to members as part of promoting positive approaches and attitudes to age management.

7.2. Employers

Develop age awareness throughout the organization and ensure that age is not used inappropriately in recruitment and training. Union representatives should take part in age awareness training as a matter of routine; collective agreements should cover training measures that rectify the disadvantages experienced by older workers.

7.3. Aging Workers

Take advantage of training and lifelong learning opportunities and develop the awareness of training and career requirements.

8. CONCLUSION

In considering effectiveness of age-related policies in work environments, parties on various levels can take responsibility for action. However, the responsibility is not always felt or the need for action is not acknowledged. In a sense, actions depend on the preparedness for change and any questions surrounding the action.

In a workforce with an increasing average age, it is often discussed how proactive policies can be designed and implemented in work organizations. Here lies a dilemma: anticipating change usually demands some kind of investment and revenues may only be seen after many years. Therefore it is rare to see proactive age-related policies specifically aimed at individual changes over time. From this perspective, training and education are the tools for improving the quality of future work.

The ability to learn is of major importance. As information processing abilities change over the life span, it is evident that learning abilities also change. Accordingly, deprivation of learning may affect the motivation to study. Learning abilities are related to intellectual capacities, personal style and effectiveness, and preferences in learning strategy. Preparing for modern work at a later age requires learning efficiency which takes into account the factors stated above.

It is clear that age-related policies entail more than creativity with retirement schedules or work flexibility programs. Attention should be devoted to extension of the working career in a way that is rewarding for all actors.

Work Hazards and Risk Assessment in Human Performance

A. Genaidy

Department of Mechanical Industrial and Nuclear Engineering, University of Cincinnati, OH 45221-0072, USA

W. Karwowski

Center for Industrial Ergonomics, Department of Industrial Engineering, University of Louisville, KY 40292, USA

1. INTRODUCTION

Human performance improvement aims to balance work demands with worker abilities and needs. Human performance is often described in terms of health and safety measures with the goal of risk quantification of workplace hazards. Risk, a common assessment parameter in health and safety analysis, quantifies the degree of harm with respect to likelihood (e.g. probability) and severity (e.g. consequences) in response to workplace hazards (Cox and Cox 1993; Manuele 1997). A workplace hazard is defined as an event or situation with the potential for harm (Cox and Cox 1993). Typically, harm has been interpreted as resulting from physical hazards such as those produced by physical task demands (i.e. biomechanical, physiological) and by the environment (e.g. nuclear, radiological, biological, chemical, physical).

The modern concept of work hazard includes the non-physical hazards: specifically, psychosocial, work organization, and mental demands. These hazards address both the interactions among job content, work organization and management, and work environment and organizational conditions, and the workers' competencies and needs (International Labour Office 1986). Work-related mental demands pose challenges which, if excessive, form a source of hazard (e.g. Hancock and Warm 1989).

Occupational stress, the harm resulting from psycho-social and work organization hazards as described in its respective literature, is generally chronic in nature, persisting for a period of time during which the harm may be cumulative or progressive. Evanoff and Rosenstock (1994) reported that estimates of direct and indirect medical costs associated with occupational stress in the United States have ranged from $80 to $150 billion annually. The National Occupational Research Agenda (NORA) also named organization of work as one of its twenty-one research priorities (NIOSH 1996).

For example, the work-related musculoskeletal disorders (WMSDs) have been widely acknowledged as a major part of occupational harm resulting from the acute and cumulative exposure to physical task demands (Centers for Disease Control 1987), are among the most prevalent cause of lost time injuries and illnesses in almost every industry and, importantly, are among the most costly (Bureau of Labor Statistics 1995; National Safety Council 1995). The National Institute of Occupational Safety and Health (NIOSH) has conservatively estimated the cost of occupational musculoskeletal disorders as $13 billion annually (NIOSH 1997a) and has devoted extensive resources in the investigation of risk factors for WMSDs (NIOSH 1981; Waters *et al*. 1993; NIOSH 1996, 1997a, 1997b, 1997c). Recognizing that further research is needed, the National Occupational Research Agenda (NORA), established through a collaboration of NIOSH and over 500 stakeholders in public and private sectors for guiding health and safety efforts, identified low back disorders and upper extremity disorders as two of its twenty-one critical priority areas (NIOSH 1996).

2. INTERACTIVE EFFECTS OF WORK HAZARDS

Due to the highly interactive nature of multiple hazards comprising work systems, it is important that the health and safety assessment system takes into consideration all of the known elements and their potential and actual relationships with each other. While "zero" risk at work is an optimal goal, effective risk can be minimized to levels acceptable to the individual worker and organization members. The hazard and risk assessment methods must clearly describe and assess all fundamental elements, their relationships with each other, the potential for both acute and chronic exposure, and the harm that may result.

The adverse health effects of interactive relationships among physical task demands, mental task demands, and the physical/social/psychological/organizational environment conditions has been suggested through several studies. WMSDs have been reported as exacerbated by the occupational environment (Ulin and Armstrong 1992; Armstrong *et al*. 1993; Bongers *et al.* 1993; Chaffin and Fine 1993; Kuorinka and Forcier 1995; Moon and Sauter 1996; Smith and Carayon 1996; NIOSH 1997a, 1997b). Devereux (1998) confirmed the interactive effects of physical and psycho-social work demands on the prevalence rates of musculoskeletal disorders. However, such interactive effects are themselves contingent upon factors such as age, skill, and fitness, since personal characteristics have also been cited as additional contributors to the development of WMSDs (International Labour Office 1986; Fraser 1989; NIOSH 1997c).

The comprehensive work assessment system should include: (1) characterization of the domains of work demands (i.e. physical/mental demands and physical/social/psychological/organizational environment conditions) with corresponding outcome measures (i.e. effort/perceived risk/actual risk); and (2) assessment of the relationships between work demands and outcome measures in order to optimize human performance with respect to safety and health as manifested through the abatement of risk associated with the development of WMSDs. Work demands include the work content (i.e. the physical and mental job demands), and the work context (i.e. the physical, social, individual growth, and work organization environment).

In the past, safety professionals, ergonomists, and industrial hygienists have historically approached the investigation of the work system for hazard and risk evaluation using a spectrum of investigational methods. These efforts can be clustered into two general groups: (1) job analytic techniques and (2) system safety techniques.

3. JOB ANALYSIS TECHNIQUES

Job analysis techniques have been used to characterize work demands and their effects on workers. Shoaf *et al.* (1998) recently suggested that the term "job analysis" has become outdated as the scope and complexity of "jobs" have increased. Rather, the evaluation of jobs is more accurately referred to as "work system

assessment". Here, we use "work system assessment" throughout to address the traditional "job analysis" concept as well as advanced work-related hazard/risk assessment. As indicated earlier, work system assessment includes the characterization of work demands (i.e. physical/mental demands; physical/social/psychological/organizational environment conditions) and outcome variables (effort/perceived risk/actual risk).

Work system assessment may be applied to any unit of work — that is, to tasks, jobs, or occupations. A "task" describes a distinct part of a job, and a "job" is defined as all the work carried out by a worker or group of workers (British Standards Institution). Therefore, a job may consist of one or more tasks. An "occupation" refers to a job of a general class without regard to organizational lines (McCormick 1979). Shoaf *et al.* (1998) grouped job analysis techniques into one of three classification systems: micro-assessment methods, macro-assessment methods, and comprehensive methods.

Micro-assessment methods are specialized in technique and narrow in scope. They focus typically on one work domain or one of its specific subsets. Examples of micro-assessment techniques are: analysis of lifting demands and their effects on workers (e.g. Waters *et al.* 1993); analysis of mental demands (Hart and Staveland 1988; Reid and Nygren 1988); and psycho-social assessment (Hackman and Oldham 1976; Karasek and Theorell 1990).

Macro-assessment methods are not as detailed as micro-assessment methods and typically involve the evaluation of a particular work demand domain or may span across more than one work domain. A typical macro-assessment method utilizes a checklist approach in the form of a questionnaire. Examples include, but are not limited to, the work of Newman (1977), Keyserling *et al.* (1991), and Guo *et al.* (1996).

Comprehensive methods incorporate characteristics of both micro-assessment and macro-assessment methods. The Position Analysis Questionnaire (PAQ; McCormick *et al.* 1969) and Arbeitswissenschaftliches Erhbungsverfahren zur Tatigkeitsanalyse (AET) (Rohmert and Landau 1983) are examples of comprehensive job analysis methods. They are the among the most thorough systems in the literature, especially because they characterize the entire spectrum of work demands. The PAQ and AET, however, lack many of the detailed findings established within the last two decades and thus do not possess a sufficiently comprehensive framework for hazard and risk assessment at this point in time.

4. SYSTEM SAFETY TECHNIQUES

System safety hazard/risk evaluation techniques have been largely devoted to analysis of the physical environment. System safety techniques, which address occupational hazards, are process-based. They serve as regimented methods of analyzing system design to ensure the intended operation and mitigate possible failures. Thus, system safety hazard evaluation covers a wide spectrum of potential and existing hazards. In contrast, non-process based techniques (e.g. air or water sampling) evaluate only existing physical work-related hazards.

The following is a summary of the most common process-based hazard evaluation techniques (Gressel and Gideon 1991):

- Checklists are among the simplest forms of hazard evaluations. They can identify recognized hazards and ensure compliance with accepted design standards. Checklists can be applied to equipment, procedures or materials.
- Preliminary hazard evaluation analysis lists the hazardous materials, equipment components, and process operating conditions. As each hazard is identified, the possible causes, consequences and corrective measures are listed.
- "What If" analysis can identify both hazards and their consequences and help develop possibilities for potential hazard reduction. The analysis procedure usually starts at the beginning of the process and asks a series of questions concerning process upsets or malfunctions. Additional questions based on the initial analysis may be formulated.
- Safety reviews are conducted to identify plant conditions and procedures that may have deviated from the intended design.
- Failure Modes and Effects Analysis (FMEA) checks each process component individually and describes the function of each component and all of its potential failure modes. The method then determines the causes of these failures as well as the effects.
- Fault Tree Analysis (FTA) determines and displays the cause of a major unwanted event. This method starts with the top or end event and develops a logic tree showing the causes of the problem through the use of "AND" and "OR" gates.
- Event Tree Analysis (ETA) is similar to FTA in several ways. As in FTA, a tree structure is developed to outline the events of a hazard scenario. While FTA develops a vertically oriented tree logic, an ETA tree is constructed horizontally and begins with an initiating event and moves forward rather than beginning with the end event.
- Hazard and Operability Study (HAZOP) is a powerful evaluation technique in terms of identifying complex failure scenarios that involve multiple independent events. By using the plant equipment and instrumentation drawings, the process is broken into small segments or nodes such as the line connecting a pump to storage tank. Deviations of the process from normal operating conditions are evaluated by applying a series of guide words to the node. Recommendations for improvements or for more study are based upon the likelihood and consequences of the deviations.

In addition to hazard identification, most of the above mentioned system safety techniques provide probabilistic risk quantification (e.g. ETA, FTA, HAZOP). They are, however, limited because of their unaccountability for the role of human behavior, particularly human error (Feyer and Williamson 1998).

Human reliability analysis techniques (e.g. influence diagrams, human cognitive reliability models, technique for human error rate prediction) have attempted to improve system risk assessment by quantifying human error probability (Kirwan 1990). Still, the development of risk assessment techniques has failed to realize the enlarged definition of work hazard (International Labour Office 1986) described above in two respects. First, these techniques are designed to address acute hazards. Acute hazard exposure usually results from human error or technical failure and can be characterized as an "off–on" switch (Cox and Cox 1993). Hazards resulting from chronic exposures, to which it is much more difficult to assign a probability value, are largely neglected. Second, the domains of organizational and

psycho-social hazards have been generally disregarded with respect to their contribution to overall system risk. These omissions represent serious deficiencies in the current system safety hazard/risk assessment techniques.

5. A COMPREHENSIVE WORK ASSESSMENT

The main objective of the comprehensive work assessment is hazard identification and risk quantification. In addition, such a system can also be used for:

- Design of rehabilitation and return-to-work programs by health practitioners. Work system analysis provides information to classify, which tasks are essential, and which are non-essential regarding execution of a job. Critical tasks can be used to provide input to physical therapists as recommendations for therapy guidelines. Later, the critical tasks can serve as the performance criteria for determining when the worker possesses sufficient capability to return to work.

- Design of the most appropriate medical examinations by occupational medicine specialists. A work demands model yields task descriptions, which serve as inventories of various occupations. These inventories form a database, which can be used as a functional capacity checklist of essential job tasks, therefore aiding medical specialists. Evaluation of an individual's capabilities for a specific job as demonstrated in a pre-employment health screening is problematic without such data Additionally, an inventory of job tasks serves to identify workers who participate in hazardous tasks, and therefore, alerts medical specialists to monitor such workers for adverse health effects.

- Decision-making with respect to work restrictions and provisions of reasonable accommodations by occupational medicine physicians, human resource specialists, and business managers. In recent years, there has been considerable government attention regarding the needs of the handicapped and disabled in the active workforce. As a result, medical selection procedures for job candidates have undergone considerable scrutiny. A worker's limitations with respect to a given job can only be evaluated relative to a detailed description characterizing the nature of the essential tasks. Work system analysis provides a means for collecting and classifying this information.

- Improvements of the work processes by industrial engineers, business managers, and supervisors and work teams. To understand the complex operation of a work system, all aspects must be defined and their interrelationships described. This knowledge, which is a prerequisite for improvement efforts, can be provided by a work system analysis.

6. CONCLUSIONS

The level of risk at work depends on the intensity, frequency, and duration of the multi-faceted array of factors, which characterize the workplace as they relate to the workers' capacity to respond to work demands. The interactive nature of physical and non-physical (i.e. cognitive, psycho-social, and organizational) work system hazards and the magnitude of the resulting harm to workers, businesses, and the economy, warrant the need for an assessment tool which considers all work system

elements. NIOSH (1997c) recognized that, in general, knowledge of the relationships between risk factors and the level of risk is still incomplete. The magnitude of this problem and the recognition of its impact creates a pressing need for development of the comprehensive work system hazard/risk assessment instrument that integrates all system elements (Shoaf *et al.* 2000).

Working with Age: An Ergonomic Approach to Aging on the Job

J. C. Marquié and S. Volkoff*

Laboratoire Travail et Cognition, UMR 5551 CNRS, Maison de la Recherche, Université Toulouse le Mirail, 5 allées Antonio Machado, F-31058 Toulouse Cedex, France and *Centre de Recherches et d'Etudes sur l'Age et les Populations au Travail (CREAPT), 41 rue Gay-Lussac, F-75005 Paris, France

1. CURRENT STATE OF THE PROBLEM

Changes in the age distribution of the workforce in industrialized countries during the past few years are the outcome of two opposing movements. On one side, the aging of the population as a whole and the later age at which young people enter the working world are increasing the percentage of older employees. On the other, retirement policies designed to reduce the number of employees are decreasing the percentage of older workers in many countries, although national differences are still great in this area.

According to the most plausible predictions, the percentage of young workers will continue to drop. And given the uncertain future of the social security system and other social programs, one can assume the current trend toward early retirement will slow down if not reverse itself altogether. In any case, one can predict two things:

- An increase in the percentage of individuals between the ages of 40 and 55 in practically all industrialized nations, although at different times and different rates; the process has already begun in most countries.
- At least stabilization in the percentage of workers age 55 or older for the next two to three decades.

These overall trends are subject to large discrepancies across sectors and firms. The aging trend is particularly clear-cut in manufacturing industry, but the middle-age population bulge is also apparent in the service industries, particularly those where the employment rate soared in the 1970s.

In situations where the working conditions are highly demanding, as in shift work, time pressure jobs, and adaptation to modern technology or skill diversification, this demographic trend may cause serious problems, as demonstrated by the results of national or European surveys on working conditions today. Labor selection mechanisms, which have contributed to protecting older employees against certain types of job constraints, will become more difficult to implement if the demographic weight of individuals in this age range continues to increase.

To solve this problem, some companies are attempting to foresee the impacts of an aging staff. In their previsional management of employment and employee skills, they hope to develop ergonomic policies that will take this new dimension into account while still satisfying ever changing economic demands. They are seeking the necessary knowledge and methods for coping with the sometimes urgent practical problems they are facing.

For the individual, these numerous changes have various consequences, including providing jobs for aging workers, the state of health of employees exposed for many years to strenuous or tedious working conditions, the involvement of individuals over 45 in the technological conversion process, job training, task and workstation design, and more broadly, the overall organization of work in accordance with the characteristics of workers of all ages.

Studies that shed light on the social debate about these issues are still insufficient, but see Laville (1989), Snel and Cremer (1994), Kilbom et al.(1997), and Marquié et al. (1998); research efforts must be expanded. In addition to the disciplines that traditionally contribute to the ergonomic approach, the psychology of aging, occupational demographics, and epidemiology are all being called upon to be part of this development.

2. JOB DEMANDS AND AGE STRUCTURES

The discipline we might call occupational demographics, while still in its early stages, has set out to develop new tools for collecting and analyzing macrodemographic or microdemographic data — macrodemographics at the workforce or production sector scale and microdemographics at the company level, or even within a department or group of jobs — in an attempt to bring out facts and set forth hypotheses that can be approached through other disciplines. This branch of study has shown, in a more detailed way than ever before, that age is often a decisive criterion in the labor selection mechanisms now in effect.

Analyses of the distribution of the population by age, and changes in that distribution over time, have revealed significant differences between sectors or branches of the economy. One can find, for example, "elderly" sectors, where there is little turnover and retention measures that lead to aging of the personnel; "aging" sectors, where quadragenarians predominate; and "young" sectors, where the hiring rate is high and people frequently change jobs before the middle of their career. Many of these younger sectors are "female" and they rely more heavily on short-term contracts than other parts of industry.

Two scenarios have been proposed to schematically describe these differences and patterns. Hypothesis H (for history) is based on the history of the company and its volume of activities and jobs. In hypothesis A (for age), due to the constraints involved, certain types of job maintain a relatively stable age distribution: part of the aging employees are transferred to other positions within the same company or segment of industry via a "selection-reassignment" process (more frequent in sectors with an older age structure) or lose their jobs altogether via a "selection-exclusion" process (more frequent in sectors with a younger age structure).

A more detailed analysis of the situations that trigger this kind of age-based selection process indicates that some job demands play an important role in this process, either individually or to an even greater extent when several constraints occur in conjunction with each other. The many work constraints that contribute to age-based selection of workers include shiftwork (e.g., two-shift or three-shift systems); time pressure variables (e.g., time limits on repetitive or short-cycle tasks, machine-paced work, short deadlines); postural constraints that exert excessive stress on the skeletal, articular, and cardiovascular systems; monotonous tasks and unskilled jobs that do not increase knowledge and may even impair the worker's initial capacities; new technologies that quickly render his/her skills obsolete, or

frequent job transfers to meet the company's needs. However, their increasing impact with age should not cause us to lose sight of the fact that these very same constraints also place heavy demands on younger workers. Situations shown to have adverse effects on older workers are very often indicative of more general problems affecting all employees.

3. WORK, AGING, AND HEALTH

The way in which job constraints and demands are withstood at various ages should also be considered in relation to health, whether implicitly or explicitly, this is often a selection criterion in the workplace. The connection between work and health can rarely be described by a single causal relationship. The same job characteristic may have several effects on health, and a single health condition may be attributable to several occupational causes. Moreover, a health problem can have a feedback effect on the manner in which a job is performed. For example, an organ deficiency or impaired bodily function may lead the operator to "spare themselves" in that area, which may cause additional stress on other organs or functions, with possible new pathological consequences.

The health–job relationship is therefore a complex one, and the work activity itself may be a catalyzer. This relationship is difficult to grasp since health-related symptoms are often sub-pathological, making the task of determining what to study far from straightforward. In addition, the effects in question often lag behind their causes: the epidemiology of occupational risks must look at long-term associations between working conditions and health, taking into account occupational histories fraught with selection mechanisms that invalidate any instantaneous comparative conclusions.

It is easy to understand, then, why taking age into account in this context poses a number of methodological problems, at the same time as it offers some new opportunities. On the one hand, it complicates the analysis by introducing another variable related to health in ways that are neither solid, nor uniform, nor easily modeled, even in probabilistic terms. On the other, it promotes a more unified approach by necessitating a dynamic analysis that accounts for the evolution of the work activity plus the individual's health condition and occupational and pathological background. As such, age is both a "factor" in itself (as there is a real link between chronological age and functional age — the age of the arteries — even though it cannot be precisely determined) and a "transmission variable", since the effects of work histories and past events outside the workplace are combined with the individual's advancing years.

This fact becomes apparent if we look at interindividual variability, at a given age, across the various job categories for the three indicators of biological aging used in epidemiology:

- *Life expectancy*: how long we can expect to live based on statistical predictions and criteria such as job category and sex.
- *Physical performance*: age-related changes in abilities are measured at different functional levels of the organism.
- *Susceptibility to disease*: aging is approached in terms of the growing risk of disease or disablement with advancing years.

The differential aging process, reflected by interindividual variability on these different measures, is detected during routine physical examinations by occupational physicians. Signs of pre-

mature "wear and tear' are commonly observed. But there is little data in today's scientific literature for understanding the links between aging, health, and the characteristics of the work environments to which a given individual has been subjected.

The available findings nevertheless point out that the impact of age and exposure to adverse working conditions can be cumulative (e.g., age and exposure to noise have an additive effect on hearing acuity), interacting (e.g., age, heavy workloads, and rigid job procedures considerably increase the risk of lower back problems), or delayed (e.g., the persistence of sleep disorders in former shift workers). The expansion of research in occupational epidemiology, accompanied by longitudinal follow-up of several age and occupational groups, should help provide insight into these complex links, and thus provide a means for achieving early prevention.

4. AGE–RELATED CHANGES IN WORK ACTIVITY

Although problems linked to age do indeed arise in the areas of work and health, they are usually symptoms of modifications that have taken place in the work activity itself. To identify and understand these changes, one must first be aware of the diverse range of phenomena that age encompasses. Here are some of them:

- *Generation effects*: The cultural, social, and health conditions to which individuals born in the 1940s have been subjected, and the education and occupational training they have received, are not the same as those of persons born 25 years later. Such factors leave a long-lasting and sometimes irreversible mark on an individual's health, attitudes, and behavior.
- *Changes in capacities*: Basic biological, sensory, motor, and cognitive capacities change with the aging process. The alteration is gradual, can begin early or late, and be more or less pronounced, depending on the function under consideration. Although the decline is generally moderate between the ages of 20 and 60, its consequences may be significant when job demands are high.
- *Knowledge acquisition*: As age and work experience increase, so do an individual's knowledge and ability to meet new job requirements. However, overspecialization in some areas can hinder training in the new skills needed to adapt to changes in the work environment.
- *Length of exposure*: Long exposure to various occupational hazards and stressful working conditions can impede the development of an individual's basic physiological and cognitive capabilities, sometimes even more than the aging process itself.
- *Modifications*: Modifications in the subject's expectations, needs, and lifestyle can occur at the personal, social, and economic levels.

Precisely because of the multiplicity of these *time-linked* phenomena, whether it be *the moment in time* or the *amount of time*, chronological age is an arbitrary marker: it can mask the fact that the nature and speed of the changes that take place over time vary considerably across individuals. This makes it impossible to predict solely on the basis of age whether performance and difficulties encountered on the job will increase or decrease. Rather, this rising or falling curve is the result of the combined

effects of the wide range of endogenous and exogenous time-linked factors, unique to each and every individual.

The ergonomic approach nevertheless allows us to improve our understanding of changes in work behavior as age increases, as experience is gained, and as skills are acquired. Men and women on the job are not passive spectators of the good or poor fit between the characteristics of their jobs and their own state of functioning. Consciously or unconsciously, they modify their operating modes (movements, work pace, posture, etc.), reduce their effort level in some subtasks, make more plans to avoid emergency situations, check the outcome of their actions so as to reduce errors that would be costly to correct, and adjust the distribution of tasks in cooperative and collective work situations.

But these strategies can only be implemented if the working conditions and organization foster and promote them. This is why ergonomics stresses the need to improve work environments in order to curb the negative effects of aging. In particular, combinations of two types of environmental conditions are thought to be likely to engender greater difficulty with age: overloading of the individual's sensory, motor, or cognitive systems, and tasks that generate little know-how and require little experience (Marquié *et al.* 1998, Warr 1994). These conditions typically correspond to unskilled, time pressure jobs where the individual has little control over their own work. In the other cases, the predictable correlation between age and job difficulty (in terms of workload and performance) is zero or negative. Zero because the individual has little experience but job demands are moderate, or the worker's basic capacities are overtaxed but efficient compensatory strategies acquired through experience are devised. And negative because there is moderate taxing of basic capacities and high demands for expert knowledge; this is the most favorable situation.

5. AGING, NEW TECHNOLOGIES, AND TRAINING

The massive and rapid development of new technologies, the *knowledge obsolescence* they create, and the ensuing need for the ongoing acquisition or restructuring of knowledge may also pose some specific problems for older workers. Various national and international surveys have revealed that computer use is negatively correlated with age. The same age effect on the use of other types of technology has also been observed in industry (robots, numerically controlled machines, etc.).

Although part of this phenomenon can be accounted for by a *transitory generation effect* (e.g., cultural and educational differences in computer use between the younger generation and individuals over 45), it is also likely that the acceleration of technical change will perpetuate this aspect of the problem into the future. Besides, *resistance to change* — frequently cited as a factor in the alleged lesser ability of older workers to adapt to technological advances — says nothing about the causes of potential difficulties facing the aging worker.

A wide range of factors with seemingly cumulative effects must be explored if we hope to overcome the obstacles currently facing the aging worker. In reality, age seems to be less predictive of unfavorable attitudes toward new technologies than seniority, which in turn is less predictive than a complete lack of experience in using such tools.

A variety of other elements must also be considered in any analysis of this issue. These include the attitudes future trainees develop about the trade-off between the potential career benefits and the cost of training, employees' fears that company restructuring triggered by technological change will have a negative impact on employment, the conditions under which training will take place, the ergonomics of new workstations, the consequences of technical transformations on task content and organization, and last but not least, the practical measures taken by the company to inform, prepare, and involve the concerned employees in the upcoming changes.

This problem can be particularly significant for certain categories of employees. It is true of unskilled workers, for whom employment problems, retraining in a new occupation, eligibility for training programs, and adaptation to current teaching methods are all critical issues. But difficulties can also arise for more highly qualified individuals: overspecialization in a given job may actually be a handicap when extensive technological change takes place.

This brings us to training. Training must be considered in the light of research findings on the attitudes of both employers and employees regarding the training of employees over 45, the participation of older employees in ongoing training programs, their success rate, and the sources, types, and severity of the difficulties encountered. Several factors must be taken into account in creating training programs that are better suited to the needs of older workers plus their cognitive, metacognitive, and emotional specificities, instead of being geared to younger individuals as is often the case. These factors include being unaccustomed to learning and new teaching techniques, age-related alterations in cognitive processes, the role of past experience in the skill to be learned, the effects of mediating variables such as educational background, and the very type of work done over the years, which may turn out to engender more or less confidence in the subject's own learning ability.

Finally, in regard to the period after the working phase of life, *gerontechnology* is a new approach to the relationship between aging users and their technological environment. It aims to determine how older persons can best use the possible aids provided with new techniques and tools (home ergonomics, medical techniques designed for individual use, communication technologies, etc.), so they can maintain an optimal level of autonomy, health, and social life.

6. HOW TO STUDY THE LINKS BETWEEN AGE AND WORK

A number of methods are available for investigating the problems specific to advancing age at work. Each has its own advantages and shortcomings. As is often the case, it is a combination of several methods that is best able to lead to a finer diagnosis and to the appropriate ergonomic action.

We have already mentioned methods like age structure analysis (determining the relationship between the mean age of workers holding a given type of job and the constraints associated with those jobs) and epidemiological research (demonstrating the complex cross-sectional or longitudinal links between age, health, and work, via questionnaires about past and present health and working conditions, or by means of physiological, sensory, and cognitive measures).

Performance analysis is another method. However, in addi-

tion to the fact that no systematic correlation has been found between age and performance, these approaches are subject to a number of biases and limitations. One such bias stems from the fact that they deal with the "survivors", i.e., the workers who have adapted the best to the constraints inherent in the jobs studied, since the less "fit" will have left these positions. They have also been criticized for failing to take into account the diverse components of performance, or for having assessed performance by means of subjective evaluations offered by fellow workers and superiors who may be unconsciously influenced by age stereotypes.

Despite their tendency to simplify reality, and despite the fact they usually focus on age-linked alterations in basic biological and cognitive resources, experimental laboratory studies on aging can be useful in improving our understanding of certain problems encountered at work. They can be designed without specific regard for work-related issues, or they can be aimed at getting an in-depth view of a particular work problem. All of these approaches contribute to untangling the respective effects of the different factors of age-related change, as well as to determining the characteristics of the biological and cognitive development of adults and their capacity to adapt to high levels of demand as they grow older. However, precisely because they usually discount the role of experience, these methods as they stand cannot be used to predict behavior in all work settings.

Job analysis is one method for discerning and enhancing awareness of the important role played by experience in worker-to-job and job-to-worker adaptation and suitability. It consists of studying the actual way in which subjects carry out a task and the strategies they employ to cope with internal and external constraints. As they become increasingly refined over time, these strategies (see the earlier examples) enable the worker to substantially reduce the effects of aging in different ways: they *automate* more components of the activity (automatic processes seem to be resistant to the effects of aging); they use *compensation* mechanisms (declining capacities are compensated by skills that improve with practice); they rely on *accommodation* mechanisms (strategies for avoiding situations where difficulties might arise through modification of subgoals or use of external aids). The ability to identify these strategies is an indispensable key to designing tasks and job organizations that will give workers room to maneuver. The benefits of these means of granting greater control over one's work may be reaped not only by aging employees, but also by all individuals in the company who are in charge of managing human resources and organizing work.

Information Presentation and Communication

Alarm Initiated Activities

N. A. Stanton

Department of Design, Brunel University, UK

1. INTRODUCTION

Little advancement has been made upon the model of alarm handling proposed by Lees (1974) over two decades ago. This model comprised three stages: detection (detecting the fault), diagnosis (identifying the cause of the fault), and correction (dealing with the fault). It appears to be very similar to the process model put forward by Rouse (1983) comprising: detection (the process of deciding that an event has occurred), diagnosis (the process of identifying the cause of an event), and compensation (the process of sustaining system operation). A similar model, comprising: detection (detection of the onset of a plant disturbance), diagnosis (diagnosing the particular disturbance from presented symptoms), and remedial actions (selecting and implementing the appropriate actions to mitigate the disturbance) was proposed by Marshall and Baker (1994) as an idealized three-stage decision model to describe how operators dealt with faults. There appears to be little to distinguish these three models apart from the idiosyncratic labeling of the last stage in all cases. Rouse (1983) offers an expanded version of the process model comprising three levels: recognition and classification (in which the problem is detected and assigned to a category), planning (whereby the problem solving approach is determined), execution and monitoring (the actual process of solving the problem). Arguably this is reducible to the original three-stage model, but rather more emphasis has been place upon the interpretation of the problem. What is not clear from any of the analyses presented with these models is whether they accurately reflect processes undertaken by the operator within the alarm handling task.

2. ALARM INITIATED ACTIVITIES (AIAS)

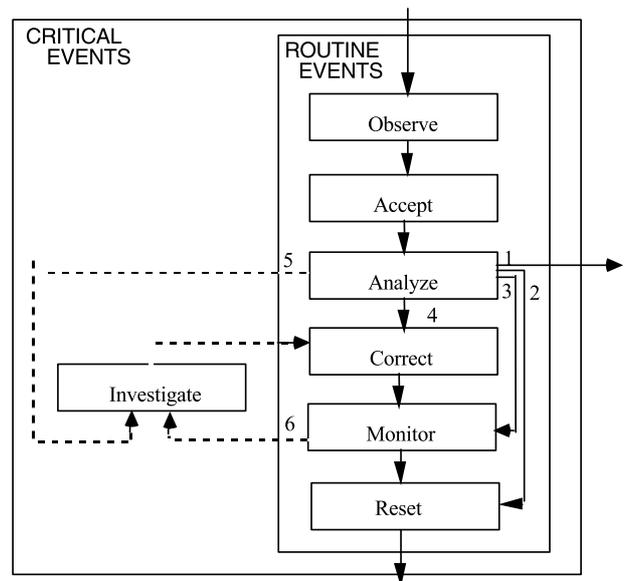
An alarm handling sequence can be described as consisting of a number of generic activity stages. These generic activities have been assembled into an analysis of alarm handling (Stanton *et al.* 1992; Stanton 1994) as shown in Figure 1. The analysis distinguishes between routine events and critical events involving alarms. Although the two types of events have most activities in common, critical events are distinctive by virtue of an investigative phase. It is proposed that the notion of AIAs is used to describe the collective of the stages in alarm event handling. The term "activities" is used to refer to the ensuing behaviors triggered by the presence of an alarm. It is posited that these activities would not have been triggered without the alarm being present, thus they are alarm initiated activities. The AIAs are linked to other supervisory control activities which can be typified as continuous tasks (such as visual scanning of instruments and fine tuning of plant variables in response to minor variations in plant) and discrete tasks (such as putting plant into service and taking plant out of service). In such tasks, alarm information may be used instead of, or in conjunction with, other information (such as data on plant variables, some internal reference to plant state, comments from other operators, or reports from engineers who are in direct contact with plant). Whilst it may be difficult to


Figure 1.

distinguish between some activities, whether triggered by alarms or otherwise, examination of alarm handling activities can be justified in terms of providing useful information regarding the design of alarm systems. This will, of necessity, involve the consideration of activities where alarm information is of primary importance (such as in a critical event) and activities where the alarm information is of secondary and/or supplementary importance to the task (such as in a routine event).

Operators report that, in alarm handling, when they observe the onset of an alarm, they accept it and make a fairly rapid analysis of whether it should be ignored (route 1), reset (route 2), monitored (route 3), dealt with superficially (route 4), or requires further investigation (route 5). If it cannot be cleared (by superficial intervention), then they may also go into an investigative mode (route 6). In the penultimate mode, the operators will monitor the status of the plant brought about by their corrective actions and ultimately reset the alarm. Routine behavior has a "ready-made" response, whereas critical behavior needs knowledge-based, deductive reasoning. The taxonomy (observe, accept, analyze, investigate, correct, monitor, and reset) is proffered as a working description of alarm handling behavior, rather than intending to represent a fully validated psychological model.

3. A TAXONOMY OF ALARM HANDLING

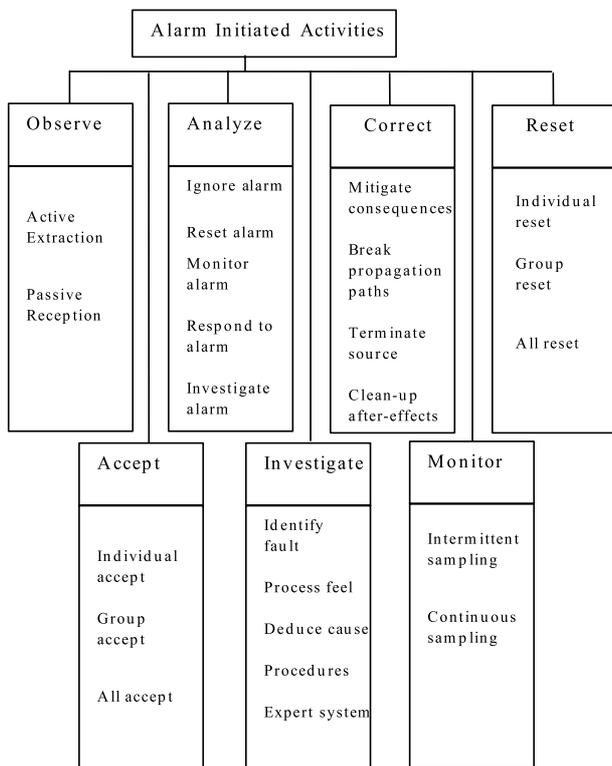
Activity in the control room may be divided broadly into two types: routine and critical. Incident handling activities take only a small part of the operator's time — approximately 10% (Reinartz and Reinartz 1989; Baber 1991) — and yet they are arguably the most important part of the task. This is particularly true when one considers that the original conception of the operator's task was one of operation-by-exception (Zwaga and Hoonhout 1994). In order to develop a clearer understanding of alarm handling, a taxonomy was developed (Stanton and Baber, in press) on the basis of a literature review, direct observation, and questionnaire data. This taxonomy reveal 24 alarm-related behaviors subsumed under seven categories: observe, accept, analyze, investigate, correct, monitor and reset (see Figure 2).


Figure 2.

The development of a taxonomy and model of alarm handling provides a focus on the design formats required to support alarm initiated activities. The human requirements from the alarm system may be different, and in some cases conflicting, in each of the seven categories of the taxonomy. The difficulty arises from the conflicting nature of the stages in the model and the true nature of alarms in control rooms, i.e. they are not single events occurring independently of each other, but they are related, context-dependent, and part of a larger information system. It is not easy to separate alarm initiated activity from general control room tasks, but it is useful to do so. While many of the activities may also be present in more general aspects of supervisory control tasks, their consideration is justified by relating them to the alarm system in particular. This leads to the following observations.

First, designers of alarm systems need to consider all manner of alarm initiated activities. Often there is little consideration of alarm handling beyond the initial 'observe' stage. Second, one could question the need to consider the alarm system as a separate entity from the other displays in the control system. It seems apparent that 'active extraction' of information would be more suitably supported by a permanent visual display. This would suggest three main changes: the integration of alarm information, the move away from the trend for sole reliance upon scrolling text-based alarm displays, and the provision of parallel displays rather than sequential displays.

These changes could support operator heuristics by making the information available to the operator at all times without requiring extensive searching activities. With the continued drive to replace traditional annunciator panels and wall-based mimics with VDUs in control rooms, there is good reason to question the use of text-based alarm displays.

Auditory Warnings

J. Edworthy and E. J. Hellier

Department of Psychology, University of Plymouth, Plymouth PL4 8AA, UK

1. INTRODUCTION

1.1. Terminology

Auditory warnings can be thought of as a specific type of alarm, although the terms "auditory warning" and "alarm" are not entirely synonymous. "Alarm" may be thought of as the generic term for all forms of sounds which attract attention, including animal calls, burglar and car alarms, equipment alarms and so on. Auditory warnings are sounds which attract attention, but for the specific purpose of providing additional support and information in potentially dangerous situations. They can be more specifically construed as attention-getting sounds that can, when well designed, both attract attention and inform the hearer so that s/he will then take appropriate action. "Auditory warning" can also be construed to include speech warnings, although these are excluded from this article as detailed discussion of intelligibility and comprehensibility are required. Other terms such as "alerts" and "attensons" (attention-getting sound) are used but there is no universally agreed terminology.

Typically, an auditory warning will remain silent unless some critical parameter value is reached (e.g. temperature, pressure or height). If the critical value is exceeded, the warning will sound. Usually an auditory warning will produce only one identifiable sound once activated, although more sophisticated warnings can produce graded levels of urgency, depending upon the criticality of the parameter being signaled. Throughout this article the hazard or danger that triggers an auditory warning will be referred to as a referent (Edworthy and Adams 1996).

1.2. Scope

Auditory warnings vary greatly in terms of the environments in which they are used, the types of sounds which are used and the type of behavior that they are expected to elicit.

1.2.1. Usage

Auditory warnings are used heavily in occupational settings, particularly where people work under conditions of high workload or are continually having to carry out a lot of visual scanning or are constantly moving around. Thus they are used extensively in aircraft, hospitals, control rooms, factories and transportation. Specific types of auditory warnings are also used in more general public facilities and buildings, signifying dangers such as fire.

1.2.2. Warning types

Auditory warnings can be non-verbal or verbal (speech). Essentially there are three categories of non-verbal auditory warnings — abstract, semi-abstract and concrete. The first, abstract, includes traditional types of warning sounds such as bells, horns, klaxons, buzzers and the like. For these types of sound the association between the referent and the warning is learned through stimulus–response association. Hearers know what the warning sound means because of a learned association between the sound and the situation it is signaling, not because of some inherent property of the warning sound itself (although sirens possess an inherent "wailing" quality, the response to which may not need to be learned). The second type, semi-abstract, are usually more technologically sophisticated, and are able convey some feature of the referent through the sound itself (e.g. an increase in pitch might indicate an increase in height or temperature). In this case, the association between the hazard and the warning should be easier to learn. The third class of auditory warning type, concrete sounds, are the sounds of real objects and events. Here, the sounds of everyday objects undergoing specific processes (e.g. the sound of a glass filling up with water) are used to signify processes which may have related features (e.g. the process of copying material from one computer disk to another). This third category of auditory warning may require minimal learning because the recognition and interpretation of these sounds relies on "everyday listening" (Gaver 1993). There is little research evidence to show which types of warning sounds are the most effective either generally or for specific applications.

1.2.3. Warning and monitoring sounds

Typically, auditory warnings exist in a binary on/off state. In many situations (in medicine, for example) they can be preprogrammed to signal when a physical parameter reaches critical state. Some more advanced warning systems are capable of signaling various states of criticality by producing sounds differing in urgency or seriousness, depending on the current state of the referent. Yet other systems will supply auditory information almost continuously, with changes in the auditory signals being used by the operator in order to monitor and track the system. Semi-abstract and concrete warnings (see Section 1.2.2.) are likely to be more effective in these kinds of applications than traditional, abstract auditory warnings. Whether the sounds used in these kinds of application should be considered as auditory warnings is not clear. A more general definition of these sounds as monitoring or tracking sounds is likely to be more parsimonious in the longer term, with the definition of an auditory warning being confined to those sounds that operate only in an on/off state.

2. AUDITORY WARNING DESIGN

The process of tailoring an auditory warning to the appropriate background noise spectrum is a fairly complicated procedure as it depends on a number of factors including the degree of fluctuation in background noise levels, the psycho-acoustic profiles of the people working in that setting, and appropriate modeling of the auditory filter. Guidelines and accompanying software have been written to make the task more straightforward for the ergonomics practitioner (Patterson 1982, Laroche *et al.* 1991). The guidelines deal largely with the acoustic and psycho-acoustic principles involved, but also offer advice on psychological issues although the latter have been embellished in more recent literature.

2.1. Acoustic Issues

2.1.1. Audibility

In order for auditory warnings to be effective, they must be heard. They must also not be too loud as the likely effect will be to startle, cause annoyance, direct attention away from instead of

towards the task in hand, and the risk might be that the warnings will be turned off and then not be available when required. Their audibility will be determined by a number of factors, primarily the background noise in which they are to be heard. Thus it is essential to model auditory filter shape in order to predict masked threshold in a given noise environment. Once this is known, an appropriate band for auditory warnings and auditory warning components can be predicted. It is also possible to predict which warning (and other) sounds will be masked by the ambient noise; it is also possible to predict which sounds will be masked by other warning sounds. Two expert systems are available which allow this to take place. A system developed by Patterson (1982) for aircraft measures noise in small bands across the spectrum, superimposes Patterson's auditory filter model over these measurements to predict masked threshold, and then generates a band 15–25 dB above threshold which is deemed to be the appropriate band for auditory warning components. At 15 dB above masked threshold sounds should be audible; by 25 dB above threshold they will be hard to miss.

A second approach (Laroche *et al.* 1991) aimed at work areas such as factories, is to take one-third octave band measurements of both noise and warnings, then to generate the excitation pattern that would be produced if those sounds were presented to the ear, and then to compare excitation patterns. Here, if one excitation pattern completely covers another then the covered sound will be inaudible if heard simultaneously with the covering sound.

Both systems can be used to show whether auditory warnings in a particular environment will be either inaudible or too loud. They can also be used to predict how auditory warnings should be adjusted so that they are appropriately loud.

2.1.2. Localizability

In practice the localizability of auditory warning signals is an important issue. The ear uses two different mechanisms for localizing sound, depending on the frequency of the sound being heard. At low frequencies phase differences between sound waves entering each ear can be used to localize that sound. At high frequencies the side of the head which receives the sound first casts an "acoustic shadow," which also allows localization. For maximum localizability, auditory warnings should be either of relatively high or relatively low frequency. High frequency sounds will be very irritating and aversive, so ideally only relatively low frequency sounds or at least sounds with a relatively low fundamental frequency, should be used. In practice, the frequency of many auditory warnings is one that allows neither of the two mechanisms to function adequately. This problem can be addressed through redesigning those sounds, particularly adjusting the fundamental frequency to one which will allow localization. The addition of several components will also help in the process.

2.2. Psychological Issues

There is a large range of psychological issues that impinges on auditory warning design. Three central issues in practical terms are the number of warnings that the operator might need to deal with, the relationship between a warning sound and its meaning, and finally its believability. Each of these factors will contribute to determining the efficacy of both single, and sets of, auditory warnings.

2.2.1. Number

Generally, the number of auditory warnings used in any particular occupational or public setting should be kept to a minimum, as problems will ensue if large numbers are used. One problem is that the more warnings there are, the more likely it is that they will mask one another if they sound simultaneously. This may lead to confusion and/or a progressive increase in the loudness of sounds, neither of which is ergonomically desirable. The second of the problems is that the more auditory warnings there are in a set, the harder it will be to identify and learn them. A third problem is that if auditory warnings are used ubiquitously as information sounds (such as they might be in a nuclear power plant control room or an intensive care ward) then this will weaken their role as specific attention-getting sounds.

Ideally only the highest priority situations should be signaled by unique auditory warnings, that is where there is one-to-one correspondence between warnings and specific hazards and events. Situations of lower priority can be signaled by using a single warning denoting the category of risk only (such as second- or third-priority). On hearing the warning, the operator can then further identify the problem through other means, such as visual scanning. By using such a strategy, the number of auditory warnings can be kept to a minimum without compromising safety.

2.2.2. Relationship between auditory warning design and function

At the time of writing there is no clear consensus as to which category of sounds (abstract, semi-abstract or concrete; see Section 1.2.2.) are best suited for use as auditory warnings *per se*. There is little consensus also as to which sorts of sounds are best suited to which sorts of function. Traditional warning sounds have the advantage that they are generally recognized as warnings (although their specific meaning may not be clear) whereas semi-abstract and concrete sounds may be intuitively more easy to identify.

A more clearly defined, but more specific type of mapping between auditory warning and referent is that of *urgency mapping* (Edworthy and Adams 1996). Urgency mapping is a process through which warnings may be mapped on to referents so that the more important, hazardous situations and events are signaled by more urgent-sounding warnings. By such a process, some degree of cognitive compatibility can be achieved between warning and referent. Assessments of importance and hazardousness of risks must be generated by experts in the occupational settings in which the warnings are to be used. Sets of warnings can then be generated from existing databases showing the relationship between perceived urgency and acoustic design (e.g. Edworthy *et al.* 1991, Hellier *et al.* 1993). One advantage of appropriate urgency mapping is that even when the precise meaning of a warning may not be known, the degree of attention that the hearer should pay to the situation being signaled is conveyed through the warning. The same process can be used for visual warnings.

2.2.3. Believability

A warning's believability is a strong determinant of its effectiveness. Any warning, no matter how well designed, will be ignored if it continually sounds when there is no danger or hazard to be found. Thus false alarm rates are an important factor

in auditory warning design and implementation. Research evidence (Bliss 1995) shows that people will match their response rate quite accurately to a warning's reliability. Thus if a warning is 90% reliable (that is, for 90% of the time when a warning sounds, there actually is a problem requiring attention) then it will be responded to nearly 100% of the time. If a warning is only 10% reliable (so 90% of the time it signals when there is no actual problem to be attended to) then the warning itself will only be attended to 10% of the time. Thus it is important to keep false alarm rates as low as possible. Setting an auditory warning so that it sounds only when it should requires close collaboration between designers, engineers, manufacturers and experts in the environments where the warnings will be used.

3. AUDITORY WARNINGS AND OTHER TASKS

Generally auditory warnings are heard and dealt with in conjunction with other tasks. In many occupational settings responding to alarms is only one of many tasks to be performed simultaneously. The balance of providing warning information in an auditory, visual or other mode (e.g. tactile) needs to be carefully considered when systems are implemented. It is thus important to take account of multiple resource models of attention (e.g. Wickens 1992) and dual-tasking approaches to cognition and performance in order to establish the likely relationship between auditory warnings and the environment in which they are to be used.

Augmented Reality

W. Barfield and E. B. Nash

Virtual Environment Laboratory, Department of Industrial and Systems Engineering, Virginia Tech, Blacksburg, VA 24060, USA

1. INTRODUCTION

An "augmented" or "merged" reality environment represents a scene with synthetic imagery combined with parts or all of a real-world scene (Figure 1). The purpose of this chapter is to review the design and use of augmented reality displays, discuss the advantages of augmented reality systems and to discuss some human factors issues that should be considered when creating augmented reality displays.

2. COMPONENTS OF AUGMENTED REALITY

Generally, to create a computer-generated augmented environment the following equipment is necessary: (1) hardware for creating and displaying visual images, (2) a position and orientation sensing system, (3) hardware for combining computer-generated images with either the real-world scene or video images of the real world and (4) the associated system software.

The two main types of head-mounted displays (HMD) used in augmented reality applications are a opaque or see-through HMD. Both types of displays are commonly used for a variety of tasks and have different advantages and disadvantages associated with them (Holloway 1997). Moreover, an augmented reality environment can also be created using a monocular HMD (one eye), bi-ocular HMD (same scene to two eyes), binocular HMD (two slightly displayed scenes shown to two eyes), or using a desktop computer or large-screen projection system.

2.1. Opaque Head-mounted Displays

As indicated, one type of display used to create an augmented reality environment is an opaque HMD. When worn over one eye, the user must integrate the real-world scene perceived with the uncovered eye with the graphical image(s) projected to the

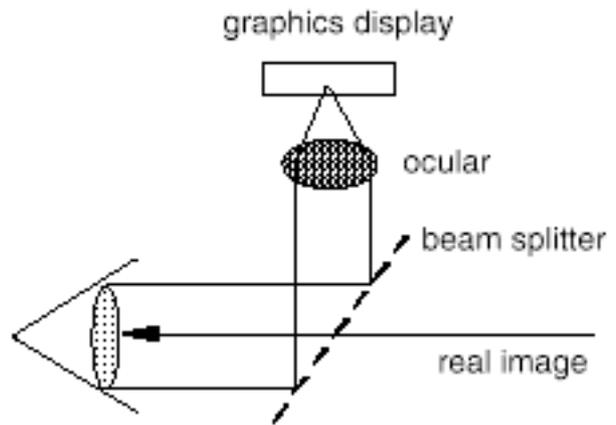
Figure 1. Graphical image overlaid onto video image. The user is wearing an opaque HMD with a CCD camera and luminance keyer. Courtesy: Virtual Environment Laboratory, Virginia Tech.


Figure 2. Diagram of a see-through display. The display includes an ocular that magnifies the displayed image that is then projected onto the retina.

other. However, when worn over both eyes, the user perceives the real world through video captured by mounted cameras. A computer then fuses (e.g. using luminance keying) video of the real world with graphical images to create a video-based augmented reality. The location of the cameras depends on the environment one wishes to augment. For instance, if the design objective is to augment the users immediate surroundings, then the ideal position to mount the cameras (typically CCD cameras) is near the user's eyes. In contrast, if augmenting is desired for a more remote environment, cameras may be mounted at the remote scene either on a robot or some ideal location with respect to the robot or other remote manipulator. Although using a single camera produces only a monoscopic (non-stereo) image of the real world, stereoscopic images may be obtained by using two cameras calibrated to provide the appropriate parallax.

2.2. See-through Head-mounted Displays

In contrast to opaque HMD, see-through HMD admit light from the outside environment allowing users directly to view the real world with the naked eye. In addition, half-silvered mirror systems fixed in front of the user's eyes reflect light from computer-generated graphic images (Figure 2). The resulting image is an optically combined view of the real world superimposed with graphical images.

2.3. Screen-based Displays

Provided that video images are used to capture the real-world scene, augmented reality scenes may be viewed using either an opaque HMD or a screen-based system. Screen-based systems can project images to users either using cathode ray tubes or by projection screens. In either case, stereoscopic images may be generated by viewing timed alternations between left and right eye views through a shutter system that occludes the left eye view when the right eye image is displayed and vice versa (Davis and Hodges 1995).

3. IMAGE REGISTRATION IN AUGMENTED REALITY

A typical requirement of augmented reality scenes is that the computer-generated images accurately register with the surroundings in the real world (Janin *et al.* 1993). Registration requires

accurate knowledge of the geometry of the real world, the computer-generated scene and the head movements of the user. One technique commonly used to register separate coordinate systems is to place a position sensing transmitter at a fixed and known location in the real environment while positioning the sensing receiver on a HMD. Then, as the user moves his head, the position and orientation of the user changes with respect to the transmitter. Using this information, updates to the virtual display can be computed based on the location of the virtual display with respect to the optics of the physical display.

4. MULTIMODAL DISPLAYS USED IN AUGMENTED REALITY

Although augmented reality displays typically combine only visual images with the real world, Barfield *et al.* (1995) proposed that auditory and haptic information can also be used to enhance the real world as well. For example, computer-generated sounds could be placed over objects in the real world to enhance their visibility or change their meaning. Furthermore, by overlaying computer-generated haptic feedback with real world objects, one will/might not only experience the sensations of the haptic feedback equipment but also of the real tactile and kinesthetic sensations from the object. This practice will likely lead to novel interface techniques for human interaction with complex systems.

5. ADVANTAGES OF AUGMENTED REALITY DISPLAYS

5.1. Conservation of Computational Resources

A major motivation for the use of augmented reality displays relates to the computational resources necessary to generate and update computer-generated scenes. In computer graphics, the more complex the scene the more computational resources are necessary to render the scene, especially for real-time applications. However, the concept of augmented reality is to enhance the real world with virtual objects. This approach does not require a scene that consists entirely of computer graphics. Instead, the graphics are used as a supplement to the real-world scene. Images created in this way can serve as an enhancement to the knowledge already existing in the real world (Feiner *et al.* 1993). For many conceivable applications the virtual images may require only wire frame graphics or text overlaid on top of the real-world scene (Janin *et al.* 1993). Such an approach may conserve computational resources that can be used for other tasks (e.g. networking).

An additional reason why it may be desirable to combine synthetic imagery with real-world scenes is to maintain the high level of detail and realistic shading that one finds in the real world. As noted, to model the complexity of the real world using entirely computer graphics would not only require tremendous computational resources, but also would be a laborious and time-consuming process to model such complex scenes. Thus, the incorporation of real-world objects in augmented reality will provide the designer with a rich visual scene, which then can be augmented with computer graphics.

5.2. Processing Capabilities of Video

One advantage associated with using video for augmented environments is the ability to further process or to edit the visual information captured by the cameras to enhance or highlight a particular portion of the image (Mann 1997). For example, parts of the video scene can be substituted with synthetic imagery. In addition, because the real-world image can also be easily changed by mounting the cameras at a remote site, this affords wide application for tele-operations tasks, especially when the site does not easily support the habitability of humans.

6. SELECTED HUMAN FACTORS CONSIDERATIONS FOR AUGMENTED REALITY DISPLAYS

6.1. Display Optics of the Camera Versus Display

Because video-based augmented reality utilizes cameras to generate the real-world scene, careful attention must be paid to the relationship between the display optics of the camera(s) and the visual parameters of the real-world scene. Generally, if video of the real world is to appear as if viewed through the user's eyes, the cameras should operate as if they are at the same physical location as the wearer's eyes. This is a difficult design task. For example, to accomplish this, the field of view must be matched between the computer-generated scene and real-world scene. Additionally, if two cameras are used to generate the real-world scene, additional considerations such as the horizontal disparity and convergence angle of the cameras should be considered. These parameters can be manipulated by adjusting the horizontal tilt and disparity of the display. The horizontal tilt represents the convergence angle of the display and the disparity represents the horizontal distance between the center of the two displays.

6.2. Limits in Graphical Display Resolution

When using see-through displays for augmented reality applications, it is desirable to match the resolution of the projected graphics with the spatial resolution of objects in the real world. However, unlike the real world, graphical image resolution is dependent on the pixel resolution afforded by the HMD, and thus is one limiting factor in the quality of visualization of the augmented scene. For example, some commercial HMD provide resolutions of 720 x 480 pixels in a 60° field of view, equivalent to 20/100 visual acuity in the real world. Disparities of this magnitude between synthetic imagery and the real-world scene would be quite obvious to the observer.

6.3. Frame Rate and Update Rate

Piantanida *et al.* (1993) define frame rate as a hardware-controlled variable determining the number of images presented to the eye s^{-1}. To contrast frame rate from update rate, consider a display that has a frame rate of 60 Hz. The update rate is the rate at which new (different) images are generated and presented to the viewer. Thus, if the update rate is only 3 Hz, the system will present 20 images of the same scene to the viewer before 20 images of the next scene are shown (Piantanida *et al.* 1993). In this way, only three different images s^{-1} will be displayed despite the frame rate of 60 Hz. Sufficient update rates will assist designers in accurately registering graphics projected in the real world with changes in the users head movements.

6.4. Sensor Delay

Piantanida *et al.* (1993) noted sensor delay as another type of system delay that affects the registration of the visual scene in

augmented reality. Sensor delay is the time required by the system to determine that the viewer has made a movement requiring an update to the display. In order for image registration to be as accurate as possible, head tracking sensors for augmented reality displays must not only be quick enough to register natural head motion, but also be accurate in tracking to a small fraction of a degree in orientation and a few millimeters in position (Azuma 1993).

6.5. Stereoscopic and Monoscopic Displays

With augmented reality displays, either the graphical images or real-world images can be stereoscopic, meaning that each eye views a slightly offset version of the same image. This quality (i.e. stereopsis) is known to provide enhanced perception of depth and three-dimensionality for a visual scene (Yeh and Silverstein 1992). However, because augmented displays work to combine two otherwise independent visual images, the stereoscopic cues provided by either may not completely support each other, and may even be in conflict (Milgram and Drascic 1997). Monoscopic displays do not suffer these complications because they lack the necessary depth cues. Yet users have been shown to make accurate distance judgements in cases where the head is allowed to move horizontally and the virtual objects are close to the viewer (Ellis *et al.* 1997).

6.6. Importance of Task

It is imperative when considering the capabilities of an augmented reality system that careful attention be paid to the task for which it is designed. For instance, medical applications such as registering CT images with the patient's anatomy will require quite accurate image resolution and registration between the synthetic imagery and the real world environment. In contrast, other applications may only require that the synthetic image or text appear in the observer's field of view, such as a maintenance task.

6.7. Mental Models

As noted, augmented reality displays consist of computer-generated imagery merged with the real-world scene. Thus, the designer must account for both the user's mental model of the synthetic imagery as well as the real image. That is, the scene should be designed in such a way that a single mental model will be formed of the augmented scene. Integrated mental models will likely result from improvements in the display parameters. Specifically, the augmented scene will likely be viewed as one singular environment as the graphics become more realistic, the two images become better matched in terms of brightness and color, and image registration improves.

Whether performance in augmented reality environments will improve as a result of such integration is not yet known. However, some preliminary information is provided by a literature review on head-up displays (HUD) (Stokes *et al.* 1990). This review suggests that it may in fact be difficult to switch attention between projected HUD symbology and the real-world scene. For example, pilots have been shown to turn off the HUD during critical phases of a mission. Thus, a relevant question to ask for augmented reality environments is the extent to which overlaid imagery may interfere with the visualization of the real-world image and performance of a task. Within this issue of interference is display clutter. Without an empirical basis for combing these two types of information (synthetic and real world), synthetic imagery may not enhance information presented in the real world but rather obscure important parts of the real-world scene. How attentional resources are allocated to augmented reality and/or the real-world image, and how display clutter affects performance are important topics for future research.

7. CONCLUSIONS

In this chapter we discussed concepts related to augmented reality. Several display technologies are available for the creation of augmented reality systems, which present advantages over conventional virtual reality systems. However, successful employment of any augmented reality system requires that the capabilities and limitations of the hardware, the task to which the technology is being applied, and the motor, perceptual, and cognitive aspects of the user all be considered. As display and tracking technologies develop along with our knowledge of the human capacity for perceiving and understanding displayed information, augmented reality displays will likely provide rich and innovative enhancements to the knowledge existing in the real world.

Automatic Speech Recognition

H. M. Khalid† and M. G. Helander‡

†Institute of Design and Ergonomics Application, Universiti Malaysia Sarawak

1. INTRODUCTION

Automatic speech recognition (ASR) is a 25-year-old technology whose time may finally have come. It is a technology for communicating with a machine using spoken words or phrases. Lernout and Hauspie, one of the forerunners in speech recognition technology, have launched a variety of speech products that enables people to control remotely the central heating, lighting, burglar alarms, cookers and video recorders with speech commands. ASR will increasingly be used for home banking, transactions on the Web, and even as security for hole-in-the-wall cash machines. Because every human voice is different, speech is considered secure.

In the past decade, there has been great advances in ASR (e.g. Westall *et al.* 1998). The error rate has reduced by more than a factor of five and the speed in recognition has increased by several orders of magnitude — brought about by a combination of faster recognition search algorithms and more powerful computers. These factors combine to make high-accuracy, speaker-independent, continuous speech recognition for large vocabularies possible in real time. The improvements in speech recognition performance are due to four factors: use of common speech corpus, improved acoustic modeling, improved language modeling, and a faster research experimentation cycle (Makhoul and Schwartz 1994).

1.1. ASR Applications

Speech recognition is now being used in many "real-world" applications (e.g. machine translation services on the Internet), despite the perception that the current technology is still not flexible enough to allow easy and natural communication with machines. Situations in which the use of speech recognition systems may be advantageous include:

- When the user's hands or eyes are busy (e.g. mission pilots, parcel sorters, VLSI circuit designers).
- When only a limited keyboard and/or screen is available (e.g. telephone operator services, banking transactions).
- When the user is disabled (e.g. motor impaired users may control household appliances and wheelchairs).
- When pronunciation is the subject matter of computer use (e.g. foreign language learning, teaching of reading).
- When natural language interaction is preferred (e.g. database access).

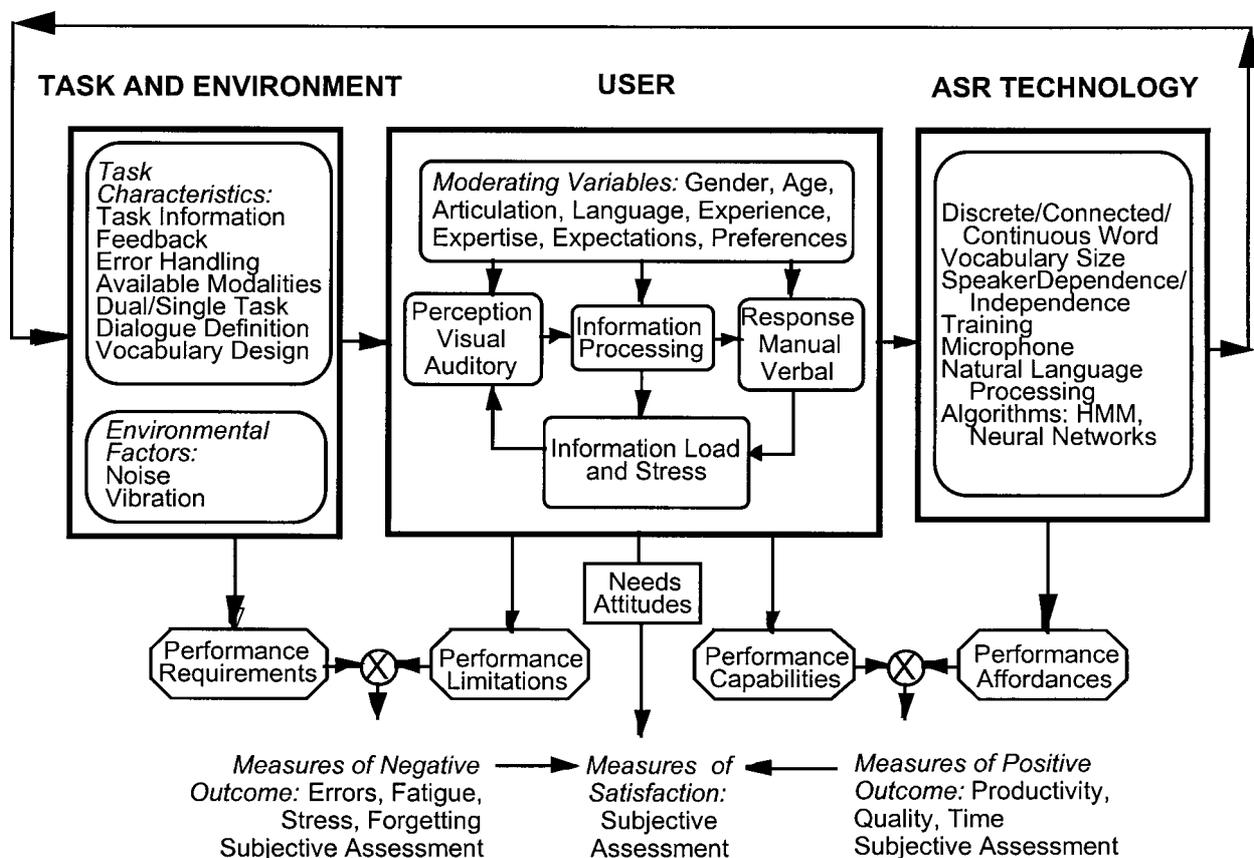
To date, efforts are continuing in the advancement of speech recognizers for a variety of telecommunication and computer-


Figure 1. Systems approach to automatic speech recognition.

based tasks. E-mails can now be translated automatically into the language of the recipient. Other facilities include: voice dialing (particularly useful in cars), automatic call-centers, computerized operator services, and messaging that allows users to pick up and send e-mails and faxes on an ordinary telephone. With improved computer processing power, memory and battery life, there will be greater demand to use speech with palmtop computers, dictation machines, organizers and smart telephones, thereby exploiting speech recognition technology in its own right. ASR systems will be more successful in the future if they can solve specific tasks, such as dictation for medical doctors, lawyers and research scientists.

1.2. ASR Types

There are two types of ASR: speech recognizers and speech understanding systems (or natural language understanding). The task of a speech recognizer is simply to identify the words spoken without interpreting their meaning. Recognition would be very useful if speech recognizers could identify words in fluent speech for any talker. Some of the more advanced recognizers on the market today approach this goal. Very few speech-understanding systems are currently being marketed. In addition to associating the acoustic input with a particular vocabulary item, speech understanding systems need syntax (parsers) and semantics (akin to a contextual dictionary) to assign meaning to speech input.

This chapter presents human factors associated with speech recognition only. The discussion is organized around major issues that are highlighted in Figure 1, in particular, the capabilities and limitations of speech technology, the characteristics of speech use, and the design strategies for speech interfaces. We also identify some human factors research that needs to be addressed to further the development of speech recognition systems. At the bottom of Figure 1 are three different kinds of measures of system performance: measures of positive outcome (efficiency), negative outcome (error) and measures of satisfaction (attitudes). These measures derive from comparisons of performance requirements imposed on the user, and performance affordances offered by the system. The measures are central to usability assessment. For example, the measures of satisfaction (i.e. attitudes) rest on subjective assessments of user expectations of ASR performance as compared with the actual measures of negative and positive outcome.

As depicted in Figure 1, the task and environment, the user and the ASR technology form a control system with error feedback. To optimize the performance of this system and to create successful applications, the user interface designer must consider not only the capabilities of the technology, but also the effects of the task requirements, as well as user's expectations, expertise and limitations. The technology will be described first, and then user and task considerations.

2. ASR TECHNOLOGY

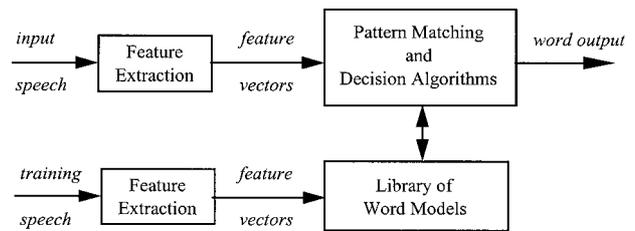
A recognition system consists of the hardware and software for storing a library of words and for comparing incoming words to the library. The ASR is first trained, meaning that features of words are extracted and stored in the library. Once a library of words has been stored, new spoken words will be compared with those already stored (Figure 2). A set of algorithms compares a feature pattern representation of the input word to a library of stored reference patterns, which have been obtained by the training process. Algorithms are used to decide which of several possible words gives the closest match.


Figure 2. Basic components of a speech recognition and training system.

There are hence four basic components of a speech recognition system. First, to know what a talker has said, the system must have some way of encoding and representing a set of utterances. Many systems represent the spectral-temporal properties of an utterance. Second, during recognition a pattern-matching algorithm compares a representation of a particular input utterance with the representations in the library of words. Many current speech recognizers use the technique of Hidden Markov Modeling (HMM) for pattern matching. An HMM model is based on a statistical representation that helps the recognizer to cope with most of the variability in human speech. The newest algorithms are based on neural networks (Kewley-Port 1995). Third, given the comparison of some input with the library vocabulary, an algorithm decides which utterance in the vocabulary was produced. Finally, to support the functions and operation of the recognition system, there must be a user interface (Nusbaum *et al.* 1995).

2.1. Characteristics of ASR

ASR are classified according to their capabilities. *Speaker-dependent* systems must be "trained" by an individual user who, using a microphone, records samples of each word. *Speaker-independent* systems can recognize speech for many users. This is done by training a large corpus of utterances spoken by many different people with different types of speech characteristics. *Speaker-adaptive* systems are speaker-independent systems that have the additional feature of updating the system during an interaction with a user, based on small samples of user speech. Thereby the match between the models in the system and the user's speech is improved (Kamm and Helander 1997). Most large vocabulary dictation systems use speaker adaptation techniques.

Some speech recognizers consider only isolated-word or *discrete speech*. These require a brief pause after every word or may allow only one word as input. Systems for *connected speech* input accept a sequence of concatenated words. Systems for *continuous speech* accept fluent speech without pauses.

Some systems recognize a large number of words (tens of thousands) or phrases, while simple systems may recognize only a few words, such as the digits 0–9. Some systems permit vocabulary switching so that different vocabularies are available contingent on the outcome of recognizing an utterance. This can be used in a hierarchical menu of choices. After each word the computer will consider a constrained set of new words, which enhances recognition.

2.2. Speech Recognition Accuracy

Vendors often describe their speech recognition hardware as offering very high recognition accuracy, but it is only in the context

of a realistic field test with noise and disturbances, that one can meaningfully compare the performance of recognizers. Recognition error rates below 1 percent are typically obtained for highly constrained vocabulary and controlled speaking conditions, but for large-vocabulary (e.g. 5000 words), connected-speech systems, the error rate may > 5% (Cohen and Oviatt 1994). Clearly, different applications will require different capabilities. Controlling a wheelchair might well be achieved with a simple system using only a few commands, but high reliability is crucial.

The major obstacle to high-recognition accuracy is the large variability in the speech signal characteristics. This has three components: linguistic variability, speaker variability and channel variability. Linguistic variability includes the effects of phonetics, phonology, syntax, semantics and discourse on the speech signal. Speaker variability, that is intra- and interspeaker variability, also includes the effects of *coarticulation*. In this case, neighboring sounds affect the acoustic realization of a particular phoneme, due to continuity and motion constraints on the human articulatory apparatus. Speaker differences such as dialect, speaking rate, and voice characteristics (e.g. pitch, hoarseness) require solutions that enable the recognizer to "learn" to recognize a particular voice. Channel variability includes the effects of background noise and acoustics, and the transmission channel (e.g. microphone, telephone). The recognition process must unravel all these variabilities.

2.2.1. Recognizer errors

Recognizer errors may be of four types (Khalid 1989, Kamm and Helander 1997). *Substitution* (or misrecognition) error occurs when the speech recognizer matches the user's utterance to the wrong vocabulary item (e.g. the user says "line" but the machine identifies the word as "nine"). *Rejection* error occurs when properly spoken words that are part of the active vocabulary are detected but not recognized, *deletion* error when an utterance that was spoken was not detected, and *insertion* (or false acceptance) error when the device fails to reject non-speech sounds (e.g. background noise, cough, sigh) by falsely matching them against a stored template.

A user interface must have a mechanism for error correction. First, the user must be able to see (or hear) that an error has occurred. Second, the user should be allowed to correct the error before it creates a problem in task performance. When the recognition system detects an error, it must present an error message visually on the screen (e.g. a blinking cursor) or aurally by using *synthetic speech* or a beep. For systems using continuous speech, error correction can become cumbersome since there is a question of what word to correct.

2.2.1.1. Vocabulary size

With a large vocabulary more recognition errors are likely. Substitution errors can be reduced by minimizing the number of words in the vocabulary as required by the task, and by ensuring that the chosen words are acoustically dissimilar. Increasing the number of templates per utterance (e.g. three to 10 samples per word) increases the chances of correct recognition. The user can manipulate the acceptance or rejection rate of spoken words by setting the reject threshold to different percentage values.

3. USER ASPECTS

A number of human factors issues arise in the design and use of speech recognition systems. Inconsistencies in verbalization lead to recognition errors. User inconsistencies may be due to several factors:

- *Stress and fatigue*. During a working day, the voice may change because of morning hoarseness and vocal fatigue as well as general fatigue. There may also be stress and psychological fatigue — particularly if there are many error corrections. Fatigue and stress affect the "task" voice. Also, memory failures due to large vocabulary size can induce stress. Using words familiar to the user may possibly alleviate this.
- *Attitude and expectation*. As with much novel technology, users tend to have unrealistically high expectations of the system. It may take a month to learn how to handle ASR, and users must adopt a more appropriate and consistent attitude towards ASR. Users must be aware of how the system works and learn how to compensate for the weaknesses in ASR.
- *Experience*. Experience with ASR and its application has a major influence on recognition accuracy. As an example, users learn to adapt their speech to the computers. With increasing experience, they automatically insert the necessary pause between words that is required for a discrete speech system.

Failure to use ASR systems consistently is also caused by idiosyncratic factors, such as gender, age, articulation, regional accent and speech habits (e.g. hm, huh). In the past, ASR algorithms were developed using the voices of the system developers, typically males with an American accent. They are not representative of the user population, and a generic approach must be taken.

3.1. Prompts and Instructions

Prompts are used to elicit spoken user responses. For example, in a banking transaction via an automated teller machine, the system may prompt the user: "If you have a personal account say 1 and a company account say 2." A careful construction of prompts (e.g. semantic and prosodic cues) can result in a productive interaction. Prompts can also be used after an ambiguous input or error condition, in order to help the user modify the next input to improve recognition. The user must also know what is expected and how the system can provide instructions. For simple tasks, the instructions may consist of a single prompt. For complex interactions, the instructions may be detailed and lengthy.

3.2. Error Recovery Strategies

Error recovery strategies may be initiated by the user or by the system, for example by flagging the errors. Users prefer error recovery techniques that require the least amount of effort. For example, during partial recognition failures, the system could repeat what was recognized and then request, by adjusting prosody (pitch, loudness, duration), that the user only repeat the section of the utterance that it has failed to recognize.

4. TASK AND ENVIRONMENTAL ASPECTS

For applications involving disabled users there may not be a choice available, so the decision to use ASR is well argued. For other applications, ASR must be carefully assessed to ensure that it is more efficient and reliable than manual input. Many early

applications focused on hands-busy, eyes-busy tasks. One typical example is the mission fighter pilot. However, the high recognition error rate of early systems made error correction cumbersome, stressful and time consuming. Since error rates have reduced, there are now new prospects for ASR.

The first assessment could be a task analysis, where necessary user input, system output and feedback from error correction are listed. Given the characteristics of the task, such as frequency of input and feedback, one can allocate control actions to either voice or manual, and feedback to either visual or auditory functions — all for the purpose of optimizing task performance.

Dialogue definition must consider the semantics of the task — is there a persistent mental model that can be utilized to select how voice commands can be sequenced during task performance to improve the "rhythm" of the task. The choice of sentences or words depend on the mental model. In addition, one must also consider that they are easy and "natural" to memorize, and that they produce distinctly different profiles in the ASR equipment, so as to minimize substitution errors.

4.1. Task Knowledge

There are two aspects of task knowledge. The first concerns training the user on how to use the device so as to maintain a consistent "task" voice during performance. This not only provides a knowledge of what constitutes successful recognition but also the procedural knowledge involved in device use. The second relates to the task at hand. By clearly specifying what the task entails and what is to be expected, first-time users may focus on the task itself and not the device.

4.2. Environmental Characteristics

Environmental characteristics relate mainly to background noise. In avionics, for example, high levels of acoustic noise, high vibration, and poor voice-communications can characterize noise. On the factory floor and office, continuous noise from machinery, air conditioning, or intermittent noises from other people, telephones, printers, etc can characterize noise. Because of its variability, intermittent noise is more difficult to compensate for. A hardware solution to background noise is to use unidirectional noise-canceling microphones.

5. DESIGN OF ASR INTERFACES

People commit errors regardless of whether they are interacting with humans or with an automated system. Errors may be reduced through a thoughtful and usable design. In developing a user interface, principles of ergonomics design should be applied, including: focusing early on the users and the tasks they will perform, collecting performance data early in the design process by using simulations and prototypes, improving design at an early stage through design iterations. During the design process, usability principles should be considered, such as: use simple and natural dialogue, speak the user's language, minimize user memory load, provide consistent voice command structure, provide feedback, shortcuts and good error messages, as well as prevent errors (e.g. Baber and Noyes 1993, Karis and Dobroth 1995, Kamm and Helander 1997).

To date, the role of the system image for a speech recognition device has not been explored systematically (Nusbaum *et al.* 1995). As the complexity of recognition systems increases,

efficient use of these devices will depend on interfaces that modulate the user's expectations about how to speak, about recognition performance, and about how to control the recognizer's functions.

6. FUTURE RESEARCH

Research and development has increased during the past decade. This reflects the increased interest, in particular from telephone and computer companies. Below are described a few potential research areas in human factors. For research relating to technological developments, see Atal (1994) and Westall *et al.* (1998).

- *Multimodal interactive systems*. These systems, in which speech is only one component, may provide more flexible and robust interfaces, besides providing more options for error avoidance and error correction by allowing users to switch to another modality when errors occur. Some of the research issues to be addressed include: conceptualizing interactions among communication modalities, defining methods of evaluating the performance of multimodal interfaces, and identifying integration issues that arise when multimodal input is permitted.
- *Improving speech recognition by recognition of user intent*. Research can be undertaken to model task-oriented dialogue to identify the structure of dialogue. Many professional tasks are procedural in nature, and they are therefore fairly easy to model. Given that the system can keep track of user input, it may also predict the next action. Goal-plan graphs have been used to predict the intentions of operators. Such technique could be used to predict what the operator would say in the future. This constrains the dialogue options, and ASR would improve.
- *Spoken language understanding*. Research supported by DARPA (Defense Advanced Research Program Agency) has developed systems that can deal with the idiosyncrasies of natural speech. Challenging problems remain, such as "repair of spontaneous speech," "detection of relevance to spoken topic" and "use of discourse and dialogue theory to create conversational interfaces."
- *Use of mental models for dialogue definition*. Experienced operators have distinct mental models of the task. Given that the mental models of several operators coincide, one might define a dialogue using a natural phraseology and natural concepts. Experienced operators could be trained to build up unitary mental models, whereby one might reduce the training requirements for ASR.

7. CONCLUSIONS

ASR will not succeed unless the system is well designed to consider variations in operator speech as well as task behavior. An appropriate model for ASR should be based on task requirements and should consider environmental constraints. Procedural guidelines for ASR design need to be developed so that implementation of ASR can appropriately consider the human factors and mental models of users.

Given the limitations of the speech recognition algorithms today, further research is needed to improve the robustness of speech recognition, to incorporate higher level linguistic knowledge, and to determine how best to integrate speech into

efficient multimodal interactive systems. The ultimate systems should be capable of robust speaker-adaptive continuous speech recognition. There should be no restrictions on vocabulary, syntax and semantics.

Chinese Keyboard Input

B. Han and P. Sun

Institute of Psychology, Chinese Academy of Sciences, Beijing 100101, PR China

1. INTRODUCTION

Computer processing information is represented in binary digits. This is suitable for processing basic alphabetic language with a limited number character set, e.g. English. However, it is not so easy to process Chinese information with > 60 000 characters in the whole set. Even if the coding capacity of the binary code system was enough for Chinese characters, the coding combination of up to 60 000 is no doubt an unbearable burden for normal users with limited capacity of attention, memory and cognitive processing. Therefore, a special coding strategy is needed to process Chinese.

The unique square feature in each Chinese character is quite different from the serial, linear word of the alphabetic language. This is possibly the main reason that Chinese word-processing was delayed ~10 years. The first English word-processing system was developed in the 1960s, but the first Chinese coding system developed in mainland China was applied to the computer in 1978. During past two decades, systematic research was conducted with respect to the Chinese language, the computer and the user. Various features in Chinese, such as initial, final, stroke, component and component combination, were used as elements to encode the character/word to the international standard small keyboard according to specifically designed rules.

Recent research has improved the coding technology greatly in the areas of speed, usability and learnability. This chapter will introduce some fundamentals and coding strategy of Chinese keyboard input (CKI).

2. FUNDAMENTALS OF CKI

Chinese can be input through varying size keyboards, by handwriting, by clicking on the computer screen, by optical character reader (OCR) or by recognizing speech. This chapter focuses on coding input using the universal international standard small keyboard with 26 letter keys, 10 number keys and other symbol keys. This is the primary method of most Chinese users in daily word-processing work (Chen and Hu 1994).

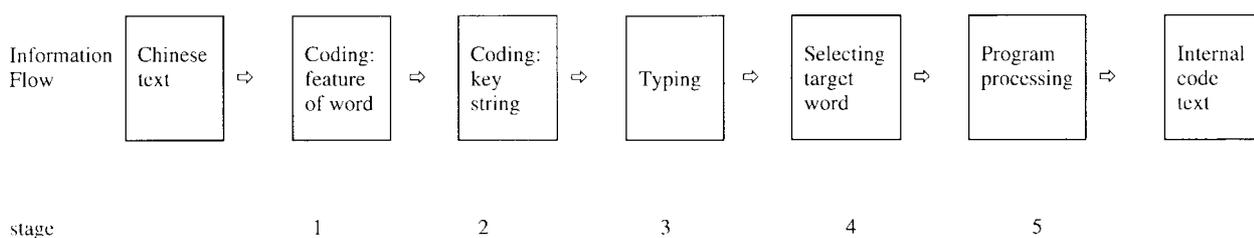
The aim of the CKI is to transfer the written text in a manual way or in the user's brain to the binary internal code text that can be processed by the computer. The standard international small keyboard is used as the human–computer interface. Figure 1 shows the program flow of Chinese keyboard inputting.

When compared with English keyboard input, stages 1, 2 and 4 are unique in CKI. Stage 5 is much more complex than the letter-internal code transforming in English inputting. This increases the workload for both user and computer.

Coding systems for CKI can be divided into rational and irrational codes. In the irrational coding system, each character is represented by a certain combination of numbers, e.g. "1412" represents the Chinese character "jiang". This is based on the Wade System invented by Thomas Wade in the nineteenth century for telecommunication using Chinese. There is no coincident code in the irrational coding system for the whole Chinese character set. But the user must refer to a special dictionary to relate the code to a specific character. Obviously, this is a difficult practice in daily Chinese word-processing work.

In the rational coding system, which is the focus here, each character is represented by a type of component combination that can be decomposed from the character be phonological or orthographical element (i.e. initials, finals, strokes or components). Users become familiar with the components through both school education, and daily reading and writing, so the rational coding system is easier to learn, remember and use. However, there are coincident codes for different characters, meaning that the users have to choose a target character between a group of characters sharing the same code. See Table 2 for examples.

The rational coding system was designed based on statistical research on the phonological and orthographical features of Chinese characters/words. The system can use either the phonetic or orthographic feature or use both of them to form the code-element set. This set is based on the operator's idea about how many elements should be used, how each character should be decomposed in the these elements, how many coincident codes are acceptable in the system, how many keys on the keyboard should be used, and how the elements should be mapped on the keys. Table 1 show some example features of the Chinese character/word. A great deal of adjustment is needed before the final arrangement is determined.

No matter how perfect the coding system is, the obvious mental load for the user is great. The user must remember the code-element set, the mapping rule between the code elements and keys in addition to possible exceptions. In a general sense, all the coding systems try to release the user's mental workload through using various coding strategies. As seen below, this has been proved very difficult and the only solution seems to be a type of balance between advantages and disadvantages.


Information Flow	Chinese text	⇨	Coding: feature of word	⇨	Coding: key string	⇨	Typing	⇨	Selecting target word	⇨	Program processing	⇨	Internal code text
stage			1		2		3		4		5		

Figure 1. Flowchart of Chinese keyboard inputting (adapted from Chen and Hu 1994).

Table 1. Features of Chinese character shown by character '将'

General features	Detailed features	Example (Simplified, 将)
Phonological(jiang, qiang, yang)	Initials	j, q, y
	finals	iang, ang
	tone	1, 2, 4
Orthographic (将)	strokes (number and relation)	丶,/,丨,丿...(9, separated, attached, or cross)
	components (radicals)	爿,夕,寸 (爿,寸)
	orthographic structure	left-right
Semantic	word-building ability	general (将军), etc.
	entries	more than 40
	grammatical roles	Adverbial (will), etc.
	context	General as noun can be subject
Token frequency (‰)	character	0.85
	component	2.57 (爿), 7.04(夕), 24.12(寸)
	component combination	1.04 (爿-夕), 0.92(爿-寸), 0.92(夕-寸)

3. CODING STRATEGIES IN CHINESE KEYBOARD INPUT

Some of the key issues in developing the CKI system are: What type of features should be used and how should they be selected? What type of mapping relation between feature elements and keys should be used and how should it be defined? What type of rules should be used to form the key element sequence for inputting Chinese characters/words?

The operator of the CKI system has many tasks thereupon. These tasks include: construct the feature set, compute the coincident code, define the code and encoding rules, define codes for common words/characters, determine code length, determine element set and encoding space, distribute features on the keyboard, and develop the human–computer interface.

There have been three stages in the historical process of technical development concerning Chinese coding and inputting strategies, as revealed by three different encoding units: character, word, sentence. During the 1970s, single characters were the main encoding unit for input, but since the 1980s the word was the main encoding unit for input and in the 1990s the sentence has been the main encoding unit for input. Coding strategy often characterized by its emphasizing on a certain encoding unit.

3.1. Single Character as Encoding Unit

3.1.1. Orthographic versus phonological feature coding

Coding systems developed in the early stages were focused on the feature of single characters. For a character, the orthographic features used as the code-element could be either a stroke, an order of strokes from the writing system, a radical component, a component combination or even a structure type (left–right, up–down, embedded) (Han and Ren 1995). Additionally, the system could also use a phonetic feature like initials or finals according to the Chinese Pinyin system (Scheme of the Chinese phonetic alphabet, proposed by the Chinese government in 1958, in which each character is represented by initial and final) for notating Chinese phonologically.

The idea behind this system consists of mapping the elements to keys according to specially designed rules the user must remember to use the coding system. Different operators used different mapping strategies. Some operators based their systems on orthographic features, such as the Biao–Xing–Ma and Wu–Bi–Zi–Xing coding systems, whereas others used phonetic features such as those in the Zi–Ran–Ma and Zhi–Neng ABC coding systems. But most operators use both orthographic and phonological features to balance the advantages and disadvantages between these two types of elements.

3.1.2. Advantages versus disadvantages

The coding system using phonological elements is easy to learn and remember because it is derived from the Pinyin system which most Chinese students learn early in their schooling. In addition, there is almost no memory load for the decomposing the Pinyin of a character. The user only needs to remember the mapping rules between elements and keys. This memory can be transferred to an automatic kinetic combination after a short period of practice. However, the disadvantage for the phonological elements is the inevitable coincident code since only 21 initials (such as zh, ch, sh, etc.), 35 finals (such as -eng, -ang, -ong, etc.), and four tones can be used as elements to encode thousands of characters.

The coding system using orthographic elements has less problem with coincident codes, fewer characters share the same code. This decreases the possibility of choosing target characters from the coincident code group, thereby speeding the typing process. However, the user must remember the code-element set that may be different between different coding systems. The user must also remember the special mapping rules between elements and keys, especially those elements that share the same key since > 100 elements are mapped onto 26 letter keys.

The phonetic coding system has obvious advantages to the orthographic system with respect to ease of learning and use. Because China is such a large country with many dialects, the people from the northern region cannot communicate with those from the south even though they use the same written Chinese system. These dialect differences have actually caused the phonetic system to loss popularity to the orthographic coding system. So the popularization of Manderian (Putonghua) is necessary for the popularization of CKI system.

3.1.3. Typing situations and coding methods

Daily users of the Chinese coding system type in a variety of circumstances, while transcribing dictation, while typing from a written page, or while mentally contemplating prose to be written. The phonological coding system is suitable for typing from dictation or from mental contemplation since the auditory modality is involved in processing phonological information. On the other hand, the orthographic coding system is best suited to typing from a written page since the visual modality is involved in processing this visual information. The users must determine themselves which coding system they prefer. There is always a balance between ease of learning, remembrance and use. They must determine their personal "pros" and "cons". As the idiom says, "there is no free lunch", so there is no perfect coding system that can simultaneously solve all the problems at the character encoding level.

3.2. Word as Encoding Unit

A Chinese word can be one single character or over two characters, compound words. When the compound word is taken as the encoding unit, i.e. use of the component in each character as a code element by the similar coding strategy as single character inputting, the input efficiency improves compared with a single character input. Table 2 shows some codes for different encoding units.

The phonetic coding system normally uses the initial of each character as an element. The orthographic coding system uses the first stroke or component in each character. However, to decrease the likelihood of coincident coding, the other element, such as the last stroke or last character component, is often used.

When using the word as the encoding unit, the code length is shortened, the input is more efficient and timely, and the coincident code is decreased. The word as encoding unit also corresponds to normal thinking and writing. The coding rule, word as encoding unit, is simplified, therefore, decreasing the mental load during input and lessening the error rate. However, the word as encoding unit cannot completely replace character inputting since most single character words have a high token frequency (over 50%) in the language (Wang *et al.* 1986, Liu *et al.* 1990).

3.3. Sentence as Encoding Unit

For the sentence as an encoding unit, Pinyin inputs the whole sentence and the computer transforms it to the orthographic system automatically based on its knowledge database, selecting of words and grammar-matching technology. To system users, his process actually realizes the no coding input of Chinese characters similar to the alphabetic language. This improvement benefits natural language comprehension and automatic translation. However, there is still a need for character or word input performance in daily word-processing for tasks such as typing tables or figures. This means that three types of encoding strategy must compensate each other.

4. DISCUSSION

4.1. Achievement of CKI Research

The role of research on CKI has evolved over the past two decades by solving some of the main problems in CKI. After the initial developments on technical issues such as program and hardware design, the quantitative research has centered on the Chinese

Table 2. Encoding unit, coding strategy, coding system, code and coincidence code in CKI system

Levels	Endocing unit (example)	Coding strategy (example)	Coding system	Decomposing Code	Characters shared the same coincident code
Character (将)	phonology (jiang)	whole syllabification	jiang	jiang	将,江,姜,浆,僵,疆,缰
		reduced syllabification	j, ang	jh	
	orthography (将)	strokes	丶,/, 丨, 丿, 乛, etc.	123451, etc.	将, 奖, etc.
		components	扌, 夕, 寸	jxc	no
word (将军)	phonology (jiangjun)	whole syllabification	jiangjun	jiangjun	no
		reduced syllabification	jiang, jun	jj	将军, 渐渐, 建交, 监禁, 坚决, etc.
	orthography (将军)	strokes	丶,/, 丨, 丶, 乛, ⼀	123167	no
		components	扌, 冖	jn	no
Sentence (将军指挥打仗)	Phonology (jiangjun zhihui dazhang)	Whole syllabification	jiangjun zhihui dazhang	jiangjun zhihui dazhang	将军指挥打仗, 将军只会打仗, 将军智慧打仗
		reduced syllabification	jiang jun zhi hui da zhang	jjzhdz	将军只好打字, etc. in addition to above three sentences
	orthography (将军指挥打仗)	strokes	丶, 丶, ⼀, ⼀, ⼀, 丿	117774	no
		components	扌, 冖, 扌, 扌, 扌, 亻	sntttr	no

Note. Following description is for the situation when character is the encoding unit, but it can also be used to infer the word or sentence.

1. In phonological coding strategy, whole syllabification code is just the same as the decomposing result; In reduced syllabification, letter 'j' and 'h' correspondent with initial 'j' and final 'iang' respectively.

2. In orthographic coding strategy, stroke '丶', '/', '丨', '丿', '乛', '⼀' correspondent with number '1', '2', '3', '4', '5', '6', '7' respectively; while component '扌, 夕, 寸' correspondent with 'j, x, and c' respectively because of phonological similarity (phonological mapping). Orthographical similarity (orthographic mapping) is shown by mapping '冖' to n. Note that the same code shared by characters '将, 奖' since they have same radical and first stroke.

characters as well as researches on the modern Chinese language. The statistical distribution of orthographic and phonological features elucidated by these researches, has guided operators in their selection of the code element set for their system.

Recent achievements in database technology, programming and CKI itself have eliminated the need for handwriting innumerable cards for sorting and memory in developing CKI system. Presently the computerized listing of internal code brings simplicity, efficiency and precision to the system. The evaluation index of the system is placed on the user's ability to learn and remember the code elements and keys. No longer is the standard unit of measure the simple velocity and coincident code input. It is essential that the user always be foremost in the operators' mind.

Generally speaking, inputting Chinese is not so difficult as before due to the research achievement on simplification, reforming, and technology of hardware and software. Users of early CKI systems have to stand most of the memory and coding workload by themselves. Most of the workload has been transferred to computer right now.

The inputting efficiency of Chinese text by keyboard coding is ~1.5 times higher than that of English text. This stems from the fact that the Chinese character or word has higher entropy value and lower redundancy than alphabetic languages. In addition, there is the ability to use reflexable combinations of characters to form words in different contexts. However, there is still a problem for the general population because of economic issues and dialect differences.

The development of CKI in past two decades is concurrent with the development of statistic research on Chinese, while the issuing of related standards produced reliable basis for the future research (Han and Luo 1999). The developing trends of the CKI encoding system can be summarized as based on a single character, an emphasis on words and an intelligent processing of sentences as future trend. Intelligent processing is regarded as the main stream of the future since it can release most of the users' mental workload for inputting Chinese.

4.2. International Communication

Issues concerning CKI (history, theory, application, achievements, technology) have seldom been presented in international journals. Even some fundamental concepts can be new to foreign colleagues. Reference retrieving in January 1999 revealed this. No match item came out when using "Chinese keyboard input" as keywords through WebSPIRS (includes PsyINFO 1967–98 and MEDLINE EXPRESS [R] 1966–98), Social Sciences Index (1989–98) and WinSPIRS 2.0 (includes ERIC 1966–98, Psyndex plus 1977–98, PSYNDEX plus Tests 1945–97, LLBA Disc 1973–98, Education Index 1983–98 and PsycLIT 1887–98) in several libraries in Stockholm.

There are two papers among the few match items retrieved keywords as "China and ergonomics" or "Chinese and computer" related to CKI directly. Ong and Shahnavaz (1987) introduced some basic statement of CKI with five short paragraphs. Kang and Boon (1987) discussed something about Chinese computing

input methodology and proposed an experimental design. Meanwhile, CKI is also a new field to Chinese ergonomists (Wang 1990, 1993)

It is an ongoing tough process for Chinese researchers to make their language fitable to computer and easy to handle in daily information processing work, although several key technical issues have been solved. Since some issues, such as the human–computer interface, remain challenging and in need of further research, international communication can be helpful to overcome the remain difficulties. The research achievements of Chinese and foreign colleagues in Ergonomics need better communication. Relevant research concerns, especially ergonomic issues, need international communication and consideration. This in a task not only for the Chinese academic field, but also for the international community which can easily exchange information with respect to scientific, economic and cultural issues.

Convergence of Telephony, Television and Computing in the Home

A. M. Lund

U S WEST Advanced Technologies, 4001 Discovery Drive, Boulder, CO 80303, USA

1. INTRODUCTION

Nearly all US homes have one or more televisions and telephones. Most have cable or satellite access to television programming. About one-half of US homes have personal computers, and almost one-half of those have access to the Internet. While penetration of personal computers into the home has slowed, it is continuing and it is expected to increase even more as easier to use information devices and computers priced closer to entertainment systems become available. A recent survey of Web use (www.gvu.gatech.edu) suggests that the demographics of Web users continue to converge on the demographics of the US population in general. When the number of people who have access to the Internet from outside the home is combined with these figures, it becomes clear that telephony, television and computing can be treated as almost ubiquitous in the experience of most people. Future experience, however, will probably be shaped at least as much by the evolution and convergence of the technologies that lie behind the three media and the impact of that evolution on the design of new applications.

2. MEDIA USE IN THE HOME

The default location in the USA for the telephone is usually the kitchen. The kitchen plays a key role in the organization of the home. The kitchen is in use much of the day for food preparation and often for eating, and therefore functions such as scheduling activities, messaging among members of the family and other communication with family, friends, organizations and businesses become associated with the kitchen. The telephone fits well into this environment, and the most feature-rich telephone in the house is often seen in the kitchen. Recently, cordless telephones that allow conversation while other tasks are being performed have been attractive to consumers. Telephony features that support the effective management of communications such as minimizing unwanted interruptions are also popular. When a new telephone is purchased a useful older telephone typically migrates elsewhere in the house. The fastest growing area of telephony is wireless (e.g. cellular and PCS phones, and pagers), and when users leave home wireless technologies often serve as an extension of the home communications environment.

The main television in the home tends to be located in one of the common living areas (with 75% of television viewing taking place in the living/family room or dining area). The default location of the television is driven by the need for a shared entertainment space, where interaction with the entertainment tends to be passive (Logan *et al*. 1995). Viewing usually happens during the week after 17:00 hours (although weekend viewing is relatively higher during the day). Of viewing, 60% is with other family members and 6% is with friends. Interestingly, while ~40%

of a person's free time is spent watching television almost two-thirds of the time television is being watched people report doing something else as well (Kubey and Csikszentmihalyi 1990). The properties of being a largely passive medium and viewable from a distance are what support the social functions of television viewing as well as the ability to use viewing time in a variety of ways.

The general-purpose, personal computer has been relatively expensive until recently and is most typically associated with a 'home office'. The home office may be something as simple as a desk near the family room or in the kitchen. The computer is generally purchased for telework or homework, but once installed its interactive entertainment role becomes one of its most frequent functions. Word processors and spreadsheets account for most software sales; entertainment applications are the next most popular purchases (and growing quickly); and home education programs are the next most frequent purchases. As the cost of entry-level computers approaches the cost of entertainment systems more families will be able to justify the purchase simply for entertainment and educational reasons.

Recent statistics suggest that Internet usage is cutting into television watching and sleeping, with ~37% of active Web users reporting watching less television than before they had access to the Internet. Nevertheless, Web usage is still more likely to range between 2 and 10 h per week compared with 10–20 h per week for television watching. E-mail and other forms of electronic communication are currently the most popular use of the Internet. A recent longitudinal study of on-line computer users, however, has found some evidence that communication within households and the size of users' social circles may decrease with Web use, with attendant increases in depression and loneliness (Kraut *et al*. 1998, homenet.andrew.cmu.edu). These findings have reinvigorated a long-standing debate concerning the social and psychological impact of computers in the home, reminiscent of a similar debate about television that took place in the 1950s.

3. TECHNOLOGY TRENDS

One way of looking at the trend that is leading to the convergence of telephony, television and computing is that it is based on the digital conversion of information to a common form (packetized data). The digitized information is being made available to an increasing variety of devices and applications through an evolving, ubiquitous network of networks. The technological barriers to creating applications that are designed to satisfy user needs and desires more effectively are rapidly falling. These trends primarily represent improvements in networking, in access to the networks and in the interfaces that people use to interact with the applications.

3.1. Networking

The principal technologies for building the networks that carry information can be divided into wired and wireless. The wired networks are typically fiber-based, and they support two-way communication with essentially unlimited bandwidth. New records for the amount of information that can be carried in a fiber are set on a regular basis. Increasingly, information and conversations will be moved in packets rather than depending on circuit-switched connections. Problems with network congestion and managing networks whose growth is accelerating

and whose capacity is unbounded are being addressed. Satellite is expected to be the most important wireless networking technology for covering broad geographic areas. Currently, the satellites are at high altitude but a variety of low altitude satellite data networks are likely in the future. The future will also see significant growth in wired and wireless networks within the home, with the opportunities for new applications such networks will bring.

3.2. Access

People access the public networks to exchange digital information using technologies such as analogue and ISDN modems, and increasingly they are using digital subscriber loop and cable modems. The bandwidths currently associated with several of these access technologies are shown in Table 1. As a comparison, it takes 1.5 Mb.s^{-1} to deliver a VCR-quality video using MPEG-2 compression today. Video of the type used for desktop video conferencing applications should have ~384 Kb.s^{-1} available for natural video that is free of artifacts and that supports enough detail to allow real-time recognition of expression. Stereo audio at CD quality requires 1.4 Mb.s^{-1}, although near-CD quality audio can be provided with 256 Kb.s^{-1}. Audio at the level used by the telephone system today and AM radio quality audio is carried at 64 Kb.s^{-1} (although with compression good quality speech can be provided at considerably lower rates). As compression technologies continue to improve higher quality will be available at lower speeds.

The wireless access technologies include satellite and the radio spectrum used by devices such as cellular phones and pagers. Satellite networks have the advantage of coverage and the ability to deliver a great deal of information quickly. Their disadvantages include the bandwidth that is available for the typical user to send data, and limits on real-time interaction. In other words, satellite networks are best for supporting broadcast-oriented content (whether video, audio, images or information) with limited interactivity. The radio spectrum used by cellular phones and pagers (and more recently PCS phones and wireless modems) tends to support relatively lower bandwidths compared with alternative technologies, but it lends itself to applications for mobile users particularly well. Efforts continue to find ways to increase the wireless bandwidth between mobile devices and networks (e.g. to support video more effectively). New ways of integrating wireless with wired applications are also being created.

The wired access technologies include the twisted pair copper that connects virtually all homes to telephone networks and the coax used to connect the majority of homes to cable networks.

Table 1. Examples of bandwidths available today

Technology	Bandwidth from the user (Kb s^{-1})	Bandwidth to the user (Kb s^{-1})
Satellite	28	400 Kb s^{-1}–30Mb.s^{-1}
Radio (e.g. CDPD)	9.6	9.6
Analogue modem	56	56
ISDN	128 (2b-channels)	128 (2b-channels)
ADSL — distance-dependent	16–800	256 Kb s^{-1}–8Mb.s^{-1}
Cable modem — load-dependent	20–200	300 Kb.s^{-1} –8 Mb.s^{-1} (10 Mb.s^{-1} single user)

Analogue modems connected to the telephone lines are supporting greater data speeds over the telephone network and can be multiplexed to boost the bandwidth available. However, it is the introduction of digital subscriber loop (DSL) and cable modem technologies that is promising to enable the convergence of telephony, television and computing. DSL and cable modem technologies provide bandwidth that allows channels for information and communication to be continuously available, and it allows synergies between the media to be exploited for new applications. It also allows hardware and software at the users location to be enhanced with the capabilities enabled by servers and processors on networks, making the location of those servers and processors essentially irrelevant.

3.3. Interface Technologies

Moore's Law (Moore 1996) predicts that the number of transistors on a microchip will double every 1.5 years. This prediction has described the evolution of traditional computers well and appears true for the near future. It has been predicted that at this rate computers will surpass the processing power of the human brain by 2047 (Bell and Gray 1997). The evolution of other components (e.g. memory) has developed with similar speed. As information and communication are converted to data, and the components inside the devices that provide the interfaces for interacting with the data become smaller, faster and cheaper, the variety of forms these devices take and the applications they support should explode.

Telephones will essentially become network computers and will be capable of receiving information from the Web and sending messages. Televisions will increasingly be used for accessing information on the Web, checking e-mail and voice mail, and managing calls (e.g. seeing who is calling during a program and sending calls to a voice mail system). Computers will receive video, and will be used to view background information associated with a given point in a video stream. Computers already support many functions that in the past have been associated with high-end telephones.

Behind the functionality that is moving across platforms, however, is the fact that inside each of the devices is, in essence, a computer that is linked to a network. Increasingly, each has a display and the resolution of the displays is improving. Each increasingly has a processor and memory; and each has some kind of an interface for entering data (including commands). Whether a given small hand-held device should be classified as a telephone, an entertainment device or a computer can be ambiguous. The cellular phone may also function as an information retrieval device or as a vehicle for receiving broadcast radio; and a child's necklace may be designed to allow a parent to track a child, send distress signals and receive messages from home. The applications supported by the devices and their interfaces will be shaped more by the users' needs and relatively less by the limitations of the technologies available for building the devices. The applications may be synchronous or asynchronous and increasingly they will be mobile. The trend of moving from a primarily mass-market approach to designing and delivering customized and customizable applications should continue.

It is unlikely that telephony, television and computers will disappear. The functionality that crosses the traditional

boundaries of the media will be successful only if it complements the ways in which people use the media. For the foreseeable future, there will be a large screen, largely passive, entertainment device in the shared living area that will have the label "television". "Largely passive" means that while functions such as interactive entertainment, information retrieval and communications will be supported, the value of the device most of the time will be as a shared and sometimes private entertainment experience.

Even though a variety of new computing devices will be available to support specific tasks in the home, it is reasonable to expect that in near future there will continue to be a higher-end general purpose computing device in the home. It will be used for homework, work-at-home (including communications associated with work) and home management functions, even if the device is used in the evening for interactive entertainment. Producers of content intended to be delivered over the television will continue to try to create a feeling of presence to touch the heart. Producers of content that is largely intended to be delivered to a personal information retrieval device like a workstation will be successful when the content is information rich.

Finally, there will be a device whose primary purpose is to be the communications center for the household. The communications center's role, however, may include accessing directory information pulled from the Internet, checking on the weather, accessing a family calendar and sending and receiving messages. The functionality of all communications devices will increase and it will be possible to communicate and get needed information from wherever one is and whenever it is needed. Nevertheless, the communications center's role will be to help make management of the home and family easier and more efficient.

4. IMPLICATIONS

4.1. Design

The domains of user interface design for telecommunications, computing and entertainment have been quite separate in the past, and each culture has been unique. For example, the software industry has been heavily influenced by methodologies that involve deploying products that may not be "perfect" and then correcting the imperfections based on feedback from the field. The telecommunications industry has had a history rooted in the old Bell System where a product was not released unless it met a high criterion for quality. Both the software industry and the telecommunications industry, however, are used to an iterative design process in which an incomplete design is gradually improved and developed through customer feedback. The entertainment industry has been based more on the culture of the artist in which feedback is not obtained until the design is largely complete. Entertainment applications are designed to provide a specific experience rather than to meet a list of requirements. Increasingly, user interface professionals will need to become familiar with the design issues and techniques in the three domains and will need to draw on their diverse methodologies and strengths.

While many of the design principles that apply to applications emerging from converging technologies apply across domains, the technologies are evolving so quickly that it may not be clear how to apply a specific guideline. Principles of layout, for example, may guide user attention to appropriate information in

each case, but color choices for appropriate contrast may differ between televisions and computer monitors. When designs increasingly involve realistic images and multimedia, guidelines about using colors in an interface may need to be redefined to be less technology-dependent and to be driven more by the properties of human perception and attention.

An additional challenge arises as the technologies converge. A given application can be accessed through a variety of devices, and designers may therefore have to create several interfaces that are both compatible with each other and also are customized for the devices and for the context of use. For example, a grocery shopping application accessed through a computer might be information intensive and allow a comparison of products based on nutritional value and cost per gram; and might support a recipe sharing bulletin board. The grocery shopping application accessed through a screen telephone might provide an easy way to place the weekly order for staples such as milk, bread and cereal. Finally, the shopping application accessed through the television might allow users to view a variety of dining experiences (e.g. a romantic evening for two or a birthday party), and then to order everything required to duplicate the experience.

4.2. Methodology

The convergence of these media requires a more complete understanding of the user and an understanding of the user in new contexts such as the home. The traditional task analysis that precedes design in industrial settings does not capture the complexity of many of the new environments in which applications based on the converging technologies will be used. In addition to methodologies designed to improve usability by reducing errors and improving efficiency, it is important to assess whether a given application supports the needs for which it was designed. It is important to determine whether the application fits the context of use. It may be important to assess aesthetic and emotional aspects of the interface. The issue of whether an interface is compelling is new to a field that has long worked hard at making the interface "disappear" for users. Thus, design for converging technologies more than ever will increasingly require a collaboration of traditional human factors and behavioral science expertise, design expertise, expertise in assessing user needs as a function of context (e.g. ethnography) and expertise in shaping a product to be desirable to users.

4.3. Standards

Technology is changing so rapidly that it is difficult for formal standards and the research that should drive the standards to match the pace of evolution. Many design standards, therefore, will evolve as *de facto* standards driven by successful designs in the marketplace and the marketing power of manufacturers. The touch-tone pad on the telephone and the IBM-style keyboard are two examples of the impact interface standards can have on application development. With appropriate standards, a wider range of people will benefit from converging technologies and they will experience the benefit sooner.

An increasing number of standards bodies are directly or indirectly addressing user interface issues in the convergence of television, telecommunications and computing. The Information Infrastructure Standards Panel (ISSP; www.ansi.org/public/iisp), for example, is attempting to identify all the standards activities

that are needed to support the evolution of a Global Information Infrastructure and to identify organizations to create those standards. Many of the issues that have been submitted to ISSP address technology convergence. The Human Factors and Ergonomics Society's ANSI-200 committee is writing standards for software interfaces. While originally the focus was on text and graphical interfaces, more recently speech interfaces have been included and standardization has been taking place with an eye towards emerging multimedia applications. The International Telecommunication Union ITU-T committee is the body developing telephony standards (www.itu.ch). But even here the working groups increasingly have been identifying and working on issues associated with new forms of communications and multimedia information.

Industry standardization activities include the Advanced Television Enhancement Forum work on the future of television and its relationship to the Internet (www.atvef.com). Standards to integrate telephony and computing (including emerging set-top boxes for televisions) include the Telephony Application Programming Interface (TAPI) defined by Microsoft and Intel, and the new JTAPI (Java-TAPI) standard developed by Sun, IBM, Lucent, Intel, Nortel and Novell. The goal of the JTAPI effort is to create an object-oriented application–programming interface (API) that allows applications to be ported across multiple platforms. While these and the many other standards bodies are often involved in the definition of technical standards, the specific

decisions made can impact the flexibility interface designers have in designing interfaces. As a result, it is important to influence the standards to reflect the needs of users, anticipating the applications that will arise from converging media.

Cross-cultural Issues in Human–Computer Interaction

Y.-Y. Choong

GE Information Services, Inc., 100 Edison Park Drive, Gaithersburg, MD 20878, USA

1. INTRODUCTION

As businesses become more international and global oriented, a large percentage of computer software developed in one country is being exported to other countries. For example, in the USA, about one-half of all software products developed by US companies are sold overseas. Human–computer interaction designers are faced with the challenges of insuring that their products are with the same level of usability and quality in foreign countries as in the country where the products are originally designed. Many companies have expanded their marketing and usability efforts to understand the new cross-culture user requirements in the vastly growing global market.

This chapter provides an overview of the design issues involved in cross-culture human–computer interaction, as well as some interface design guidelines for international users.

2. THE WORLD IS DIFFERENT

When conducting cross-culture studies, it is most obvious, though not enough, to examine the differences in the language, orthography, symbols, images and number formats used by people with different cultural backgrounds. Culture is defined as "the total pattern of human behavior and its products embodied in thought, speech, action, and artifacts, and dependent upon man's capacity for learning and transmitting knowledge to succeeding generations through the use of tools, language, and systems of abstract thought". People from around the world may be different in their appearance, perception, cognition, and style of thinking. They may hold different cultural assumptions and values. They may view the world differently and they may have very different customs that make people of a specific culture unique and distinctive from people of other cultures. To consider designing computer interfaces for international users, it is important to study cultural traits of different cultures in a more profound fashion other than simply language or symbol translation.

2.1. National Languages

Language is a key to meaningful communication among people. The communication will be most effective when the first languages or "mother tongues" of the peoples of the world are used. There are between 3000 and 4000 spoken languages, with numbers ranging from many millions of speakers down to a few dozen or even fewer. There are hundreds of different written languages in use around the world.

2.1.1. Scripts

Scripts are a collection of characters and glyphs that represent a written version of a spoken language. In many cases, a single script may serve to write tens or even hundreds of languages; for

Table 1. Popular Scripts in the World

Script	Country
Roman	English and other European languages
Chinese characters	China, Japan, and other Asian countries
Cyrillic	Russia and Eastern Europe
Arabic	Middle East
Kana	Japan
Devanagari	India
Korean	Korea
Bengali	India
Thai	Thailand
Telugu	India

example, the Latin scripts. In other cases, only one language uses a particular script; for example, Hangul, which is used only for the Korean language. The writing systems for some languages may also use more than one script; for example, Japanese makes use of the Han (or Kanji), Hiragana, and Katakana scripts.

In Table 1, it shows examples of some popular scripts and the countries where the scripts are used (Fernandes 1995).

2.1.2. Directionality

Written language can be bi- or unidirectional. Most languages are unidirectional. For example, English; it is written from left to right in a unidirectional fashion. Chinese is another example of unidirectional scripts, but the direction can be left to right, right to left, or top to bottom. A bidirectional script, such as Arabic, can be written from right to left and left to right (in certain situations, such as numbers) in the same context.

2.1.3. Collation sequence

Collation sequence is the sorting order that people prefer using a particular written language. It should be noted that even in languages that use the same script, the collation sequences might vary. For example, in Finnish, A is the first letter but Å comes after Z; in French, Å comes after A. Far-Eastern languages like Han (or Kanji) have ideographic characters that represent concepts. The western alphabetic notion of collation does not apply for scripts like Kanji. There are three different ways of sorting Kanji characters: by radicals, by strokes, and by phonetic order. Often, a combination of the sort orders is used: by strokes within radicals, or by radicals within strokes.

2.2. Cultural Issues

As discussed previously, culture consists in patterned ways of thinking, feeling and reacting, acquired and transmitted mainly by symbols, constituting the distinctive achievements of human groups. The essential core of culture consists of traditional ideas and especially their attached values. Different human groups can be different in their cognitive characteristics, in their surrounding societies, and may carry various cultural biases. When designing for cross-culture HCI, all these cultural-related issues will greatly affect the effectiveness of the design if the issues are not taken into account carefully.

2.2.1. Cognitive styles

The ways of thinking vary from culture to culture. For example, the Americans tend to classify things on the basis of functions, while the Chinese tend to group things based on their interrelationships and thematic relationships. The American way

of thinking tends to be analytic, abstract, and imaginative or beyond the realm of the immediately apprehended. The Chinese way of thinking tends to be synthetic, concrete and remains on the periphery of the visible world. In a recent study, it was reported that the Chinese users performed better when the computer system had concrete representation and the user interface was structured in a thematic fashion, in comparison with using a system with abstract representation and functional interface structure (Choong 1998).

2.2.2. Color coding and affect

There is no difference for the perception or coding of colors among people since there are common physiological bases for color vision. However, while color vision is universal, what people feel about color is definitely more subject to cultural variation. Color associations with various concepts or conditions revealed different population stereotypes due to cultural variation. For example, in the USA, it is very common to associate *red* with *stop* or *danger*, *yellow* with *caution*, and *green* with *go*. In Japan, *red* is usually associated with *anger*, *yellow* with *grace* or *nobility*, and *green* with *future* or *energy*. In France, *red* may mean *aristocracy*, and *green* means *criminality*; yet in Egypt, *green* could mean *fertility* or *strength* and *yellow* mean *happiness* or *prosperity*.

2.2.3. Cultural patterns

Human behaviors can be greatly influenced by their social patterns. One of the major dimensions of cultural variation is individualism and collectivism. Individualism pertains to societies in which the ties between individuals are loose. People are expected to look after themselves and their immediately family. Its opposite, Collectivism, pertains to societies in which people from birth onwards are integrated into strong, cohesive in-groups, which throughout people's lifetime continue to protect them in exchange unquestioning loyalty. Examples of countries that value individualism include USA, Canada, France and Germany. Examples of countries that value collectivism include Japan, Korea, Mexico and Costa Rica.

The cultural patterns will sometimes have impacts on computer system usage and evaluation. As pointed out by Ito and Nakakoji (1996), the collective nature of Japanese culture has impacted their use of groupware, especially group decision-supporting systems. Individual workers' contributions to the company are appreciated as teamwork, not as individual contribution, even if a single individual has come up with a really good idea. Individuals do not want to be recognized among the others. This makes it important to keep anonymity in using groupware since Japanese users would not speak up or object to any opinions especially when their bosses were present.

2.2.4. Cultural biases

There are four major components defining a specific culture: values, rituals, heroes and symbols. These components are built one on top of the other.

Values represent a culture's belief about what's right or wrong, what's good or bad, and what's proper and improper. Issues such as gender, race, formality, hierarchy and family values can have great impacts on cross-culture HCI design if not taken into account carefully. For example, some cultures would find images depicting such common things in the US as women in senior executive roles as offensive.

Rituals are established procedures taken by people that often reflect a culture's value. Rituals include mannerism, work ethic, political processes, problem-solving processes, and religion. User interface designers often develop metaphors from rituals based on their own cultural backgrounds that could be problematic when deigning cross-culturally. For example, some American products use terminology or concepts such as the "penalty box" from hockey and being "at bat" from baseball that could be totally unheard of by people in other countries.

Heroes in a specific culture often represent an idea or are valued for their talent in one of the cultural rituals. Heroes can be real or fictitious. When products with cultural-specific heroes or icons of this type embedded, they are prone to misunderstanding and misinterpretation for cross-culture HCI.

Symbols can represent positive messages of national identity, good luck and many other beliefs. Symbols can also represent negative messages such as death, bad luck, or threat. Even the same symbols may mean different things in different cultures, for example, hand gestures. Some American products utilize the "thumb-up" hand gesture to represent "OK" or "Good". However, the same "thumb-up" gesture is used to insult people in Australia. When designing for international users, be sure to use internationally accepted symbols and avoid using taboos in icons, logos, sound effects or clipart.

3. DESIGN FOR CROSS-CULTURE HUMAN–COMPUTER INTERACTION

3.1. Input and Output Devices

When designing for the users in different cultural contexts, it is the designers' responsibility to make sure that the products provide adequate input and output mechanisms.

The most common text input device is keyboard. Keyboard layouts vary throughout the world. The layout used in the USA is called QWERTY. Germany uses a QWERTZ layout and France uses an AZERTY keyboard. For Asian languages such as Chinese, Japanese and Korean, some input-method-editors (IME) need to be introduced to make text entry possible with the Western keyboards. There are other text-input devices available such as handwriting recognition devices and speech recognition devices. These alternative approaches are especially promising for Asian languages users due to the difficulties they have experienced using the Western keyboards for text input.

An international product must be able to provide the appropriate scripts used in the target cultures in all user output formats such as displaying or printing.

3.2. User Interface

From our discussions on the cultural-related differences from around the world, there are some components of the user interface that need to be considered when designing cross-culturally.

3.2.1. Language issues

As discussed above, people are using difference languages around the world. Often times, there are dialect differences within the same language used in different locales; including spelling, word usage, grammar and pronunciation. Cross-culture HCI design will also need to take into account physical language variations such as directionality, hyphenation, stressing, fonts, sizes, orientation, layouts, spaces, wrapping, and justification. The

various sort orders are also imperative factors for effective cross-culture interface design.

There are some key linguistic differences that need to be considered when translating the user interface form one language to another. Adequate screen space needs to be allocated for possible text expansion due to translation. For example, German words are usually longer than their counterpart English words. Composite messages should be avoided, such as warnings with a word or words dynamically determined. The composite messages will not be translated well since sentence structures could vary dramatically across cultures. The rules for word wrapping may also be very different from one language to another.

Sometimes, it is essential to support multiple languages simultaneously. It should be avoided using national flags to toggle among languages or using words in one language for selecting among languages. Using national flags for language selection may be offensive to some users since there are often times more than one country using the language. For example, English is used in the US, UK, Canada and many other countries. Using one language for language selection is also inappropriate since the users will have to know that language to make the selection. For example, in an English user interface, a Chinese user will have problem in picking out the Chinese from a selection list consisting of language options written in English if he or she does not understand English.

3.2.2. Format conventions

Formats are an artifact and are specific to different locales. Numeric values can be represented in different ways. Separators are not always used. And, even they are used, different locales are using different symbols for separators and with different formats. For the same number, "1,234.56" is used in the US, Canada; whereas "1.234,56" is used in Germany, Holland and Italy; and "1 234,56" is used in France and Sweden. The numeric glyph shapes can be different as well.

Other format conventions that need to be taken into account include currency, calendars, date and time formats, names and addresses, and telephone numbers.

3.2.3. Cultural references

Cultural-specific references should be avoided for they are prone to misunderstanding and misinterpretation cross-culturally. Visual and verbal puns should not be used since they won't be translated well. For example, a very popular icon with a "light bulb" is used to represent "bright idea" in the USA. However, to the rest of the world, it might merely mean a "light bulb" after all. Another example is the use of a US mailbox to represent electronic mails. Interface designers cannot make any assumptions about what people will look at and understand as a mailbox. Mailboxes have very different looks in other parts of the world. A better alternative for representing electronic mails is probably to use an envelope that is more recognized around the world.

3.2.4. Symbols and taboos

As discussed above, the designers for cross-culture HCI should stay alert with any potential political, religious or other symbolism which may affect the meanings perceived in a particular country. Though it should be avoided using human body language, extra care needs to be practiced if any human body language is introduced into the user interface. The designers should try to use internationally acceptable symbols wherever possible, and allow for localization where necessary.

3.3. International Usability Testing

Usability testing with real users is the most fundamental usability method that provides direct information about how people interact with computers and what problems they experience with the system being tested. The importance of usability testing becomes more prominent with cross-culture HCI since there may be many more unforeseen problems in the interface due to national and cultural issues.

There are some key points to consider when planning for an international usability testing. The first step is to pick a target locale. Pick a city in the specific locale that you have a contact, that has many representative users, and that can provide you an adequate test site.

The second step is to determine what equipment you will need for the testing such as audio, video, logging software, etc. It is better if the equipment is available onsite; otherwise, use highly portable equipment with adequate plugs and voltage converters.

The third step is to recruit target users for testing. Most likely, someone other than you will be doing the recruiting task since the target users may speak a different language. Make sure criteria for recruiting the users are developed and well explained to the recruiter.

The preparation is keen to the success of the test. Care must be given prior to leaving for the target locale since international traveling can be expensive and time-consuming. If a foreign language is involved, an interpreter needs to be arranged. Often times, since the interpreters are not trained usability professionals, they can interfere by giving users advice, thinking that they are being helpful. You need to make sure enough time is allocated before the test for you and the interpreter to go through the usability testing process in details.

The last step is to analyze and to report the results. Make sure you go over the data collected right after each session with the interpreter since it will be costly if you need to contact the interpreter after you come back from the test site. In reporting the results, you will need to refer both to usability problems experienced by the participants and to issues you observed yourself while preparing for the test (Nielsen 1996).

4. CONCLUSION

As the computer technology becomes more globally accessible, how to effectively design for the cross-culture HCI becomes greater challenges to the designers. The designers will need to acknowledge the cultural related differences among users for whom the systems are designed. The designers will also need to take into account all issues involved when planning the design for international users. International usability testing is irreplaceable for the success of delivering a usable product for cross-culture use.

Cultural Aspects of User Interface Acceptance

D.L. DAY

Computer & Information Sciences Department, Towson University, Towson, MD 21252 USA

1. INTRODUCTION

In a 1980 film classic, *The Gods Must Be Crazy*, a bushman in the Kalahari Desert is bombarded by an empty Coke bottle thrown overboard from a private plane. To the bushman, the bottle represents a totally alien technology. However, he and his extended family assess its properties and soon find productive uses for this artifact. Among other things, it is ideal for rolling out tortilla-like foodstuffs — and for making whistling sounds. Neither use was intended by the creators of the thing, but that is unknown and irrelevant in the bush. But in the end the bushmen reject the bottle despite its usefulness, because this technology becomes a source of conflict among members of the family.

The adaptation of artifacts by one culture that were created in another is instinctual. Culture — the sum of all shared values, practices and expectations of a socially defined group — brings often unique perspectives to the assessment and use of technology. In many cases, e.g. a Coke bottle in Botswana or a personal computer in Mongolia, the peculiar perspectives brought to technology by local culture can profoundly affect the degree to which it is accepted — and, therefore, how it is used. They can also lead to uses for artifacts that were never dreamed of by their creators.

This chapter describes an expanding effort on several continents to understand how cultural factors affect users' acceptance of computerized technology — in particular, computer interfaces. This effort is seen both as it draws upon several contributing disciplines, such as anthropology, and within the context of a widespread attempt to globalize (and localize) computer information systems.

2. THE ANALYSIS OF TECHNOLOGY ACCEPTANCE

User acceptance of technology is a complex concept. Unlike the Kalahari bushman, modern users of technical systems — whether they be automated garage door closers, cellular phones or computers — often have no choice in whether to use a system: they must. Either they depend on such systems for their livelihoods or the intricate fabric of "civilized" society would deteriorate without such devices. This lack of choice complicates acceptance enormously.

Why? First, because peoples' attitudes and perceptions are affected significantly when the obvious option — total rejection — is removed. When forced to use a tool that in their gut they would rather discard (like the Coke bottle), many people not only become less productive or effective: they seek means to vent their frustrations. They unconsciously, in many cases, decide to *make* the technology fail.

The study of technology acceptance is inherently multi-disciplinary because of its psychological, technical, and social context. Often people must adapt to technology rather than adapting it to their needs, including their cultural preferences. Culture is the ultimate context that molds peoples' expectations of technology and their behavior towards it. In a world intent on globalizing computer information systems, the culture brought to the technology experience by individuals inevitably takes on substantial importance.

The very nature of technology acceptance across cultures makes its analysis difficult. Concerns intrinsic to this area include:

- The appropriateness of technology.
- Cognitive decision-making styles versus those implemented by technology.
- Knowledge representation (e.g. semiotics and iconography).
- Social control (e.g. mechanisms and impact).
- Change management and adaptation.
- Globalization and localization standards.
- Technology transfer and diffusion of innovation.
- Interface design techniques or (more broadly) implementation for cross-cultural applications.

The appropriateness of technology is perhaps most critical, because change management and adaptation merely addresses the styles of implementation, once a suitable technology has been selected. Styles of implementation are a moving target, since technology mutates at an ever increasing rate. Principles of appropriateness, however, are based on cultural factors with a much longer timeline.

3. DIFFICULTIES IN ASSESSING CULTURAL ASPECTS OF TECHNOLOGY ACCEPTANCE

Studies of technological fit to task demands and decision making styles are difficult enough within single, somewhat heterogeneous cultures. However, when an attempt is made to evaluate technology acceptance across cultural boundaries, the task is complicated significantly (del Galdo and Nielsen, 1996). The difficulties, however, are mirrored by the potential payoffs, because of the imperative to manufacture goods for a global marketplace.

Given that technology acceptance is human-centered, the identification of representative people for evaluating acceptance factors and behavior is critical. Unfortunately, the modern world of satellite TV, global wire services and offshore manufacturing makes it very difficult to identify people who are largely of one culture versus another. In this work, the cross-national influence of disparate cultures is somewhat indelicately termed "contamination," only because the significant characteristics of one culture naturally meld with those of another, as soon as they come into contact. However, crisply distinct cultures are important methodologically to any research that claims cultural background plays a major role (e.g. in technology acceptance). But the availability of relatively distinct cultures in evaluating technology acceptance relies either on extensive (and expensive) international travel or painstaking segmentation of domestic populations along ethic boundaries.

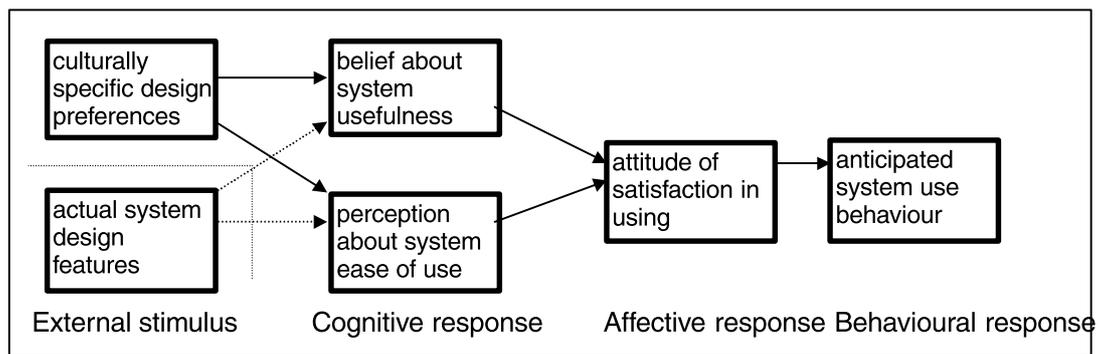
Aside from subject selection, assessing cultural aspects of technology acceptance challenges the types of instruments typically used for such data collection. Most evaluation depends upon language — but language is a major variable between cultures. Therefore, a major issue arises as to whether instruments that seek to gauge technology acceptance should be in the


Figure 1. Modified technology acceptance model (Eves and Day 1997).

respondents' native tongues or in the vernacular of the assessor. Writing instruments in native language obviously increases understanding among respondents, but at the same time reduces methodological control by the assessor.

4. MODELS OF TECHNOLOGY ACCEPTANCE

Although significant work has been done in anthropology and other fields in regard to technology acceptance, its seminal treatment may be the series of articles in the late 1980s and early 1990s by Fred Davis. His work addressed the acceptance of computer systems.

Davis's Technology Acceptance Model (Davis, 1993) proposes that users' beliefs about system usefulness and their perceptions about system ease of use contribute substantially to their attitudes of satisfaction in using a technology, which in turn impacts actual system use behavior. "Usefulness" is essentially effectiveness, whereas "ease of use" is natural facility by the user in application of the technology. Cultural aspects added to Davis's approach in this chapter suggest that culturally specific user expectations (taken largely from anthropology and sociology) and specific styles of system design features (e.g. interface elements) precede and act upon beliefs about usefulness and ease of use. The combined effects are shown in Figure 1, which elaborates Davis's original model.

5. THE SUBSTANTIAL CONTRIBUTION OF ANTHROPOLOGY

"Culture" is a very contentious concept, because of its enormous breadth not only geographically but also over time. Although often considered esoteric and remote, anthropology contributes much to our understanding of man's responses to technologically sophisticated tools. Desmond Morris was not needed to remind societies that man has not changed much socially since soon after he stood upright, as the "naked ape." The basic instincts, interpersonal interactions, feelings and behaviors of men and women may change in application context, but in very fundamental terms the creature acts in accordance with its original design.

That design is the blueprint of culture (Hofstede, 1991), which is imposed in all societies soon after birth and which in some cases overwhelms the influences of family and physical environment. Culture put simply is a set of socially defined, shared values through which the individual's experiences are filtered. The filtering is subconscious in most people, but nonetheless powerful.

Technology acceptance studies have borrowed heavily from anthropology's explanations of man's reactions to his environment. For example, the notion of field dependence (also accepted in disciplines other than anthropology) can be ported to a technological context by anticipating the reactions of individuals to control features in computerized technology. Man inevitably anthropomorphizes his machines, especially those that seem to react to him in some of the same ways that other humans do. In cultures where the opinions of others are considered more important than individual judgement (i.e. field dependent societies), it is reasonable to assume that relatively high degrees of control and correspondingly limited freedom of action with the technology would be acceptable. On the other hand, in field independent societies — those in which individual volition is considered more important — technology users can be expected to resist control by their machines. The stimulus is computerized, but the context of the response is cultural.

Other factors from anthropology that figure significantly in technology acceptance begin with Geert Hofstede's universal cultural variables. These distillations of the human experience and context can be translated directly to anticipated technology acceptance behaviors — because in important ways technology is just another element in the environment to which individuals react. The cultural variables form a program for human behavior that transcends the character of the stimulus. Technology cannot expect to escape their influence.

Hofstede's variables, and others contributed by Edward Hall and Fons Trompenaars, include:
- Uncertainty avoidance: whether uncertainty is perceived as threatening.
- Preference for parallel versus sequential action: to do "more things at once" or "one thing at a time."
- Preference for diffusion versus specificity: whether business and personal relationships are separated clearly.
- Particularism versus universalism: whether behavior is rule-based versus relationship-based.
- Collectivism versus individualism: whether people like to work and make decisions in groups versus alone.
- High context versus low context: whether meaning draws in part from context or instead must be stated explicitly.
- Tendency toward transference: the extent to which a person blames others or one's self when a problem occurs.
- Power distance: the perceived degree of separation between an individual and figures of authority in his or her environment.

Each cultural variable influences the acceptance of technology, to varying degrees. For example, people from a culture that abhors uncertainty will be more comfortable with an unambiguous computer interface. And people from a culture that values group input to decision-making will be more influenced by co-workers in terms of accepting workplace technology. Of course, individuals' behaviors will vary from such generalities. The point is that cultural background predisposes large numbers of people toward widely held attitudes toward tools in the environment, technology included.

Base cultural variables may influence interface acceptance subtly, over an extended period. However, cultural reactions to technology *implementation* can be immediate. Work largely in industry has demonstrated that target cultures (as opposed to source cultures, where a technology is developed) take immediate notice of many interface features that impact computer use (Taylor, 1992; Hall and Hudson, 1997). These include sorting sequences; number, date, currency and time formats; the connotations of color usage; icon recognition and functionality, and reading direction (left-to-right, right-to-left, top-to-bottom).

6. ADVANCES IN ACCEPTANCE RESEARCH

The intercultural marketing of information technology products is part and parcel of the personal computing and telecommunications revolutions. Software in particular has become an ambassador of its culture of origin, thanks to the Internet and to worldwide standards in computing. This diaspora is accompanied by an accelerating attempt by multinational corporations to market wares in every culture where a buyer has the wherewithal to make purchases. So it is that "globalization" has become a driving concern of business everywhere, whether the product be motorcars, fax machines or computer software.

Software is a special case, however, due to its potential to be customized relatively easily to fit the needs of users — users with differing cultural expectations and experiences. In recognition of this potential, firms such as Intel, Claris, Sun and Microsoft have been evaluating cultural factors in interface acceptance for several years (Fernandes, 1995). Although many of their findings are considered proprietary and therefore not readily available to the public, enough has been published to form a basis for technology acceptance studies. A useful summary of work to date appeared in a review by Jane Carey of Arizona State University, in an early 1998 special issue of *Interacting with Computers* (Day, 1998). In reviewing a handful of books published in this area during the early 1990s, Carey provided a snapshot of efforts to internationalize and localize computer software.

Software that is "globalized" is merely packaged for use outside its culture of origin. Aspects unique to the culture of origin are removed from "internationalized" software, and changes are made to accommodate the specific cultural preferences of target cultures in software that has been "localized." Localization is facilitated by a movement within industry to engineer products in highly modular fashion, separating functionality from representational "resources." This makes it easier to substitute resources that are attuned to target cultures, in place of those used as defaults in cultures of origin.

Advances in technology acceptance research depend not only on product customization efforts by multinational business, but also on basic academic research. In one such study, Vanessa Evers and Donald Day found that the path to acceptance of interfaces in globalized software products varied significantly with users' home cultures (Figure 1).

7. APPROACHING THE BOTTOM LINE

At the beginning of this chapter it was noted that the peculiar perspectives brought to technology by local culture can profoundly affect the degree to which it is accepted — and therefore, how it is used. Users confronted by a technology (e.g. a computer interface) grounded in alien perspectives, with an implementation that is insensitive to local practice and values, inevitably will be less efficient and less effective in the use of that technology. Users certainly can learn to apply such technology, however awkwardly. But, as in all usability engineering, a key objective in developing software products for intercultural use is to minimize training while maximizing ease of use and usefulness. The flowering interest among multinational firms in the cultural preferences of overseas customers is founded upon very practical concerns: recent experience has shown that if they do not adapt interfaces to the needs of their other culture users, local firms rooted in target cultures will (Uren, Howard and Perinotti, 1993).

Describing and Predicting Human Interaction with Technology

N.A. Stanton
C. Baber

1. SUMMARY

In this article, the cognitive ergonomics of using public technology is investigated. A methodology for predicting human error with technology has been developed. Predictions from the method (combined with observation of user performance) form the foundation of the concept of "rewritable routines". This is in keeping with the tradition of building models of user cognition on the basis of observed and predicted errors. The concept is introduced and illustrated with examples. Implications for cognitive ergonomics are discussed.

2. INTRODUCTION

A method for predicting user error in transactions with simple machines has been developed (Baber and Stanton 1994; Stanton and Baber 1996) which is called Task Analysis for Error Identification (TAFEI). This method combines a description of human activity (using hierarchical task analysis) with a description of human–machine interaction (using state–space diagrams). The method has been used to describe and predict human interaction with devices for a variety of tasks such as boiling a kettle, withdrawing money from an automated teller machine, purchasing a rail ticket, recording a television program, and copying music from tape-to-tape. An example of the latter is illustrated in Figure 1, and further details may be found in Baber and Stanton (1994).

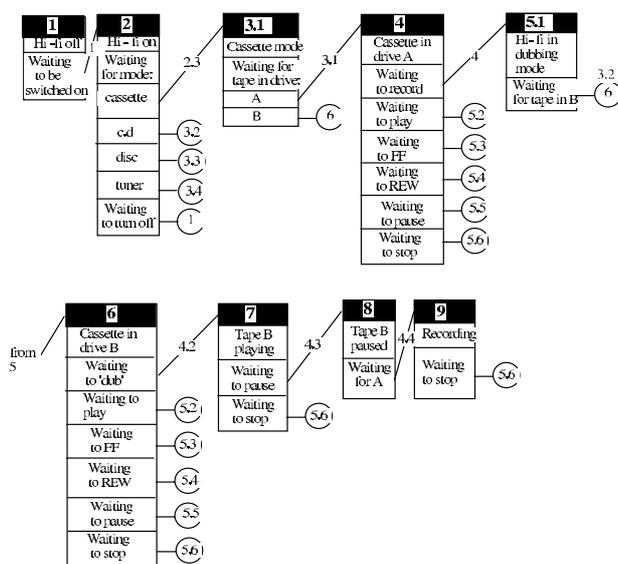
In Figure 1, the TAFEI diagram shows how task activity is mapped onto the device states for the goal of recording music


Figure 1.

tape-to-tape. As the diagram shows, the user does not explicitly press the "record button" to make a recording. This design is contrary to the task requirements for recording from other devices on the same music center. To record from the radio tuner, record player, or compact disc, the user is required to insert a tape into the cassette recorder and depress the play and record button together. The TAFEI approach makes inconsistencies in task structure explicit. This analysis can be useful to designers in helping them to understand why users may find it difficult to comprehend the task requirements. As the concept of recording from one device to another is similar across devices, the actions required of the user should also be similar. If they are different, as in this case, errors are likely to occur. To further understand the power of the analysis methodology, the theoretical basis underpinning user–device interaction are considered within a problem-solving framework.

3. PROBLEM SOLVING AND PUBLIC TECHNOLOGY

TAFEI, like other HCI methods, is based on Newell and Simon's (1972) ideas of movement through a problem space. As people move through the problem space, so they change their knowledge of the problem, acquiring new information and rejecting old hypotheses. Newell and Simon (1972) propose that this problem-solving behavior requires the person to hold current knowledge in short-term memory and goals in long-term memory. Problem solving then involves processes to reduce the gap between current knowledge and goals. This is a form of the means–ends analysis approach to Problem solving. People tend to employ means–ends analysis when they lack expertise to develop more sophisticated strategies. Interaction with public technology is performed on an intermittent basis and people are unlikely to try to reach "expert" level. Thus, we assume that means–ends analysis will be a common feature of such interaction. Further, we assume that while a goal can be reached via a limited number of relevant states, the interface of the machine could present states which appear relevant. In using public technology, the user will attempt to move from current state to the goal via relevant states. This is known in the problem-solving literature as "hill climbing". Actions are selected by comparing the current state with the goal, and the action which looks likely to lead to the goal will be chosen. This means that errors can arise when people reject "correct" actions which do not look as if they will reach the goal, or can perform actions which look as if they will reach the goal.

The notion that Problem solving involves movement through a defined problem space can be contrasted with that of Miller et al. (1960) who viewed Problem solving as a continual adaptation of behavior to a changing environment (in the test–operate–test–exit scheme). Other stances on Problem solving see the use of feedback as paramount in influencing activity, or view planning as largely dependent on environmental cues. Taking these views, we propose the second assumption in this article is that goals are decomposed into state-specific entities; Problem solving then involves generating a routine which will satisfy the immediate goal. TAFEI is based on the assumption that human–machine interaction follows a sequence of states, and at each state users will employ simple sequences of action to move them on to the next state. Thus, planning of action will be relevant only for each state. This assumption is shared with Simon and Young (1988: 591) who

propose "users engage only in simple forms of planning, [and] we can predict certain errors in user behavior due to the characteristics of a particular interface design". Suchman (1987) has also noted that much of human–machine interaction (HMI) is situated in the immediate context of the transaction with plans being developed on an ad hoc basis. It is not difficult to apply these assumptions to the description of HMI proposed by TAFEI. Thus, the first assumption in this article will be that people develop plans which are relevant to the current state in their interaction with a machine. In order for this to work, we need to have some means of defining the relationship between current state and goal state. We term this relationship "relevance".

4. RELEVANCE

The use of public technology is goal directed (Stanton and Baber 1996). This means that there will be a specific end-state of the interaction, e.g. obtaining a valid ticket from a ticket vending machine, withdrawing cash from an automated teller machine, etc. Possession of a goal does not imply possession of plans to achieve that goal. However, the range of possible actions will be constrained by the design of the machine and the user's interpretation of the machine. TAFEI assumes that for each state in human–machine interaction there will be a finite number of following states. The number of states will be limited by the design of the machine and the goals of the user. Furthermore, there will be several states from which a path to the goal can be seen (irrespective of whether such a path is "true"); these states will be termed relevant states.

We assume that users will interpret the relevance of actions in terms of the relationship between the current state and the goal. This is known in the problem-solving literature as "back chaining", where people create sub-goals which are achievable in the current state to allow progression to the goal. This means that the user has to work forward to the goal (to consider possible states) and backward from the goal (to determine relevant states). As Duncan (1993: 63) says, "Thus, the stimulus actually selected for control of behavior is not simply the best match to a pre-existing specification of what is needed in pursuit of a current goal. The goal itself may change; the selected stimulus is the one most relevant to the selected goal." We assume that the user will seek relevant information during the interaction, where relevance is determined by goal definition, machine state, and previous actions. The activity of seeking information is not intended to imply exhaustive search; rather the user will be defining the problem space at each state. Chi *et al*. (1981) demonstrate that problem classification can have a bearing on solution strategy and will vary between novice and expert. We assume that interaction with public technology involves a continuous process of problem classification.

5. REWRITABLE ROUTINES

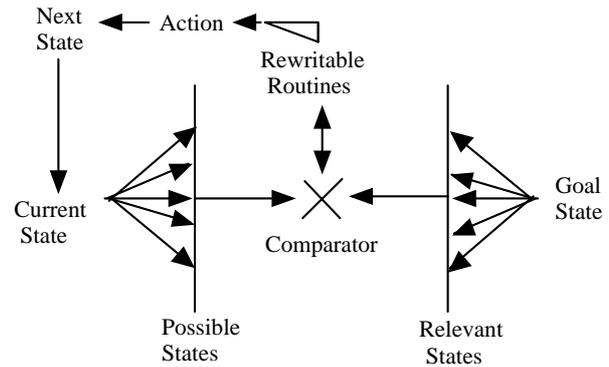
In order to move from current to relevant states, eliminating other possible states, the user needs to retain some record of the interaction and to have some means of assigning relevance to states. At each state, this record will be modified. Thus, it will need to be rewritable. We assume that the record will be held in working memory, presumably in the articulatory loop which has a limited duration. This means that unless the record is updated, it will decay. As the record will also guide the next action, we see


Figure 2.

this as a rewritable routine. To some extent this notion is similar to the 'partial provisional planning' hypothesis of Simon and Young (1988). Figure 2 presents a simple schematic of this process. The possible states (interpreted by the user from the machine) are compared against states which could lead to the goal. The comparator has a two-way connection to the rewritable routines (with the routines both influencing the comparator, i.e. by defining relevance, and taking the output to define action).

Example 1: A Rail Ticket Vending Machine

A number of errors which people make when using a ticket vending machine were observed. Around 80% of these errors could be predicted by TAFEI (Baber and Stanton 1996). The main errors were related to the mode of the machine, i.e "change given", "exact money only", "closed", "waiting". From the observations, people tended to use all machines as if they were in "change given" mode. This suggests that state indication on the machine was sufficiently poor to allow confusion, or that users were only employing some of the information. The machine studied had a wall-mounted LCD one meter above the machine to indicate mode, with a further display on an LED on the machine. From this we see that mode state is indicated. The fact that users missed these indications suggests that the comparator was operating on limited information, either because the users did not see the indicators or because the users took no notice of them. Not seeing the indicators would be a function of conspicuity (and this is certainly a possible explanation). Not noticing the indicators would be a function of relevance; users would hold a definition of relevance in their rewritable routines which would not require the mode indication, e.g. the routine could prompt users to find an available machine (i.e. one with no one waiting); by definition, this could take users to machines which were in states other than "change given" (there might be no one waiting at machines which were not "working" or which were "wait for assistance", and other users might have moved from "exact money" when they realized the mode).

Errors were observed in button use. This could be attributed to slips, with a large number of buttons in close proximity being likely to lead to the wrong button being pressed. While no data was collected on the buttons used, it seems unlikely that slips would account for all of these errors. A possible explanation lies in the fact that the button errors were often attributable to errors in sequence rather than operation. For example, from post-observation interviews, people in London reported having

difficulty in finding particular train and underground (subway) stations because these are listed alphabetically by type. This means that if a user is looking for "Euston", which is a train station, he is unlikely to find it by pressing an "E" key in the list of London Underground stations, and may well select "Embankment" instead. (Similarly, on machines in Birmingham, looking for "New Street" under "N" will not be successful because the station is listed as "Birmingham New Street".) This suggests that users work to a routine which differs from that devised for the machine.

The initial TAFEI study failed to predict a minority of the observed errors. These were "lose place in interaction", "lose ticket exit", "confusion due to options not available". It is proposed that each of these errors can be attributed to the description illustrated in figure 2. If the progression through states is not indicated, then the routine might not be updated appropriately. This would leave the user with a "gap" in the routine. "Lose ticket exit" referred to occasions when users were unable to locate the tray in which the ticket appeared. One explanation of this was that the ticket tray also served as the coin return tray; assuming that coin return and ticket dispensing were separate functions could lead to user seeking the ticket dispenser in another location. "Confused by operations not available" relates current state to users' interpretation of relevance, i.e. users could be seeking information which was either not present or was presented in another form.

Example 2: A Confectionery Vending Machine

In another study, we observed a number of errors which people make when using a confectionery vending machine. Around 70% of these errors could be predicted by novice users of TAFEI. Although purchasing confectionery from a vending machine is a relatively simple task, it is remarkably productive of error. Around 25% of the observed transactions resulted in errors of one form or another. The task required users to complete the following sequence of steps: (i) enter sufficient money to cover the purchase; (ii) check the nomenclature of the item of their choice; (iii) press the relevant number and character on a keypad; (iv) remove the item of confectionery; (v) turn the "change return" handle and collect the change.

The main errors people made were as follows: inserting the wrong money (the machine would only accept coins and would not accept pound coins), pressing the incorrect character or number, failing to turn the "coin return" handle and, consequently, failing to pick up their change. Most errors were associated with the latter two failures. We suspect that the delivery of the chosen item of confectionery, which satisfied the overall goal of the user, served to "close" the routine. If the change had been delivered before, or together with, the confectionery fewer errors of this type would have been observed.

Again, TAFEI failed to predict all the errors that occurred. Typically these errors occurred outside the state-based analysis of human–machine interaction. For example, TAFEI did not predict the occasion when a user attempted to insert a coin in an indent in the surface of the panel which resembled a coin slot. From the notion of relevance, this action could be interpreted as follows: the user sought some part of the machine with characteristics sufficient to satisfy the concept 'coin insertion place', and mistakenly selected an indent. This mistake could be compounded by the fact that a number of vending machines

keep the coin insertion slot covered until the user is intended to insert money, e.g. this is the case in the ticket vending machine.

DISCUSSION

In this article we demonstrate an initial specification for a theory of human-public technology interaction. The theory contains three main concepts:

1. Human–machine interaction with public technology is state-dependent. This means that the amount of preparation and planning conducted prior to the transaction will be limited. Hence, there is little need to read the instructions on machines. Observations have suggested that people tend not to read the instructions, or if they do, only to read part of the instructions. We suggest that the user will seek information regarding action to perform in the initial state, but will not seek information relating to subsequent states until those states are reached.

2. Human–machine interaction with public technology relies on rewritable routines. Users of public technology will plan actions which are relevant to the current state. When the next state is reached, the previous plans will be discarded. We believe that this is why even expert users of graphical-user interfaces are not able to recall the screen layout accurately; not necessarily because the users rely solely on information in the world, but because the planning of activity is focused on sequences of states. This would mean that users would recall only state relevant information (and not other details), and that users would primarily recall state exiting information (i.e. the details which take them from one screen to another). This issue is currently receiving attention in a series of studies.

3. Human–machine interaction with public technology should be designed to support opportunistic planning. Users interpret information from the machine in terms of relevance, and relevance is state-dependent. This means that presenting information too early will either confuse users or will lead to the information being ignored (as in the ticket vending machine example).

The approach taken in this article differs from previous research into public technology. Our concern has been to develop both a theory and method which can allow technology to be evaluated prior to its construction. This approach takes a model of human performance and applies this model through TAFEI. The aim is to have a means by which both user activity, cognition, and errors can be explicitly considered so that a theory of the use of the product can be developed during the early stages of design. This approach contrasts with other approaches which can be applied during the early stages of design, such as cognitive walkthrough. Whereas cognitive walkthrough, like other techniques in the verbal protocol family, requires people to describe and explain their activity; such approaches are not without their critics (Praetorius and Duncan 1988). While cognitive walkthrough may lead to people concentrating on issues of "relevance" (as discussed above), our concern is with the situations where relevance breaks down. This requires a form of investigation which allows us to capture the relationship between cognition and action in the context of human–machine interaction. Such a context is described in the TAFEI diagrams used in our work and is the focus of the analysis. Our research has been directed towards the

theory-led development of a methodology for human error identification. The theory of rewritable routines has helped to inform the development of TAFEI. Through this work gulfs between evaluation and execution may be bridged.

Design of Menus: Choosing Names, Organizations and Selection Devices

K. R. Paap

Department of Psychology, New Mexico State University, Las Cruces, NM 88003, USA

1. INTRODUCTION

A menu can be defined as a set of options, displayed on a screen, where the selection and execution of one (or more) of the options results in a change in the state of the interface. The contents of a single screen will be referred to as a menu panel. Menu panels usually consist of a list of options. The options may consist of words or icons. The word or icon conveys some information about the consequences of selecting that option. When one of the options is selected and executed a system action occurs that usually results in a visual change on the screen. The complete set of options is usually distributed over many different menu panels. This allows the system to prompt the user with options that are likely to be useful and to hide options that are unlikely or illegal. However, layering the options across many menu panels also requires that the user be able to navigate between panels to find options that are not available on the panel currently in view. This brief description of a prototypical menu-driven interface highlights the fundamental issues of menu design that will be discussed. That is, how can designers choose good names for options, how should the options be organized within and between panels, and which selection technique should be implemented.

2. SELECTING NAMES FOR OPTIONS

2.1. Good Names

The name or phrase used to designate each option should be precise and permit the user to infer exactly those actions or objects that are controlled by this selection. It is easy for a designer to mistakenly believe that s/he can intuit the obvious name for a menu option. Furnas *et al.* (1984) determined that when people are asked to name things in a variety of domains (e.g. index words for cooking recipes) the probability of any two people generating the same name or description ranges from 8 to 18% across domains. Experts are no better than others at generating names with high intersubject agreement.

The goodness of a name or phrase is very much determined by the other names appearing on the menu panel. Error rates can increase by 45% when a *miscellaneous* option is added to a menu panel. A vague name like *miscellaneous* will poach selections that would otherwise be attracted to the correct option.

2.2. Adding Descriptors

Most errors in menu-driven systems occur because the meaning of the options is not clear to the user. One method of increasing the clarity is to append an expanded descriptor to each key word or phrase. Lee *et al.* (1984) report a direct comparison between the same set of options with and without descriptors. The descriptors were simply a list of the options that would appear next if a specific option were selected. The menus with descriptors were much preferred and had 82% fewer errors. The results clearly demonstrate that descriptors can be very effective when users have had limited experience with a menu panel that consists of options corresponding to fairly abstract categories. There are, of course, some costs associated with descriptors. Search times are probably somewhat longer and descriptors take up valuable screen space.

2.3. Using Icons

Options can also be represented or supplemented with icons. Icons afford two possible advantages over verbal options. First, if icons replace words as target alternatives, then there are situations in which the display can be searched in parallel and there is no cost associated with having a large number of options on a single panel. Second, even if users are considering one option at a time, categorizations of pictures can be faster than of words. This makes icons sound too good to be true, and owing to some inherent tradeoffs it is, indeed, impossible to reap all of the above benefits at the same time.

When the distinctiveness of an icon is enhanced by using simple figures that vary with respect to features like global shape, size, and orientation; it is likely that the simplification will make the icon more abstract and, thus, more error prone. On the other, more *representational* icons will be scanned sequentially, just like words. Relevant experiments reviewed by Paap and Cooke (1997) led them to conclude that supplementing category labels with icons is equivalent to adding a one-word example.

3. DESIGNING A SINGLE MENU PANEL

3.1. Three Types of Comparison Operations

The first stage of interaction with any menu panel involves the user forming a goal. The user directs his fixation to one of the options and evaluates the option in relation to the goal. If the option does not match the goal, then attention must be redirected and search continues. The best design depends on the type of search and comparison operations that are likely to occur as users consider the contents of the menu panel.

3.1.1. Identity matching

The fastest type of search occurs when users have generated a specific target that is literally displayed as one of the options. When this situation exists, the user can engage in identity matching, that is, the user compares each option to the specific goal held in memory to see if they are identical. This type of matching is fast because a holistic comparison can be made on low-level visual codes. Identity matching is likely to occur when the user knows precisely how the target is presented on the menu. For example, when a user knows that the target *delete* will be listed as *delete* and not as *erase*, *drop*, *zap* or anything else.

The following guidelines apply to the design of a menu panel that is likely to engage identity matching. If the options consist of a set of conventional names and the names also have a conventional order, then list the options in that order. If there is no conventional order and the set of options is small, then list them alphabetically. If the list is long and the list can be subdivided into distinctive categories, then present the options as alphabetized subsets.

3.1.2. Class-inclusion matching

Class-inclusion matching is likely to occur near the top of a hierarchical menu organization. The top panels frequently consist of a list of abstract categories. Users must make judgments about class inclusion, that is, whether the target is an instance of the category specified by an option. For example, is *delete* an instance of the category *editing commands*? Category decisions will be faulty if there is conceptual overlap between the categories and many targets might belong to two or more categories.

3.1.3. Equivalence search

Equivalence search occurs when the user knows what he wants, but does not know what it is called. Sometimes the target for an equivalence match will be formulated as a fairly abstract intention expressed as either a phrase or a possible synonym. Consequently the user cannot rely on a fast holistic identity search, but must engage in a slower semantic analysis of the relationship between the target and each option. The following guidelines apply to the design of a menu panel that is likely to engage equivalence matching. If some selections will be selected with far greater frequency than other selections, then list the options in descending order of frequency. If the options are equally likely to be selected, then list them in meaningful and distinctive categories.

3.2. Search Strategies

The preceding section on types of comparison operations focuses on the type of judgment the user makes when an option is evaluated. This section examines a related issue, namely, the strategies used to determine which options will be evaluated and the order of evaluation.

3.2.1. The search-time function

Search time surely will increase as a function of the total number of options that must be considered, but what is the shape of the function? Norman (1991) and other sources claim that the search time function will usually be logarithmic. The basis for the prediction is the assumption that the Hick–Hyman Law applies when users visually search a menu panel for a specific option. Paap and Cooke review the relevant data and conclude that: (1) one should *not* expect the Hick–Hyman Law to govern visual search for word targets and (2) empirically determined search time functions tend to be more linear than log-linear.

3.2.2. Stopping rule

A search is exhaustive if *all* the options are considered and, in contrast, is self-terminating if the user stops when an acceptable option is found. MacGregor *et al*. (1986) assume that users evaluate each option with respect to both a low- (L) and high-criterion (H). Any evaluation that yields a probability less than L will lead to the permanent rejection of that alternative and continuation of the search. An option that exceeds H will be immediately chosen and produce, by definition, a self-terminating search. Options that exceed L, but not H, are considered candidates. If the end of the list is reached the user will reexamine the candidate set. When the model was tested the mean number of options processed was approximated by multiplying the number of options on a test panel by the constant 1.2. Thus, users often examined all the options at least once and a small set twice. Self-terminating searches were rare in this environment, but they are likely to be more common if users can engage in identity matching, particularly on panels they are familiar with.

The dual-criterion model initially proposed by MacGregor *et al*. has been extended by Pierce *et al*. (1992). This work shows how characteristics of a menu design can influence the placement of the two criteria. In turn, the location of the criteria determines both the proportion of self-terminating, exhaustive, and redundant searches and the quality of system performance. One conclusion is that H becomes more lax as the number of options per page increases. In contrast, increasing the number of alternatives induces users to adopt a stricter L. Another way of summarizing these assumptions and their implications is to say that as the number of options increases users are less likely to tag promising options and more likely to gamble on the first attractive option they encounter.

4. ORGANIZATION AND NAVIGATION BETWEEN MENU PANELS

This section examines the factors important to deciding how the total set of options should be distributed across the individual menu panels. The distribution of options to panels will determine the navigation pathways, that is, the sequence of selections that will be required to get from one menu panel to another. Most menu systems are organized into a hierarchical tree, in which each node (menu panel) in the hierarchy can be reached only from a single superordinate node that lies directly above it in the hierarchy. Depth is usually defined as the number of levels in the hierarchy. Breadth is defined as the number of options per menu panel. A hierarchical structure with several levels requires the user to either recall or discover how to get from where s/he is to where s/he wants to go. The navigation problem (i.e. getting lost or using an inefficient pathway to the goal) becomes more and more treacherous as the depth of the hierarchy increases.

Despite the navigation problem there are three reasons for considering a system with greater depth: *crowding*, *insulation* and *funneling*. *Crowding* is the straightforward constraint imposed by the amount of available space on a panel. When the available space is exceeded, some depth must be introduced. *Insulation* refers to the opportunity for menu systems to prompt selections that are likely to be needed and hide those that are unlikely or illegal. *Funneling* refers to a reduction in the total number of options processed that is achieved by designing a system with more depth and less breadth. When greater depth is traded for less breadth, funneling can generate efficiency gains, particularly when the processing time per option is long.

There has been more theoretical and empirical work on the depth–breadth tradeoff than on any other issue related to the design of menus (for extended discussions, see Paap and Cooke 1997, Norman 1991). Much of the theoretical work uses mathematical models that compute the optimal organization given assumptions concerning various temporal parameters. Although interpretations remain debatable, it is safe to say that most designers will be tempted to use too much depth. In terms of both speed and accuracy optimal performance can often be achieved by presenting as many as 80 options on a single menu panel, providing that the options can be organized into distinctive categories.

Many factors conspire to make increasing depth a dangerous practice. Recall that adding depth provides the potential benefit

of funneling (i.e. fewer options need to be examined). However, this potential advantage is only important when the processing time per option is rather long. But, processing time per option is long when users need to make a slow semantic evaluation of each alternative. These types of decisions are much more error prone than quick identity matches. Furthermore, it has been empirically demonstrated that the top levels are of a hierarchy are more error prone than lower levels. When users make an error near the top of the hierarchy it takes longer to detect the error and then longer to recover from the error. Depth sinks efficient navigation.

The semantics of a menu system is probably much more important than the syntax (i.e., the depth–breadth structure). Let the natural subdivisions of the options dictate the organization. If some depth is required to avoid unacceptable crowding then user testing, at least at the top levels of the hierarchy, is essential. Modifications following a single phase of user testing have sometimes reduced the number of navigation errors by > 90%! Do not let an expert's intuition by your guide. Lee *et al*. had a group of experts design a menu. Another group of experts rated the menus for ease of use and the correlation between experts was virtually zero! In contrast, when the same set of menus were give to a representative sample of end users there was much higher agreement and, furthermore, the end-users preferences were highly correlated with actual performance.

Displaying a history of how the user arrived at the current panel may facilitate the navigation problem. A history helps the user consolidate a sequence of correct choices, enhancing the chances of being able to recall the correct pathway later. When an error is made, the history may help the user backtrack and find the correct path. Maps of the menu structure also aid navigation, but this is impossible for large systems. Map size can be compressed either by reducing the scope and showing only the area of current interest or by reducing the detail by showing only the major highways. The former should be better for helping users who are stuck in a specific place, but the latter may be better for improving the users' overall mental model of the system and, hence, their long-term performance. Furnas (1986) has been developing a *fisheye view* that blends both local detail and important distant landmarks. The contents of the current panel are based on a degree of interest function that takes into account the distance of each node in the system from the node currently in focus and the a priori importance of each node.

5. CHOOSING A SELECTION TECHNIQUE

There are a number of different techniques for selecting items from menus. Menu selection techniques all involve selection from a list of items that can be presented in a variety of formats (e.g. pull-down, pop-up, pie). By convention a horizontal layout that is always in view is often found at the top of the screen. In most other cases, however, menus items are arranged vertically and if not fixed can be opened and closed using pull-down or pop-up menus. Pull-down menus are menus that are selected and displayed in the same location each time they are selected, whereas pop-up menus appear at the current cursor location. Given a specific list format, the items in that list can be selected using a pointing device or an identifier.

5.1. Pointing
Menu items can be selected by moving a pointer to the location of the desired option and selecting that item. The location of an on-screen pointer or cursor can be manipulated with cursor keys, joysticks, trackballs, touch screens, pens and mice. Pointing with a sequence of cursor keystrokes is not very efficient, but it is difficult to rank the other alternatives because there is much variability in performance between alternatives of the same type.

5.2. Identifiers
Another family of techniques for selecting menu items involves direct entry of an identifier associated with each menu item. The identifier is typically a letter or digit, but sometimes a letter string or abbreviation. Perlman (1984) makes several cogent recommendations based on empirical results. If the menu panel is used in an application where users make frequent selections and if the set of options do not change over time, then it may be worthwhile to use letter identifiers that can be compatibly paired to each option (e.g. "d" for delete). Another advantage of compatible letter identifiers is that they will be easier to remember than number identifiers. If the list of options is dynamic rather than static, the use of digits is a good compromise. Incompatible letter identifiers should be avoided. If should be noted that the best case, compatible letters, turns into the worse case if the menu options are translated into another language.

5.3. Prompts and Feedback
Providing default options and appropriate feedback is likely to be an important part of the design of any selection mechanism. Default options are particularly desirable when one option is selected much more often than any of the others. Under these circumstances search and selection operations can be made more efficient by highlighting the default option or preselecting it by having its identifier automatically displayed. Regardless of the selection mechanism, the system should provide feedback indicating: (1) which options are selectable, (2) when an option is under the pointer and, therefore, can be selected (assuming a pointer is used), (3) which options have been selected so far and (4) the end of the selection process.

Two techniques are commonly used to prevent users from selecting inappropriate choices. One approach is to gray-out or otherwise mark those options that do not make sense in a given context. The unselectability of the faded option is reinforced when it is under the pointer since it will not become highlighted. The second approach is dynamically to alter the visibility of the options, i.e. inappropriate options simply disappear from the screen. It is difficult to offer guidelines with respect to these two techniques since their relative benefits and costs have not been explored empirically. Norman advocates graying-out because it provides the user with stable cues regarding presence and location of items. In addition the inaccessible though visible items can help the user to achieve a more complete model of the items that are available and how they are related to other items.

Ecological Interface Design—Theory

G. L. Torenvliet and K. J. Vicente

Cognitive Engineering Laboratory, Department of Mechanical & Industrial Engineering, University of Toronto, Toronto, Ontario, Canada

1. INTRODUCTION

Ecological Interface Design (EID) is a theoretical framework for interface design that attempts to extend the benefits of traditional direct manipulation interfaces (DMI) to complex human–machine systems. While traditional approaches to the design of DMI may work well within some domains, they cannot address the unique challenges posed by complex work domains. EID has been developed specifically for complex domains and it uses the unique challenges of these domains as its starting point. Once the challenges of a specific domain have been characterized, EID addresses the domain-relevant capabilities and limitations of the human operator, and develops prescriptive interface design guidelines on this basis.

This article shows how the EID framework is a specific instantiation of the broader ecological approach to human factors described by Hajdukiewicz and Vicente (1999). The theory of EID can be captured in three broad principles, but the rationale behind them is important for their understanding. Accordingly, one will begin by structuring the interface design problem using two fundamental questions. These will lead to a discussion of two foundational concepts driving EID: the abstraction hierarchy (AH) and the skills–rules–knowledge (SRK) taxonomy. These concepts are then integrated into a statement of the central tenets of EID, in the form of three prescriptive guidelines. Finally, a few comments on the limitations and generalizability of EID are made. For a number of examples of how EID has been applied to various application domains, see Chery and Vicente (this volume).

2. ECOLOGY OF THE WORK DOMAIN: A CENTRAL ISSUE FOR INTERFACE DESIGNERS

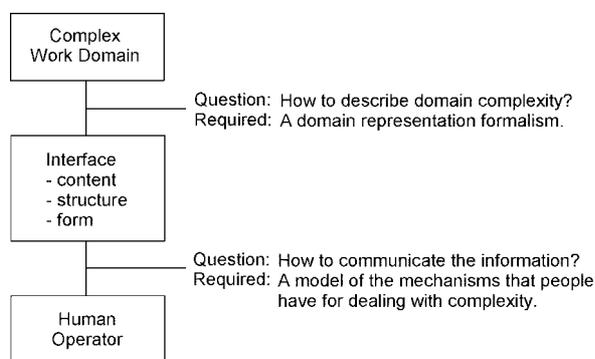
The point of departure for EID is the unique set of challenges faced by operators of complex human–machine systems. In the course of their work, operators must respond to a range of events that can be categorized under three groupings:


Figure 1. Basic structure of the interface design problem (adapted from Vicente and Rasmussen 1992).

- Most frequently, operators must respond to *familiar events* for which they have acquired the necessary skills through repeated exposure.
- Less frequently, operators must respond to *unfamiliar, but anticipated events*. While operators may not have developed the requisite skills that address this class of events directly, designers have anticipated these events. As a result, operators can rely on tools and aids provided by the designers to deal with this class of events.
- In rare cases, operators are called upon to respond to *unfamiliar and unanticipated events*. In addition to being unfamiliar, designers did not anticipate these events, and, thus, operators cannot rely on preplanned solutions in these situations. Instead, they must improvise a solution themselves through discretionary decision-making.

Traditional theories of interface design are generally well suited to helping operators cope with the first two classes of events, but are ill-suited to helping operators cope with unfamiliar, unanticipated events. While one valid solution might seem explicitly to design for a larger number of these rare events, this history of industrial accidents shows that all possible events cannot reasonably be enumerated. Unfamiliar and unanticipated events will always be a reality in the operation of complex systems. Thus, one needs a framework that can help to identify and provide the support that operators need to adapt to the unanticipated.

The first step in developing such a framework is to reconsider the most basic questions that should guide interface design so that the work domain is explicitly represented. As shown in Figure 1, the interface design problem includes at least three fundamental elements: the complex work domain; the human operator; and the interface that mediates between them. This structure naturally leads to two questions. The first can be generated from the relationship between the complex work domain and the interface: how should the designer describe the complexity of the work domain? The second follows from the relationship between the interface and the human operator: how should the complexity of the work domain be communicated to the operator? It is important to note that these questions capture the organism–environment reciprocity that is foundational to both ecological psychology and the ecological approach to human factors (Hajdukiewicz and Vicente 1999). It is for this reason that this framework is referred to as *ecological interface design*.

To answer the questions just described, two conceptual tools are needed. First, a representation formalism is needed to describe the content and structure of the work domain. Second, a model of the mechanisms that people have for dealing with the complexity of the work domain is needed to design the form in which to communicate this information to the operator.

3. DESCRIBING DOMAIN COMPLEXITY: THE ABSTRACTION HIERARCHY (AH)

A formal description of the work domain — independent of any particular worker, automation, event, task, goal or interface — drives EID. EID describes domain complexity using the AH (Rasmussen 1985). While the use of hierarchies is common in system design, AH has unique properties that sets it apart. It belongs to the class of stratified hierarchies (Mesarovic *et al.* 1970), and so has five general properties:

- Each level of the hierarchy describes the same system, but each different level provides a unique description (or model) of the system.
- Each level provides its own unique set of concepts, terms and principles.
- The selection of levels for describing a system depends on the observer and their knowledge and interest in describing the system. For many systems, however, there may be some levels that appear as natural or inherent.
- The requirements for proper system functioning at any level appear as constraints on the meaningful operation of lower levels, while the evolution of the state of the system is specified by the effect of the lower levels on the higher levels.
- Understanding of the system increases by crossing levels: by moving up the hierarchy, one obtains a deeper understanding of system significance with regard to the goals that are to be achieved, while in moving down the hierarchy, one obtains a more detailed explanation of the system's functioning in terms of how these goals can be carried out.

The structure of AH is further specified by a structural means–end relationship between levels (i.e. for each pair of adjacent levels, the upper level defines a set of ends, while the lower level decomposes these ends into structural means by which they can be accomplished). Thus, in contrast to other types of hierarchies, the elements included in an AH are explicitly related to work domain purposes. For an example of a completed AH, see Vicente and Rasmussen (1990).

Note that AH is not a specific representation, but rather a framework for developing representations for different work domains. The exact number of levels and their content will vary from one application domain to another as a function of the different types of constraints inherent in each domain. For instance, five levels of constraint have been found to be useful for describing process control work domains: the purposes for which the system was designed (functional purpose); the intended causal structure of the process in terms of mass, energy, information or value flows (abstract function); the basic functions that the plant is designed to achieve (generalized function); the characteristics of the components and the connections between them (physical function); and the appearance and spatial location of these components (physical form). Regardless of the application domain, however, the resulting hierarchy will have the properties described above.

The structure of the information contained in an AH makes it useful in helping operators to cope with unanticipated events. When operating in a 'normal' state, any work domain can be viewed as a set of constraints that describe the relationships between variables (e.g. at steady-state, the inflow into a reservoir is equal to the outflow). When unanticipated events occur, the structure and function of the work domain will change, and the constraints that usually hold under 'normal' circumstances will be broken (e.g. if a leak occurs in a reservoir, making the inflow and outflow equal will no longer lead to steady-state). Fault detection is thus equivalent to the detection of broken constraints. Because it is not possible to know in advance which constraint(s) will be violated, the complete set of goal-relevant constraints governing the work domain must be represented to permit operators to detect and diagnose broken constraints. An AH representation does just that by describing the physical and functional relations between variables. Representing these relations should make it possible for operators to cope with the entire range of operating demands, including unanticipated events.

In addition, there are also psychological justifications for adopting an AH representation. AH allows operators to manage the work domain at a variety of levels of detail, and so provides a mechanism for coping with the complexity of the domain. Operators can gain a bird's-eye view by using a high level representation or can drill down to a faulty object by moving to a lower level. This property of AH allows operators to cope with systems that would be unmanageable if they had to observe them in full detail and all at once.

While it can be argued that this property is shared by many hierarchies, AH is unique because it is explicitly goal-oriented. Each level in the hierarchy is connected to adjacent levels by structural means–ends relations. This type of functional structure deliberately supports goal-directed problem-solving. Consequently, workers can search the problem space in an economic fashion by evaluating the means that are relevant to the current set of goals.

Furthermore, research has shown that people find it natural to reason within an AH representation (Vicente and Rasmussen 1992). Researchers have had success in mapping the problem-solving protocols of world-class chess players, computer programmers, electronic trouble-shooters and nuclear power plant operators onto AH representations of their domains. Many of these studies have also shown that subjects' problem-solving trajectories begin at a high level of abstraction and then 'zoom in' to levels of more structural detail. Thus, there is evidence to indicate that the AH is a psychologically plausible problem-solving representation.

4. COMMUNICATING DOMAIN INFORMATION: THE SRK TAXONOMY

The next question to be addressed is: what mechanisms do people have for dealing with the complexity of a domain? Answering this will reveal effective ways to communicate the information in a work domain representation to the operator. As will be seen, the approach adopted by EID is to present information in a form so that operators can take advantage of the power of human perception. To do this, one needs to know something about the different mechanisms that people have for processing information, how they can be induced and their relative efficacy.

In the cognitive engineering community, the SRK taxonomy (Rasmussen 1983) is a widely accepted framework for describing these mechanisms. In brief, it asserts that information can be interpreted in three mutually exclusive ways — as signs, signals and symbols — and that the way in which information is interpreted determines which of the three levels of cognitive control is activated — skill-based behavior (SBB), rule-based behavior (RBB) or knowledge-based behavior (KBB) respectively. Thus, cognitive control may rely on a repertoire of automated behavioral patterns (SBB), a set of cue–action mappings (RBB) or problem-solving operations on a symbolic representation (RBB).

The three levels of cognitive control can be grouped together into two categories. SBB and RBB deal with perception and action, while KBB deals with analytical problem-solving. In general, perceptual processing is fast, effortless and can be

executed in parallel, while analytical problem-solving is slow, laborious and is only executed serially. Analytical problem-solving also tends to be more error-prone than perceptual processing. SBB and RBB, however, can only be activated in familiar situations because they require that the operator be attuned to the perceptual features of the environment. KBB, on the other hand, allows operators to cope with novelty. This description shows that there is a trade-off between cognitive economy and the ability to cope with novelty, so no one level is superior to any other.

How can the SRK framework be applied to design? Two characteristics of complex work domains make this possible. First, operators of these domains are highly skilled and have extensive experience in controlling the work domain. Second, interfaces for these domains are generally system-specific and generality is not required. Operators always deal with the same work domain, and thus transfer is not an issue. These two characteristics imply that complex work domains afford designing for SBB and RBB. Since operators will have extensive experience with the system, they will be able to attune themselves to the perceptual properties of the control room interface. Because operators always deal with the same work domain, if a way can be found to describe that work domain comprehensively, then the need for dealing with unanticipated situations can be minimized. This implies that reliance on KBB should be reduced.

The above assertions are backed by empirical evidence (for a review, see Vicente and Rasmussen 1992). Many researchers assert the immense power of perception, and other studies have found that perception is superior to analytical problem-solving in terms of errors and efficiency. Furthermore, research has shown that people naturally favor the less effortful route of perceptual processing over the more effortful path of analytical problem-solving, and that, given the proper conditions, a proficient level of performance can result from perceptual processing.

While people naturally prefer lower levels of cognitive control, presenting information in such a way that all task demands could be fulfilled by SBB alone does not imply that operators will not activate higher levels of cognitive control. Rather, the current demands of the task, the person's experience and the form in which information is presented together determine the level of cognitive control that is activated. Thus, the argument here is not that all interfaces should attempt to support all actions via SBB and RBB, but rather that all levels of cognitive control should be supported as operators tend to switch between levels freely. KBB needs support just as much as does SBB and RBB.

The discussion to this point has been somewhat of a simplification. The three levels of cognitive control cannot be treated independently, as a realistically complex task will usually require consideration of all three levels. The implication is that information should be presented to operators in a way to support all three levels of control. Taken as a whole, this discussion leads to a goal for interface design: to design interfaces in such a way as to not force cognitive control to a higher level than the demands of the task require, while at the same time providing the appropriate support for all three levels. The benefit of the SRK taxonomy is that it indicates the constraints on inducing each of the levels of cognitive control. For instance, SBB can only be activated when information is presented in the form of time–space signals, familiar perceptual forms (signs) trigger RBB and KBB is activated by meaningful relational structures (symbols).

5. ECOLOGICAL INTERFACE DESIGN

The preceding theoretical development is the foundation of the principles of EID, a set of prescriptive principles that allow designers to develop interfaces that satisfy the goal for interface design just presented (Vicente and Rasmussen 1992). This framework consists of three principles, each corresponding to one of the levels of cognitive control.

1. SBB — to support interaction via time–space signals, the operator should be able to act directly on the display, and the structure of the displayed information should be isomorphic to the part–whole structure of movements. This principle attempts to structure the interface to take advantage of SBB. Since the operator cannot usually act directly on work domain components, action at the SBB level is concerned with the manipulation of on-screen elements. The use of a mouse, trackball or some other direct manipulation device is preferred over command languages for this task because it maintains the communication of spatial–temporal aspects of the perception–action loop intact. Further, to aid skilled perceptual-motor performance in complex work domains, the interface should be designed in such a way that the aggregation of elementary movements into more complex routines corresponds with a concurrent chunking of visual features into higher level cues for these routines. In other words, the structure of the displayed information should be isomorphic to the part–whole structure of movements. This aim can be accomplished by revealing higher level information as an aggregation of lower level information. In this way, multiple levels are visible at the same time in the interface, and operators can guide their attention to the level of interest, depending on their level of expertise and the current demands.

2. RBB — provide a consistent one-to-one mapping between the work domain constraints and the cues or signs provided by the interface. This principle attempts to support RBB. At this level the interface should provide operators with signs that they can use to select appropriate actions. Conventional interfaces do not provide a consistent mapping between the perceptual cues they provide and the constraints that govern the work domain's behavior. This underspecification can lead to procedural traps, situations in which operators rely on their normal rule set but to little effect. EID attempts to overcome this problem by developing a unique and consistent mapping between the constraints that govern the behavior of the work domain and the cues provided by the interface. This approach should reduce the occurrence of errors, because cues for action will uniquely define the work domain state. Adherence to this guideline should make it possible for operators to often operate the plant by relying on perceptual cues instead of having to resort to KBB. There are two advantages to this approach. First, since RBB is less effortful than KBB, this approach is more economic. Second, because there is a 1:1 mapping between symbols and signs, operators can exhibit what looks like KBB by invoking RBB. The advantage of knowledge-based control is that it is not restricted to specific and/or frequently encountered situations like rule based control. Therefore, the second principle of EID allows operators to take advantage of the cognitive economy of RBB, while at the same time preserving the wide applicability of KBB.

3. Represent the work domain in the form of an AH to serve as an externalized mental model that will support knowledge based problem-solving. This final principle attempts to provide support for KBB. This is essential because KBB is usually an effortful and error-prone activity. The limitations of KBB are amplified when applied to complex systems that require problem-solving within a complex net of causal relations.

The approach of EID to this problem is to reveal the problem space, in the form of an AH representation, to the operator (for an example, see Vicente and Rasmussen 1990). This principle thus inherits all of the properties of the AH described above: it provides a psychologically relevant domain representation that contains the information that operators need to cope with unanticipated events. In addition, making the AH visible in the interface provides operators with a normative model of the work domain that can support thought experiments and other activities. In short, it relieves operators of some of the burden of keeping track of the causal net within which they are reasoning.

6. LIMITATIONS AND GENERALIZABILITY

While the EID framework enjoys considerable theoretical and empirical support, a number of limitations must be acknowledged. First, an AH representation can only be developed if the designer has an adequate understanding of the work domain. Thus, the EID framework may not be applicable to application domains that are not very well understood. Second, the robustness of an EID interface in the face of sensor noise and failure is not yet known. Empirical research is needed to address this issue. Third, in some cases, EID may require the measurement of some property that is not available via current sensor technology. While in some cases this problem can be overcome through programmed analytical routines, sensor technology may limit the applicability of EID.

Finally, although EID has been successfully applied to a broad range of domains (including process control, nuclear operations, aviation, medicine, and information retrieval; Chery and Vicente 1999), the generalizability of these ideas to a broader range of application domains needs to be assessed empirically. As the primary prerequisite for applying the framework is knowledge of the constraints inherent in a domain, there is good reason to be optimistic about EID's generalizability. In principle, it is irrelevant what these constraints are as long as they can be described in some way that can be mapped onto the perceptual features of a display. However, the generalizability of these claims needs to be continually tested empirically for new application domains.

Ergonomics of CAD Systems

H. Luczak, J. Springer and L. Schmidt

Institute of Industrial Engineering and Ergonomics, Aachen University of Technology, Aachen, Germany

1. INTRODUCTION

Design departments are usually equipped with highly complex CAD systems. Their application is supposed to increase the efficiency of the design process and to rationalize the product development process. However, more and more experiences of CAD users reveal a gap between the goals and the reality of CAD implementation. Also, experiments in different design departments show that users do not take full advantage of the functional capacities of CAD systems. This is one reason for poor performance in the production of technical drawings.

The characteristics of CAD systems that are most in need of improvement are their suitability for task requirements and their ability to adapt to different user qualifications. However, if ergonomic design rules are ignored, the consequence will be low design effectiveness, low efficiency and a higher strain level.

2. DESIGN WORK AND CAD SYSTEMS

2.1. Characteristics of Design Tasks

Any ergonomics approach to solving a design problem starts with an analytical procedure to identify and systematize the features and characteristics of the respective work or task (Luczak 1997). Hence, if the objective of this chapter is to describe and order the facts and regularities and to show how CAD systems interfere in design work, it is necessary to divide the task into a sequence of individual actions, so that the essentials of this (design) work become obvious.

Technically speaking, in the generation cycle of a product, the design department is the functional unit in a company where customer orders specified as customer demands or technical requirements are transformed into a mostly graphical model of the product. This model's work results consist of parts lists, parts drawings and composition drawings derived from the application of natural science and engineering knowledge about the product domain. The purpose of the CAD system in this context is to have the work result coded in a computer-compatible form, so that all functional units in the company can access the engineering data produced in the design department.

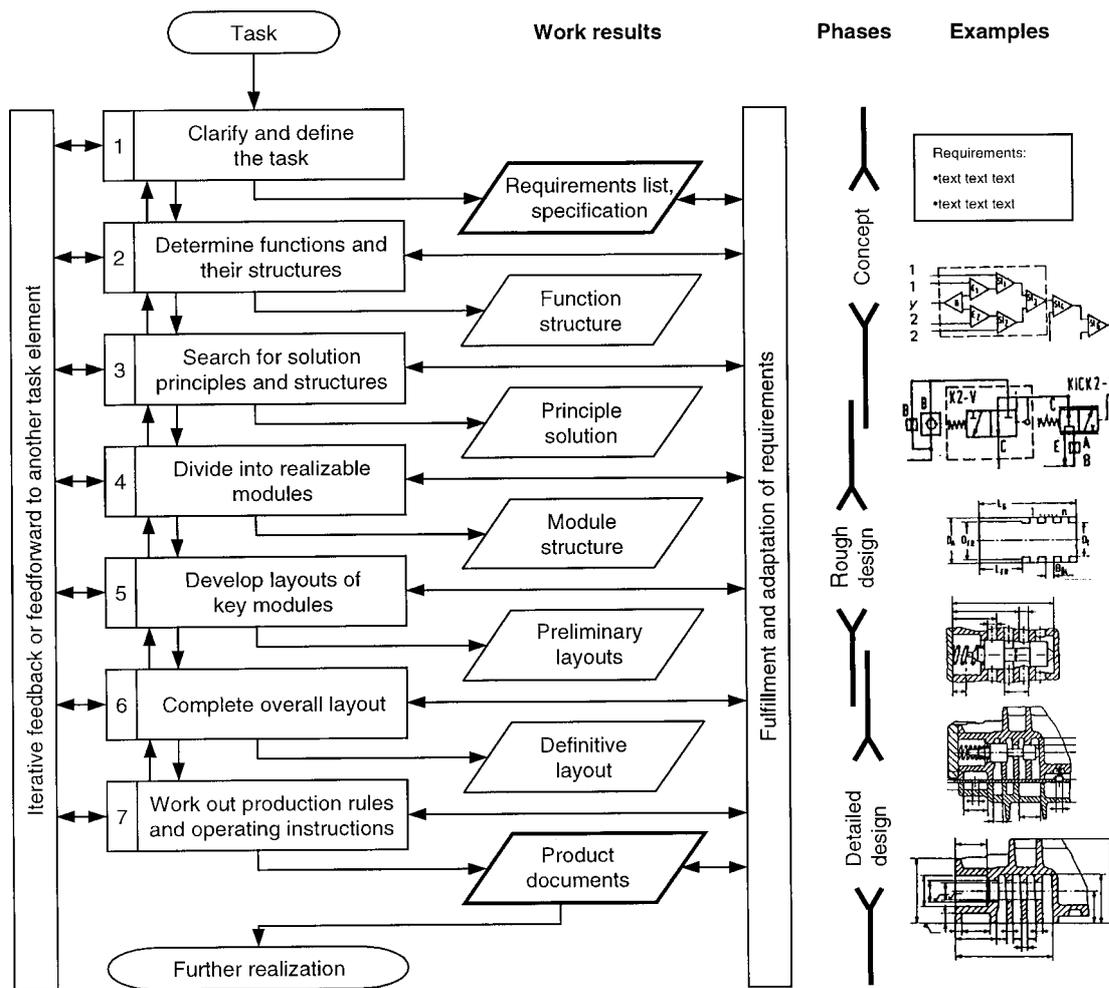
Organizationally speaking, the design process consists of phases in which a product order is subdivided into tasks and subtasks with a specified intermediate or final work result (Figure 1). Besides this phase-oriented sequential labor partition, a


Figure 1. Steps and work results in the design process (according to VDI 1993, Pahl *et al.* 1996)

hierarchical partition from the academically qualified design engineer down to the draftsman can be found, as well as a competency oriented labor partition into mechanical, electrical, hydraulic, etc. problem-solving and integration procedures. The CAD system has the functions of rationalizing the operations management of information handling and of integrating different information chunks into a complete work result: the completely documented technical product.

Ergonomically speaking, design work is "informatory work" in that it consists of human information processing procedures only, but with different levels of cognitive control. According to Rasmussen (1986), three primary levels of cognitive control can be identified:

- Knowledge-based processes, such as defining objectives of a product, setting goals for development procedures, identifying problem domains, and initiating problem-solving where methods are unknown, or even developing the problem-solving methods themselves.
- Rule-based routine processes, such as task execution using prescribed methods and procedures with algorithmic and perhaps iterative characteristics, such as the application of iterative optimization tools or simulation procedures to test functional components of the product; mathematical model formulation and calculation; creation of parts lists or transforming sketches into drawings.
- Skill-based automated processes, such as data entry, data transfer or data recall without invoking conscious information processes.

2.2. Knowledge Representation for Problem-solving and Decision-making

To take these technical, organizational and ergonomic aspects of the product development process into account, it is necessary to adopt a complete and unambiguous structure for design work as a basis for CAD systems engineering. This structure forms a conceptual analytic framework for the task-specific representation of knowledge in a kind of navigation and solution space, according to the knowledge-based level of human information-processing procedures mentioned above. The framework is characterized by the compatible representation of the product developer's mental model, with the aim of supporting problem-solving and decision-making in every design process phase.

Fundamental definitions are made in the early, conceptual phases of the product development process when there is still little definite information available. Therefore, when developing CAD systems, special attention must be paid to these first phases: an abstract description of the design problem must be supported by suitable tools and an appropriate problem representation. During the whole design process a homogeneous structure should integrate various media (including data not digitally available) and access methods on information units. It should be possible to address information in its context using a uniform search strategy, as in a knowledge base.

A further important demand on the structure of a CAD system is its correspondence to an intuitive way of thinking, as well as to conscious systematic design methods. Design tasks can be performed more efficiently with computer-generated structures of knowledge representation and methods of interaction compatible with mental models, because unnecessary transformation effort is avoided. Together with the mentally compatible visualization of the product model structure as the carrier of semantic information, partial situation analyses then become possible. This is necessary to evaluate solution variants concerning different product and process versions to obtain construction alternatives.

Rasmussen (1986) described a normative structure for the development of design guidelines based on human information-processing abilities and limitations. His conceptual framework

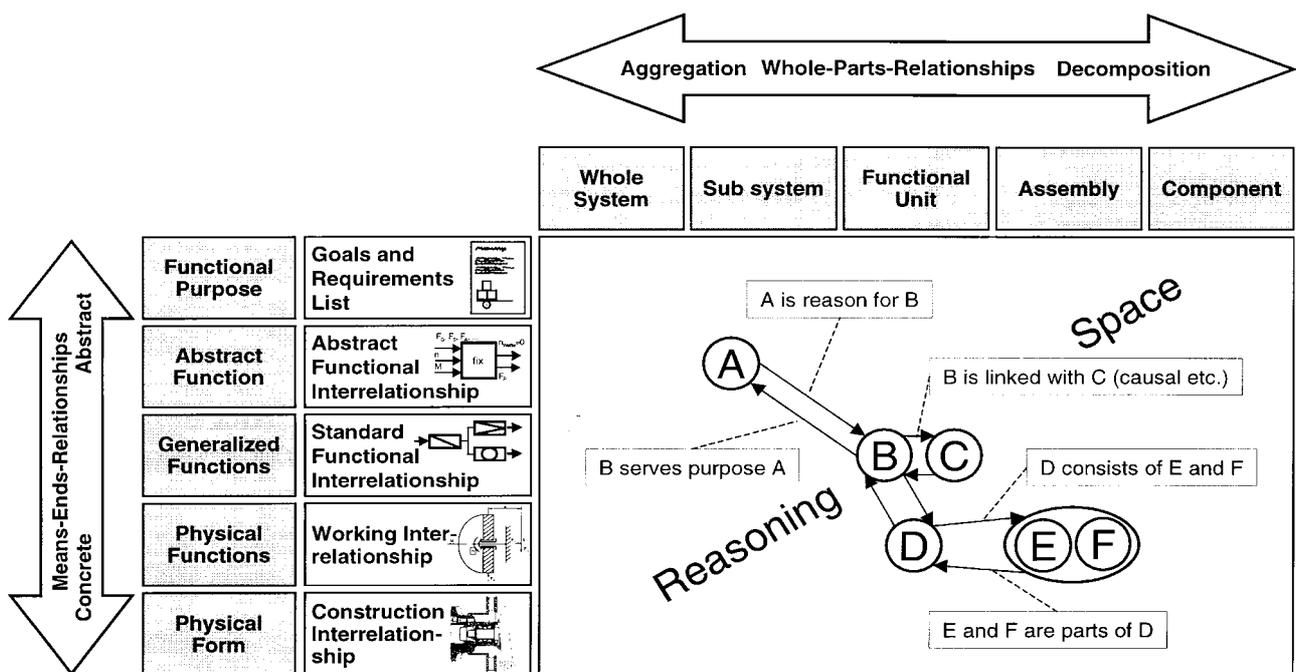

Figure 2. Reasoning space as reference structure for cognitive CAD systems engineering.

can be used to analyze cognitive tasks and subsequently to develop mentally compatible systems. A means-ends abstraction hierarchy represents functional properties of technical systems. This hierarchy describes bottom-up what components and functions can be used for, how they may serve higher level purposes, and, top-down, how these purposes can be implemented. Independently, and orthogonal to this functional dimension, various aggregation levels describe the whole-parts relationships of the system as a hierarchy of parts.

Concerning CAD work, a two-dimensional reasoning space can be the reference structure for cognitive CAD systems engineering, because design process phases can be assigned to different levels of abstraction (Figure 2). The designer's mental model of the task can compatibly be represented in this framework. For example, in the dimension of means-ends relationships, five abstraction levels can be separated.

The requirements list is a result of task definition and clarification to describe essential functional purposes at the most abstract level.

Identification of functional interrelationships in the next design phase refers to the level of abstract function, where conversions of energy, material and signals are defined.

The description of standard functional relationships (e.g. with the standard function items "transform," "modify," "link," "conduct" and "store") is the basis for principal solution variants.

To perform these generalized functions and working principles, physical effects and general material properties (like "solid," "liquid," "resistant to corrosion") are used.

Results of final design in the construction interrelationship are the complete set of drawings, parts lists and detailed production documents.

The hierarchy of parts shown in Figure 2 consists of five levels in this example, in structural analogy to the abstraction hierarchy concerning the whole-parts relationship of technical systems: "whole system," "subsystem," "functional unit," "assembly" and "component."

2.3. Structural Levels of Human–Computer Interaction

To obtain a model of human–machine systems design, it is necessary not only to think of appropriate knowledge representation, but also to focus on structural levels of interactions between people and machines. General guiding principles can be derived from the semiotic model — as first described by Morris (1946) — which has frequently been applied to human–computer interaction. It is capable of bridging the gap between a person- or work-centered view and a support-centered view based on tools or means and measurements. It may also be used to describe the interaction between a design engineer and his CAD system (Figure 3). This description emphasizes the tool-character of the CAD system for the individual work of the design engineer.

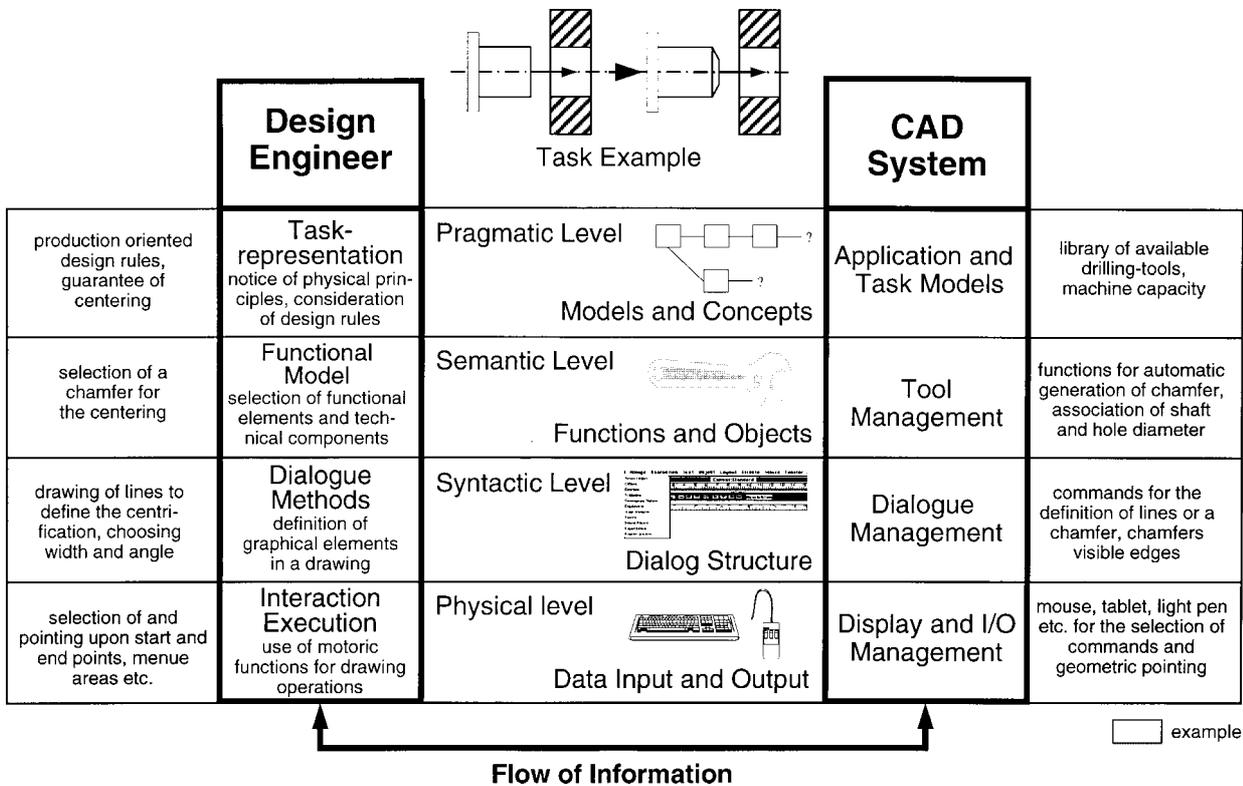
As outlined previously, the design engineer and his CAD system are bound to an organizational context by responsibilities for certain types of product orders. This may be a "manufacturing and assembly oriented design in layers," as shown in Figure 3. These orders are redefined as tasks or task elements on a pragmatic level. In a cyclic or stepwise process of order processing, task elements are assigned to the human designer or to the respective tool in the CAD system. In the above example, the designer must consider the physical principles of layer functioning and production, whereas during task execution, the task-representation and modeling in the CAD system leads to provision


Figure 3. Example of a design task and its execution in the semiotic model of human–computer interaction (according to Luczak and Springer 1997).

and support with a "library of available drilling tools," a survey on "machine capacities for achieving a given surface quality," etc.

On the semantic level, functions of the CAD system are used to specify and generate functional elements and technical components of the artifact to be designed. For example, the selection of a chamfer for centering the shaft is supported by tools for object generation or manipulation in the CAD system. The chamfer is then automatically generated according to shaft diameter and the shaft and hole diameters are associated with a certain fit.

On the syntactic level, the definition of graphical elements in the drawing comes into focus, which means that the user selects dialogue methods to allow easy definition and arrangement of lines and other standardized graphical components of the drawing (center lines, visible edges, etc.).

Last but not least, the physical level also concerns input–output devices as shown in Figure 3. These ensure that dialogue steps are executed by physical operations and represented by perceivable representations on displays. This represents a technical information aspect: the signs must be expressed in a physical way, e.g. visual, auditory or kinesthetic information.

The semiotic model is not only useful for the overview and the example shown, but also it may serve as a structuring guideline for specifying the features of CAD systems used in industry today.

3. ERGONOMIC REQUIREMENTS FOR CAD SYSTEMS

The structure elaborated above can be used to identify the requirements of CAD systems in a task- and user-specific way. The task-appropriate representation of knowledge and the design of the user interface dependent on semantic and pragmatic aspects become the essential factors of success where an effective, efficient and accepted use of a CAD system is concerned.

3.1. Pragmatic Level

Requirements on the pragmatic level of the semiotic model are related to application models and concepts used in the design process:

- The designer should use a CAD internal model with characteristics compatible with his mental model, thus decreasing coding and decoding effort.
- The CAD system should have an easy-to-use functionality for changing the characteristics of models and for generating task- or user-specific models by the combination of different default models.
- The designer should describe characteristics using fuzzy data, especially in the early phases of the development process.
- Different models and different views of a model should be managed simultaneously and the designer should have the ability to switch between them, e.g. switching between global and detail problems (aggregation level) as well as between concrete and abstract definitions of model characteristics (abstraction level).
- Activities directly related to the design task should be aided by the following conceptual characteristics of a CAD system:
- Special functions should exist that allow the designer to mark solutions that have not reached their final state or for which better solutions might exist.
- Because the designer is using various abstraction levels for

the description of the solution, all descriptions must be related to each other. Hand sketch drawings (of functional structures as well as of geometrical layouts) play an important role. The path of a designer through the "reasoning and solution space" (as seen in Figure 3) is characterized by a large number of iterations between the various information resources. This requires parallel handling of the different resources as well as the connections between the representation modes.

- Different concepts should be incorporated for problem-solving or optimizing solutions (e.g. simulation, application programs like solution databases, advanced calculation methods like FEM — Finite Element Method).
- Different concepts for evaluation (e.g. use value analysis) should be integrated. The designer should thus use task or user specific evaluation parameters to verify the evaluation results.
- Furthermore, effective information management is necessary for an effective design process:
- The designer should access and use different information sources based on both alphanumeric and graphical information, such as standards, company standards, supplier information, similar designs created previously, handbooks or legal regulations. It should be possible to manage different information resources simultaneously.
- Information should be given in a consistent way to the designer.
- Functions for navigation, for activation and deactivation of constraints, for visualization and for the control of consistency should be integrated.
- Information must be actualized permanently.

3.2. Semantic Level

The activities of the designer are highly dependent on the availability and suitability of functions to operate on the various objects in a design. Therefore, the characteristics of functions and objects (the semantic level of the HCI model) of the CAD system are important for effective design. Requirements for functions based on the designer's activities are:

- Direct object manipulation should be used intensively in correspondence to the interactive tool metaphor (transparency of the result). Direct object manipulation supports generation of objects (rubber bendings to visualize the effects of generation), geometrical manipulations like stretching, bending, pressing, moving, rotating, etc., as well as deletion of complex objects by simply using virtual erasers as they are used in conventional drawing. Therefore, functionality must be integrated into the objects themselves, and must be visualized by dialogue metaphors as parts of the objects.
- Because most geometrical definitions must contain exact dimensions, numerical feedback must be given continuously during the design process. It can be implemented through written dimensions like those in technical drawings, through numerical displays, software rulers or snap modes based on user-defined grids. The user should be able to switch between scaled drawings and unscaled visualization, as often used in hand sketch drawings, e.g. to make a special functionality transparent (tolerances, functional measures like eccentricity, etc.).

- Hand sketch functionality should be integrated into the CAD systems, but the CAD system should allow the user to decide whether the hand sketch should be changed into the final geometry (CAD elements), or if the hand sketch is used to visualize the unfinished character of a solution.
- An UNDO function should exist to reverse an error and to aid an iterative design process. Mechanisms for storing a design history are also required, which means that copies of different design states must be stored in a user-defined way for documentation of the decision processes as well as for returning to previous design steps.
- The whole functionality of the CAD system must be adaptable dependent on the requirements of the task as well as the individual strategies of problem-solving.
- Objects of the CAD system are data, which are operated on by the functions of the CAD system. Because of the various demands on the product to be designed, the designer must handle a large number of different objects. Therefore, the type and structure of objects managed by a CAD system are important for an ergonomic system design:
- All types of geometric information should be integrated into a homogenous and consistent data structure. Constraints between geometry and related geometric objects like dimensions, crosshatches, etc. should be defined when the designer creates these related objects, and they should be managed by the CAD system automatically.
- The user needs continuous information about the characteristics of defined objects and their relations to other objects outside the CAD system (costs, technological data, etc.).

3.3. Syntactical and Physical Level

Requirements at the syntactical and physical level can be taken from International Standards Organisation (ISO) standards for CAD non-specific requirements, because in CAD offices these factors are basically the same as in normal offices. ISO has worked out a set of standards (ISO 9241) that provide a scientific basis for planning and evaluating workplaces with visual display units (VDU) based on ergonomic criteria. The standard currently comprises 17 parts: General introduction (part 1), task design (2), hardware and environmental factors (3–9), and software and usability (10–17). Parts 3–17 are implicitly adjusted to the semiotic model so that the reader can find the appropriate standard quickly.

For an improved design of CAD hardware and software, the needs of the designers must be recognized and formulated clearly for the system developers. With this requirement, the ISO standards as well as the "EU directive on the minimum health and safety requirements for work with display units" provide a general guideline, which must be specified to meet the needs of designers and the tasks and working conditions in the design department.

Functional Systems Design versus Interface Design

V. A. Riley

Honeywell Technology Center, 3660 Technology Drive, Minneapolis, MN 55418, USA

1. INTRODUCTION

In the traditional systems development process, a system is built to solve an operational problem, and the functions of the system (what the system does) and the operational logic of the system (how the system does what it does) are defined according to the engineering requirements. The user interface is typically defined toward the end of the development process. Because the functions and operational logic of the system have already been defined, the interface must then build a bridge between how the user thinks about the task and how the system was designed to operate. This requires the user to learn the system's functions and operational logic; when the user must perform a task using the system, he/she must first decide which system functions are appropriate to accomplish the task, then apply the appropriate procedures (based on the operational logic) to use those functions. For a complex system, this can require extensive training requirements and may cause errors during system operation.

In contrast, human-centered functionality seeks to define the functionality and operational logic of the system based on the user's task requirements and on how the user thinks about the operational environment. The interface is then a natural extension of how the user thinks about the task and environment, and the interface definition drives the definition of system functionality. This reverses the traditional process, by beginning with the interface requirements and ending with the engineering requirements. But because the final system works much more like the user thinks, extensive training is no longer required, and the user no longer has to grapple with error-prone complexity.

It should be noted that this approach is most effective when the system and the plant are different entities. For example, in aircraft operation, the operational environment and the aircraft exist separately from the systems that guide the aircraft, such as the flight management system; this provides an opportunity to employ the pilot's existing mental models of the environment and the aircraft in the design of the flight management system's functions, logic and interface. However, in process control, there may not be a similar external criterion; the plant may be the system that the user is operating. In the first case, the engineering solution to flight management system functions and operational logic may seem superfluous or arbitrary to the pilot because there is no apparent direct relationship to the characteristics of the aircraft or environment. Thus, learning to use the system requires learning arbitrary rules of operation that are specific to the system and are not directly relevant to flying the aircraft. In the second case, the process control plant establishes the operational criteria, so learning the system's operations is fundamental to using the plant. Consequently, human-centered functionality may be most valuable in those cases where the user has an existing mental model of plant operation that is separate from the operation of the system being designed, or where knowing the underlying operations of the system is not fundamental to operating the plant.

2. SYSTEM-CENTERED FUNCTIONALITY VERSUS HUMAN-CENTERED FUNCTIONALITY

The functionality of a system is the set of functions that the system can perform. The interface provides the means for the operator to control and monitor these functions. The operational logic is the set of procedures by which these functions are controlled and monitored. Typically, functions and operational logic are defined based on the engineering requirements, and the interface is added to the system as a means of representing the functions and operational logic to the operator.

An example of system-centered functionality is given by how the flight management system of a typical modern aircraft is used to set up a holding pattern. If the pilot is given a clearance such as "Hold at 20 miles south-west of Farmington", he/she must first determine what functions are provided by the system that would meet the requirements of the clearance. Once the pilot decides on the proper functions, he/she must remember how to access the functions through the interface. Finally, the pilot has to recall the procedure (operational logic) to be applied. In this case, the flight management system calculates trajectories in terms of waypoints (artificial locations on the ground), so the pilot must first define a waypoint at the place designated by the clearance (20 miles south-west of Farmington). The pilot must then insert that waypoint into the proper position in the flight plan, then define a holding pattern around it. This example demonstrates how system-centered functionality requires the user to think about the process in terms that are peripheral to the required operation but are dictated by the design of the system. In other words, the pilot must translate from the logic of the clearance to the logic of the system in order to tell the system how to comply with the clearance.

More human-centered functionality would remove the need for the pilot to perform this translation, instead enabling the pilot to enter the clearance requirements directly. For example, the system may require the pilot to enter "Hold 20 south-west Farmington", a sequence of steps that matches the logic of the clearance (Riley *et al.* 1998). In other words, the human-centered operational logic establishes system functionality that is compatible with task logic, so the input to the pilot and output from the pilot into the system are essentially the same.

3. FUNCTIONALITY VERSUS INTERFACE

It is important to note that the essential difference between a system-centered solution and a human-centered solution is at the level of system functionality instead of at the level of the interface. There is nothing about the functionality or operational logic that would necessarily dictate a textual or graphic interface, or any particular interface look and feel. While it is often tempting to apply graphic user interfaces to systems, the mere fact that the interface is graphic may not ensure, or even improve, usability.

The value of concentrating on functionality as the focus of usability efforts was demonstrated by researchers at NASA Langley Research Center (Abbott 1995), who applied a graphic user interface to an existing flight management system, while preserving the underlying functionality and operational logic of the existing system. Pilots who performed complex flight

procedures with the new, graphic interface showed no training or accuracy benefits when compared with pilots who performed the same procedures with the existing text-based interface.

4. FUNCTIONAL COMPLEXITY VERSUS CONCEPTUAL COMPLEXITY

Many users are concerned with the growing level of systems complexity, and some are calling for reduced complexity as a means to greater usability. However, many systems are complex because the operational environment and the tasks to be performed with the system are themselves complex; arbitrarily reducing system complexity may therefore make the system even less usable because its performance would be compromised.

One way of addressing this problem is to separate functional complexity from conceptual complexity. A good illustration of this distinction is provided by personal computers using the desktop interface; although these systems are far more complex (functionally) than the DOS machines that preceded them, users find them conceptually more simple. This is because the desktop interface translates the underlying functionality of the system into a conceptual world that the user already understands; file management functions, for example, are translated by the interface into operations involving virtual paper documents, file folders, rubbish bins or recycling bins, etc. To the extent the on-screen world works the way the real-world does, the user can perform tasks with little or no training.

This demonstrates how a suitable metaphor can make the underlying system-centered functionality appear to be human-centered. However, the metaphor is not a panacea; in the case of personal computing, the metaphor was imposed on the operating system after the essential functions of the system were already defined. This means that only a subset of system functions fall under the metaphor; secondary metaphors (such as the distinction between "radio buttons" for mutually exclusive options and "check boxes" for non-exclusive options) are applied where appropriate, but in the current desktop interfaces, many sophisticated system functions still require learning because the metaphor does not dictate their logical operation. The most powerful application of a metaphor, then, would be before system functions are defined, so the greatest amount of system functionality can fall under the logic suggested by the metaphor.

5. TECHNOLOGY-CENTERED VERSUS HUMAN-CENTERED SYSTEMS DEVELOPMENT

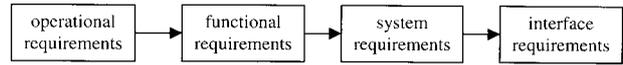
Truly human-centered functionality is defined based on how the user thinks about the operational environment and the logic of the tasks the user must perform, apart from the actual operation of the system. This suggests that the traditional system development process must be turn around. Figure 1 illustrates the current process, where operational requirements (the problem to be solved by the system) drives functional requirements (what the system will do to solve the problem), which in turn drives system requirements, which in turn drives the interface requirements. Figure 2, on the other hand, illustrates a more human-centered process, where task requirements drive interface requirements, which in turn drive system and functional requirements.


Figure 1. The traditional systems development process begins with engineering requirements; the interface is added after system functions and operational logic have been defined.

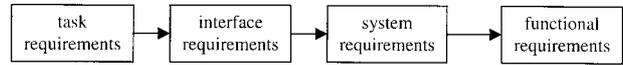

Figure 2. A more human-centered process begins with the user's task requirements and interface requirements; these, in turn, drive the engineering requirements.

Technology-centered system development has been appropriate where the capabilities of the technology limited the functionality of the system, and functionality had to be provided as efficiently (in terms of processing power) as possible. However, the current level of technology is making truly human-centered systems more possible. In the past, the user had to accommodate the system because the system was severely limited. In the future, more capable technology will enable the system to accommodate the user.

6. ROLE OF HUMAN FACTORS IN HUMAN-CENTERED SYSTEMS DEVELOPMENT PROCESS

All of this implies that the role of human factors in systems development processes will change. Since the beginning of human factors practice, practitioners have advocated an earlier role for human factors in the systems development process. One justification for this is that a better interface can be developed if the system's functions and operational logic are known earlier. Another justification is that early involvement by human factors experts can help influence the functionality of the system better to support the operator. A third justification, though, would represent the other extreme from the first, that human factors requirements drive the engineering requirements, rather than the other way around. This would require a much larger role for task analysis and other human factors methods at the beginning of system development, as a means to defining what the system will do rather than just how the system will be represented to the operator.

HCI Hypermedia: Usability Issues

A. Dillon

HCI Laboratory, Indiana University, USA

1. INTRODUCTION

hypermedia is a general term used to describe the presentation of graphical, textual, audio and video information in nodes (chunks) that can be linked together and accessed in a manner determined by the immediate interests of the user. Originating as an idea for mechanized information access and organization that better reflected the natural workings of the human mind by Vannevar Bush (1945), the potential of the computer to provide the best means of supporting hypermedia was recognized early on by thinkers such as Ted Nelson and Doug Engelbart (for a historical overview see Conklin 1987). The move toward hypermedia-based digital documents holds with it the promise of user-controlled, immediate access to the world of published information and stored data. While originally a specialist application domain, in the last few years the World Wide Web has brought to everyone's desktop the power and problems of hypermedia interaction. Yet from the outset, human factors researchers have noted a range of user issues that prevent the simple transition from analog to digital resources.

2. THE RANGE OF HUMAN FACTORS CONCERNED WITH HYPERMEDIA

Relevant research on the subject of interface design for information access in electronic domains began several decades ago, but it is only in the last 15 years or so that the technology existed to support empirical research into hypermedia interfaces. Since then, there has been an explosion of studies examining such standard user-performance issues as speed and accuracy of screen reading, the design of navigation aids for information spaces, the combinatorial value of images and text for information exploration, and the educational value of hypermedia information.

Dillon (1994) reviewed the ergonomic literature on digital documents and reported findings on the outcome and process differences between digital and analog documents at the physical, visual, and cognitive levels. Since then, interest in the social aspects of hypermedia creation and use has also blossomed and there now exists a large and sometimes contradictory research literature on the human factors of hypermedia design. Of particular interest to most researchers are the questions of what factors most affect user performance with digital documents and how best to exploit hypermedia for real-world tasks.

3. FUNDAMENTAL DIFFERENCES BETWEEN DIGITAL AND ANALOG MEDIA

Dillon (1994) outlined five outcome and three process variables that have been studied by researchers in hypermedia. The outcome variables are:

- Speed
- Accuracy
- Comprehension
- Fatigue
- Preference

In general, people have repeatedly been shown to read 20–30% slower from typical computer screens than paper (see, for example, Gould *et al.* 1987) and this has given rise to a concern with image quality and research at the perceptual level of use. "Accuracy" of use has proved more difficult to measure and many researchers have used highly constrained tasks such as error location in proof-reading or searching for target information in an information space as indices of performance accuracy or effectiveness. The results are highly task-dependent, but there are some suggestions that hypermedia is better suited to search and comparison tasks than complex learning tasks.

The effect of presentation medium on comprehension is particularly difficult to assess because of the lack of agreement on how comprehension can best be measured. However, in a detailed review of the learning outcomes of hypermedia and other instructional presentations, Dillon and Gabbard (1998) reported that the experimental findings show little support for the use of hypermedia over any other medium in educational settings.

There is also a popular belief that reading from screens leads to greater fatigue, but the results are inconclusive. The perception of fatigue or eye strain from screen reading is obviously linked with the user's preference for screen or paper-based reading, where it seems that paper retains popularity with many users, although this is highly contingent on task.

The major process differences that have been experimentally studied include:

eye movements

manipulations

navigation

Comparison of eye-movements with paper and hypermedia documents shows that there is little difference although screen readers may make slightly more regressions (Gould *et al.* 1987). Manipulation and navigation, however, are much more commonly assessed and the results indicate significant effects, with large hypermedia documents in particular producing navigation problems for users, leading to increased disorientation and poorer mental model formation of layout and narrative flow.

4. EXPLAINING THE DIFFERENCES

A range of potential explanations for these differences has emerged hand in hand with the findings of significant process and outcome differences between the media. Following Dillon's (1994) review, these are grouped by human factors under physical, perceptual, cognitive, and social issues.

4.1. Physical Sources of Difference

There are wide ranging physical differences between paper and hypermedia that affect the manner in which readers use them, such as:

orientation

aspect ratio

handling and manipulation

display size

While myths abound on the theme of display size or orientation, research indicates that the major problems occur in designing appropriate manipulation facilities for the digital medium where there are few standards beyond the use of a mouse

as a pointing and selection device. On balance, though, the empirical literature would seem to indicate that the primary causes of the reported performance differences between the media do not lie at the physical level of use.

4.2. Perceptual Sources of Difference

The user's visual processing of text and images is contingent on image quality which varies on computer screens as a function of the refresh rate and resolution. This has led to research into the relationship of image quality to user performance with digital documents. Some of the major areas of attention have been:

    flicker
    screen dynamics
    visual angle of view
    image polarity.
    anti-aliasing

The definitive work on perceptual variables in reading from computer screens was carried out by Gould *et al.* (1987) who empirically demonstrated that under the right conditions differences between the digital documents and paper disappear. Their results suggested that the performance deficit in speed was the product of an interaction between a number of individually non-significant effects: display polarity (dark characters on a light, whitish background), improved display resolution, and anti-aliasing. This image quality hypothesis has been replicated by Muter and Maurutto (1991). It is fair to conclude that high image quality is a necessary (but insufficient) precondition of efficient and effective use of any hypermedia.

4.3. Cognitive Sources of Difference

While the identification of the role of image quality was an important breakthrough for our understanding of human response to digital information, the potential of hypermedia to represent information in novel and configurable forms is what truly interests designers and users. This potential has served to emphasize the importance of cognitive issues in design. To date, researchers have focused on the following type of variables:

    Visual memory for location and layout
    Schematic representations of concepts and relationships
    Navigation patterns and mental map formation
    Comprehension of various information structures

Issues relating to re-structuring of information, together with the nature and amount of linking involved with hypermedia, have become central questions of human factors researchers (see, for example, Nielsen 1995). It is almost taken on faith by many that analog documents consist of a linear format which demands serial interactions, while hypermedia allows non-linear formats which offer more flexible and "natural" methods of use. Such a distinction would appear dubious and there is little evidence to support either assumption.

Systematic research on cognitive issues shows that users can become overwhelmed with highly interlinked nodes of information that fail to cohere or conform to expectations of structure. This has given impetus to studies of the strategies people adopt in navigating through information spaces, the best representations of location and order to provide users at the interface, and the best combination and organization of images, text, and sound to ensure learning. To date, few definitive answers

have emerged and it remains a major design challenge to produce a hypermedia document that outperforms its paper equivalent.

5. SOCIAL SOURCES OF DIFFERENCE

In recent years, interest in the social aspects of digital information creation and use has increased. As hypermedia becomes the universal interface style for so much of the information with which people interact, researchers have started to address the social and cultural variables that influence use and acceptance of digital documents. Issues that are seen as central at this level include:

    The sharing of meaningful representations
    Control of authorship
    Formation and application of document genres
    Collaborative hypermedia creation and use

It is clear that image quality is necessary but insufficient to ensure usability and that any hypermedia system invariably exists in a socio-cognitive environment of use that transcends physical space. Creators and users of hypermedia might be physically and temporally separated, of different language communities, and may create and shape personal hypermedia spaces that are unique. To date, most work on these issues has been discursive rather than empirical.

6. DESIGNING USABLE HYPERMEDIA: USERS, TASKS AND INFORMATION SPACES

The World Wide Web is essentially a hypermedia environment and its rapid growth has increased the need for understanding how best to design hypermedia. The lesson from research is that while it is important to take account of the visual ergonomic issues, any hypermedia application will only be of benefit to users if it supports their navigation, location, and sharing of information. Few computer-based innovations have proved as difficult to design so that users benefit significantly. Successful examples of hypermedia have only been developed through long-term iterative design processes involving frequent usability evaluations (see, for example, Landauer *et al.* 1993).

While following an iterative user-centered design process is usually beneficial, it can be slow and costly. In one respect, hypermedia applications share many of the standard interface design problems of any other application in terms of icon design, color coding, error message and documentation design, screen layout, etc., thus enabling designers to call on a large existing database of human factors research to guide parts of their design. What is specific to hypermedia, or at least what hypermedia places greater emphasis upon, is the flexibility afforded users to access any part of the information space they choose, the combinatorial form of the information types, and, with the WWW, the potential to traverse multiple sites which share nothing in common but a link.

Of necessity, any usable design must be grounded in the context of intended use which requires developers to analyze the users, their information tasks, and the environment in which they will work. Large individual difference effects have been observed and hypermedia presentations often seem to hinder rather than help the people at whom they are aimed (Dillon and Gabbard 1998). Clearly users with experience with any information type have expectations of form and organization that might be leveraged in hypermedia designs.

While it was recognized early in the research literature that not all information was well served by being presented in hypermedia form, few definitive answers have been provided concerning just which types of information work best. Shneiderman (1989) stated that the best hypermedia were information types that were naturally fragmented and that users only want to access in parts. This might suggest some natural limits on the type of information that users wish to explore in hypermedia form, but as yet there appears to be no slowing of the push to digitize any and all types of information. Furthermore, such a perspective is limited to imagining hypermedia versions of existing forms of information; as hypermedia evolves we should anticipate the emergence of new document genres and types that have no analog equivalent.

Any analysis of information type cannot be divorced from task requirements users have for it. For example, the complete works of Shakespeare may not seem an ideal candidate for fragmentation and hyperlinking, yet a digital version would prove highly useful to a scholar searching for quotations or seeking parallels across plays or poems. Certainly, where location is supported by search facilities, hypermedia offers tremendous potential to users exploring large documents. However, once located, many users seem to prefer viewing a printed version of the target information. This suggests that thinking about hypermedia should move forward from comparisons with analog documents toward an appreciation of what contexts of use it best serves and how it might supplement and be supplemented by existing media to support any given users and tasks.

7. RECOMMENDATIONS

hypermedia offers a powerful means of presenting large amounts of rapidly accessible information to a user that can be explored as needed. However, hypermedia can also overwhelm and disorient users if it is not well-designed. The concept of hypermedia is sufficiently wide-ranging to prevent simplistic design guidelines on link density or screen size to be specified, although there is an ever-expanding list of design recommendations being pushed by web-designers. However, to maximize the advantages and minimize the potential problems, the following general recommendations have emerged from the human factors research on hypermedia:

1   Provide high image quality screens to improve readability.
2   Use colors sparingly; black text on white backgrounds is optimal for reading lengthy text.
3   Support simple manipulation of screen contents with a mouse or equivalent input device; minimize repetitive motion such as scrolling through use of directly accessible navigation controls.
4   Links should clearly signify destination and be retraceable; increasing link density can increase the cognitive load on users.
5   Structure the information to conform to user expectations, or provide structural cues such as maps or overviews to introduce new structures. Determine new structures by considering the tasks being performed.
6   Use animation only to attract attention or convey a process.
7   Minimize load time. Users strongly dislike waiting for screens to load.
8   Add value by offering facilities to perform desirable or advantageous tasks that are impossible, difficult or time-consuming with analog media.

However, all the above recommendations are context-dependent and are less critical to the success of any hypermedia application than the central HCI recommendation of testing any design on real users.

Human Acceptance of Information Technology

A. Dillon

SLIS, Indiana University, Bloomington, IN, USA

1. INTRODUCTION

Despite significant investments in information technology in developed nations over recent decades, concern exists over the extent to which such expenditures have produced the intended benefits. At least part of this concern is based around the issue of whether any information technology is accepted by its intended users. Human factors professionals are interested in understanding the determinants of acceptance and ensuring new designs are built and implemented so as to minimize resistance. This concern has extended the traditional ergonomic concern with usability, or ability to use, to cover acceptance, or willingness to use.

2. DEFINING AND STUDYING ACCEPTANCE

User acceptance can be defined as the demonstrable willingness within a user group to employ information technology for the tasks it is designed to support. Thus, acceptance theorists are less concerned with unintended uses or non-discretionary use of technologies and more interested in understanding the factors influencing the adoption of technologies as planned by users who have some degree of choice. By developing and testing models of the forces shaping user acceptance, human factors researchers seek to influence the process of design and implementation in a manner that will minimize the risk of resistance or rejection by users.

The scientific concern with user acceptance is comparatively recent, since traditionally, developers and procurers of new technology could rely on authority to ensure that technology was used, at least in many industrial/organizational contexts. However, current working practices, as well as the large market for leisure and educational applications of information technology have enabled greater discretion among users thus increasing the need to determine the dynamics of acceptance.

The literature on acceptance is broad, ranging from case studies of accepted technologies, to the individual psychological characteristics of acceptors or resistors (Dillon and Morris 1996 has a detailed review of various theories and models of user acceptance). Each facet of the literature can provide some understanding of what makes users accept or reject a system but, since the issue is complex, it is unlikely that a single-variable explanation can be derived of the level of acceptance any information technology will receive among its intended users. For present purposes it makes sense to consider the evidence on the characteristics of the accepted (or rejected) technology separately from the evidence on the characteristics of the accepting (or rejecting) user, before reviewing the interplay of both these factors in current models of acceptance.

3. CHARACTERISTICS OF ACCEPTABLE TECHNOLOGY

According to Rogers' (1995) innovation diffusion theory, five characteristics of a technology determine its acceptance:

- Relative advantage (the extent to which it offers improvements over available tools).
- Compatibility (its consistency with social practices and norms among its users).
- Complexity (its ease of use or learning).
- Trialability (the opportunity to try an innovation before committing to use it).
- Observability (the extent to which the technology's gains are clear to see).

Numerous diffusion studies have demonstrated that innovations affording relative advantages, compatibility with existing practices and beliefs, low complexity, potential trialability, and observability, will be more extensively and rapidly accepted than an innovation with the opposite characteristics. In particular, three of these characteristics seem to have the greatest influence: relative advantage, compatibility and lack of complexity. While the diffusion model has broad appeal, there are concerns that the characteristics Rogers lists are too loosely defined to provide a sound basis for a complete theory.

The importance of complexity and trialability have long been raised in the human–computer interaction (HCI) literature where these concepts find resonance in the literature on usability and user evaluations (e.g. Nielsen 1993). Usability is frequently linked to certain qualities of the user interface that are under the control of the designer and HCI professionals place great emphasis on ensuring, through systematic usability evaluations, that users can operate a technology effectively, efficiently and satisfactorily. However, HCI research has concentrated less directly on the concept of acceptability or adoption of new technology, making the plausible assumption that usability is a prerequisite of acceptance.

Shackel (1991) is one of the few HCI researchers to make explicit the link between usability and acceptability. According to his formulation, an acceptable system is one that appropriately satisfies the requirements of its users for utility, usability and cost. These attributes can be easily linked with Rogers' five characteristics showing a close overlap between two distinct perspectives. However, while ability to use any technology is obviously necessary, it is not sufficient to ensure acceptability, and many technologies that are demonstrably usable are never accepted by the target users.

4. CHARACTERISTICS OF ACCEPTING USERS

Many researchers have attempted to identify psychological variables that distinguish users who accept or reject technologies. In a meta-analysis of research, Alavi and Joachimsthaler (1992) suggest that the most relevant user factors determining technology acceptance are cognitive style, personality, demographics and user-situational variables.

Cognitive style refers to the characteristic ways in which individuals process and use information and can be seen in information processing terms as a stable pattern of handling incoming stimuli and formulating responses. More than 100 different dimensions can be found in the literature, although a core cluster accounts for the majority of the work on this topic. To date, however, few cognitive style dimensions have been shown to predict user behavior with technology reliably.

Personality traits such as need for achievement, degree of defensiveness, locus of control and risk-taking propensity are

frequently proposed as important predictors of acceptance. The literature on this topic tends to blur the distinction between personality and cognitive style and the results of studies into such traits have equally failed to yield significant insights.

Among the demographic variables that have been studied, age and education have been shown to influence system use in some contexts. As expected, higher educational attainment and lower age both seem to influence use positively, but the relationship is weak. Coupling demographic variables with contextual knowledge improves matters substantially and variables such a training, experience, and user involvement, correlate well with acceptance of new technology. Alavi and Joachimsthaler (1992) found that the broad group of user-situational factors was more important than individual difference variables.

Innovation diffusion theory also suggests that factors at the level of the individual user are important. Rogers (1995) divides technology or innovation adopters into five categories depending on their speed of uptake: innovators, early adopters, early majority, late majority and laggards. Rogers plots these categories over a normal distribution where the division between early and late majority is viewed as the mean, and thus laggards and late adopters constitute 50% of the population. Rogers estimates that early adopters and innovators (~16% of the population according to his theory) are more likely to manifest risk-taking, adventure seeking personalities as well as being wealthier and more educated than the norm.

Thus, there is some agreement on the individual and situational factors influence the acceptance of new technologies but the weight of evidence suggests context might be more important than personality or individual psychological factors alone.

5. MODELING THE PROCESS OF ACCEPTANCE

While the identification of core technological and psychological variables underlying acceptance has provided some insight, few human factors researchers have attempted to link both sets of variables explicitly into a unified theory for design and implementation purposes. The most important theoretical work in this area however has involved socio-cognitive analyses of the dynamics of user action. Models of acceptance have emerged from this work which place emphasis on the attitude of users, and in so doing, seek to predict long-term user acceptance by measuring early affective responses to any new technology.

Of these models, the most widely cited is Davis *et al.* (1989) Technology Acceptance Model (TAM). TAM predicts user acceptance of any technology is determined by two factors: perceived usefulness and perceived ease of use. Perceived usefulness is defined as the degree to which a user believes that using the system will enhance his or her performance. Perceived ease of use is defined as the degree to which the user believes that using the system will be free from effort. According to TAM, both perceived usefulness and perceived ease of use have a significant impact on a user's attitude toward using the system.

Davis' research shows that TAM can explain ~50% of the variance in acceptance levels for many routine office applications, and the results from several studies of TAM indicate that usefulness is the most important predictor of use, explaining significantly more variance than ease of use ratings by users.

Impressively, TAM has been widely applied across different application types with consistent results. Furthermore, it is easy to administer since it involves little more than asking users to provide ratings of agreement/disagreement to a series of short statements such as "Learning to use this application would be easy for me." However, research on TAM is typically based on a single time period when users are exposed to a ready-made system. This makes it useful for choosing between competing technologies at the implementation stage but less applicable in the early stages of design where designers are trying to determine how best to design a technology so that it will prove acceptable.

6. DESIGNING AND IMPLEMENTING ACCEPTABLE TECHNOLOGIES

While significant inroads have been made into the determinants of user acceptance, there remains the tricky issue of applying these insights in the design process to ensure the resulting technologies are likely to be accepted. This poses the joint challenge of determining acceptance before any technology is fully developed and then implementing it in a manner that supports uptake.

One cannot simply rely on models such as TAM since these require the user to experience the technology in order to formulate their perceptions. To date, little work has been carried out on the reliability and validity of TAM scores for early prototypes. Furthermore, it is a fundamental tenet of most organizational theories that the collective response to a new system in any working or social environment is likely to be determined by more than the isolated, individual ratings of the members.

Within the user-centered systems design tradition of HCI emphasis is placed on the early and continuous involvement of users. Primarily this is to serve as testers of prototypes and to provide insights into task and work practices that need to be supported by any technology. Even if a technology is engineered to be highly usable, and be shown to be so through formal testing, there exists no guarantee that this will lead to acceptance.

Theorists from the socio-technical systems tradition such as Eason (1988) argue that information technologies are embedded in working practices and that these practices manifest a network of social relationships such as cooperation among users, management relationships and so forth. Accordingly, any technology cannot be fully analyzed or understood in terms of usability where this is conceptualized in isolation of the goal-oriented organization or work context it is intended to support. To optimize jointly both the social and technical attributes of any organization, allowance must be taken at the design level of the social dynamics of any organization or group within it

Socio-technical systems theory has given birth to a framework for technology design that emphasizes the analysis of all stakeholders, not just the direct users of a technology, the formation of planning groups to oversee the design, the performance of prototyping exercises, and the analysis of likely impact the technology will have on the organization. The intention of such a design process is to avoid unpleasant side effects in working practices (which would lead to resistance) and to ensure as much a social solution as a technical solution to the computing needs of an organization.

Eason (1988) views acceptance in terms of two competing forces: control and enhancement. Control factors are those that

impose rules or structures upon the users, thereby removing autonomy (control over their own actions) from them. According to socio-technical thinkers, working group autonomy is to be encouraged since it is considered to increase satisfaction and long-term performance. Among the control issues raised with respect to technology design are: access, reliability, confidentiality, monitoring, pacing, stress, social contact. Low or high presence of certain factors (e.g. low reliability, high pacing) with the introduction of a new technology is likely to reduce the users' perception of control and thus increase the risk of resistance.

Enhancement factors include sense of mastery, growth of knowledge, discretion, ability to act informally, requirement for certain skills, and enabling worker cooperation. These factors should all be maximized as appropriate for the context (though skill requirements are not to be inherent for certain situations). A technology that is designed to support such factors is likely to increase user acceptance in an organization.

To date there has been little controlled study of the importance of such control and enhancement variables. Socio-technical researchers tend toward case studies of designs and their implementation rather than controlled experiments rendering specific and individual weighting of control and enhancement factors problematic. However, this perspective offers insights that might prove amenable to further research that moves us beyond the search for single technological or user variables.

7. SUMMARY

Determining user acceptance of a system is a difficult but important part of human factors research and application. While there is currently no complete theory or model that explains and predicts acceptance, there is an emerging understanding of the key variables in the technology, the user and the implementation process that affect acceptability. To be accepted, a technology must satisfy basic usability requirements and be perceived as useful by its intended user community. User experience and training will impact acceptance levels as will the manner in which the technology is implemented to contribute to organizational goals and working practices.

Human–Computer Interaction (HCI) Standards

T. Stewart and T.F.M. Stewart

System Concepts Ltd, 2 Savoy Court, The Strand, London WC2R 0EZ, UK

1. INTRODUCTION

Although standards can be unwelcome constraints, they can also be useful tools, saving designers from repeating others' mistakes or "re-inventing the wheel" and helping to ensure that human–computer interaction (HCI) issues are taken seriously in the design process. The paper therefore starts with a brief discussion of the importance of standards followed by an overview of selected standards activities. It ends with a review of where different standards fit into the system development process.

2. WHY STANDARDS ARE IMPORTANT IN IMPROVING USABILITY

Standards promote consistency, good practice, common understanding and an appropriate prioritization of user interface issues.

2.1. Consistency

Most users have horror stories about inconsistency between, and even within, systems. Standards provide a consistent reference across design teams or across time to help avoid confusion. In other fields, consistency, for example, between components that should interconnect, is the prime motivation for standards. It is certainly a worthwhile target for user interface standards.

2.2. Good Practice

In most fields, standards provide definitive statements of good practice. In user interface design there are many conflicting viewpoints about good practice and standards, especially international ones, can provide independent and authoritative guidance. International standards are developed slowly, by consensus, using extensive consultation and development processes. This has its disadvantages in such a fast-moving field as user interface design and some have criticized any attempts at standardization as premature. However, there are areas where a great deal is known that can be made accessible to designers through appropriate standards and there are approaches to user interface standardization, based on human characteristics, that are relatively independent of specific technologies.

2.3. Common Understanding

Standards do not guarantee good design but they do provide a means for different parties to share a common understanding when specifying interface quality in design, procurement and use.

- For users: standards allow them to set appropriate procurement requirements and to evaluate competing supplier's offerings.
- For suppliers: standards allow them to check their products during design and manufacture and to provide a basis for making claims about the quality of their products.
- For regulators: standards allow them to assess quality and provide a basis for testing products.

2.4. Appropriate Prioritization of User Interface Issues

One of the most significant benefits of standardization is that it places user interface issues squarely on the agenda. Standards are serious business and whereas many organizations pay little regard to research findings, few organizations can afford to ignore standards. Indeed, in Europe, and increasingly in other parts of the world, compliance with relevant standards is a mandatory requirement in major contracts.

3. CURRENT USER INTERFACE STANDARDIZATION INITIATIVES

The International Organisation for Standardisation (ISO) is the worldwide standardization organization responsible for developing international standards in the field of mechanical standardization.

ISO is organized into technical committees (TC) and the ergonomics committee responsible for HCI standards is ISO TC159 SC4. Table 1 shows the main stages of ISO standards development.

International standards are important, partly because the major manufacturers are international and partly because the regional European Standardisation Organisation (CEN) has a strategy of adopting ISO standards wherever appropriate as part of the creation of the single market. The activities of the relevant CEN working group (CEN TC122 WG 5) are also described.

3.1. ISO TC159 SC4: Ergonomics of Human– System Interaction

This committee is responsible for ergonomics standards in the field of human–system interaction. The primary technical work takes place in working groups (WG) and each of these has responsibility for different work items. WG 2–5 are responsible for ISO 9241 (Table 2). WG 5 is also working on ISO 14915: *Multimedia User Interface Design — Ergonomics Requirements for human–computer multimedia interfaces*. This four-part standard will establish software ergonomics requirements and recommendations for interactive multimedia user interfaces that integrate and will synchronize different media (static-like text, graphics, images and dynamic media like audio, animation and

Table 1. Main stages in the development of an international standard

WI	Work Item — an approved and recognized topic for a working group to be addressing that should lead to one or more published standards
WD	Working Draft — a partial or complete first draft of the text of the proposed standard
CD	Committee Draft — a document circulated for comment and approval within the committee working on it and the national mirror committees. Voting and approval is required for the document to reach the next stage.
DIS	Draft International Standard — a draft standard circulated widely for public comment via national standards bodies. Voting and approval is required for the draft to reach the final stage.
FDIS	Final Draft International Standard — the final draft is circulated for formal voting for adoption as an international standard.
IS	International Standard — the final published standard

Note: documents may be reissued as further CDs and DISs

Table 2. Parts and status of ISO 9241

ISO 9241: Ergonomics Requirements for Office Work with Visual Display Terminals (VDTs)	Responsible working group	Status end 1998
Part 1. General Introduction	WG6	IS
Part 2. Guidance on task requirements	WG4 (finished)	IS
Part 3. Visual display requirements	WG2	IS
Part 4. Keyboard requirements	WG3	IS
Part 5. Workstation layout and postural requirements	WG3	IS
Part 6. Enviromental requirements	WG3	FDIS
Part 7. Display requirements with reflections	WG2	IS
Part 8. Requirements for displayed colors	WG2	IS
Part 9. Requirements for non-keyboard input devices	WG3	FDIS
Part 10. Dialogue principles	WG5	IS
Part 11. Guidance on usability	WG5	IS
Part 12. Presentation of information	WG5	IS awaiting publication
Part 13. User guidance	WG5	IS
Part 14. Menu dialogues	WG5	IS
Part 15. Command dialogues	WG5	IS
Part 16. Direct manipulation dialogues	WG5	IS
Part 17. Form-filling dialogues	WG5	IS

Table 3. Parts and status of ISO 11064

ISO 11064: Ergonomic Design of Control Centers	Responsible working group	Status end 1998
Part 1. Principles for the design of control centers	WG8	DIS
Part 2. Principles of control suite arrangement	WG8	DIS
Part 3. Control room layout	WG8	FDIS
Part 4. Workstation layout and dimensions	WG8	WI
Part 5. Displays and controls	WG8	WI
Part 6. Enviromental requirements for control rooms	WG8	WI
Part 7. Principles for the evaluation of control centers	WG8	WI
Part 8. Ergonomics requirements for specific applications	WG8	WI

video). WG 6 is mainly concerned with ISO 13407: *Human-centred Design of Interactive Systems*. WG 8 is concerned with ISO 11064: *Ergonomics Design of Control Centres* (Table 3).

3.2. European Committee for Standardisation (CEN)

CEN is the European equivalent of ISO. Its members are the national standards bodies of the countries in the European Union (EU) and in the European Free Trade Association (EFTA).

The European Commission (EC) declared that 1992 represented the end of trade barriers in Europe and that from then there would be a single European market for goods and services. Different national standards are at least potential barriers to trade and so part of this initiative involved the replacement of national standards with European ones.

There was therefore a flurry of activity to create CEN standards where none existed before. The chosen strategy was to adopt international standards, where appropriate, and short circuit the standards-making process. The CEN Ergonomics Committee TC122, through its WG 5 (Ergonomics of VDTs), was given the brief to facilitate and support the ISO TC159 SC4 user interface work with a view to adopting the International Standard ISO 9241. Since then, the other standards under development by ISO TC159 SC4 have been included in the work program of CEN TC122 WG 5.

4. USING STANDARDS IN SYSTEM DEVELOPMENT

The contents of the main user interface standards, including those under development in the context of how these standards might be used during a number of typical HCI activities are described briefly (Table 4).

The activities follow an approximate time sequence with some additional activities added towards the end of the list. They are not intended to represent the "right way" to approach user interface design nor are all the activities necessary in every project.

4.1. Feasibility Studies and Market Research

Standards are not primary sources for designers looking for new ideas and approaches or inspiration for innovative designs but

Table 4. Typical design activities and issues

Feasibility studies and market research
Requirements analysis including business analysis/task analysis
Interface specification and task specification
Initial design, simulation, prototyping and modeling
Design and build   Dialogue design, interface navigation, display design
Keyboard/input device
Workplace and console
User support, documentation, manuals and training
Safety critical systems
User-centered design methods
Health and safety issues
Job design, group working organization
Users with special needs, children, the disabled and the aged

they often represent important constraints on the potential design. During the feasibility stage it is important to identify which standards if any are relevant. For published standards, the primary source is the national standards organization, e.g. the American National Standard Institute (ANSI) in the USA, the British Standard Institute (BSI) in the UK. Standards under development are more problematical and although much information is potentially public, knowing where to look can be difficult. In the first instance, use the standards numbers and the committee references and contact your national standards organization. They should put you in touch with those involved from your country. Most of the ISO member bodies operate mirror national committees that not only comment on drafts as they are developed but also can provide up-to-date information about the work-in-progress.

4.2. Requirements Analysis Including Business Analysis and Task Analysis

At present, there is little help from standards for this stage although a Technical Report on Human-centred Methods is under development. Engineering usability into products requires a commitment to usability requirements as well as functionality requirements. However, setting usability objectives on these requirements only make sense if there is an agreed way of specifying usability. ISO 9241-11: 1998: *Guidance on Usability* was developed to provide a framework for such a statement of usability. It provides guidance on usability specification that includes descriptions of the context of use, the evaluation procedures to be carried out and the criterion measures to be satisfied when the usability of the system is to be evaluated. There are various situations in which usability may be evaluated, for example in product development, in procurement or in product certification. The common framework presented in this section should be useful in all of these situations.

4.3. Interface Specification and Task Specification, Initial Design, Simulation, Prototyping and Modeling, Design and Build

Specification, design and build involve different HCI activities, but the same standards are relevant. Standards offer specific guidance on well-established design requirements, e.g. the pressure required to operate a key, or the contrast required for an image to be distinct from its background.

4.3.1. Dialogue Design and Interface Navigation

ISO 9241 10: 1996: *Dialogue Principles* presents high-level ergonomic principles that apply to the design of dialogues between humans and information systems. These include suitability for the task, controllability and error tolerance, among others. The principles are supported by scenarios that indicate the relative priorities and importance of the different principles in practical applications.

ISO 9241-14: 1997: *Menu Dialogues* provides recommendations on menu structure, navigation, option selection and execution, and menu presentation (by various techniques including windowing, panels, buttons, fields, etc.).

ISO 9241-15: 1998: *Command Dialogues* provides recommendations on command language structure and syntax, command representations, input and output considerations, feedback and help.

ISO FDIS 9241-16: 1998: *Direct Manipulation Dialogues* provides recommendations on the manipulation of objects, and the design of metaphors, objects and attributes. It covers those aspects of "graphical user interfaces" that are directly manipulated and not covered by other parts of ISO 9241.

ISO 9241-17: 1998: *Form-filling Dialogues* provides recommendations on form structure and output considerations, input considerations and form navigation.

4.3.2. Display Design

"Display design" refers both to the design of display hardware and to the presentation of information on the display.

Display hardware specification and design for office VDTs is covered in ISO 9241-3: 1992: *Display Requirements*. This part deals with the design of screen hardware for visual display terminals. In addition to design specifications, this part also contains a proposed user performance test as an alternative route to conformance. (Note that the ergonomics requirements for flat panels are dealt with in ISO FDIS 13406-2: 1998.)

ISO 9241-7: 1998: *Display Requirements with Reflection* deals with the ergonomic requirements for, and details of, methods of measurement of reflections from the surface of display screens, including those with surface treatments. ISO 9241-8: 1997: *Requirements for Displayed Colours* deals with the ergonomic requirements for multicolor displays that supplement the monochrome requirements in Part 3. Displays for control rooms are dealt with separately in ISO 11064.

Software aspects of display design are covered in ISO FDIS 9241-12: 1998: *Presentation of Information*. This part deals with the specific ergonomics issues involved in representing and presenting information in visual form. It includes guidance on ways of representing complex information, screen layout and design, as well as the use of windows.

There is already a substantial body of material available in guidelines and recommendations and this part represents a distillation of the most useful and relevant ones.

4.3.3. Keyboard and Input Device Design

Keyboard specification and design (in terms of the operation of the keys and its ergonomic qualities) is covered in ISO 9241-4: 1998: *Keyboard Requirements*. This deals with alphanumeric keyboard design. In addition to design specifications, this part also contains a proposed user performance test as an alternative route to conformance. It deals with the ergonomic aspects of the keyboard, not the layout that is specified in ISO 9995: *Keyboard Layouts for Text Office Systems*.

Non-keyboard input devices are becoming increasingly popular and ISO FDIS 9241-9: 1998: *Requirements for Non-keyboard Input Devices* deals with the ergonomic requirements for pointing devices including the mouse, tracker ball, etc. that can be used in conjunction with a visual display terminal.

4.3.4. Workplace and Console Design

Office workplaces incorporating VDTs are covered in some detail in ISO 9241-5: 1998: *Workstation Layout and Postural Requirements*. This part deals with the ergonomic requirements for a visual display terminal workstation that will allow the user

to adopt a comfortable and efficient posture. Workplaces in control rooms are dealt with separately in ISO DIS 11064-3: 1998: *Control Room Layout*. Environmental considerations (visual, acoustic, thermal) are covered in ISO 9241-6: 1998: *Environment Requirements*.

4.4. User Support, Documentation, Manuals and Training

In assessing the usability of a product in practice, real users take account of the documentation, manuals and training received as well as the specific characteristics of the product. ISO 9241-13: 1998: *User Guidance* covers some of these aspects and provides recommendations for the design and evaluation of user guidance attributes of software user interfaces including prompts, feedback, status, on-line help and error management.

4.5. Safety Critical Systems

Although many user interface standards are generic and apply to a wide range of different task situations, safety critical systems pose special risks and may demand special standards. For example, the size, spacing, force and travel of keys on a keyboard to be used in an office environment may not be achievable when the same keyboard has to be used in a control room where protection from sparks or use by operators wearing gloves may override normal requirements.

ISO 11064 Parts 4–8 will address a number of HCI issues in safety critical systems.

4.6. User–centered Design Methods

Although there may be disagreement about what user-centered design means in detail, most HCI specialists would argue that it is fundamental to the practice of human–computer systems. Indeed, much of ISO 9241 has an implicit user-centered design philosophy behind it.

ISO FDIS 13407: 1998: *Human-centered Design Process for Interactive Systems* describes the ergonomic process to be applied within the design process to ensure that proper attention is paid to the human and user issues. Coverage includes usability design and evaluation, user-centered design methods, the use of ergonomics standards in design activities and evaluation methods. The standard is aimed at those responsible for managing design processes and it presents a high level overview of what activities are recommended for human centered design.

4.7. Health and Safety Issues

Health and safety concerns were the starting point for a number of the standardization and regulatory measures. The Council of the European Economic Community (as it then was called) published a Directive on 29 May 1990 on the minimum safety and health requirements for work with display screen equipment (90/270/EEC). This Directive comes under Article 118a and is concerned to ensure that there is a minimum level of health and safety in member states and is aimed at employers. The directive does not therefore refer to the product standards (e.g. ISO 9241) even though they deal with much of the same technical content. With the exception of the UK, they are unlikely to be used formally in national implementations of the Display Screen Directive.

In practice, the European Standards EN 29241 developed by TC122 (based on ISO 9241) can be used by suppliers to demonstrate compliance with the ergonomics state-of-the-art.

4.8. Job Design, Group Working and Organizational Issues

In developing ISO 9241, there was a clear recognition that many of the problems often attributed to poor equipment or workplace design may in fact stem from poor job design. Thus ISO 9241-2: 1992: *Guidance on Task Requirements* provides guidance on the design of display screen tasks based on nearly half a century of research and organizational practice in socio-technical systems.

4.9. Users with Special Needs, Children, the Disabled and the Aged

Many users of information technology feel that little account is taken of the requirements of so-called "normal" users. Users with special needs — whether transitory or permanent — are even less well catered for. One of the major benefits of information technology is its potential to extend human capacity and to complement human skill. A new work item has recently been started on accessibility for users with special needs.

5. CONTACTS FOR FURTHER INFORMATION

For the latest information about the status of standards, contact your national standards body or the regional organization in Europe (CEN) or the ISO:

Human Factors and Digital Networks: Intranets, Extranets and the Internet

C. Forsythe and E. Grose

Statistics and Human Factors, Sandia National Laboratories, Albuquerque, NM 87185–0829, USA

1. INTRODUCTION

Forget the fanciful props of popular science fiction. Instead, extrapolate from current technology trends to envision the world of 2005, 2010 and beyond. It seems reasonable to suppose that most electronics will be linked via digital networks. Your wearable computer will provide access to a current inventory of items on your kitchen shelves. Likewise, it will let you start your dishwasher or adjust your home climate control after you have left the house. There will be a fusion of technologies. Your television, stereo and home computer will be merged and you will make on-demand selections of programming from libraries containing an endless breadth of recorded media. This will require a simple download that will occur within seconds, if not fractions of a second. Here is only a sampling. The intent has been to portray a world where nearly every facet of our lives has been interconnected through digital networks.

Now, put aside the promise imaginable with digital networks. Continuing to extrapolate from current trends, there is a downside. Imagine that the 1960s sitcom you downloaded the previous evening was infected with a tenacious virus. This virus quickly spread to corrupt the operating system software linking each of your home electronics and appliances, as well as software running locally on several devices. Over the course of a few hours virtually every electronic device in your home becomes completely unusable. Your initial inconvenience might only last the day or so needed to eradicate the virus and reinstall software that had been infected. However, to your chagrin, you may find that there are unanticipated problems. Over the past few years there have been software upgrades. In reinstalling the operating system software and various other software applications and peripheral devices, you encounter incompatibilities between software applications. Consequently, some devices are not recognized by the operating system and others do not function properly. You expend countless hours attempting to fix the problems. Technicians install and reinstall software. And in the end, you may attain the same degree of functionality you had prior to contracting the virus.

These scenarios are mentioned as a means of drawing attention to the more dramatic problems faced with digital networks. For the past three decades, Human Factors has focused tremendous effort on identifying aspects of user interface design that affect the moment-to-moment efficiency and satisfaction of users. These efforts have been justified through time savings, reduction of human error and general customer approval. However, for the typical user, these gains might seem incremental.

It is our belief that there are human factors issues associated with digital networks, and associated advances in technology, that dwarf the issues that have been the primary focus of Human Factors' past efforts. As users become increasingly reliant on digital networks, they also become increasingly vulnerable to malevolent acts and technical failures that have the potential to leave them sidelined for hours, if not days. The remainder of this chapter will address these issues, and others, discussing the unique problems the Human Factors profession must address as digital network technology continues its forward march.

2. VULNERABILITY TO MALEVOLENT ACTS

One must be concerned with two general types of threats. First, there are direct threats whereby hackers gain access to computer systems for purposes of theft, espionage or sabotage. The second type of threat is indirect and involves the dissemination of viruses that spread uncontrolled, infecting mostly unknown victims. In either case, the outcome can be costly, whether the victim is an individual or an organization. Interestingly, the mainstream media often presents a somewhat inaccurate representation of the security risks. Almost daily reports of obscure vulnerabilities in popular commercial software create an impression that the main impetus of most hackers is to discover and exploit such shortcomings. In reality, hackers primarily take advantage of human nature. For example, lists of the most commonly used passwords are readily available. Likewise, users rarely change their passwords, they leave slips of paper with their passwords in the open, and if asked over the telephone, they will often divulge their passwords to a stranger under marginally credible pretenses.

Two Human Factors issues arise. First, we are currently witnessing a proliferation of passwords, Personnel Identification Numbers (PIN) and other mechanisms for authenticating one's identity. With the technology commonly in use today, users cannot be expected to adhere to the most minimal security provisions (i.e. create a unique password, memorize passwords so they are not written anywhere and change passwords on a regular basis). This dilemma will only worsen as the Internet enables increasing access to remote resources. Being knowledgeable of memory processes, Human Factors experts should be uniquely capable of devising concepts that enable reliable verification, without the drawbacks currently faced with simple password-based concepts, or the intrusive and sometimes questionable reliability of biometric devices.

Second, for most organizations, protection of their computer network resources depends on a relatively small number of personnel assigned to computer security and/or network administration. Human error by these personnel, be they errors of omission or commission, may leave network resources vulnerable to intruders. Previous analysis has identified that human system components are one of the weakest links in networked systems (Forsythe 1997). Furthermore, techniques are available for identifying failure modes associated with human error and assessing the adequacy of existing and proposed measures to preclude these failures (Forsythe and Grose 1997). This is a role for which Human Factors is uniquely qualified due to our familiarity with Human Reliability Analysis and other methodologies for assessing and preventing human error.

Avoidance of viruses presents an especially difficult challenge. The current model is one wherein virus detection software is used to scan files to determine if they have been infected by any of the thousands of known viruses. Because a virus must be known and a means developed to defeat the virus, at best, this solution

provides only partial assurance. An ingenious hacker can easily introduce a new virus to millions before it is detected and virus-scanning software updated. And this does not consider the delinquency of most end users with respect to updating their virus scanning software, another human vulnerability to exploit.

A second solution requires users to rely on certification sites that provide some level of guarantee that the files they certify are virus-free. Certification can be easily forged. Furthermore, the presence of such organizations offers an invitation for malevolents to engage in games of cat and mouse wherein the objective is to induce mistaken certification of infected files. With virus-resistant software unlikely, the remaining option is to modify user behavior. Warnings and cautions are of limited effectiveness. A more promising approach would be to develop interfaces that unobtrusively alert users to the risk associated with specific on-line behaviors. There has been extensive research concerning the perception of risk and devising means to heighten the awareness of risk. Facilitating objective assessments of risk is a job well suited to Human Factors.

3. COMPLEXITY OF COMPUTER SOFTWARE AND HARDWARE

With each new version, there is a tendency for popular commercial software products to add "Internet-ready," and other features. These additional features introduce increased complexity to the software. This trend is evident with all types of software: operating system, server, browser and office products such as word processing and spreadsheets. The problem is that each type of software must interact and greater complexity results in increased potential for incompatibilities. These incompatibilities may have minor consequences (e.g. unavailability of software features and system errors) or more significant consequences (e.g. system crashes with subsequent data loss or complete system inoperability).

It may appear that these problems only involve software reliability and may be corrected through more rigorous testing and evaluation. However, there is a proactive course of action. It should not be forgotten that human actions are the immediate cause of software incompatibilities. Users upgrade software following irregular schedules. They install and uninstall software and hardware. And they move and delete systems files. Consequently, software must operate in an environment that often exhibits far greater heterogeneity than intended by software developers. In organizations, standardization has often been proposed as a solution. This has been based on a belief that problems with software incompatibility may be alleviated by restricting the ability of users to diverge from standard hardware/software configurations. However, it has been commonly observed that users resent and resist such attempts to impose conformity and will inevitably find means to deviate from the standard.

Heterogeneous computing environments are partially a product of the variability in computer users. For many users, it represents a means of personal expression. In contrast with efforts aimed at stifling heterogeneity through standardization, a characterization of variability in the behavior of computer users would allow the design of products that accommodate the resulting variability in computing environments. The characterization and accommodation of user populations is a familiar problem for Human Factors. In fact, it is the basis for anthropo-

metrics. The same strategies used to characterize the physical and cognitive dimensions of user populations may also be applied to describe user-generated variability in computing environments. With such knowledge, levels of accommodation based on divergence from a population mean could be incorporated into software requirements (e.g. accommodate 98th percentile user). These requirements could address concepts such as the percentage of overall storage space that is utilized, the frequency of software upgrades and the tendency to simultaneously run multiple applications. Furthermore, concepts may be applied that involve definition and qualification of software products with regard to a parameter space that incorporates different dimensions of user-generated heterogeneity in computing environments (Forsythe *et al.* 1995).

4. OPPORTUNITIES FOR HUMAN FACTORS

The most important aspect to understand about digital networks, such as the Internet, is the wealth of opportunities that they enable. As a profession, Human Factors has been routinely relegated to a subservient role within the product development process. Even so, the profession has certainly flourished over the past decades. However, the profession has also been frustrated and left to regret what might have been possible if usability had received fair consideration.

Within product development environments, power tends to be associated with the ability to control funding and to control design. Traditional businesses and organizations offer very limited opportunities for Human Factors to wield influence over either means of exerting power. Consequently, we argue that the potential for Human Factors has barely been realized and as a direct product, we have yet to witness the true potential afforded by computing technology.

In human history, there probably has never been a more significant challenge to traditional business and economic models than that posed by the emerging "digital economy" (Kelly 1997). The ability is unprecedented for ordinary individuals, operating from a $1000 home computer, to communicate and interact with large numbers of people. Consider publishing. Traditionally, there have been limited channels by which writers could publish their work with hopes of high volume distribution. Those controlling these limited channels possessed enormous power to censor available information, promote certain perspectives and determine the success or failure of talented individuals. With the Internet, ordinary home computer users have been given a low-cost means of readily broadcasting to millions of potential consumers. Publishing is only one of countless examples. It is this freedom to operate outside of established business models that creates an extraordinary opportunity for innovation and provides avenues to success that have never before existed.

The emergence of digital networks has created an atmosphere ripe with opportunities for Human Factors to realize its true potential to positively shape everyday life. Likewise, our profession is held back by nothing more than the willingness of individuals to pursue their ideas. Human behavior permeates all levels of interaction with digital networks and by exploiting our unique knowledge of human behavior, Human Factors has an opportunity to step forward with solutions that will make a genuine difference.

Consider a simplistic example. Keyboard errors are well

understood and data is available for the most common errors. Spelling errors are similarly well understood. When entering an Internet address, it is reasonable to expect that one in every hundred entries, or so, will contain either a keyboard error or misspelling. Knowing these highly predictable occurrences of human error and aware that certain Internet sites receive thousands, if not millions, of visitors every day, an opportunity was realized. Entrepreneurs purchased the domain names similar to those of popular Internet sites, such as Microsoft Corporation, but with minor errors in the Internet address (e.g. microsof.com) and then, for a modest fee, offered to redirect misdirected Internet traffic to the desired destination. In this case, a business has emerged on the basis of knowledge of the simplest characteristics of human behavior.

After an hour using their computer to access the Internet, reasonably astute Human Factors professionals applying their expertise should be able to identify similar, although likely more sophisticated, means of improving the user's experience with this technology. This is the opportunity that the rampant spread of digital networks has extended to the Human Factors profession.

5. CONCLUSION

The Internet of the future will be quite different from the one to which we have now become accustomed. Ascending technologies such as wave division multiplexing, fiber optics, satellite, asymmetric digital subscriber lines, and wireless ethernet are laying the foundations for tremendous increases in bandwidth. This promises an explosion of electronic activity on the global network. The popular media have warned that the impending "information explosion" will somehow leave users paralyzed. In reality, the Internet, in its current form, demonstrates that human beings are superbly equipped to filter unwanted data. Far from being paralyzed by "information overload," users have shown a capacity to function effectively despite a substantial increase in day-to-day information exchanges.

However, with the information explosion, or actually the media explosion, there is an increasing awareness that time is a precious commodity, and perhaps more valuable than money. Young, old, rich or poor, there is a growing resentment toward anything that steals or squanders our time. In this regard, it becomes unacceptable for computers to add tasks to our already busy schedules. This not only drives the need for more usable products, but also creates the need to be able to measure usage

patterns in order to focus developers on why products succeed or fail. With its connectedness, the Internet offers an unparalleled opportunity to collect such usage data. In this regard, the Internet offers a unique capacity for self-correction.

To take full advantage of this capacity for self-correction, it is necessary for someone to ask the appropriate questions, and no discipline is better positioned than Human Factors. The vast majority of web products fail to attract the level of usage initially expected by their developers (Grose *et al.* 1998). Usage statistics reveal that a relatively small number of factors are needed to predict the usage of web products. Products that are relevant to a large population, have relatively little competition, and satisfy the needs of users will see extensive usage. Similarly, more complex questions may also be answered. To realize the potential of Human Factors to impact the Internet, it is necessary to ask and answer questions regarding the interactions of humans with digital networks, and in the answers, there resides the opportunity for the Human Factors profession to realize its potential.

Human Speech Digitization and Compression

P. R. Michaelis

Lucent Technologies, Bell Laboratories, 11900 N. Pecos Street, Denver, CO 80234, USA

1. INTRODUCTION

Nearly all modern speech-based computer and communication systems transmit, route or store speech digitally. One obvious advantage of digital techniques over analogue is the ability to provide superior audio quality (e.g. compact discs versus phonograph records, or digital cellular telephones versus analogue). Other advantages include the ability to send many more simultaneous transmissions over a single communications channel, route speech communication through computer-based switching systems and store speech on computer disks and in solid-state memory devices. This paper describes techniques that reduce the amount of data required to digitize speech.

2. SPEECH DIGITIZATION

The simplest way to encode speech digitally is to generate a sequence of numbers that, in essence, trace the 'ups and downs' of the original speech waveform. For example, if one wished to digitize a waveform in which all of the important acoustic information is < 4000 Hz (4000 cycles s^{-1}), the basic steps of this analogue-to-digital conversion would include:

1. Filter from the original signal all information > 4000 Hz.
2. Divide the original signal into 8000 segments s^{-1}.
3. Go through the segments in order, measuring and recording the average amplitude of the waveform within each segment.

The purpose of the first step is to prevent 'aliasing' — the creation of false artifacts caused by the undesired interaction of the sampling rate with the frequency of the observed events. The phenomenon in motion pictures, where the spokes of a rapidly rotating wheel may appear to be standing still or even moving backwards, is an example of aliasing.

The second step, sampling at twice the frequency of the highest-frequency sine wave, is necessary to capture both the peaks and the valleys of the wave.

To envision the third step more easily, imagine that the original waveform is drawn on a sheet of paper. Within every segment, each of which represents 1/8000 s, the height of the waveform is measured with a ruler. The sequence of numbers obtained in this manner constitutes a digital representation of the original waveform.

Regarding the "ruler" used to measure within-segment speech amplitudes, speech quality comparable with that of a modern telephone requires 12 bits per segment, 8000 segments s^{-1}. (As a point of comparison, audio compact discs use 16 bits per segment, with 44 100 segments s^{-1}.) The resulting data rate of 96 000 bits s^{-1} means that a typical 1.44 MB floppy diskette can hold only ~2 min of telephone-quality speech.

Modest reductions in the data rate can be achieved by using logarithmic amplitude encoding schemes. These techniques, which represent small amplitudes with greater accuracy than large amplitudes, achieve voice quality equivalent to a standard 12-bit system with as few as 8 bits per segment. Examples include the m-law (pronounced "myoo law") coding found on many US digital telephones, and the A-law coding commonly used in Europe.

For many applications in which the cost of transmission or the cost of storage is important, such as wireless telephony or voice mail systems, the data rate reductions achieved with simple m- and A-law encodings are inadequate. One way to achieve significant reductions in the data rate is to extract and digitize the frequency content of the waveform (rather than simply to digitize the shape of the waveform).

Many coders that work in this manner have software components that map to physical components of the human vocal mechanism. They reduce the data rate by encoding only the parameters that control the changeable components of the speech production model; for example, the parameter that controls overall amplitude and the parameter that adjusts the fundamental pitch of the electronic "vocal cords".

3. THE HUMAN SPEECH PRODUCTION MECHANISM

Given that many components in these coders have physiological counterparts, it is helpful to understand the human vocal mechanism prior to examining the coders.

The major physical components of the human speech mechanism include the lungs, the vocal cords and the vocal cavity. When a person speaks, the lungs force air past the vocal cords and through the vocal cavity. The pressure with which the air is exhaled determines the final amplitude or "loudness" of the speech. The action of the vocal cords on the breath stream determines whether the speech sound will be voiced or unvoiced.

Voiced speech sounds (e.g. the "v" sound in "voice") are produced by tensing the vocal cords while exhaling. The tensed vocal cords briefly interrupt the flow of air, releasing it in short, periodic bursts. The greater the frequency with which the bursts are released, the higher the pitch.

Unvoiced sounds (e.g. the final "s" sound in "voice") are produced when air is forced past relaxed vocal cords. The relaxed cords do not interrupt the airflow; the sound is instead generated by audible turbulence in the vocal tract. A simple demonstration of the role of the vocal cords in producing voiced and unvoiced sounds can be had by placing one's fingers lightly on the larynx, or voice box, while slowly saying "voice"; the vocal cords will be felt to vibrate for the "v" sound and for the double vowel (or diphthong) "oi" but not for the final "s" sound.

The mechanisms described above produce what is called the excitation signal for speech. Many properties of the excitation signal will differ when comparing one person to another. However, when examining an individual only three parameters in the excitation signal will vary as they speak: amplitude of the sound, proportion of the sound that is voiced or unvoiced and fundamental pitch. This can be demonstrated easily. If one were to hold one's mouth wide open, without any movement of the jaw, tongue or lips, the only remaining changeable characteristics of sound generated by the vocal system are the above three parameters.

At any given time, excitation signals contain sounds at many

different frequencies. A voiced excitation signal is periodic. The energy in its frequency spectrum lies at multiples of the fundamental pitch, which is equal to the frequency with which the vocal cords are vibrating. An unvoiced excitation signal contains a random mixture of frequencies similar to what is generally called white noise.

The vocal cavity "shapes" the excitation signal into recognizable speech sounds by attenuating certain frequencies in the signal while amplifying others. The vocal cavity can accomplish this spectral shaping because it resonates at frequencies that vary depending on the positions of the jaw, tongue and lips. Frequencies in the excitation signal are suppressed if they are not near a vocal cavity resonance. However, vocal cavity resonances tend to amplify, or make louder, sounds of the same frequency in the excitation signal. The resulting spectral peaks in the speech sounds are called formants. Typically, only the three or four lowest-frequency formants will be < 5000 Hz. These are the formants most important for intelligibility. (The upper frequency limit for many audio communication systems, including the public telephone system in the USA, is ~3400 Hz. This is why speech sounds that differ chiefly in their upper-frequency formant structure, such as "f" and "s", tend to be hard to distinguish on these systems.)

For spoken English, a simple classification of speech sounds according to manner of formation would include vowel, nasal, fricative and plosive sounds. In the formation of vowels, such as the "ee" sound in "speech" and the diphthong "oi" in "voice", the breath stream passes relatively unhindered through the pharynx and the open mouth. In nasal sounds, such as the "m" and "n" in "man", the breath stream passes through the nose. Fricative sounds are produced by forcing air from the lungs through a constriction in the vocal tract so that audible turbulence results. Examples of fricatives include the "s" and "ch" sounds in "speech". Plosive sounds are created by the sudden release of built-up air pressure in the vocal tract, following the complete closure of the tract with the lips or tongue. "Talk" contains the plosive sounds "t" and "k". Except when whispering, the vowel and nasal sounds of spoken English are voiced. Fricative and plosive sounds may be voiced (as in "vast" or "den") or unvoiced (as in "fast" or "ten").

4. SPEECH COMPRESSION

The parameters computed by coders that follow this vocal tract model fall into two categories: those that control the generation of the excitation signal and those that control the filtering of the excitation signal.

Two different signal-generating mechanisms are required to produce a human-like excitation signal. One mechanism generates a periodic signal that simulates the sound produced by vibrating human vocal cords. The other produces a random signal, similar to white noise, suitable for modeling unvoiced sounds. Thus, when a voiced sound must be produced, such as the "ee" in "speech", the output from the periodic signal generator is used; for the unvoiced "sp" and "ch" sounds in "speech", the random output from the other generator is used.

In some systems, a weighted combination of the random and periodic excitation is used. This can be helpful in modeling voiced fricative sounds, such as the "z" sound in "zoo". However, many coders restrict the excitation so that it is modeled entirely by either the voiced or unvoiced excitation source. In these coders,

selection of the excitation is controlled by a two-valued voicing parameter, typically referred to as the voiced/unvoiced decision.

In addition to the voiced/unvoiced decision, the excitation function is scaled by an amplitude parameter, which adjusts its loudness. Finally, if the system is to generate something other than a monotone, it is necessary for the period of the voiced excitation source to be variable. The parameter that controls this is called the pitch parameter. In summary, three parameters are sufficient to control a simple excitation model (i.e. a model that does not take into account vocal tract differences among people): an amplitude parameter; a voiced/unvoiced parameter; and, if voiced, a pitch parameter that specifies the fundamental periodicity of the speech signal.

Various techniques have been used to simulate the manner in which the human vocal cavity imposes a particular spectral shape on the excitation signal. One of the first techniques developed uses a bank of band-pass filters, similar in many respects to the adjustable multiband 'graphic equalizers' found on some high-end stereo systems. The center frequencies of these filters are fixed; an adjustment in the gain of each filter or channel allows the desired spectrum to be approximated, in much the same way that adjusting the tone controls may vary the spectral characteristics of a stereo system.

The chief drawback to this approach is the large number of filters required. The number of filters can be reduced if it is possible to control their center frequencies. Specifically, by matching the center frequencies of filters to the desired formant frequencies, one can encode speech with only three or four tuneable band-pass filters. The important point is that even though the center frequencies of the filters must now be encoded along with the gains of the filters, the total number of parameters required for accurate shaping of the excitation signal is reduced greatly.

Although early speech synthesis systems relied on analogue mechanisms to filter and shape the excitation signal, modern speech compression systems rely entirely on digital filtering techniques. With these systems the decoded speech signal heard at the receiving end is the output of a digitally controlled filter that has as its input the appropriate excitation sequence. Digital control of the filter is accomplished through the use of a mathematical model — in essence, an equation with constants and variables in which the desired spectral filtering is specified by setting the appropriate values for the variables. Great reductions in the data transmission rate are achievable with this approach because the same mathematical model is preloaded into both the encoder and decoder. Therefore, the only data that must be transmitted are the relatively small number of variables that control the model.

A good example is the technique known as linear prediction, in which speech samples are generated as a weighted linear combination of previous output samples and the present value of the filter input. This yields the following expression for each output sample ($S[i]$) as a function of previous samples ($S[i-1]$, $S[i-2]$, …, $S[i-n]$), the prediction weights ($A[1]$, $A[2]$, …, $A[n]$) and the filter input ($U[i]$):

$$S[i] = A[1]S[i-1] + A[2]S[i-2] +… + A[n]S[i-n] + U[i].$$

The filter input in this equation ($U[i]$) is the product of the amplitude parameter and the excitation sequence. The total

number of coefficients in the equation (*n*) determines how many spectral peaks, or formants, may be approximated.

Once the complete set of parameters (amplitude, voicing, pitch, spectral parameters) has been specified, a speech decoder can produce a constant speech-like sound. To generate intelligible natural-sounding speech, the model parameters need to be updated as often as 40–50 times s^{-1}. To envision this process, it is helpful to recall how motion pictures work: apparent motion — in this case, a smoothly varying speech sound, rather than a smoothly varying image — is achieved by updating with sufficient frequency what are, in fact, still images. (Some systems that store speech in this format, such as the Lucent Technologies Intuity™ AUDIX®, voice messaging system, allow users to adjust the playback rate without the shift in tone that would accompany, for example, playing a 33 RPM phonograph record at 45. This is accomplished by adjusting how long each set of speech production parameters stays "in the gate" before being updated, in much the same way that "slow motion" is achieved with motion pictures.)

One of the first products to incorporate this style of speech compression was a children's learning aid introduced by Texas Instruments in 1978, the Speak & Spell,. It used 10-coefficient linear predictive coding (LPC-10) to model speech. The data rate for this LPC-10 model was 2400 bits s^{-1}. (The actual data rate in the Speak & Spell is considerably less than 2400 bits s^{-1} because a one-bit repeat code was used when adjacent parameters were judged sufficiently similar.) This low data rate was achieved, in part, by "hard-wiring" the excitation parameters that tend to vary from person to person. This meant that if people's vocal tract characteristics differed from those that had been built into the speech production model, their voices could not be reproduced without distortion.

The ability to model a wide variety of voices accurately is achieved by systems in which the excitation function is not hard-wired, but is instead under software control. A good example is the Intuity AUDIX voice messaging system, which uses code-excited linear prediction (CELP) to model speech. The data rate for typical CELP-based systems ranges from 4800 to 16 000 bits s^{-1}. (The higher data rates are seen more frequently in systems where it is important to maximize the speech quality or to reduce the computational complexity of the coder.) Compared with similar-quality uncompressed digitized speech, these techniques yield data rate reductions of at least 6:1, and as high as 20:1.

Human Ecology: Developing Ecological Auditory Warnings

N. Stanton
Department of Design, Brunel University, UK
J. Edworthy
Department of Psychology, University of Plymouth., Plymouth PL4 8AA, UK

1. INTRODUCTION

Auditory alarms take many forms. Despite more advanced ergonomic warnings (Patterson 1982) many warnings consist of horns, klaxons, whistles, sirens, bells, buzzers, chimes, and gongs. There are various characteristics and features associated with the different technologies of auditory alarms, such as intensity, frequency, conspicuity, and noise penetration ability. Although much research has already been conducted in this area and improvements suggested and made as a result (Stanton 1994; Stanton and Edworthy 1999), this does not mean that all the problems have been solved, or that the information which already exists has filtered its way into current design practice. Case studies in coronary care, intensive care, aviation, manufacturing, and power generation show that although auditory signals may be successful in attracting attention, they can at times be disruptive distractions carrying little useful information about the problems of which they are informing. Further, a study by Patterson (1982) suggests that between four and seven warnings can be acquired reasonably quickly, thereafter performance slows down dramatically. Up to seven warnings can be retained, even after one week of absence, and this figure could be up to nine if the warnings were presented regularly. However, it is not just the sheer number of alarms, which cause problems for the user; in many cases the alarm sounds themselves are confusing because they are similar to one another either in sound quality or in meaning. There are also some problems in extrapolating from laboratory and in situ testing to the way in which alarms are most likely to be heard in the actual work environment. For example, Weirs and Kershner (1984) suggest that although twelve auditory alarms may be discernible on a relative basis (in tests at nuclear power plants), if absolute identification is required, this number is likely to be halved. There are at least two fundamental design problems. The first is how to design auditory alarms so that their meanings are conveyed to the listener in the most effective way. The second is the question of how many auditory alarms can be learnt and recalled comfortably. The two problems are interrelated, and one way to tackle them is to capitalize upon what the users understand about sound (including alarms and warnings) and its meaning.

The amount of information that can be transmitted by auditory tones is clearly very limited although it has also been shown that more advanced ergonomic alarms can convey larger amounts of information. The idea of transmitting some information about the nature of the problem through the auditory medium is an attractive prospect. There are a number of research projects which suggest how sound might be used to enrich the working environment that could be applied to the design of warnings and monitoring sounds. There are also methods from other areas of warning and information design research which might fruitfully be applied to auditory warning evaluation (Zwaga and Easterby 1984).

2. THE METHOD

Blattner, Sumikawa, and Greenberg (1989) suggest that there may be some principles common to visual symbols (icons) and auditory messages (earcons) in transmitting information to the user of a computer system. Earcons have been divided into two classes, in the same way as icons, known as representational and abstract. Representational earcons are perhaps the easiest to design in that they sound like the thing they represent to some degree. This requires that the representational object has a sound, and that the sound will be recognized and easily interpreted by the human observer. Gaver (1986) investigated symbolic (e.g. applause for approval) nomic (e.g. the sound of a closing metal cabinet for the closing of a file) and metaphoric (e.g. falling pitch for a falling object) mappings for representational earcons. He suggested that representations need not be realistic, but they should capture the essential features of the thing they represent if they are to be successful. Other research shows that the essential psychological features of events are conveyed through particular acoustic aspects of those events. Abstract earcons, on the other hand, require the development of a distinctive audio pattern which appears to be very like the construction of traditional auditory alarms. There are problems with the use of abstract sounds, because they can often be associated with several different types of meaning, which could result in confusion. However, some traditional sounds may already contain meaning, e.g. the symbolism of the fire bell. Gaver's classification (i.e. symbolic, nomic, and metaphoric) enables us to reinterpret sounds and understand the type of information they contain.

Development and construction of auditory symbols could follow a procedure similar to the one used in the development of visual symbols — for example, the method for the development of public information symbols (ISO TC 145/SCI DIS 7001) as proposed by Zwaga and Easterby (1984). Figure 1 illustrates our first iteration of an alarm construction and evaluation methodology adapted from this method. The figure distinguishes between the process (those activities required by the method, i.e. design, testing, and modification) and the output (the results produced by the aforementioned activities). The principal parts of the process are dealt with in more detail by the following sections. The activities may be likened to a funneling process: many sounds are entered into the testing procedure, but only a small subset of refined and modified sounds are left at the end.

2.1. Generate Trial Sounds

First of all, the number of potential referents needs to be identified. Some care needs to be taken not to identify too many of these as learning problems will be encountered later on. Rationalization may therefore be necessary at this stage. As well as any existing sound that may already be available (e.g. from the equipment currently being used), designers may wish to generate new sounds. This can be done by recording natural sounds (e.g. the sound of rapid heartbeat) and using synthesizers to create sounds (e.g. falling pitch for a falling blood pressure). Quite sophisticated mechanisms are available at relative low cost for sampling, mixing, and editing sounds which offer the alarm designer almost infinite

possibilities. The extensive range of options available leaves the designer in a quandary regarding which sound to choose for each function and this procedure would go some way in alleviating this problem. Part of the design process could be allocated to the user. For example, structured interviews or a free-association paradigm could allow potential users of the system to generate their own ideas about which sounds would be most appropriate. These ideas could then be modified by the designer.

2.2. Appropriateness–ranking Test

The appropriateness-ranking test involves initial screening of the potentially large number of sounds from the initial set. Sounds are presented to respondents together with their referent function. Respondents are requested to rank order the sounds for each function until the entire set has been presented. The purpose of this phase is to select a subset of highly ranked sounds for further testing. For each referent function two or three potentially useful sounds may be taken forward as potential warning sounds for inclusion in the final warning set. If a referent function has no appropriate sound, some modification of the sound set may be necessary, otherwise that referent may have to be returned to the initial design stage.

2.3. Learning/Confusion Test

A paired-associate learning task is then invoked to train participants in the referent functions for the set of sounds. After learning the sound set, participants would be tested immediately and again after a one-week interval. The dependent variables might be the time taken to learn the function of each sound and the ability to recall the function when the sound is played immediately after the learning phase and after a one-week interval. Confusions are also noted in order to determine which sounds are mistaken for other functions. The confusion matrix is an important part of this process. A whole sound set should be presented which corresponds with all of the sounds that will be presented in situ in order to identify any overlaps which may exist. Some confusion between sounds may occur because of a similarity in function rather than in acoustic properties. Whilst this is a theoretically interesting issue, which needs to be explored, it presents something of a problem in the initial identification of referents that should be borne in mind at that time.

2.4. Urgency Mapping Test

The urgency mapping test requires respondents to rate the urgency of each sound as it is played to them. Previous studies by Edworthy et al. (1991) have shown consistent and predictable effects through adjustments to certain characteristics of the sound. These findings may be used to carry out modifications where inconsistencies are found between subjective ratings of urgency for a sound and the objective urgency requirement of the function. The purpose of this exercise is to obtain ranking data on the relative acoustic urgencies of the warnings without knowledge of the objective urgencies of the referents. The relative urgencies of the referents should be rank-ordered if possible — although this would be difficult if the urgency of the referent was context-specific — and then correlated with the acoustic urgencies already obtained. If the matching between warning and referent is poor, the sounds can be modified in order to increase, or decrease, their urgency appropriately.

2.5. Recognition/Matching Test

The matching test requires the participant to assign a sound to one of the referent functions from a list they are given. They may assign more than one sound to a function if they see fit. This information is used for a preliminary modification of the sounds where required. Sounds that are successfully matched to functions at this stage proceed for further testing.

In the recognition test, respondents are required to recognize the situations to which the sounds refer. Sounds are presented to respondents who are required to write down the sound reference number and what they think the sound represents until all of the sounds have been presented. Some development of the most pragmatic procedure will be necessary for auditory warnings, as opposed to public information symbols, because of the demands that listening to the complete set of warnings will make on the respondent. (It is relatively easy for the respondent to scan a set of symbols in a few seconds — this is not the case for auditory warning sounds.) It is important that the respondent is aware of the nature of all the sounds which are later to be linked to referents before the procedure begins. An iterative procedure, such as response surface methodology, is envisaged as being appropriate. Respondents should be free to write more than one sound reference number against a particular function if they wish. These responses are then evaluated against the referent function that they were intended to convey. Again, if any function fails to reach an acceptable criterion level (e.g. ISO suggest 66% recognition accuracy as a minimum for visual symbols) then it is modified or referred back to the initial design stage.

2.6. Generate Standardized Verbal Descriptions

The verbal descriptions of the sounds serve as identifiers only and are given to label sounds with referent functions. In a similar way to public information symbols, these verbal descriptions would allow some flexibility in the application of the designs while retaining the essence of the sound.

2.7. Operational Test

An operational test may be carried out in a simulated or real environment. While this sort of testing often lacks the controlled rigor of experimental laboratory studies, it may provide the users with the ecological validity necessary to gain acceptance. At this stage, it is important to carry out an audibility test, especially if the warning set would typically be heard under noisy conditions. The operational test also has the advantage of testing sounds within the environmental context in which they are to be used. To do this effectively would require an observer (or observers) to collect data on the responses of the participant(s) to a set of alarms as they occurred. The appropriateness of these responses could then be evaluated during a debriefing session with the participant(s). This evaluation would indicate the success with which the alarm system was able communicate the problem to the participant(s).

3. CONCLUSIONS

Further refinement of the methodology is likely to include developing viable methods for carrying out the generation of trial sounds by respondents, the recognition and matching tests, and the degree to which urgency mapping is a necessary (or indeed

feasible) feature of the particular warning set being designed. However, the design of a representational auditory alarm system could communicate the nature of the fault to the human observer (e.g. pilot, nurse, or central control room operator). This type of display has the potential to bring the human observer 'closer' to the system (e.g. aircraft, patient, or power generation equipment) being monitored.

Representational auditory alarm displays could mean an increase in the amount of information that can be conveyed by a non-speech medium. The procedure would also allow already learned associations between 'traditional' alarms and their meanings to be capitalized upon, because the production is a two-way exchange between designer and potential user. Auditory displays of the nature discussed in this article may also benefit by the fact that they could be universally understood by all users, independently of spoken language. However, it is essential that they are first tested on a representative sample of the user population, and that once standards have been established they are adhered to. By ensuring that a multiplicity of alarms is not used for the same function, this would alleviate some of the problems associated with current systems.

Human–Computer Interaction (HCI)

G. Salvendy

School of Industrial Engineering, 1287 Grissom Hall, Purdue University, West Lafayette, IN 47907, USA

1. WHAT IS HCI?

Human–Computer Interaction (HCI) deals with the design of computing systems for human use. In accomplishing its objective, HCI design considers the limitation and availability of technology, the specific population that will use the computing systems and the tasks and functions for which it will be utilized. In pursuit of its objective, HCI researchers and designers consider the physical, cognitive, perceptual and social attributes and limitations of the human. Thus, HCI arrives at designing systems which all users, independent of skill level, cultural background or functional limitations resulting from disability, aging or circumstance, can effectively use.

The discipline of Human Factors and Ergonomics, since its inception more than 50 years ago, has been the leading force in designing machines for human use. HCI design is a specific case in Human Factors and Ergonomics, requiring the design of a system which is currently utilized by > one billion people. No other system or machine has ever existed with the physical, social and cognitive complexity so widely utilized, as the computer. For this reason, HCI evolved some 20 years ago as a separate professional and scientific discipline.

There are currently > 30 000 HCI professionals worldwide for whom three major international conferences specifically on HCI are held (ACM's CHI annual conference, Interacting with Computers biennial conference and the International Conference on Human–Computer Interaction biennial conference). In addition to these, there are national conferences on the subject-matter.

The HCI discipline is very well researched, having > 20 000 publications, which are disseminated via conference proceedings in five specifically dedicated journals on the subject matter (*Behaviour and Information Technology*, *International Journal of Human–Computer Interaction* [published in cooperation with the International Ergonomics Association and the Human Factors and Ergonomics Society], *International journal of Human–Computer Studies*, *Human–Computer Interaction* and *Interacting with Computers*) and books. Despite these significant activities in HCI, the description suffers from the following shortcomings:

- Less than 1% of corporate research and development in computer technology is dedicated to HCI.
- HCI lacks its own scientific base, and is neither respected by industry or academia.
- HCI is pulled by technology rather than pushing technology.
- HCI is primitive in its comparison to human–human communication.

2. TAXONOMY AND FRAMEWORK

HCI does not yet have a scientifically based and operationally oriented taxonomy which could provide a basis to pool together the large quantity of diversified research in a unified conceptual and operationally model that could be utilized by designers to further improve HCI and by researchers more effectively to target their research studies. This is partly because HCI professionals predominantly come either from computer science or human factors and ergonomics. The computer scientists do not get enough (and frequently get no) background in behavior science; the ergonomists do not get enough (and frequently get no) background in computer science. Yet, the HCI discipline is the interaction between the two.

Because of this lack of taxonomy in HCI, researchers and designers have developed a framework for capitalizing in designing HCI on representing the mental model of a user associated with a specific task performance. The original Macintosh computer had nicely taken advantage of this by, for example, requiring discarded materials to be placed in a wastebasket by using the mouse to drag the item to the wastebasket icon.

Another framework for HCI research and design is to minimize the complexity of task performance. This is achieved by chunking items of similarity, reducing the number of alternatives presented to the user, providing decision support to the user to reduce the mental load associated with task performance, designing an intelligent software to do a part of the task which originally was schedule to be performed by humans or, finally, by the use of visualization and multimedia enablers, in certain situations, for the presentation of information in a significantly less complex form than would be required in the presentation of similar information for decision making.

The emphasis by HCI researchers and professions to simplify the computer interface design is contrary to the finding by industrial psychologists who advocate enriching rather than simplifying, since the former results in both higher job satisfaction and performance, lower error rate, absenteeism and lower labor turnover. If so, why are the HCI professionals not enriching HCI design? The reason is presumably that HCI professional view their task as an interface design, when in effect it determines the structure, content and nature of the task performed by the user. This lack of understanding on the part of the HCI professional creates major social and psychological problems associated with computer based work. These, among others, include increased stress, anxiety, depression, and social isolation, and decreased job satisfaction in the workplace.

3. DESIGNING AND USING COMPUTERS

Nine key attributes need to be considered when designing and using computers. Each is presented along with a discussion of the key considerations for each attribute:

3.1. Design and Development of Software Systems

In designing and developing a software system, the following two items are most important: that it provides adaptability of use to fulfill each individual's needs and that it is enabled easily to correct errors created by the user. The software should enable the user to perform the task in a logical manner in which the user would like to perform the task.

3.2. User Interface Design

In this attribute, the most important two considerations are to minimize mental workload and ambiguity, and to maximize task strength.

3.3. Evaluation of HCI

HCI should be evaluated for consistency in design, extent of usability of the interface, and for the design of satisfaction associated in using the interface. For each of these three attributes standardized checklists and questionnaires are available.

The ultimate objective for evaluating HCI is to derive an evaluation index that would provide quantitative evaluation of the effectiveness of each HCI. This could be tested by an independent laboratory (such as an independent laboratory in the USA used by hardware products). By so doing, the consumer would be well informed regarding which products may be the best for their use.

3.4. Individual and Cultural Differences

Regarding individual and cultural differences, there are two main considerations: the spectrum novice versus the expert. As an example, experts perform better when using commands whereas novices perform better when using menus. In cultural differences, both format and structure are important. For example, Americans perform better when menus are presented horizontally, whereas people in Mainland China perform better when menus are presented vertically.

3.5. Multimedia and Visualization

The term "multimedia" implies the use of more than one of such items as voice communication, graphics, color and alphanumeric presentation. Multimedia is most helpful in either presenting complex problems or if one wishes to present both a trend and an exact presentation. An example of the latter is well illustrated in watch design by presenting the time digitally (which gives exact time but takes longer to read than analogue presentation) and with the dial by analogue presentation.

Visualization is most effective for presenting abstract concepts such as the sum of squares in a statistics procedure of analysis of variance.

3.6. Intelligent Interface and Systems

Computerized systems that the human cannot perform very effectively or systems for which intelligent interfaces can be designed economically such as the tuning of electronic tuning machines are prime candidates for intelligent system design. In this case, the procedure and thought processes involved in the tuning were documented, and based on this information a fuzzy logic-based combined neuronet and knowledge-based system was developed for intelligently (without human intervention). The machines can now be tuned at a fraction of the time and with greater accuracy than was possible with human tuning.

Intelligent interfaces can also act as decision supports in HCI operations. For example, in supervisory control of flexible manufacturing systems, a real-time look-ahead capability is provided to the computer interface supervisor in which information is used by the supervisor better to schedule the machine utilization and, thus, minimize throughput time.

3.7. Input Devices and Design of Work Stations

The physical part of HCI is concerned with input devices and workstation design. The effective design and implementation of these in the workplace will result in reduced fatigue and lower muscle skeletal discomfort than what otherwise would be possible. Three-way adjustable chairs with good back support and arm rests are as essential as wrist and foot rest devices and the use of input devices which require the use of minimum force.

Carpal tunnel syndrome frequently results from prolonged use of computers. This effect can be reduced by using open ergonomically designed input devices and workstations, and by providing rest periods during the workday. However, the most critical factor in determining the occurrence of carpal tunnel syndrome in computerized work is the length of time one works on the computer. Hence, job rotation between computerized and non-computerized work is an essential element for reducing the probability of carpal tunnel syndrome occurrence.

3.8. Computer–supported Collaborative Work and Organizational Issues

The key issues here are how organizational learning can be accelerated by utilizing and improving the intranet, and how the web can facilitate collaborative publishing, manufacturing and commerce. The key requirement for achieving these objectives is the design of adaptive interfaces which accommodates for differences in design requirements for different collaborative partners.

The more enriched (as opposed to simplified) the task of each collaborator, the better the understanding of cognitive style and cognitive aspects of their collaborator which results in increased effectiveness of the collaborative work.

3.9. Standardization

There are national and international standards for the design and use of computer related hardware, software and system operations. These standards should be consulted before designing and using HCI. These standards are good, but they frequently provide the minimum, rather than optimum or maximum, of requirements to achieve a most effectively functioning system. Additionally, these standards are for interface design and, as such, do not consider the psychological aspects of task content which are associated with the task performance. As such, these standards do not provide guidelines on the design of HCI jobs, break schedules, requirements, job rotation needs or derivation of acceptable work performance.

> "The human mind does not work that way. It operates by association. With one item in its grasp, it snaps instantly to the next that is suggested by the association of thoughts ...."
>
> Vannevar Bush (1945)

1. INTRODUCTION

Hypertext is intended to overcome the artificiality of index-based systems of storage and retrieval by providing computer-supported *links* between related pieces of information (*nodes*) (Figure 1). By doing so, hypertext permits non-sequential (or non-linear) associative mode of information access, which is both more direct and more immediate than possible in a conventional paper-based system of information storage.

In addition to being a non-linear mode of information access, hypertext may refer to one or several of the following:

- Information creation: hypertext is described as "non-sequential writing" — a *liberating* medium, where readers can annotate and make their own links making different paths through the text.
- Information storage and management: hpertext is also an approach to information management in which data are stored in a network of nodes connected by links.
- Information presentation and access: Nielsen (1995) characterized hypertext more by its "look and feel" rather than the technology; hypertext users should *feel* that they can move freely through the information according to their own needs. This ability to navigate non-linearly using links is probably hypertext's most important characteristic.

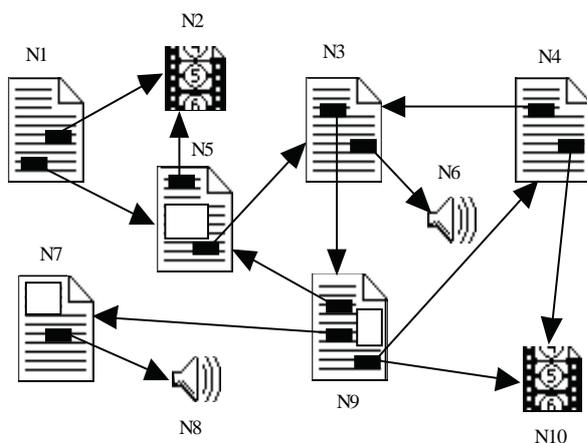
Hypertext and hypermedia are often distinguished, with the former referring to text-only systems and the latter referring to systems that support multiple media. This distinction is not made in this chapter, however; the term "hypertext" is used generically to refer to both text-only and multimedia systems.


Figure 1. A simplified representation of hypertext. N1–10 are nodes; the arrows between them are links. N2 and N6 are nodes with video content, whereas N6 and N8 are nodes with audio content.

2. A BRIEF HISTORY OF HYPERTEXT

The concept of hypertext is credited to Bush (1945) who envisioned "memex" to support intellectual work using the complex interlinkage of accumulated knowledge. However, it was T. H. Nelson who coined the term "hypertext" and offered his vision of "Docuverse," which would contain the entire world's literature, accessible and interlinked from any point in the global network. And it was Doug Engelbart (1963), who emphasized the need to augment human intellect through cooperative work environments via shared electronic spaces, where groups of workers could manage and exchange concepts and ideas in the form of linked structures.

Despite the differences in their visions, they described hypertext as a means for enhancing idea processing by allowing the freedom to read non-sequentially, annotate freely and to collaborate on writing of complex documents.

3. REALITIES OF HYPERTEXT USE

The main justification for hypertext is the claim that useful information retrieval is much easier through associations, rather than through indexing. The ensuing freedom to browse is the single most important advantage of hypertext technology. However, the freedom and flexibility offered by hypertext often accompany the well-known problems of *cognitive overhead* and *disorientation* (Conklin 1987).

Cognitive overhead applies to both readers of hypertext as well as its authors. For readers it is the overhead of making decisions as to which links to follow and which to abandon, given a large number of choices. Whereas for authors it is the additional mental overhead to create and keep track of nodes and links. Disorientation, on the other hand, is the tendency to lose one's sense of location and direction in a non-linear document — the "lost in hyperspace" problem.

To mitigate these problems associated with information seeking in hypertext, users are offered several navigation support features, to help answer their questions such as: Where am I? Where to go next? How do I get there? How do I return?

4. INFORMATION SEEKING AND NAVIGATION SUPPORT

Fundamentally, there are two forms of information seeking: *navigation* and *browsing*; information retrieval (IR), yet another form of information seeking, is discussed below. The main difference between navigation and browsing is based on user goals. In navigation, users information seeking behavior is goal- or purpose-oriented. Whereas, in browsing users explore the available hypertext to get a general idea about one or several topics.

Hypertext designers use one or more of the following techniques to help users navigate in hypertext.

4.1. Paths, Guided Tours and Tabletops

Paths or *guided tours* are pre-authored linear paths through the document. They are comparable to the notion of "trails" suggested by Bush (1945), where the authors ("trailblazers") suggest a useful path through the information. This "ordered sequence of nodes" does not mean restricting the presentation to only one node at a time. Trigg (1988) suggested using *tabletops*, where a screenful of nodes is presented.

Although paths and guided tours violate the fundamental notion of non-linearity and browsing freedom in hypertext, they may facilitate navigation for novice users.

4.2. Backtrack and History Lists

Probably the most important navigation facility in hypertext is allowing the users to *backtrack* — that is, to return to the nodes they have visited before. Unlike backtrack, which allows users to return to previous nodes one at a time in a reverse temporal sequence, *history lists* allow users to jump directly to any of the previously visited nodes. History lists may be presented textually by listing the node names, graphically by showing visited nodes in an iconic form, or by a combination of both.

4.3. Bookmarks

Some hypertext systems allow users to bookmark nodes so that they can return to them later. Bookmarks are particularly useful for browsing large hypertext systems such as the World-Wide Web, where users stumble across interesting information that they may wish to peruse later.

4.4. Landmarks

Like both natural and man-made landmarks, hypertext landmarks help users to identify their current position in the hypertext network and help in orientation. One approach to identifying landmarks is based on connectivity. The basic idea is that important topics tend to be connected either to many other topics directly or to topics that are in turn well connected, e.g. Home Page on a Web site.

4.5. Overview Diagrams or Maps

The approaches to support navigation discussed so far help readers locate pertinent information quickly. *Overview diagrams* (or *maps*), on the other hand, support navigation by helping readers understand the overall structure of hypertext. Similar to table of contents in linear texts, overviews or maps attempt to delineate hypertext's scope and organization. However, in many situations, the design problem is constructing a usable map-like representation. For even a medium-sized hypertext with moderate connectivity, the node-link structure may appear to be a "visual spaghetti" (Conklin 1987). Proposed solutions, such as those listed below, allow users to examine local detail while still maintaining a global perspective — also referred to as "focus + context" methods.

4.5.1. Fisheye views

A fisheye view displays in detail the area of interest, while presenting distant areas in successively less detail (Furnas 1986). Fisheye views have been found to significantly improve user performance when compared with the traditional zooming on a hierarchically structured network.

4.5.2. Three-dimensional (3D) representations

Some of the 3D visualization techniques, developed under the *Information Visualizer* project at Xerox PARC, include *Cone Trees* for visualizing hierarchies and *perspective walls* for visualizing linear structures (Card 1996). Cone trees are hierarchies laid out uniformly in three dimensions, either vertically or horizontally. Whereas, perspective walls represent linear structures having wide aspect ratios that are difficult to accommodate in a single view.

Usability of the 3D representations is often enhanced by the use of color, lighting, shadow, transparency, hidden surface occlusion, continuous transformation, smooth interactive animation, motion cues, and 3D perspective. However, an important usability problem with 3D representation still remains — the choice of input device for manipulation of 3D objects on two-dimensional display surfaces.

4.5.3. Multi-level overviews

Another solution to the problem of representing large information spaces may be to abstract information at several levels to provide progressive disclosure of the content. These overviews are often presented as hierarchical structures with various levels of detail. This approach can be useful not only for navigation, but also for improving comprehension.

4.6. Filtering Hypertext Network

Filtered views of hypertext network are possible when hypertext systems classify (or *name*) nodes and links. Users can then specify their interests in terms of node and link types and the system can generate a filtered hypertext. Furthermore, some hypertext systems may lend themselves to "structure search," where a user could ask for a diagram of all subnetworks that match a given pattern of node and link types.

4.7. Adaptive/Intelligent/Personalized Navigation

Intelligent navigation support mechanisms help users select a path through the hypertext that is tailored (or personalized) for a particular purpose. For example, one may generate hypertext by computing the degree of relatedness between member nodes of a hypertext system rather than using explicitly hard coded links. Most adaptive hypertext systems consider either the user goals or user characteristics to provide intelligent navigation support.

5. INFORMATION RETRIEVAL AND INFORMATION FILTERING

Finding information in hypertext simply by traversing links, especially in large hypertexts, can become cumbersome and compromise usability. Therefore, most reasonably sized hypertexts provide additional ways of accessing information via *information retrieval* (search or query) and/or *information filtering*. In *Information retrieval* (IR), users *search* for specific keywords by querying the content of the hypertext system. Whereas, in information filtering (IF), the system presents only those documents to the users that match their profiles (or interests). For example, information retrieval might be to find the name of the companies that make supercomputers; whereas, information filtering might be used to inform a user every time a new supercomputer is introduced in the market.

A caveat is in order. Neither IR nor IF guarantee increase in hypertext usability. A good user interface is important to ensure that information is used effectively and that the users can quickly get to the relevant information.

5.1. Integrated Information Retrieval and Browsing

To access information from large databases, information retrieval and browsing are likely to be integrated in future hypertext

interface. One example is *Starfield display* by Ahlberg and Shneiderman (1994). In this approach, users perform information retrieval (or query) simply by dragging a set of sliders representing different characteristics of the hypertext system. The results of queries are presented continuously on a spatial display, the "starfield" display, which is a two-dimensional scatterplot with additional features to support selection and zooming. The user can progressively refine the query using sliders or select any object (displayed as a dot or a "star") in the scatterplot.

5.2. Improving Hypertext Comprehension

An implicit assumption in hypertext's interaction model is that the readers are capable of creating coherent cognitive maps of underlying hypertext structures by selective browsing through nodes. Reality, however, is that unless the structure of hypertext is made comprehensible to the user, the user will find hypertext fragmented and incoherent. Many researchers believe that it is incomprehensibility of hypertext that causes disorientation, not non-linearity *per se* (Vora 1994, Thüring *et al.* 1995)

There are two ways of improving comprehensibility of hypertext: by using appropriate metaphors and by improving design of hypertext documents.

5.3. Use of Metaphors

By using familiar metaphors, the structure of hypertext can be made intuitively recognizable; users can transfer knowledge and skills from a familiar domain to another less familiar area and can predict the behavior of objects. Several types of metaphors have been used in hypertext systems: Cards, books, encyclopedias, libraries, cities and maps. Metaphors should be selected carefully, however. Badly chosen metaphors are counter-productive. Often, a non-metaphorical interface, with well-designed features, works better.

5.4. Design of Coherent Hypertexts

Design of coherent hypertext systems requires that necessary cues are provided at both the individual *node level* and at the organizational or the *structural net level* (Vora 1994, Thüring *et al.* 1995). This is similar to writing coherent linear text, where comprehension is required at the microstructure, macrostructure and superstrucutre level (van Dijk and Kintsch 1983). For example, one may comprehend the words, but not the meaning of a sentence, or one may understand sentences and still be confused by the overall organization of the text.

In hypertext, to improve comprehension at the node level, one can use the traditional reading models to improve comprehension. And at the net level, the designers should attempt to limit the "fragmentation" so users can understand how the text is distributed over several nodes and what they have to do with each other. A coherent hypertext could then be achieved by the following measures:

- Labeling the links: link labels make explicit the semantic relationships between the nodes and enable readers to identify the links of interest and make hypertext easier to read and navigate. Vora (1994) found that graphical representation of information with labeled links helped in comprehension and improved navigation and search performance.
- Providing continuity through context: conveying a sense of continuity across nodes is important for comprehension as it helps readers form semantic relationships among nodes in a hypertext application.
- Aggregating the information into higher order units: *aggregate* or *composite* nodes help users to identify important themes (or functional categories) of hypertext.
- Providing a graphical overview: graphical representation or maps can convey the structure to the user. If the target user population is diverse, it may help to offer multiple overview diagrams or access paths through the hypertext (Vora 1994).

6. HYPERTEXT USABILITY

Although, like software interfaces, hypertext interfaces can be evaluated for usability along the usability dimensions of *Learnability*, *Efficiency*, *Memorability*, *Errors* and *satisfaction* (Nielsen 1995), it is crucial that they be evaluated on two additional usability dimensions: *disorientation* and *comprehension*.

6.1. Disorientation

Four kinds of disorientation are particularly relevant when evaluating the usability of hypertext systems: not knowing where to go next; not knowing where one is; not knowing how one arrived at a particular node; and knowing where the information is, but not knowing how to get there. In addition to commonly used measures of disorientation (e.g. number of "backtracks" to previously visited nodes, restarts from the "home" node and subjective feelings of disorientation), a useful measure of hypertext usability and disorientation is user perception of the size of hypertext. This is important for hypertext because, unlike linear text, which present clear boundaries, hypertext readers have no cues available for its size and scope.

6.2. Hypertext Comprehension

Although the term comprehension includes understanding of the content of hypertext, hypertext comprehension as described here means understanding hypertext's structure in terms of relationships among the nodes and links. Therefore, useful indicators of comprehension are users' mental models of the information organization in hypertext. This can be achieved directly by asking the users' to construct the maps of information in hypertext or indirectly by extracting the structure from their verbal protocols (requiring participants to think aloud about what they are doing, how they are doing it and why they are doing it).

Yet another alternative is to use a *teaching method*, where after a users have learned the system by browsing or retrieving information using pre-determined tasks, they are asked to *teach* another participant (a confederate) how the system is organized (Vora 1994).

7. APPLICATIONS OF HYPERTEXT

Although hypertext has been used in several computer, business, intellectual, educational, and entertainment and leisure applications, probably the most important application of hypertext is the World-Wide Web (or W3 or the Web). Since its introduction at the Hypertext '91 conference, the growth of the Web has been astronomical; Web servers on the Internet has risen from 130 in December 1993 to > 4 million sites in January 1999 (www.netcraft.com) (see the chapter on the Internet and the World-Wide Web in this volume).

8. FUTURE OF HYPERTEXT

Undoubtedly, most of the hypertext-related research in the future will involve the Web. Therefore, the following predictions of the future of hypertext include the technological advances made on the Web.

8.1. Content–based Linking and Retrieval and Integration of Virtual Reality

In the future, linking and retrieval of information will be based not only on text or simple graphics, but will also use images, sound and video. Probably the biggest advances will be made in linking among temporal media such as sound and video, where links are not just present on a page, but become spatial and temporal opportunities for hypertext readers. Inclusion of temporal media and interactivity will finally merge with virtual reality to create hyperworlds offering not just richer interactive hypertext environments, but immersive experiences as well.

8.2. Personalized Hyperspaces

Considering the growth of the Web and the vast amount of, importance of personalized hyperspaces can not be overemphasized. Creation of such personalized hyperspaces will be driven by intelligent agents, which will not only gather information in its raw form, but also interpret information to create personalized hyperspaces and personalize to fit user tasks and needs. They will aid not only in information access and organization but serve as negotiators for its owners for transactions for exchanging information that may or may not involve money.

For the agent technology to be successful, however, it is necessary that the information objects are richer and carry extensive metadata and there is an agreed upon standard way to describe different types of information objects.

Without a richer, expressive, and standardized language to describe the information, retrieval and discovery of information and structure will not be possible and the agents' technology will remain in a nascent stage.

8.3. Cooperative and Ubiquitous Hypertext Systems

Cooperative hyperspaces will become a reality through improved methods of collaboration and improved mediums of communication. Collaboration will be both asynchronous and synchronous. It will support "nomadic" environments (mobile participants) and create what Streitz (1996) called "Ubiquitous Collaboration" which supports *polyphasic activities*. In other words, incompatibilities due to differences in presentation format and media will disappear.

8.4. Open and Interoperable Hypertext Systems

To enable creation of personal and collaborative hyperspaces, interoperability and availability of open hypermedia systems (OHS) will become an absolute necessity. Traditional hypertext systems have often used private formats to store both links and data, thus limiting interaction. Open hypertext systems will also require increasing emphasis on standards and interoperability. This will eventually make Neslon's vision of "Docuverse" a reality; it would contain the entire world's literature, accessible and interlinked from any point in the global network.

Finally, as all ubiquitous and usable technologies, hypertext will become a *transparent* technology — it will become *the way* to interact with information on computers.

1. WARNINGS IN THE HIERARCHY OF HAZARD CONTROL

There is a number of approaches to the control of safety hazards that can generally be hierarchically arranged, in order of preference, as (1) design-in, (2) safeguarding and (3) administrative controls. Design-in safety relies on creating systems that have inherent safety due to hazards being either lacking or at a level, from the user's perspective, insufficient to harm. In many cases, attempting to achieve this level of inherent safety can result in the loss of the original utility of the system. More often, one sees a spectrum of engineering safeguards applied, ranging from those that are tightly integrated to the design to those that are added in the field. The effectiveness of safeguards depends, in large measure, on how independent their performance is from the actions of the people they are design to safeguard. At the extreme, a transition occurs to administrative controls that depend on proper procedures, adequate information, and effective action of people. The application of warnings as a form of hazard control is usually placed here.

Warning signs and labels necessarily must rely on people to read, understand, and follow any explicit or implicit information given. However, overwarning can cause habituation that can result in reduced overall effectiveness. Therefore, warnings should be considered a supplement to engineering of the system itself. The purpose of a warning is to alert people to the presence of a hazard, in hopes of avoiding unsafe or risky behavior.

The errors that people make can be classified into three broad categories: (1) errors that occur when performing routine behavior, (2) when performing non-routine behavior and (3) intentional violations. Warnings that interrupt performance of a task can successfully remind people to not perform incorrect behavior before it occurs. As well, warnings can stimulate recovery from errors. Warnings, though, should be used with care, especially when considering the level of one's experience, as it is found that experienced users, familiar with the task and the product, often fail to read warnings. One potential reason may be that the user is highly focused on task-related goals, only looking for information that will satisfy the end-goal of task completion. Interrupting the performance of a task may also take the user out of an automatic form of behavior and encourage them to enter a less routine information-seeking mode of behavior.

2. GENERAL GUIDELINES FOR DESIGN AND APPLICATION OF WARNINGS

Many general guidelines can be inferred from warnings research. These include: (1) conforming to standards and population stereotypes when possible, (2) making warnings conspicuous and each component legible, (3) simplifying the syntax of text and combinations of symbols, (4) making symbols and text as concrete as possible, (5) making sure that the cost of compliance is within a reasonable level, (6) being selective, (7) integrating warnings into the task and hazard related context, and (8) matching warnings to the level of performance at which critical errors occur for the relevant population. These general guidelines can be expanded upon and classified into three broad categories; format, content and mode of presentation.

2.1. Format

The format of a warning refers to its physical aspects, which include text, iconic and/or graphic information, both in individual and in collective form, and the size of the label, methods of color-coding, and the arrangement of the components. Twelve specific guidelines (F1–12) have surfaced from the literature:

- (F1) Provide a signal word or words in capital letters at the top of a warning sign or label to indicate the sign or label is a warning.
- (F2) Use lowercase for text within a warning sign or label.
- (F3) For text within smaller labels, a visual angle of at least 10 min of arc for the intended viewing distance should be provided. For text within signs, a visual angle of a minimum of 25 min of arc should be present for the intended viewing distance.
- (F4) For short messages or signal words, text characters should be sans serif.
- (F5) Text characters should be dark against a light background.
- (F6) The stroke width-to-height ratio of text characters should be between 1:6 and 1:10.
- (F7) The width-to-height ratio of alphanumeric characters should be between 1:1 and 1:3.5.
- (F8) Provide for a brightness contrast of at least 50% between the warning text and its background.
- (F9) Consider color-coding schemes consistent with ANSI Z35.1/Z535.1.
- (F10) Avoid crowding of components on the sign or label, ensuring that each component is legible.
- (F11) The presence of adverse viewing environments, such as the presence of dirt, grease and other contaminants, can degrade the legibility of warning components.
- (F12) Consider the use of symbols/pictographs when users are performing routine behavior.

Consider using text when employees need to make decisions or are performing non-routine behavior.

2.2. Content

The content of the warning refers to the message itself, its level of abstraction, and its syntactic structure. Some specific guidelines (C1–17) that can be derived from these generic guidelines and from the research follow:

- (C1) Messages should focus on critical errors that cause a significant safety problem. When choosing warnings, one should be selective to avoid habituation and warning overload, and thus reduce the potential for ignoring the warning. Therefore, avoid long lists of hazards and messages that describe trivial hazards or hazards that are obvious to the intended audience.
- (C2) Focus on developing messages for the following two types of error situations: (1) forgetting to perform an action

ordinarily performed (i.e. the sign or label reminds), and (2) not knowing the consequences of performing or failing to perform some action.

- (C3) When a user's performance is skill-based, meaning they are performing an automated set of procedures, and they commit an error based on their failure to perceive a condition or motor variability, provide a warning signal and consider training.
- (C4) When performance is rule-based, meaning the user is following a set of rules and the behavior is not yet automated, and the error is caused by a incorrect or inadequate rule, determine whether the rule was originally developed on the basis of knowledge or judgment-based behavior. If it seems to be judgment-based, such as when people speed on the highway, focus on enforcement. If it seems to be knowledge-based, determine whether a warning sign or label can be used to interrupt the task (i.e. to place its message into short-term memory at the time it is relevant).
- (C5) When performance is knowledge-based, meaning the user is problem-solving, and the error is caused by inadequate knowledge, the amount of knowledge necessary to prevent the error should be determined. If the knowledge can be described with a small number of rules, consider a warning sign or label containing these rules in the form of step-by-step instructions. Otherwise, focus on training, instruction manuals, or other forms of education.
- (C6) When performance is judgment-based, meaning the user is experiencing an affective reaction of some sort, and the error is caused by inappropriate priorities, evaluate the user's behavior pattern. If the undesired behavior pattern appears to have significant value to the user (i.e. pleasure, comfort, convenience, etc.) or is likely to be entrenched, focus on enforcement through supervision.
- (C7) Regardless of the level of a user's performance, consider messages that minimize the cost and increase the benefits of compliance.
- (C8) If a large number of potential warnings is present after applying these guidelines, increasing the probability of overloading the user, other means of providing the information (such as instruction manuals or training courses) should be considered to reduce warning overload.
- (C9) When subjects are inexperienced, consider pictographs (having a more detailed design) instead of symbols.
- (C10) When performance is at a skill- or rule-based level, consider brief messages that describe conditions or actions. Also, consider symbols or pictographs instead of text, since these make the warning more memorable.
- (C11) When performance is at a knowledge-based level, whereas the user needs to understand the reasoning "why" an action or behavior needs to be performed, consider more detailed messages that describe both conditions and actions.
- (C12) When performance is at a judgment-based level, in that the incoming information is processed as values that evoke an affective reaction, consider messages that describe the hazard and the benefits of compliance. Also, consider citing highly credible sources.
- (C13) When the hazard is complex or occurs in different manifestations, consider abstract text, which better covers hazard contingencies, rather than a long list of concrete examples or symbols.
- (C14) When knowledge or understanding of a product or task is low, consider concrete text instead of abstract symbols or pictographs. Concrete text is easier to comprehend and the interpretation of symbols has been found to vary across different cultures.
- (C15) Use text and symbols that people in the intended user population can comprehend. Consider language, reading level and cultural effects.
- (C16) Use short, simple sentences; complex conditional sentences, particularly those containing negations, should be avoided. Longer messages are not necessarily better comprehended.
- (C17) Symbolic signs or labels should focus on describing conditions (i.e. flammable). With few exceptions (i.e. a slash/bar to indicate negation) they should not combine multiple meanings or be used to describe complicated sequences of actions.

2.3. Mode of Presentation

The mode of presentation of a warning refers to the location and task-specific timing of one's contact with a warning. Specifically, the following guidelines (M1–5) should be followed:

- (M1) The warning sign or label should be presented at a location and time in which the danger is still avoidable.
- (M2) The location and timing of presentation should minimize the cost or difficulty of compliance.
- (M3) Make an attempt to present the warning sign or label at a time when the person has available attentional capacity.
- (M4) When performance is skill-based, determine if the task can be interrupted to bring attention to the label. If this can be done, consider a warning sign or label that describes the condition and prescribes an action. If this cannot be done, consider providing a warning signal, training or modifications of the product.
- (M5) Avoid imbedding sign or label in a cluttered background.

3. ASSESSMENT OF WARNING LABELS AND SIGNS

3.1. Assessment of Effectiveness

The steps that must occur before a warning can prevent an accident include: (1) attention, (2) comprehension, (3) decision-making, (4) action-taking and (5) sufficiency of the action to avoid the accident. The probability of avoiding an accident can never be greater than the probability of successfully completing a single step.

The dependent variables related to the effectiveness of warnings can be grouped into three areas: perceptual factors, comprehension levels and those factors associated with behavior patterns. An assessment of the perception of warnings should give insight as to the conspicuity, or attention attracting ability of the sign. Variables related to the perception of warnings include reaction time, accuracy of task completion, attention to different elements of the warning, the use of tachistoscopic procedures and measures of legibility distance. When assessing the comprehensibility of a warning, four variables are often used: symbol recognition or matching, message recall, psychometric (rating)

scales and readability indexes. Assessing behavior patterns also offers some insight about the effectiveness of warnings under realistic conditions. The most common approach is to conduct an experiment in which two groups of subjects are tested on the same task, one group is the control without the warning, and the other group receives the warning. Field observations are also useful in determining warning effectiveness.

3.2. Role of Standards in Assessment

Published US standards helpful in the design or assessment of warnings labels and signs include:

- *ANSI Z535 Standards*. This series of standards replaced the ANSI Z35 and ANSI Z53 standards and includes: (1) ANSI Z535.1, Safety Color Code; (2) ANSI Z535.2, Environmental and Facility Safety Signs [typical sign consists of multiple panels for signal words, messages, and symbols]; (3) ANSI Z535.3, Criteria for Safety Symbols [methodology for the development of understandable symbols]; (4) ANSI Z535.4, Product Safety Signs and Labels [similar to ANSI Z535.2, except generally smaller]; and (5) ANSI Z535.5, Accident Prevention Tags [for temporary hazards].

- *ANSI Z129.1, Hazardous Industrial Chemicals – Precautionary Labeling*. This standard is applicable to chemical products and mixtures and is complementary in scope to ANSI Z535.2 in the environmental or facility area, and to ANSI Z535.4 in the product area.

- *OSHA 29 CFR 1910 General Industry Standards*. Three sections of these standards are particularly applicable: (1) 29 CFR 1910.145, Specification for Accident Prevention Signs and Tags; (2) 29 CFR 1910.144, Safety Color Code for Marking Physical Hazards; and (3) 29 CFR 1910.1200 Hazard Communication Standard. The first two sections are very similar to ANSI Z35.1/Z53.1/Z535.1. The last, also known as the Right-to-Know Standard, requires employers to provide specific information to employees about the hazardous chemicals they are or may be exposed to through on-container labels and Material Safety Data Sheets (MSDS).

- *DOT 49 CFR 170 Hazardous Materials Transportation Regulations*. These regulations address the "diamond" signs on the outside of trucks, whose primary purpose is to alert emergency response personnel to potential hazards, and are comprised of nine classes of hazards, with corresponding colors, symbols, and text.

- *NFPA 704, HMIS®, and ASTM D 4257*. The Standard System for the Identification of Fire Hazards (NFPA 704), the Hazardous Material Identification System® (National Paint and Coatings Association) and the Safety Alert System (ASTM D 4257) are all designed to aid workers and/or emergency response personnel in the identification of hazards and the appropriate procedural response. They address fire, health, reactivity levels and specific hazard concerns.

4. THE CONTINUING EVOLUTION OF WARNINGS

As knowledge accumulates regarding the factors that impact the effectiveness of warnings, criteria for the design and assessment of warning signs and labels found within both mandatory and voluntary standards evolve accordingly. Since most standards are revised every 5 years or less, one should always try to obtain the latest versions of standards referenced here.

Finally, bear in mind that in a court of law compliance with standards is generally not a sufficient sole defense as standards are often viewed as minimum requirements (often due to a "one size fits all" strategy in their development). Therefore, it is necessary fully to understand the potential hazards of any system being analyzed (i.e. environment, facility, product, etc.), apply the hierarchy of hazard control to achieve the most effective protection for those who use or are exposed to the hazards, and apply warnings as a sole remedy sparingly.

Interactive Speech Technology

C. Baber

University of Birmingham, UK

1. INTRODUCTION

Interactive speech technology is that collection of technologies which permit humans and computers to communicate through speech. In this entry, attention will be given to speech recognition systems (see also speech-based displays). This area has been growing apace for many decades and has a reached a stage where it has confidently moved from academia to industry (this is not to deny that industry has often a played crucial role in developing speech technology, but to point to the fact that interactive speech technology is now commercially viable). For ergonomists, the issues relating to speaking to a computer, as opposed to using some other form of control device, are only now beginning to surface. As we see more speech-based applications on the market, it is likely that the question of how best to design interactive speech technology for human use will become paramount.

2. TECHNOLOGY AND APPLICATIONS

Over the past few years, the technology used in speech recognition systems has improved dramatically. In 1991, most commercial products were speaker-dependent, i.e. you had to undertake rather laborious training of the speech recognizer to get it to recognize your way of speaking and had to train all the words you wanted to use before you could use it. In 1998, most commercial products are speaker-independent, or at least speaker-adaptive. This means that the speech recognizer comes with a vocabulary already in place and with patterns of speech which it can try to match against your speech. The speaker-adaptive systems modify stored patterns to get a better fit with your speech as you continue to use the recognizer. Not only has this aspect of the technology changed, but also the manner in which patterns are created and stored has developed to a point where most systems use some form of statistical pattern matching algorithm, rather than simple template matching. The upshot of this development is that speech recognizers are able to spot boundaries between words and recognize individual words from a stream of speech; of course, users still need to speak clearly and not mumble, but they no longer need to carefully enunciate each word and pause before they say the next. Some researchers have suggested that the capability of speech recognition algorithms are beginning to reach a plateau.

Typically, speech recognizers are given a score out of a hundred to indicate their performance. This score relates the number of words which have been correctly recognized out of each hundred words spoken. Thus, a score of 95% indicates an error rate of 5%. Generally, speech recognition systems continue to work most effectively with phonetically balanced vocabularies. A further measure to note at this point is perplexity, i.e. the number of possible vocabulary items at any given point in the dialogue. The greater the number of alternative words which can be spoken, the higher the perplexity, and the greater the possibility of misrecognition. Various types of syntax have been applied to limit perplexity in vocabularies.

We have also seen changes in the proposed uses of the technology over the past decade. In 1991, there was much interest in using speech for industrial data entry or military command and control applications. While these applications are still receiving interest, they have been superseded by the rapid expansion in telephone-based speech systems. Early telephone-based systems relied on very small vocabularies, such as "yes" and "no", and tortuous dialogues that involved listening to a long string of menu options before emphatically declaring "yes" to the required option. In contemporary systems, the vocabulary is gradually expanding and the dialogues are becoming more human-like (although whether one wants a human-like conversation with a computer remains a moot point).

3. FEEDBACK

Feedback can be thought of as reactive, instrumental, and operational. Reactive feedback refers to the feedback a person receives when operating a control, i.e. when a button is pressed, it moves and makes a clicking sound. Unfortunately, there is no reactive feedback inherent in speaking into a microphone. How is one to know that the microphone is "live", or that one is speaking loudly enough, or that there is no noise or distortion in the connection between microphone and speech recognizer? This means that some form of artificial feedback is required. For example, auditory beeps were used to pace speakers using speaker-dependent systems in the 1980s. The beep would indicate that a word had been recognized and the next word could be spoken; the general consensus was that this helped first-time users but very quickly became irritating. With the development of connected-word recognizers, the pacing beep is now obsolete. However, the problem of how to provide users with reactive feedback remains. Typically, this problem is circumvented by using instrumental feedback as reactive feedback, i.e. reactive feedback is provided by the fact the recognizer is working, which can be confusing to the user and can make it difficult to determine the cause of false rejection errors.

Instrumental feedback concerns the performance of the recognizer itself and allows the user to answer the question, has the word I have just said been recognized? Instrumental feedback can be provided to users of a speech recognizer at various points in the interaction: the most obvious point will be after each individual subunit of dialogue (word, digit, letter) or after each complete dialogue unit (command, phrase, digit string, etc.). Designers faced with limited screen space, or with a purely audio channel, might be tempted to provide feedback on a word-for-word basis. However, this can introduce a very high working memory load for the user and will require recognition errors to be corrected as soon as they occur, which will disrupt the production of a command and hence be undesirable. It has been suggested that instrumental feedback should be provided at the end of a complete dialogue unit (Hapeshi and Jones 1989), but this introduces a further problem for error handling: if the user is forced to wait until the end of a dialogue unit before receiving any feedback, then it is difficult to decide which of the words has been misrecognized, especially if a substitution error has occurred. A solution to these problems is to provide a text window for the complete dialogue unit, but to display each subunit as it is

recognized. This is found to be the most acceptable form of textual feedback, and the one which gives the best user performance (Schurick, Williges, and Maynard 1985).

Operational feedback relates to system functioning; for example, if one speaks the command "Close file" and the file on the screen closes, then the system has correctly recognized and responded to the command. If the wrong operation is performed, then an error has occurred. However, this makes error correction somewhat laborious; the wrong operation has to be undone and the correct action repeated. Baber *et al.* (1992) demonstrate that operational feedback can also take the form of a symbol, representing the command, appearing adjacent to the object being controlled, e.g. an arrow icon adjacent to a valve on a process control display. If the symbol fails to appear, if it appears elsewhere on the display, or if the wrong symbol appears, then a recognition error can be identified.

4. ERROR CORRECTION

People assume that human speech is error-free, and are not particularly forgiving of errors in speech recognition. However, it is doubtful whether human speech really is free of error so much as overlain with a well-established set of rules and procedures of correcting and otherwise handling error. It is proposed that a peculiar problem with interactive speech systems is that the user must follow quite formal and rigid rules of dialogue that do not currently have the flexibility of human conversation, and which can become frustrating if these "rules" appear to be broken by the computer. For example, having to speak words from a fairly restricted vocabulary set at a slower than normal pace requires a different style of speech than conversation, and there does not appear to be any recognized "rules" for handling errors in this style of speech. Some systems employ specific error correction dialogues, such as "comma" (a different word is recognized) — "No", "Back", "comma" — while other systems require the user to repeat the misrecognized word (although this can prove difficult in connected word recognizers). Baber and Hone (1993) demonstrate that selection of error correction dialogue can be related the recognition accuracy, i.e. if accuracy exceeds 95%, then simple repetition will suffice, but if accuracy falls below 90% then some form of error correction dialogue might be required.

It has become customary to divide recognition errors into three types: rejection, insertion, and substitution. Rejection errors occur when a legal vocabulary item is spoken by the user and the ASR device does not respond. This suggests a problem in the communication between user and device. Brown and Vosburgh (1989) found that rejection errors accounted for between 2–3% of recognition errors in their studies. Thus, while rejection errors can occur, they are rare and can often be dealt with by improving communications. The next type of error, insertion, occurs when spurious noise, originating from either the user or the environment, is recognized as a legal vocabulary item. Brown and Vosburgh (1989) found that insertion errors accounted for between 5–6% of recognition errors. This problem could be reduced using a number of techniques, such as altering microphone position, providing some means of masking for ambient noise, performing enrolment in similar ambient noise levels to task performance, etc. The final type of error, substitution, occurs when a legal vocabulary item is spoken by the user and

the device "recognizes" a different item. This type of error accounts for over 90% of recognition errors (Brown and Vosburgh 1989), and is the main focus of efforts to develop error correction techniques. As the most common form of recognition error will be substitution error, there has been much interest in the design of dialogues which will either reduce the likelihood of substitution — for instance, by employing a vocabulary set of phonetically distinct words or through the inclusion of error correction commands.

5. VOCABULARY

The issue of perplexity was discussed in relation to technology. One approach to dealing with perplexity is simply to limit the number of words that a speaker can use. A feature of early applications was the limited choice of words offered to users, e.g. users might be restricted to using the digits 0–9 and "yes" and "no". While this limitation can allow some operations, it necessarily restricts functionality and leads to devices operating in what might be termed "Spanish Inquisition" mode with users having to answer a long string of questions before finding the information they require. It is apparent that, even with questions designed to elicit "yes" or "no", some users will reply with other words (Baber et al., 1997). Thus, using a restricted vocabulary with apparently unambiguous questions need not eliminate out-task vocabulary. An alternative approach is to develop an exhaustive vocabulary, containing all the words which people are likely to use. However, increasing vocabulary could return us to the problem of perplexity (without a sound syntax to support such a vocabulary). Rather than increase vocabulary size, one could employ a form of "word-spotting", i.e. the speech recognizer is "tuned" to search for specific words in the incoming speech. The implications of this approach are that appropriate, relatively unambiguous keywords can be defined and that people can be encouraged to limit their extraneous speech. A recent trend in large vocabulary systems has been to move from word spotting to topic spotting, i.e. rather than simply "listen" for particular words, the recognizer is able to detect keywords associated with a given topic and can call upon appropriate subsets of vocabulary pertaining to that topic.

6. WORKLOAD AND STRESS

One of the key issues for applications of automatic speech recognition is the effects that different environments may have on human speech production. As the technology becomes efficient enough to be considered for deployment in situations which were previously considered "adverse", then it becomes important to consider how workload and stress could influence performance. Baber (1995) reported a series of studies investigating the effects of workload and stress on speech production and proposed the following problems. Given the tendency to revert to well-learned behaviors under stress, people may attempt to structure their utterances without due regard for the syntax. This problem could also manifest itself in speech errors, which involve violation of vocabulary constraints in using speech recognition systems, where users revert to more familiar words and phrases. If the quantity of information in feedback increases, people will be more likely to treat this in general rather than specific terms. This will lead to an increase in the likelihood of user error (i.e. not responding to erroneous feedback). People vary their response strategy in

terms of task load, and if the number of tasks a person performs increases, there will be a tendency to narrow attention on specific cues, which may mean that feedback is treated in general rather than specific terms. This problem will be exacerbated if feedback competes with the primary task modality. In terms of speech production, increased demands lead to an increase in speech rate. Furthermore, as demand increases, people will reduce the amount of speech they utter, either by saying nothing or "fitting" their speech to the demands of the situation.

Many of these problems are typical of other forms of human performance under stress, but serve to highlight some of the problems peculiar to speech. It is proposed that, while some of the problems can be solved through technological innovation, many of the fundamental problems relating to speech under stress require ergonomic solution.

Internet and the World Wide Web

P. R. Vora

US WEST, 1515 Arapahoe Street, Denver, CO 80202, USA

1. HISTORY

The Internet — "network of networks" — grew out of an initiative of the US Department of Defense in the late 1960s. The motivation for the creation of the network (originally named ARPAnet after the government's Advanced Research Projects Agency) was to help scientists and researchers share scarce and physically remote computing resources and information.

The Internet gave rise to several applications to help users communicate with each other, to find information and to share resources on the Internet. These include e-mail, FTP (File Transfer Protocol), Telnet, Usenet, archie, Gopher and several others. Excluding e-mail, despite their usefulness, most other applications were not very "usable"; they required at least some working understanding of UNIX –the most common operating system on the Internet. However, with Gopher, developed at the University of Minnesota and named after its mascot, which provided a menu-based interface to organize and access information, the Internet became a little more usable.

Although Gopher made information access easier, several problems remained with the use of the Internet because of its size and diversity:

- users needed to use several different applications to access the Internet resources;
- users could not see the content before downloading a file to their local computer and viewing it; and
- there was no simple way to get to the resources related to the current piece of information.

The World-Wide Web (or the WWW or the Web), a hypertext-based application, offered solutions to all of these problems and made itself a "killer app" for the Internet.

Work on the Web began in March 1989, when Tim Berners-Lee of CERN, the European Laboratory of Particle Physics, proposed a project to be used as a means of exchanging information and transporting research and ideas throughout the organization. CERN and MIT (Massachusetts Institute of Technology) now share the Web project.

A common misconception is that the Internet and the Web are the same. It is not so. The Internet is the infrastructure — it is the physical medium used to transport data. The Web is a collection of protocols and standards used to access the data available on the Internet. Specifically, the Web is defined by three standards:

- URI (Uniform Resource Identifiers): a method to specify the location of a resource on the Internet;
- HTTP (HyperText Transport Protocol): a protocol for transferring hypertext-based information over the Internet; and
- HTML (HyperText Markup Language): a language of interchange for hypertext on the Web.

2. REASONS FOR THE WEB'S SUCCESS

Although standards and protocols existed before the Web, they were designed as "closed" systems; they did not interact with other Internet applications and protocols in a seamless way. In addition to this interoperability, the following characteristics contributed to the success of the Web:

- Open and extensible architecture: the Web's open architecture is easily extensible and can accept advances in technology, including new protocols, object types, and data formats. This allows the Web to evolve with users' needs.
- Consistent access interface: the Web, through its simple hypertext link-based navigational model, provides users a consistent means to access a variety of media in a simplified fashion. And all documents, whether real or virtual (i.e. dynamically generated), look similar to the user.
- Universal readership and platform independence: information on the Web is accessible from any type of computer, anywhere, as long as it is connected to the Internet and has a Web browser. This also makes it easy and almost instantaneous to distribute information on the Web.
- Ease of publishing and universal authorship: because of the simplicity of writing HTML and relatively low cost of having a Web presence, almost any person can publish information on the Web.

3. USABILITY ISSUES WITH THE WEB

Despite the seductive benefits of the Web outlined above, many Web sites have failed to realize their potential. Some of the common problems that compromise usability on the Web are discussed below.

3.1. Slow Response Time or Download Speed

In the GVU's Ninth WWW User Survey (GVU 1998), across all groups of users, taking too long to download pages (i.e. "speed") was the most commonly experienced problem with the Web (64.8% of respondents). In the same survey, ~53% of respondents reported that they had left a Web site simply because the site was too slow. The percentage of respondents reporting the problem of "speed" has been consistent over the last two surveys — 63% in the Eighth and 66% in the Seventh survey respectively.

3.2. Linkrot or Dangling Links

The next most frequently cited problem on the Web is a growing one — dangling links (or *linkrot*). Although solutions for dealing with broken links are well-known to Web designers, i.e. automated link-checking, redirecting URL, comprehensible error pages, redirecting broken links to a search page and so forth — most sites do not seem to employ these techniques. And the users are still presented with the "404-File Not Found" errors. This problem can be attributed to the embedded nature of links (as HTML markup) on the Web pages. Moving (or deleting) a page involves checking all references to this document within all other documents. For the Web this would involve checking all other documents in the world which, obviously, is not feasible. The result is linkrot.

3.3. Inefficient and Ineffective Navigation

The links provided on the Web are often cumbersome, irrelevant, or trivial. This problem is compounded by inconsistencies in

indicating link anchors: what aspects of words or phrases should be marked as links have not been addressed. There are several occasions, where instead of linking the words describing the destination Web page, hypertext links are made to the action of clicking (e.g. "Click here for Information on Usability" instead of "Information on Usability"). Another common problem is use of the links from graphic images, which do not afford the action of clicking and readers are often unsure as to which graphics are linked on a Web page.

Navigation problems on the Web are also caused by the single-window design of Web browsers, which preclude the preservation of context that could be achieved if both anchor and destination were displayed. Although *frames*, which permit partitioning a Web browser window into independent sections, have provided a partial solution to this problem, they have caused problems related to bookmarking, printing and accessibility.

3.4. Difficulty in Finding Information

Granted, the link-based navigational model of the Web is easy to understand. However, finding relevant information on the Web is neither easy nor effective by simply browsing the pre-authored hypertext links. To aid in finding information on the Web, several Web sites now maintain indexes that categorize and organize information by subject (e.g. Yahoo!, http://www.yahoo.com). Although the categorization, done by humans for such indexes, is helpful, their scope is limited considering the volume of data that is made available daily on the Web. Search engines, on the other hand, are more exhaustive in their coverage (e.g. Alta Vista, www.altavista.digital.com; Lycos, www. lycos.com; InfoSeek, www.infoseek.com). However, Web users who type in a search request are often presented with thousands of "hits," many of which contain references to irrelevant Web sites while leaving out others that hold important material.

3.5. Poor Content Quality

The Web's strength of universal authorship is also its weakness. There are no intermediaries on the Web that can validate the usefulness, correctness and quality of the content on the Web. Furthermore, a considerable amount of information on the Web is either outdated or not updated; such Web sites are commonly referred to as "cobweb" sites. Without a clear indication of the life of the content or a well-defined expiration date, the useful content gets lost and becomes more difficult to identify.

4. ACCESSIBILITY

Although universal readership is an important benefit of the Web, a significant portion of the users are unable to access all the information available on the Web — in particular, those with visual, hearing, and physical impairments. In this respect, the Web has tended to become exclusive or excluding. As the Web has embraced "new" technologies, it has pushed assistive/adaptive devices beyond their current capability. And it has made it difficult for people with disabilities to participate as equals in work, education and leisure.

5. CAUSES OF USABILITY PROBLEMS ON THE WEB

5.1. Perceived Need to Have a Web Presence

Although there are several reasons for unusable designs on the Web, many usability problems on the Web can be attributed to "Web-site Envy" or the perceived need to have an immediate Web presence. Many organizations rush to be on the Web without spending sufficient time to understand the needs of potential users or to analyze or judge the scope of the content to be put on the Web. This rush to have a Web presence causes them to disregard any methodology or guidelines for designing and organizing information on the Web.

5.2. Use, Activity and Poor Design

Both the use and the activity on the Internet have led to severe degradation in response times. According to the Internet Traffic Report (www.internettrafficreport.com) on a Sunday 14 February 1999 at 18:45 GMT, the Global Internet Traffic Index was 52 (on a scale of 0–100, with 100 being the best response time); this is usually much lower during the week. Not all the blame can be placed on the traffic on the Internet, however. Compared with the text-heavy pages on the Web in its infancy, Web pages have become bandwidth-hungry with inclusion of images, animations, multimedia and scripts, which take extra time to download.

5.3. No Metadata: Impoverished Content

In contrast to human indexers, automated programs used by search engines have difficulty identifying characteristics of a document such as its overall theme or its genre–whether it is a poem or a play, or even an advertisement. The Web, moreover, lacks standards that would facilitate automated indexing. As a result, documents on the Web are not structured so as to allow programs to reliably extract the metadata information such as author, date of publication, length of text, and subject matter that a human indexer might find simply through a cursory inspection.

5.4. Usability of Web Browsers: Poor Support of Standards

Although graphical Web browsers have made the Web more accessible, several usability issues need to be addressed in their design — in particular, their non-compliance with the standards. With the Web browsers competing for the market share, very little attention is paid to standards. Even dominant browsers, like Netscape Navigator and Internet Explorer, which claim to support the new HTML 4.0 standard in their recent releases, do not support them completely and reliably. The presentation of Web pages is, therefore, unpredictable and requires Web page designers to either spend more time testing their Web pages with a variety of browsers, design their Web pages for more than one type of browser, or design for the lowest common denominator.

5.5. Usability of Web Authoring Tools

The current crop of WYSIWYG Web page authoring tools is also responsible for poor design. Many WYSIWYG tools of today not only generate excessively redundant and unnecessary code, but also place more emphasis on the presentation and consequently add unnecessary graphics to remain true to the user-generated layout. Both these practices add to the download time for Web

pages (Vora 1998b). Finally, emphasizing presentation, a majority of them do not offer good support for designing accessible Web pages.

5.6. Use of Opaque Technologies

The technology is no longer transparent to users who now not only need to understand terms such as plug-ins, helper applications, Shockwave, PDF, JavaScript, Java, ActiveX and so forth, but also are able to install appropriate applications on their machines to take full advantage of the Web.

6. SOLUTIONS TO THE USABILITY PROBLEMS ON THE WEB

6.1. Follow a Human Factors Methodology

Although the Web technology makes evolution, enhancement or changes to content relatively easy, Web site design should not proceed in a haphazard manner. A human factors methodology for designing Web that includes *planning, analysis, design and development, testing, implementation* and *maintenance* should be followed for designing usable Web sites (Vora 1998).

A particularly important stage is usability testing, where the design assumptions and decisions are tested with representative. Relative simplicity of the Web technology also makes it possible to conduct remote usability evaluations with a distributed population of users.

Another critical stage is maintenance, where the challenge is to provide current and updated content while maintaining the integrity of the Web site. Maintenance also requires that Web site usage trends are analyzed and changes are made to accommodate users' needs. Finally, it is important to keep up with the advances in technology, and implement them if it improves usability and offers a richer interaction environment for the users.

6.2. Understand the Needs of Content Owners and Authors

When designing Web sites the focus should not be exclusively on the users; the needs of authors and content owners should be addressed as well. This is necessary because the authors and owners are responsible for ensuring ongoing usability of a Web site after its deployment. Knowing who the authors are, how knowledgeable they are about computers and Web technology, and where they are located (at one location or at different locations) are all important to determine whether any training is necessary, and what approach is best for managing Web sites.

6.3. Separate Structure, Presentation and Semantics of the Web Content

Although originally intended as a simple mark-up language, HTML has become a mish-mash of markup and presentation language. Changes are happening in the Web world in the form of Cascading Style Sheets (CSS) and Extensible Markup Language (XML) to complement HTML, which not only address the current concerns with HTML, but also help enhance the user experience when interacting with the Web.

CSS is a language for describing layout and graphical style. CSS can be used to control colors, white space, multicolumn layouts, fonts and more, allowing designers to leverage document styles without modifying each page. CSS is uniquely powerful because it defines the look-and-feel for a document by annotating its semantic structure.

XML, on the other hand, allows creation of documents using tags beyond those specified in the HTML standard. This allows development of tag-sets that are more meaningful in the context of the subject-matter and with an associated style sheet language (i.e. Extensible Style Language [XSL]) offer better control over presentation. In the future, XML is likely to be the language of choice for building other languages so as to make interoperability and information sharing possible. In fact, several XML-based applications have already emerged to offer a variety of functionality including:

- Multimedia functionality, SMIL and HTML+TIME.
- Describing specialized languages, Mathematical Markup Language (MathML), Chemical Markup Language (CML).
- Distributing and updating software, Open Software Description (OSD).
- Electronic Commerce, OBI (Open Buying on the Internet).

However, CSS and XML are not universally and reliably implemented in the browsers. It will be at least a few years when their use becomes common.

7. FUTURE OF THE INTERNET AND THE WEB AND ASSOCIATED HUMAN FACTORS ISSUES

Undoubtedly, the Internet and the Web will continue its exponential growth with the potential of exacerbating the current human factors issues related to responsiveness, interoperability, and interactivity. Although some of the future technologies will address these concerns, the applications of the Web in different domains will give rise to different kinds of usability problems. Some of these upcoming technologies and associated human factors issues are discussed below.

7.1. Higher Access Speeds: Still Higher Bandwidth Demands

With the technologies such as cable modems, Digital Subscriber Line (DSL) and satellite-based network delivery, the speeds that the users will have to access the Internet will increase. However, user experience is likely to remain the same because the content providers will demand still higher bandwidth by packaging more multimedia content.

7.2. Narrowcasting or "Personalizing" the Web Content

It is almost a cliché to talk about "information glut" on the Web. To manage access to information and to help users "filter" information, an emerging solution is narrowcasting or personalizing the content on the Web. Rather than providing the information, which appears the same to all the users, the users will be increasingly offered the option of customizing the content to meet their unique needs and interests. The challenge will be to determine what the users want — that is, identifying the "user profile." Currently, two approaches are used to solve the problem: by asking the users to specify their interests and use that information to customize the content and by "watching" their interaction with site and extracting a profile from the gathered information. In the future, personalization will become essential for usability and the burden will be placed on the information

providers to separate relevant and irrelevant information for the users.

7.3. E-Commerce: Addressing Security, Privacy and Trust

Considering the growth estimates of electronic commerce by Forrester Research (1998) — from $48 billion in 1998 to $1.3 trillion by 2003 in the USA and $3.2 trillion globally — the distinguishing characteristics of successful presence for business on the Internet will be ease of use, customer service and efficiency.

A successful user experience for electronic commerce will make it imperative that the user concerns about security, privacy and trust on the Internet are mitigated. In the GVU's 9th survey, the reasons for not making purchases over the Web were:

- not trusting that credit card number will be secure (39.1%);
- not being able to judge the quality of the product (39.3%); and
- not trusting that personal information will be kept private (26.9%).

The World-Wide Web Consortium (W3C), the industry, and the government are working together to address these issues with minimal legislation. In May 1998, the W3C released a public working draft of the Platform for Privacy Preferences (P3P) to provide a framework for informed online interactions (http://www.w3.org/P3P/). P3P allows Web sites to disclose their privacy practices by outlining which data they collect from users, what they use the data for, whether the data will be shared with other parties, and if the data will be shared in an identifiable manner. At the same time, it allows the users to express their own privacy preferences by outlining what information they would like to be made available and in what context. When a disagreement arises between a site's privacy practices and the user's privacy preferences, user is prompted to resolve the negotiation and offered other options to proceed.

Although P3P allows a mutually convenient way for the companies and the consumers to transact business over the Web, the issue of trust, however, still remains. That is, how do users know that a site is not misrepresenting its privacy practices? A number of services such as TRUSTe (http://www.truste.org) and BBBOnline (http://www.bbbonline.org) will provide the assurance that Web site's policies accurately reflect their practices. These assurances are manifested on the site as visual labels ("seal of trusts") on Web sites.

As more privacy safeguards are deployed, the consumer confidence in the Internet should increase. However, in addition to the technology, the design question about "trustworthiness" of a site is still open: What design elements make one site more "trustworthy" than the other?

1. INTRODUCTION

In the relatively short history of Human–Computer Interaction (HCI), several approaches have been developed to account for the design of computer-based interactive artifacts. The most prominent have been the paradigms of Human Factors evaluation, cognitive science, and more recently, user-centered design (UCD). (It should be noted that in recent years there has been a growing interest in more developmental approaches to HCI design (Carroll 1991), such as activity theory, distributed cognition, situated action models, etc. As these approaches still seek their ultimate formulation in the field of HCI, they will not be addressed here. However, their potential value as new prescriptive frameworks for designing computer-mediated human activities in an Information Society is fully acknowledged.) Human Factors evaluation and cognitive science have been criticized with respect to the underpinning scientific ground and the means (e.g. instruments, methods and tools) for achieving a specific set of objectives. The literature in the field of HCI reports many on-going debates (e.g. Nardi 1996), and offers an insight into the diversity that characterizes the field. The essence of the critique is that, on the one hand, traditional large-scale user testing (e.g. the Human Factors evaluation paradigm) is both costly and suboptimal, while on the other hand any attempt for a generalized model or theory (e.g. the information processing psychology approach of cognitive science) for designing interactions between humans and machines is simply not feasible.

Instead, techniques are needed that focus on the requirements of end users and provide early feedback to design, to reduce the cost of designing defects and to meet specific usability objectives. The term that was coined to this approach was user-centered design and the first comprehensive collection of papers on the topic appeared in Norman and Draper (1986). The normative perspective of UCD is to fulfil the need for usability by providing techniques that foster tight design–evaluation feedback loops, iterative prototyping, early design input, end-user feedback, etc. In recent years, due to the compelling need to cost-justify usability throughout a product's lifecycle, the field moved towards a variety of UCD techniques (Figure 1), and the consolidated experience gave rise to several computer-based tools to facilitate the process.

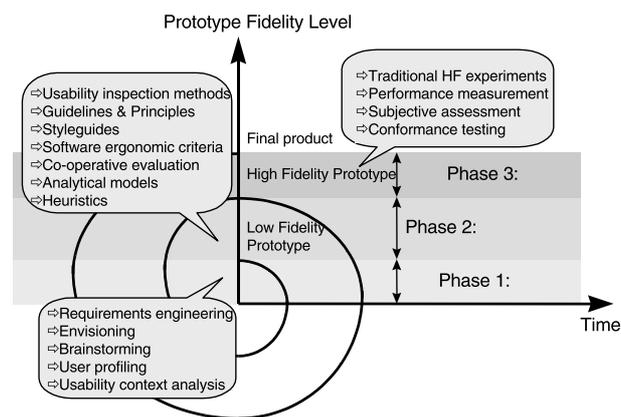
Here the major categories of these tools are described to identify their underpinning assumptions, to assess their contribution to UCD in HCI and to elaborate some of the requirements that future HCI design support environments need to address and satisfy. The following section classifies the state of the art in computer-aided HCI design into six categories of tools. These categories are representative of the three prominent HCI design perspectives already mentioned. Then, a retrospective


Figure 1. User-centered design — techniques, methods and tools.

account of these tools is provided to pinpoint shortcomings and limitations. The next section formulates the proposal of knowledge-intensive design environments (KIDE) as a new category of tool aiming to address the requirements of interaction design in the emerging Information Society. Subsequently, a brief case study is presented as an example of a design environment exhibiting the properties of KIDE.

2. COMPUTATIONAL SUPPORT FOR HCI DESIGN

The efforts to provide computational support for HCI design have emerged from the compelling need for cost-justified usability and more effective means to an end. This section focuses on how the consolidated wisdom has been embedded into computational tools for design support. In this context, we will be concerned with the categories of computer-supported design environments that have emerged to provide support for the various stages of the user interface software design process. (It is important to mention that this account will cover only software systems that have been developed specifically for user interface design support tasks, i.e. tools supporting prototyping and/or development of user interfaces, or design as applied in software; other engineering disciplines (e.g. architecture, civil engineering) will not be addressed.) It should be noted that the prime intention is to depict a road map for user interface design support software, rather than to provide an exhaustive description of specific systems.

2.1. Categories of Tools

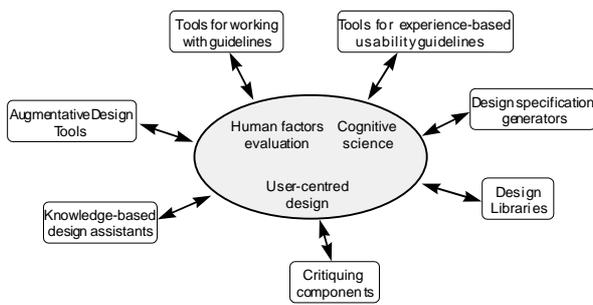
Figure 2 depicts schematically the major categories of tools that are currently available. (For a more elaborate account of each class of tool, see Stephanidis and Akoumianakis 1999.) The first category comprises *tools for working with guidelines*. Such tools are primarily intended to substitute the paper-based medium for propagating guidelines into design, by tools which either provide on-line hypertext access to guideline reference manuals; or, integrate a subset of relevant guidelines into knowledge bases that could subsequently augment the design phase; or, automate the evaluation of certain components of a user interface according to recommendations resulting from general, or context specific guidelines. A more recent development in the above line of work, is the effort to advance *tools for experience-based usability guidelines*. This approach extends the scope of tools for working with


Figure 2. Prominent categories of user interface design support tools.

guidelines to facilitate depositing and retrieval of design experiences and the construction of "living" design repositories.

Critiquing systems and components aim to empower designers when designing low level details of a user interface. In user interface design, critiquing has been employed to facilitate an exchange of reasoned opinions about a product, or action, which triggers further reflection on, or changes to, the artifact being designed (Fisher *et al*. 1991). In the recent literature, this notion of critique has given rise to dedicated and domain-specific implementations of critiquing components embedded into design environments (e.g. Fisher *et al*. 1991).

Knowledge-based design assistants aim to bring Human Factors knowledge closer to the development process of a user interface, by integrating a collection of ergonomic design rules with user interface management systems. In such efforts the content and scope of the Human Factors design input provided is limited to heuristic or style rules. Thus, the level of design assistance offered is limited to identifying, and sometimes automatically correcting, faults in the design that can be traced through the available rules.

Design libraries have emerged from the effort to provide support for design re-use. They constitute a relatively recent development in the area of HCI design and have been closely related with work in the area of design augmentation and rationale. Despite the recognized potential of this approach, the relevant literature reports only very few efforts dedicated explicitly to this line of activity (e.g. Grammenos *et al*. 1999).

Design specification generators have their roots in the model-based paradigm for user interface development (Szekely 1996). The common characteristic of such tools is their reliance upon models of design knowledge (e.g. user, task, environment) to derive specifications and some times generate the code of the interactive components of an application. Existing systems, typically offer some form of modeling tools to assist designers or developers in building the models. These tools range in scope, and include text editors for building textual specifications of models, form-based tools to create and edit model elements, specialized graphical editors, etc.

The categories of tools reviewed so far, are commonly characterized by the fact that they are artifact oriented. In other words, they encapsulate design knowledge (in the form of rules, heuristics or alternative representations) that relates to a particular artifact. As a result, they offer little support for assessing the underlying reasoning, or the process that gave rise to a given artifact. In addition, they offer limited support for collaborative design. To account for these shortcomings, but also as a result of

a more fundamental shift towards analytical design support, recent efforts have been exploring *argumentative design tools* towards design rationale capture and retrieval (Carroll and Moran 1996). Design rationale in the context of HCI refers to a cluster of techniques aiming to provide rationalization for design. In the recent past, several efforts have been undertaken to support design rationale capture and retrieval in HCI (Carroll *et al*. 1996).

2.2. Retrospective

The current generation of design support tools exhibits several shortcomings that impede their wider use and adoption by practitioners. In certain cases, these shortcomings are related to the HCI design strand into which the tool is rooted and therefore they cannot be easily remedied. In other cases, remedy can be attained by extending the capabilities of the tool to interoperate with other tools or design environments. In any case, the critique that follows does not intend to delimit the usefulness of the tools, but to illustrate the shortcomings of providing non-integrated and partial support for HCI design.

Scope of design input. A well-known and documented shortcoming of the current generation of design support tools is their insufficiency to capture and reason about context-oriented parameters. It is frequently found that the recommendation offered by a tool remains the same, irrespective of the context of use. A typical example of such tools is the systems available for working with guidelines. Their underlying model for managing the guidelines does not reflect any context-oriented attributes, thus making customization impossible. Recent developments attempt to provide a remedy for this shortcoming, by following alternative pathways. One approach is that reported in (Grammenos *et al*. 1999) where the tool allows the designer to encode the reasoning behind a particular decision as well as the constraints pertaining to a particular design case, that led to that decision. Another approach is based on compiling usability cases and presenting recommendations by correlating context-specific attributes.

Loose coupling/integration with user interface development systems. In the majority of the cases, design support tools do not interoperate with popular user interface development environments. The primary reason for this is that developers of such systems to not wish their systems to be tied to a particular user interface development environment, as this entails frequent updates to reflect versioning. On the other hand, the problem that is brought out is that the design knowledge encoded in design support tools can rarely be automatically articulated into prototypes that can be experienced by end users. As a result, design outcomes are loosely accounted during development.

Extensibility, maintenance and versioning of encoded knowledge. In currently available tools, design knowledge is typically encoded as collections of ergonomic design rules. However, there is no practical (e.g. non-programming) support for: (1) maintaining the rule base (e.g. supporting updates, identifying competing rules, coping with conflicting recommendations); (2) extending the scope of the rule base (e.g. dedicated programming functions for implementing new rules); (3) versioning of rule bases, so as to depict specific requirements of particular design cases. Once again, more recent efforts such as that described in (Grammenos *et al*. 1999) explicitly account for these shortcomings by offering techniques to automatically identify and resolve conflicts, as well

as extensible Application Programming Interfaces for the transparent integration of new rules once they have been encoded into the rule base.

Corporate support. Another important shortcoming of existing tools, is their lack of supporting corporate practices. This does not only relate to customizing a guidelines reference manual, but also to developing domain-specific styleguides and offering organization-wide support for appropriating the recommendations of these styleguides. In other words, it is not possible for an organization to encode a corporate style guide into the representation supported by an existing tool and subsequently provide this representation as an internal company standard to be observed by different business units and development sections. As a result, it is practically impossible to support consistency and persistency in the use and application of Human Factors knowledge.

Reporting. Reporting design defects and alternative solutions is another important issue that needs to be supported by design support tools, if they are to provide an effective and efficient medium for integrating good design practices, into software design and management. To this end, designers need to be able to effectively document and report the results of their assessments so that they can be communicated to developers, management and other stakeholders.

3. PERSISTENT HUMAN FACTORS KNOWLEDGE MANAGEMENT IN HCI DESIGN

To overcome some of the above shortcomings and to meet the emerging requirements of the Information Society, it is necessary to reconsider several aspects of HCI design and the tools through which it is conducted and practiced. To this end, this section describes some of the critical requirements that should characterize the next generation of design support tools, and provides highlights of some of our efforts towards attaining these requirements, by means of a case study.

3.1. Requirements for Computational Environments

To accomplish their tasks effectively, designers need support, which is not uniform, throughout the various phases of design. Consequently, there is no single best category of design support tool that is preferable to others. Instead, what is needed is a conscious and purposeful effort towards *knowledgeable environments* for *informed* and *rationalized* HCI design. The basic objective of such environments (Figure 3) is to provide computer-mediated instruments to bridge the gap and preserve interoperability across design activities (as performed by human designers), design perspectives (as reflected in the various approaches to design such as analytical/prescriptive, predictive, process versus artifact orientation) and the corresponding design support tools (e.g. engineering models, rational capture and retrieval, critiquing components, specifications generators, prototyping tools). Such environments should exhibit several characteristics, which are briefly described below.

First of all, they should be integrated systems of interoperable design components to provide a greater scope for design input. In this context, an integrated system implies a computational tool that bridges across alternative design regimes (e.g. descriptive/predictive, augmentative/reflective, proactive/reactive), the tools

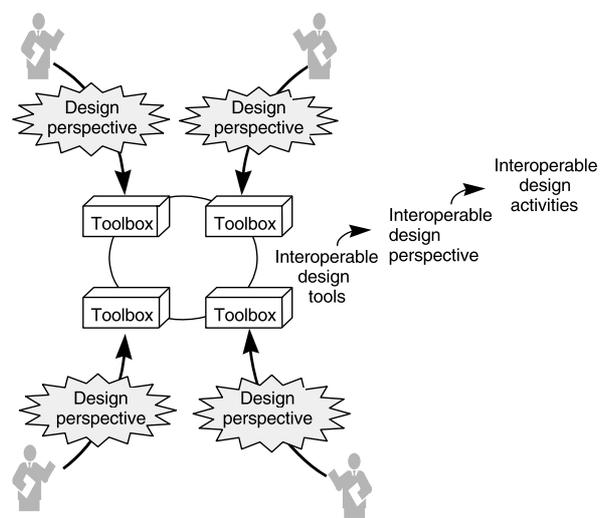

Figure 3. Bridging across design activities, perspectives and corresponding tools.

that serve them, and the humans that employ them. On the other hand, the notion of interoperable design components means that different tools (e.g. engineering models, design rationale editors, critiquing components, specification generators) facilitating alternative design perspectives (e.g. reflection, argumentation, critiquing and automation respectively), can expose data to, and receive data from, one another, so as to support the broad variety of design activities through an evolutionary and persistent computational protocol. In this manner, KIDE can provide a corporate means to effective design processes.

Second, the scope of such computational environments should not be limited to mere propagation of design knowledge, but should also facilitate design knowledge construction as related to the new virtual spaces likely to emerge and the new range of end user experiences likely to be encountered. To facilitate this task, design environments should allow for knowledge to flow and be articulated in generative manners. As information technology is used pervasively within modern organizations, it qualifies as a medium to facilitate both the flow and the generation of knowledge. A related aspect is that the type of designs that should be supported by the new generation of these tools should not be constrained to traditional interaction metaphors, such as the visual desktop. In particular, the scope of design support to be offered by computational environments should be extended beyond the conventional desktop, as in the future, it is expected that new means for interacting with computers will emerge to facilitate the novel virtualities which will increasingly predominate computer-mediated human activities.

Third, due to the iterative and evolutionary nature of HCI design, focus on the user interface artifact being designed is not sufficient. Equally important is the process through which the artifact evolves, the design rationale behind it and the collective wisdom that has been progressively accumulated and can be reused to inform future design cases. It is, therefore, important that emerging design environments provide a more analytic support for unfolding alternatives, building scenarios to envision and understand the design options, as well as for sharing and reusing past design experience and best practice. Meeting this

target, also bypasses the shortcoming on current tools to facilitate extensibility, maintenance and versioning of the encoded knowledge.

Finally, the above characteristic properties of knowledgeable design environments for HCI should be conceived within a broader organizational shift in perspective whereby the currently prevailing paper-based medium for documenting and propagating design knowledge is replaced by "living design memories." The term living design memories is used to refer to the use of technology as a novel, interactive medium for knowledge management in HCI design. To this end, knowledgeable computational environments for HCI should provide reusable, extensible and evolutionary repositories of encoded knowledge which can be used to shape and inform future designs, as well as to facilitate knowledge persistency within and across organizational units.

3.2. Case Study Overview

The above have motivated the development of a KIDE to demonstrate the applicability of the above mentioned four principles. The target application domain covered is the area of accessibility of user interfaces by disabled and elderly people.

The conceptual overview of the KIDE is depicted in Figure 4. The accessibility KIDE integrates four distinctive software tools, each offering a particular service. Thus, for instance, DESIGN-AID follows the design argumentation paradigm for analytical HCI design to allow the designer to articulate elements of a design language and accordingly augment the interaction capabilities of a toolkit. Additionally, the system provides tools and facilities for encoding and retrieving rationale for specific interaction elements, constructing scenarios, encoding argumentation, as well as for reusing past experiences and practice. ELICIT is a user modeling environment which elicits user characteristics and compiles rules regarding suitable interaction elements. ADAPT is a user interface adaptation environment which comprises several tools to facilitate the automatic compilation of a lexical specification scenario for an accessible and user-adapted interface.

Finally, CRITIC-AID embodies a theory of "error and repair" common to critiquing systems. The tool cooperates with ADAPT to check and verify correctness and consistency of adaptation decisions. This cooperation is implemented as a salient-critiquing component that is activated, as soon as a particular test is invalidated. CRITIC-AID encapsulates and implements a three-phased critiquing process. In the first phase, the tool identifies the problem. Then it compiles a representation of the problem that explains to the designer how the problem was encountered, and how it may be addressed. Finally, it repairs the problem upon the designer's instruction.

What is important to note in relation to these developments are: (1) each tool is a separate and autonomous entity; (2) the design perspectives adopted by the tools (figure 4) and their respective contributions to the design activity are radically different; (3) these tools are intended for different people (e.g. the user modeling analyst, the designer, the assistive technology expert). Despite such variation in scope and intended objectives, all tools interoperate to constitute the integrated KIDE. In this case, the basis of interoperation is design abstractions in the form of unified interaction object classes (or abstract interaction object classes). These are platform and metaphor independent interaction constructs capable of polymorphic instantiation to facilitate alternative accessible faces for different user groups (Stephanidis *et al*. 1997).

A second important property of the KIDE, as depicted in Figure 4, is its interoperation with a user interface development environment. Interoperation in this case is based on well-founded semantic protocol, making use of the unified object classes; such a protocol can be implemented through simple message-passing. (It is important to mention that the unified object classes constitute the common and shared vocabulary between the KIDE components, as well as the KIDE and the user interface development environment.) An example of the type of information that is exchanged between the accessibility KIDE and the user interface development toolkit is depicted in Figure 5. It illustrates the contents of the accessibility recommendations server which can be interrogated either prior to user interface implementation (Figure 5) to review the type of recommendations available, or alternatively, during user interface implementation, provided that the toolkit provides the required Application Programming Interface functionality.

As shown, the accessibility server compiles recommendations per attribute of interaction object classes. Additionally, it provides information on how the recommendation was compiled (e.g. which design criterion was assigned and what preference and indifference expressions gave rise to the recommendation). In this manner the designer may review the recommendation for a particular attribute, or all recommendations per dialogue state, or all recommendations which comply to the same design criterion.

From the above, it follows that the accessibility KIDE unifies not only alternative design tools (Figure 4), intended for different users and embodying different design models, but also the different perspectives on design possessed by the human users of these tools. Thus, analytical and process-oriented instruments, such as DESIGN-AID, are "glued" together with artifact-oriented design tools, such as ADAPT, and critiquing components, such as CRITIC-AID. The basis for such a unification is a common vocabulary (e.g. unified interaction object classes) and well-defined communication protocols between the tools and across the KIDE and the user interface development environment.

4. SUMMARY AND CONCLUSIONS

This article has provided an outline of prominent HCI design traditions and identified the type and scope of computational

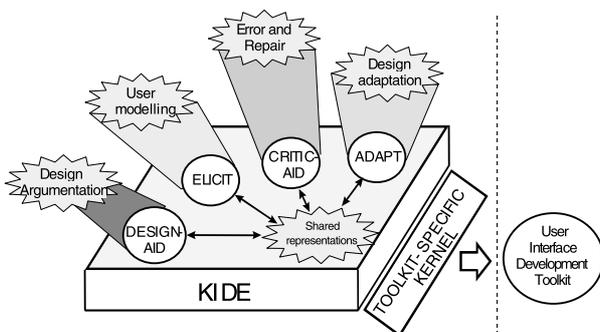

**Figure 4. Conceptual overview of the accessibility KIDE.**

Figure 5. Interrogation of the accessibility recommendations server.

tools which have risen to support design activities. Additionally, a proposal for a new generation of design-support tools in HCI was advanced to facilitate the increasingly complex nature of user interface design in the context of the emerging Information Society. From the account and arguments presented in this article, we can draw a number of conclusions. First of all, it was pointed out that design support is not uniform throughout the various phases. Second, there is no specific category of tool that is best suited for the broad range of design tasks; instead there are different tools that can be used to facilitate different tasks. Third, designers will increasingly need support that exceeds the functional scope of any particular category of tool, thus the requirement for supporting environments of integrated and interoperable design components.

In conclusion, it should be pointed out that, design support tools are not a panacea for the designer, as their capability to automate parts of the design activity is constrained by the inherent complexity of the design activity. Consequently, in the future, the focus should be on computational design support tools that: (1) combine design functionality (e.g. specifications generation, exploration, reflection on past experiences, automation, reuse, and critiquing) in an integrated manner; (2) augment the capabilities of the human designer by offering suggestions, and context bound assistance; and (3) facilitate collaboration between members of the design team through tight design-evaluation feedback loops, so as to assure timely and effective design input.

Knowledge-based Man-modeling: Job Design Procedure (Man-modeling for Job Design)

K. Landau

Darmstadt University of Technology, Department of Ergonomics, Petersenstrasse 30, 64287 Darmstadt, Germany

1. THE NEED FOR CAD PROCEDURES IN JOB DESIGN

As technology at the workplace becomes increasingly complex, many designers of work processes are sorely tempted to regard the skills and abilities of the actual worker as being of secondary importance or even to ignore them completely. It is, however, a well-known fact that the benefits of ergonomically correct job design and job environment include not only improved worker performance and well-being, but also, over the longer term, the prevention of job-related disease.

Extensive ergonomic job design input is an essential factor in the prevention of job-related and occupational diseases. For some time now, insurance companies in the USA have postulated that ergonomic job design could reduce the incidence of musculoskeletal diseases by one-third (Snook 1978). More recent data indicate that roughly 30% of all diseases and injuries are attributable to overloading and that overloading accounts for something like 22% of all traumata in the dorsal region (Putz-Andersen and Waters 1991). Data collected by the Federal German Statistics Office also reveal that industrial accidents and occupational diseases are responsible for only a very small proportion of the health erosion attributable to work activities. The available statistics on rehabilitation measures show that patients suffering from occupational diseases and recovering from industrial accidents (not including accidents occurring on the way to and from work) accounted for only 6.5% of total rehabilitation procedures. In the majority of the remaining cases (89% of total rehabilitation procedures), it is mainly chronic diseases that are involved, e.g.

- musculoskeletal disease;
- cardiovascular disease;
- respiratory disease; and
- gastrointestinal disease.

Work stresses are, at the very least, a contributory cause to these diseases and they should therefore be classified as "job-related diseases." In the sphere of physical work it is mainly the handling of loads that can lead to increased disease susceptibility and, consequently, to frequent, long absences from work.

These data demonstrate clearly that practice-oriented methods of evaluating physical work, in particular load handling, are needed to eliminate or reduce short- and long-term health risks. It must be remembered that simple stimulus–response models (if–then relationship between occupation, job and disease) are of only limited value because they fail to take account of numerous relevant factors from both the work and the private spheres. The resulting standard deviation in the data obtained is so large that no meaningful juxtaposition of work stress and worker health is possible. To reflect the real conditions prevailing in a person's working life, it is necessary to use a multi-causal, retrospective approach that makes allowance for the individual's constitutional makeup and also for extra-occupational stresses to which he is exposed.

This means that detailed knowledge of the design conditions prevailing at the workplace and of the tools and equipment used there must be known and that any evaluation of the job design must be based on valid ergonomic knowledge. A given workplace design will thus give rise to stresses of a given intensity which are *potentially* capable of causing a given symptom or disease with a predetermined percentage probability. Unfortunately, scientifically validated data from which "maximum permissible stress" tolerance limits can be derived are frequently lacking and it is consequently necessary when preparing job design proposals to cobble together data obtained from investigations performed with different evaluation procedures. Software tools can be of considerable assistance here.

The state-of-the-art is considerably more advanced in the design of jobs involving physical work than is the case with information-intensive work. It is thus not surprising that the majority of the software tools on man modeling are for the design of jobs involving physical work.

All the methods described naturally have their specific fields of application, advantages and disadvantages, varying degrees of both accuracy and cost, and focus on different points in the ergonomic design process.

2. HISTORICAL REVIEW

The European Union's Guidelines on Work Safety and Machine Design will exert a lasting influence on the work of job designers and production planners and also on industrial medicine and work safety regulations. They also raise the question as to whether those responsible for implementing ergonomic workplace and job design requirements in industry have at their disposal the tools needed for the analysis, evaluation and design of the man–machine interface.

The former two-dimensional (2D) diagrams of man at the workplace have now been largely replaced in industry by the computer-aided, man-modeling, anthropometric procedures of the 1980s and 1990s. Mutually competitive procedural approaches now being used were frequently developed for a specific purpose, e.g. for the automobile industry, the aircraft manufacturing industry or for other products where anthropologic, ergonomic design is a key factor.

The scientists developing these procedures seldom exchanged ideas and it is consequently safe to assume that a lot of work was duplicated and that the potential advantages of synergy were largely ignored.

Nearly 100 different man-modeling software packages are available on the market at the time of writing. The fields of application of the first packages were workplace design, especially in aircraft and motor vehicle cockpits, and also in industry. Their aim was to portray the human form to scale and in as realistic a way as possible, so that the postures imposed on the worker by tools and equipment and by the work object could be simulated. Later refinements made it possible to portray visual and reach

distances and to perform collision investigations. All in all they were useful tools to replace tedious former procedures using body outline stencils.

Further refinements subsequently built into these software packages gradually transformed them into multivalent instruments for the ergonomist. Attempts are currently being made to improve their modeling accuracy, i.e. to make them produce realistic postures automatically instead of the user having to go through a complicated dialog procedure. Simulation of routine body movements and of the spinal column and the hand–arm system, etc. has improved substantially and work is now proceeding on making the programs capable of showing computer algorithms for applied forces, maximum permissible loads and many other data relating to the worker and the workplace.

3. DEFINITIONS OF AND REQUIREMENTS TO BE FULFILLED BY MAN–MODELING PROCEDURES (MMP)

MMP can be defined as graphic and alphanumeric models using available knowledge on human physiology and on technical aspects of body movements and information reception and processing to produce a model of man at the workplace that is as realistic as possible.

The illustration must not be static. Appropriate simulation techniques must be used to portray the work sequences at the workplace during the course of a shift.

MMP are intended to aid the performance of the fundamental tasks involved in ergonomics — analysis, measurement, evaluation and design. In the field of *analysis* they should facilitate definition of the work system, its elements and its structure. In *measurement,* they should provide support in determining body angles, forces and movements in typical working postures. *Evaluation* is the area where the most extensive requirements exist. Here they must be able to assess energy turnover, force limits and areas of reach and vision, etc. They must be capable of creating stress profiles and of predicting degree of worker fatigue or reliability of a given work system. The evaluation must not be restricted to feasibility and tolerability of the work. It must also indicate whether the work can reasonably be expected of a worker and what discomfort parameters will apply.

The actual purpose of MMP is, however, to provide support to designers and production planners in their *design work.* Their role here is to visualize the man–machine interface, to animate movement sequences, e.g. for workers of different shapes and sizes, and finally to integrate the MMP results into other planning tools, e.g. the planning of plant layouts, facilities management systems, etc.

4. CURRENT RESEARCH STATUS

Only very few of the MMP currently available contain mathematical processes with which the program can process predetermined target points to produce the resultant postures. Sophisticated solutions capable of doing this are a significant breakthrough because they can take into account factors like angle limitations of joints, interdependent factors involved in movements of arm–shoulder system or the pelvispinal region, etc. and thus produce typical human postures that obey the laws of gravity. The body movements in most of the available man models are also still highly simplified and cannot be generated

by the computer internally. One very important development is the use of closed movement cycles that are obtained by video analysis of typical movement sequences.

Another significant development in recent years is body scanning, the collection of anthropometric data by opto-electronic methods. Although the initial accent here was on the sitting position, mainly for research on vehicle design, body scanning has now been extended to cover a wide variety of postures and fields of application. Figure 1 shows the VITUS 3D Body Scanner and the RAMSIS software package as an example of this method.

Over the past 10 years there has been significant progress in the evaluation of physical work involving load handling. It would be logical to integrate this newly acquired knowledge in MMP.

Four types of models — physiological, psycho-physical, biomechanical and epidemiological — (cf. Ayoub 1993, for example) have now been developed for the evaluation of load handling procedures.

The physiological models are based mainly on knowledge relating to cardiovascular and respiratory strains. They are suitable primarily for assessing the long-term effects of a given type of work against the criterion of tolerability. They are not capable of predicting traumata caused by isolated peak stresses.

Psychophysical models establish the relationship between the objective intensity of a physical stimulus and its subjective perception by the worker against the criteria of whether a type of work can reasonably be demanded from either individual workers or groups of workers.

Epidemiological models provide information on the covariance of occupational stresses and job-related or occupational diseases against the criterion of tolerability.

Biomechanical models have a special role to play. This is to provide data on the interaction of work content-related, physical factors and the living body. Mechanical analyses and cover obtain these data:

- body stability;
- maximal physical strength;
- movement sequences;
- mechanical strains affecting individual organs; and
- the mechanical work performed.

Segment models in which the human body is portrayed in the form of linked segments are widely used. The individual segments are rigid, have defined physical properties (mass,

Figure 1. Collection of anthropometric data with the VITUS 3D Body Scanner (source: Tecmath, TUM).

dimensions, focal point coordinates, etc.) and linked together flexibly. Segment models can be static or dynamic and either 2D or 3D. Whereas static models ignore the inertial effects of both the loads being handled and the parts of the body involved, quasi-dynamic models take account of the inertial effects and moments of the external loads only and dynamic models take account of the inertial effects of both the loads and the body parts.

Two-dimensional models are symmetrically constructed in the sagittal plane and cannot register asymmetrical movements or, for example, twisted body postures. This is unfortunate because it is precisely this type of factor that can have injurious effects.

Single Equivalent models illustrate the reactions between muscles and ligaments in a single force vector. Optimization and EMG-controlled models can handle multiple force vectors.

Some of these different types of models are contained together with graphic man models in the software tools RAMSIS, AnySIM or ErgoMan (see below and Landau 1999). There is nowadays an increasing tendency to supplement the graphic portrayal of a load handling operation with an evaluation of the data obtained from a biomechanical model.

The integration of the MMP into the workplace design software is a key feature of several program systems (Figures 2 and 3).

This can offer substantial productivity benefits to industrial users by making it possible to prepare complete plans of both micro- and macro-work systems, starting with the choice of materials and equipment and proceeding via posture optimization and visual geometry to timing calculations and forecasts of personnel requirements. Given the sophistication of these systems, it is not surprising that a considerable amount of development and also ergonomic validation still remains to be done.

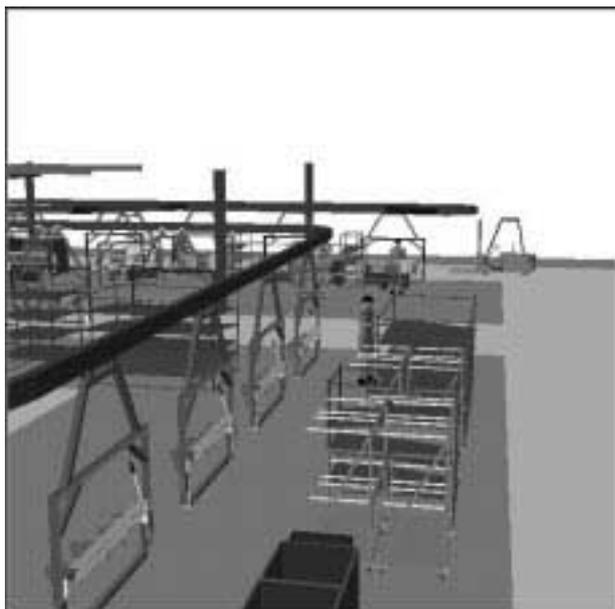
It is at present impossible to be sure that the designers and production planners are able to recognize critical body postures and movements, to predict the physiological cost of various types


Figure 2. An extract from the Ergoman planning software (source: Delta).

Figure 4. Anthropos as an example ov Virtual Ergonomic Prototyping (source: IST).

of physical activities or to appreciate the effects of stress accumulation during a shift or from daily repetition of given postures and movements.

One development following a course of its own is Virtual Ergonomic Prototyping that establishes a link between genuine man and virtual man. An example of this is CAVE visualization systems which check questions of assembly feasibility under critical spatial conditions (Figure 4).

5. CRITICISM OF MMP

Although man-modeling clearly offers major advantages, the risks inherent in a perfectionistic procedure should not be forgotten:

- Could simulation software one day start to dictate the individual actions to be performed by people at work and turn human beings into flesh-and-blood robots?
- Could it happen in a globalized labor market that a preference develops for workers from some specific corner of the world because their body measurements, strength and psycho-mental characteristics correspond best to the computer simulation sequence?
- To what extent will the workers be able to become involved in the design of their own jobs?
- Will man modeling, initially developed to portray and understand the human being, be used to manipulate or

replace him? This is not the vision of human work activity currently prevailing among international ergonomists.

Although these programs certainly offer substantial benefits, those using them should never lose sight of the basic ethical tenet of ergonomics — adaptation of work to the human being for the benefit of mankind.

Models of Graphical Perception

G. L. Lohse

The Wharton School, University of Pennsylvania, Philadelphia, PA 19104-6371, USA

1. AN OVERVIEW OF THE GRAPHICS LITERATURE

1.2. Use of Graphics

Graphics are a powerful tool for the discovery of ideas (Lohse and Walker 1994). Exploratory data analysis helps identify relevant information from a set of data as well as gain new insight or understanding of a problem. Often verbal and numeric cues are insufficient to trigger some insight into the specific nature of the problem (Larkin and Simon 1987). Drawing a picture or a graph often helps break a mental block by providing a memory structure to aid the decomposition of information in the problem. Graphics also allow users to digest a lot of information quickly. Decision accuracy and decision speed have always been important reasons to use graphics. Graphs aid data reduction, data summary, improve information search (Robertson *et al.* 1993) and facilitate computation. Graphics, diagrams and pictures transcend language barriers. Icons and international signs are examples of symbols used to communicate across language barriers. Cognitive psychologists found that visual information can benefit observable behaviors such as recall, comprehension and retention of information (Arnheim 1969, Umanath and Scamell 1988). Graphics enhance persuasion (Vogel *et al.* 1986). Vogel *et al.* also found that color overheads increased comprehension and retention of information when compared with black and white.

1.2. A Historical Perspective of the Evolution of Graphs and Charts

A historical perspective of the evolution of graphics provides insights about contemporary graphics usage (Daru 1989). Playfair is considered the founding father of quantitative graphics. His intent was to improve the general understanding of facts normally shown in tables. It took over a half century after Playfair's death before graphs gained acceptance among even a small group of economists and statisticians. An additional 20 years passed before governments used graphs in widely circulated publications. Since the turn of the century, many experiments examined the effectiveness of different types of graphs and tables for displaying data (Eells 1926, Croxton 1927, Croxton and Stryker 1927, von Huhn 1927, Washburne 1927). Businesses increased the use of visual means for advertising and presenting their products. Graphics also gained wide acceptance in the mass media.

As early as 1915, the American Society for Mechanical Engineers set standards for graphic presentation (JASA 1915). From the 1940s to the 1960s, scholars compared the relative effectiveness of presenting numerical data by the use of graphs and tables (Carter 1947, Feliciano *et al.* 1963, Schutz 1961a, b, Vernon 1950, 1953, 1962).

Graphics emerged as a specialized field called drafting or graphics design. Computers returned graphics to the masses by automating the manual drafting components. Unfortunately, many people are unable to produce pleasing, ergonomically correct, substantially true and statistically valid graphs (Johnson *et al.* 1980). Indeed, Cleveland (1984) found that 30% of the graphs reported in the 1980 (volume 207) of *Science* contained one or more errors.

In summary, three major points arise from this historical review of graphics. First, graphs are a tool for reasoning about information. At some point in the evolution of science, the transformation of knowledge into visual and graphical representations ought to be considered an advancement of the thinking tools of the time. Second, people invented graphs on an *ad hoc* basis as the need arose. The final point is that despite a relatively long history, there is not a common theory for testing the effectiveness of graphic data displays. While it is easy to invent a new graph type, it is hard to invent one that works well.

2. DESIGNING GRAPHS AND CHARTS

Bertin (1983) provides a structural taxonomy of graphs, network charts and cartograms (graphical maps). All other things being equal, if one graph requires a shorter viewing time than another, Bertin hypothesized that it is more efficient for that particular question. Ideally, the answer to a question posed to a graph should be perceivable instantly. One should not need to engage in an arduous deciphering task to decode the answer from the graph.

Tufte (1983, 1990) presents a fascinating collection of illustrations and graphics. He discusses graphic design quality and develops empirical measures of graphic performance. His central tenet was that well-designed, powerful graphics are the simplest. His novel ideas for well-designed graphics are supported by excellent examples; however, Tufte does not offer any empirical support for his design guidelines.

Most "how-to" graphics handbooks rely solely on the author's intuition and experience. Although some handbooks are based on empirical research (Cleveland 1985, Kosslyn 1989), recent research in visual psychophysics discredits some of the sweeping generalizations suggested by other graphics handbooks (Legge *et al.* 1989, Spence 1990, Spence and Lewandowsky 1991).

The literature is rife with experimental data assessing differences in graphic design (e.g. tables, line graphs, grouped bar graphs, etc.). Experimental variables that influence performance include: characteristics of the task, graphic display design variables and expertise of the decision-maker (Ives 1982, DeSanctis 1984, Jarvenpaa and Dickson 1988, Jarvenpaa 1989, Kleinmuntz and Schkade 1993). Without a theory for predicting results, it should come as no surprise that this literature is fraught with conflicting outcomes and a paucity of robust findings.

3. MODELS OF GRAPHICAL PERCEPTION

This section describes research that facilitates the evaluation of graphic displays (Gillan and Lewis 1994), automates the evaluation of graphic displays (Tullis 1983, 1988, Lohse 1991, 1993, 1997, Kieras and Meyer 1995), or automates the design of a graphic (Mackinlay 1986, Casner 1991).

3.1. MA–P – Gillan and Lewis

Gillan and Lewis (1994) developed a componential model of human interaction with graphs called the mixed arithmetic–perceptual model (MA-P). MA-P derives a model of the user from task analyses of users performing graphical perception tasks. The

task analysis used in MA-P identified five component processes: search, encode, arithmetic operations, spatial comparisons and respond. MA-P assumes (1) subjects execute component processes in sequence, (2) each component process requires the same amount of time to execute and (3) total time to complete the task is the sum of the number of component processes. MA-P predictions do not reflect WM capacity constraints.

An empirical study compared actual performance to MA-P predictions. Overall, a simple linear regression model explains 90% of the variance in mean reaction times (n = 24). However, like GOMS, MA-P yields an identical prediction for color or monochrome displays with or without grid lines. Thus, MA-P would need more detailed process operators for detection, discrimination, and perceptual grouping to explain performance for subtle differences in graphical presentation formats.

3.2. DAP – Tullis

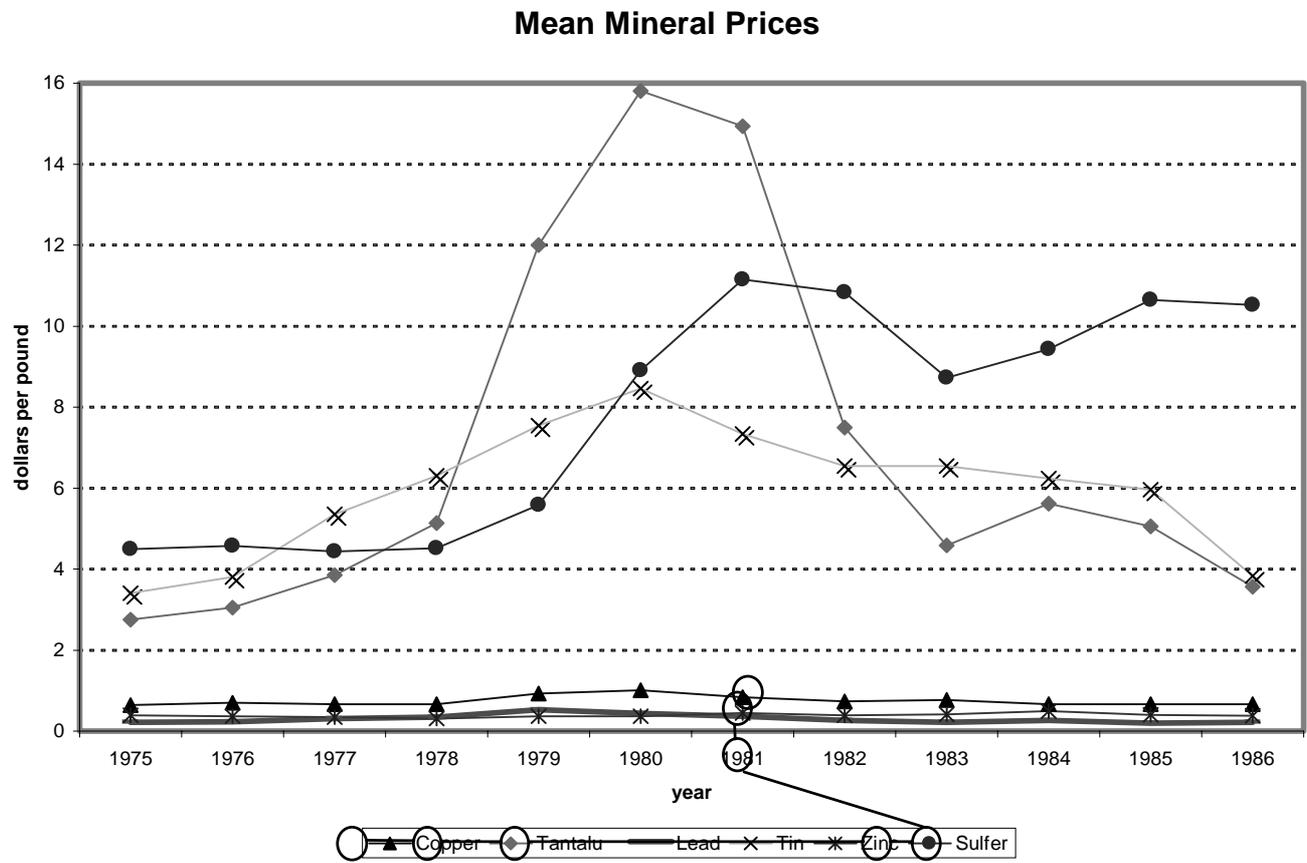
Tullis (1983, 1988) identified six parameters for objectively evaluating screen formats. Based on a usability analysis of these six parameters from 520 displays, Tullis developed regression equations to predict average search time and display quality. His program analyzes screen displays, makes an assessment of usability, recommends improvements in the screen layout, calculates an average visual search time and rates overall quality.

Predictions generated by the program rely heavily on the Gestalt principle of proximity. Although the predictions generated by DAP are quite good (r = 0.71), DAP only analyzes monochrome, alphanumeric tables whereas graphical displays afford more determinants of grouping in addition to spatial proximity.

These determinants include color, graphical borders, highlighting, typefaces and multiple fonts. Items coded with the same color are a perceptual group. Rectangular boundaries also help form groups, although not as effectively as color since containment is detected serially. Highlighting, using reverse video, increased brightness, flashing, underlining or color, can be very effective in attracting user attention. For graphical displays, DAP needs to be extended to include these other display features.

3.3. UCIE Lohse

UCIE (Lohse 1991, 1993) simulates how people answer certain questions posed to bar graphs, line graphs and tables by predicting a sequence of eye fixations that contains the information needed to answer the query (Figure 1). Within each fixation, UCIE identifies the perceptual and cognitive subtasks. Next, UCIE assigns each component task a known cognitive engineering time parameter (e.g. 300 ms to process a six-letter word; John and Newell 1990). UCIE predicts total task execution time by summing the time parameters over all the component tasks. UCIE time predictions reflect subtle differences in similarity, proximity, color and overlap among adjacent non-target objects in each fixation. UCIE also simulates the flow of information through WM (Kosslyn 1985).

An empirical study compared actual performance to UCIE predictions for 576 combinations of presentation formats and question types from 28 subjects (n = 16,128). For conditions that predominantly involve serial processing, zero-parameter predictions from UCIE explained 60% of the variance in reaction times. While UCIE time predictions are good, additional research is needed to explain individual differences in performance.


Mean Mineral Prices

Figure 1. Sequence of eye movements to answer the question "In 1981, did zinc cost less than copper?" posed to a line graph.

3.4. APT – Mackinlay

Mackinlay (1986) developed a compositional algebra for systematically generating a wide variety of graphics from a small set of presentation elements. For example, length encodes quantitative relations (e.g. largest) whereas color does not express quantity well. In contrast, color facilitates perceptual grouping among nominal data categories whereas length does not readily promote perceptual grouping. APT provides two important advances for automating graphic design. First, nearly every graphic presentation tool designed after APT, including BOZ (Casner 1991) uses APT's formal graphical language. Second, APT designs graphics with a minimal amount of input from the graphic designer.

APT has some limitations. The rankings of visual primitives for expressiveness of ordinal and nominal data are based on intuition and conjecture. APT also lacks knowledge about choosing font sizes, selecting line widths, and positioning objects for rendering the graphic design. Finally, APT does not consider the end user task of answering some question posed to the data. This prevents APT from generating different graphic presentations of the same data to support different questions.

3.5. BOZ – Casner

BOZ renders graphs from raw data and a task analysis of a specific question posed to the data (Casner 1991). It replaces demanding logical operators in the codified task description with less-demanding visual operators that reduce visual search. For example, BOZ might replace a comparison of numeric values with a perceptual judgment comparing the heights of two bars. BOZ renders multiple presentations of the same data customized to different task requirements.

Using BOZ, Casner and Larkin (1989) create four displays of one set of complex airline reservation data and predict the efficacy of the four displays using a LISP. Except for display 4, each visual operator reduced visual search time in the manner predicted by the simulation. The major contribution of BOZ is that it creates graphic designs that support a specific task. BOZ does have several limitations. It does not consider fonts, typeface, or color. The graphical presentation language does not compute task completion time. BOZ also does not consider general conventions (left to right reading order, spatial numbering patterns, etc.).

3.6. GOMS – John

GOMS models have four components: (1) a set of goals, (2) a set of operators to perform actions, (3) a set of methods to achieve the goals and (4) a set of selection rules for choosing among competing methods for goals (Card *et al.* 1983). GOMS assumes that routine cognitive skills are a serial sequence of perceptual, cognitive, and motor activities. Each of these actions has a time parameter.

Chuah *et al.* (1995) used GOMS to model the airline flight reservation tasks used by Casner (1991). They used one information search algorithm for each display to make precise predictions about the number of eye movements required to complete the information acquisition task. Chuah *et al.* compared zero-parameter predictions from the GOMS model to the empirical data collected by Casner and Larkin (1989). The average absolute error was 8%. These early results are very encouraging. They demonstrate that GOMS models provide accurate measures of performance for a relatively complex graphical perception task.

3.7. EPIC – Kieras and Meyers

The EPIC architecture is a computational modeling environment for simulating a range of human perceptual-motor and cognitive tasks (Kieras and Meyers 1995). EPIC requires, as input, a set of production rules that specify what actions must be performed to do the task. The model generates a specific pattern of activities necessary to perform the task. Model simulations explain specific patterns of effects in quantitative detail (Meyers and Kieras 1995).

Unlike other production rule systems, EPIC executes multiple actions in parallel. At the start of each cognitive cycle, EPIC updates the contents of WM with new inputs from perceptual and motor processes. WM does not include any mechanism for rehearsal, decay or overflow. The production rule interpreter tests the contents of WM against all conditions of rules stored in the production-rule memory. At the end of the cycle, EPIC executes associated actions in parallel. Thus, there are no central-processing bottlenecks in EPIC. Extensions of the visual processor will allow EPIC to handle such tasks as answering a question posed to a line graph.

4. FUTURE DIRECTIONS

Table 1 compares some of features supported by the graphical perception models reviewed here. All models, except APT, stem from detailed analyses of the user's task. All models, except APT and BOZ, predict task completion time. Time predictions using MA-P can be invariant to the graph type. For example, MA-P lacks detailed operators to predict processing time differences between two bar graphs of the same data with and without grid lines. Tullis designed DAP for analyzing screen designs. DAP does not handle charts and graphs. UCIE only models information processing from bar graphs, line graphs or tables. EPIC incorporates a model of WM, although the WM component of the EPIC architecture is in the early stages of development. CPM-GOMS and EPIC are designed specifically for parallel tasks.

None of the models fully examine individual differences in user capabilities. Individual differences include levels of skill, practice acquiring information from particular graph formats, knowledge of the graphical perception tasks, learning to process information from new or novel graph formats, age, and culture (e.g. most Asian reading patterns are not left to right). In addition, all models only consider skilled, error-free behavior. All of the models function in the domain of static, two-dimensional, graphic displays. Animation and dynamic displays are beyond the scope of current models. Such extensions would be difficult for two reasons. First, little is known about the perception and cognition of animated displays. Second, models would need to incorporate episodic memory.

This chapter motivates a computational cognitive engineering approach for quantifying the effectiveness, efficiency and quality of graphic designs. Unlike empirical graphics research, a quantitative cognitive modeling approach can provide robust objective predictions using an algorithm that could be incorporated into software for automated graphic design. Quantitative models provide a falsifiable theory of graphical perception and cognition that can be tested empirically by comparing decision time predictions from the model with actual decision times. The next generation of graphics research not only should enhance our understanding of graphical perception and cognition but also provide quantitative predictions that facilitate the objective evaluation of the effectiveness, efficiency and quality of graphic displays. Clearly, models of graphical perception are still in their infancy. Much work remains in extending the basic foundation to an understanding on all of the underlying graphical perception phenomena.

Multimedia Production

H. M. Khalid

Institute of Design and Ergonomics Application, Universiti Malaysia
Sarawak, 94300 Kota Samarahan, Sarawak, Malaysia

1. INTRODUCTION

The convergence of computing and media presentation technologies has led to the coining of *multimedia*, a term that encompasses a variety of computer-controlled *interactive* media. "Media" refers to various forms of presentation that can be captured and processed using a computer, such as video, audio, text, graphics, images; while "multi" indicates that several of these media elements are used in the same application. The Interactive Multimedia Association defines multimedia as delivery of information, usually via a personal computer, that combines different content formats (text, graphics, audio, still images, animation, motion video) and/or storage media (magnetic disc, optical disc, video/audio tape, RAM).

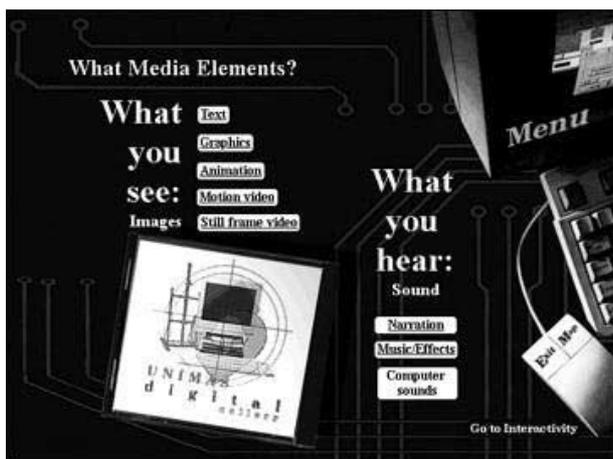
Multimedia thus implies that although the presentations are designed and authored by one or several experts ahead of time, the information presentation is controlled by the user. Interactivity, therefore, is essential for multimedia. A multimodal interface may exploit different user senses, such as touch, hearing and seeing. Multimedia communication, then, aims at providing a rich environment of images, graphics, sound, text and interaction, which supports a variety of human activities from decision-making to emotional involvement. Once a buzzword, today multimedia is ubiquitous in most forms of information presentation and documentation; the World Wide Web is a good example.


Figure 1. Unimas Digital Gallery presentation (Khalid 1997) is a display of various artworks illustrated in text, graphics, video, sound and animation. By clicking on keyword-buttons, users can view directly illustrations of media elements and return to the main screen via the "menu" button. The interface is easy to use with a clearly marked exit and a map to support user navigation.

Multimedia has various user contexts: information kiosks and games for home users, presentations and desktop conferencing for office workers, training and education for students and teachers in the classroom, data visualizations for scientists, and user manuals for engineers. The challenge for the ergonomist, then, is how to blend and integrate the media elements so as to improve human–computer communication. The purpose of this article is to highlight ergonomic aspects of multimedia production, involving the skillful use of different modalities and forms of presentation to communicate essential ideas and concepts. Focus will be on ergonomics guidelines for multimedia design and multimedia usability. Additional information on human factors aspects of multimedia interaction are in Waterworth (1992), and Chignell and Waterworth (1997). Research and theories on multimedia interface design are discussed in Blattner and Dannenberg (1992), the technical aspects of multimedia technology are described in Vaughn (1995), while Furht (1996) presents various tools and applications in multimedia.

1.1. Ergonomics and Multimedia

The design of an informative interface that provides a rich sensory experience of multimedia poses a considerable challenge, and ergonomics' tools can be used to exploit multimedia to its advantage. The highly engaging and interactive style of multimedia communication has the potential of providing effective human–machine interactions. However, multimedia can also be overwhelming, disconnected and difficult to understand; thereby, effective multimedia requires a conscientious design effort. Generally, multimedia design involves both micro- and macro- issues. At the micro- level the concern is with local coherence of information content and presentation that does not result in overcrowding of screen output. Principles of ergonomic screen design may be applied, such as highlighting important information, using appropriate fonts and colors, and organizing blocks of information within screen layouts. At the macro- level the concern is with connectivity, navigability and global coherence of a set of individual presentations that constitute the multimedia application. Landmarks, that is, superimposed visual artifacts, may be used to maintain the orientation and can aid in navigation. Therefore, general principles of ergonomics design in Human–Computer Interaction (HCI) also apply to multimedia design (Helander *et al.* 1997).

2. MULTIMEDIA USES AND APPLICATIONS

The goals of multimedia are to create a user interface that is interactive, pleasing to the senses, and enables the assimilation of information. To this end multimedia should be used when rich media, hyperlinking and interactivity can add significant value to an information presentation. For example, multimedia can enrich and enhance traditional conference presentation, such as in Figure 1 — a creative mix of content comprising text, graphics, video, music and voice narration. This creates an aura of superimposed expressions that, when crafted artfully, increases the interest of the viewing audience. At the same time it allows for multiple channels of information which reinforce the message and integrate the information presentation.

There are many applications of multimedia:

- *Training and education* — the ability to provide access to

remote multimedia stored in databases and to interact with a remote instructor.

- *Distributed work groups* — may benefit from multimodal information presentations, such as in engineering design.
- *Remote experts* — providing images from inaccessible locations, e.g. oil rigs, to experts who can communicate advice, or medical doctors for diagnosis and treatment.
- *Information/sales terminals* — located in shops, departure lounges, public places, providing information on products or services, with videotelephone access to a salesperson.
- *Interactive television* — entertainment, shopping, education and information services utilizing domestic television or Internet.
- *Computer-based information services* — built around personal computer access to information services, e.g. Internet.

Multimedia technology has become important to governments in several countries as a vehicle to enhance information exchange and control. The Information Super Highway in the USA, once a government initiative, later became a private industry initiative. In Asia, Malaysia's Multimedia Super Corridor provides high-capacity broadband network with the purpose to serve industry in the design and production of multimedia products and services. In Singapore the IT2000 initiative ensures that all households are networked using broadband connections. At present this is primarily used for entertainment, while professional applications are being developed.

2.1. Multimedia and Learning

The development of computer-aided instruction and audiovisual media has created much interest in applying multimedia in education and training. Although research findings are not entirely conclusive, using multimedia material people may remember ~10% of what they read, 20% of what they hear and 30% of what they see (Khalid 1998). Most studies in multimedia-based training have focused on learner satisfaction rather than on what has been learnt. Concerns such as whether learning occurs, whether reflective thought is involved or merely sensory experience, has revived some interest in certain theoretical perspectives. Dual Coding Theory, when applied to design of multimedia material, can enhance learning by the simultaneous presentation in visual and auditory modalities. Constructivist Theory, on the other hand, can support learners to develop cognitively flexible processing skills and to acquire knowledge structures that are coherent in terms of content. But these concepts still remain to be proven in research.

3. MULTIMEDIA DEVELOPMENT

An ergonomics framework for multimedia development is summarized in Figure 2. Generally the design evolves through different developmental phases: formulation of purpose, needs analysis, information design, usability features, production planning and evaluation.

Basic design issues that must be addressed early in the multimedia development process include:

- Inputs to the multimedia design process:
- What is the objective of the multimedia application?
- Who is the audience?
- What is the nature of the content?
- What is the delivery platform?
- What are the available development resources?
- What are the user's expectations?
- Multimedia design outputs:
- What combination of media?
- Where and when will various media be used?
- What is the overall quality of production elements?
- Will media elements be synchronized or user invoked?
- What primary branching structure?
- What user navigation features?
- What type of interactions and how frequent?

3.1. Multimedia Metaphor

There are various approaches to multimedia, each is based on different metaphors. Chignell and Waterworth (1997) differentiated between performance, presentation and document metaphors. *Performance* multimedia uses an orchestration of actors and events to create a sensory experience like a stage play. Timing is very important to synchronize the media elements. The media elements must then be coordinated with the user so that it is possible for the user to interact. This type of presentation can be created using Macromedia Director, and it is frequently used in edutainment.

Presentation multimedia uses slides or snapshots to present a set of ideas that form the focus and intention of the presentation. To detour from the linear presentation sequence, links can be offered between slides. This type can be created using Microsoft PowerPoint and it is often used in business or conference presentations.

Document multimedia is concerned with detailed text and ideas similar to a book. It consists of pages or nodes that are organized around a textual framework. This type can be created using Authorware Professional or ToolBook.

The development of HTML and the Web has given a boost to document multimedia. Web documents combining text, pictures, sound and video can be accessed on the Internet. Today, performance multimedia is typically distributed on CD-ROM, document multimedia on the Web, and presentation multimedia is delivered directly to an audience, typically using a notebook computer, and a data projector for projection on a large screen.

3.2. Multimedia Authoring

Authoring is the task of creating or developing multimedia. In multimedia development the concept is much more complex than writing a book given the numerous steps involved in the authoring process. Authoring tools are used for designing interactivity and user interface, and for assembling multimedia elements into a single cohesive application. Some useful tools include: card/page-based tools (e.g. Hypercard, Toolbook), icon-based (e.g. Authorware Professional, IconAuthor), and time-based authoring tools (e.g. Macromedia Director, Passport Producer).

3.3. Navigation in Hyperspace

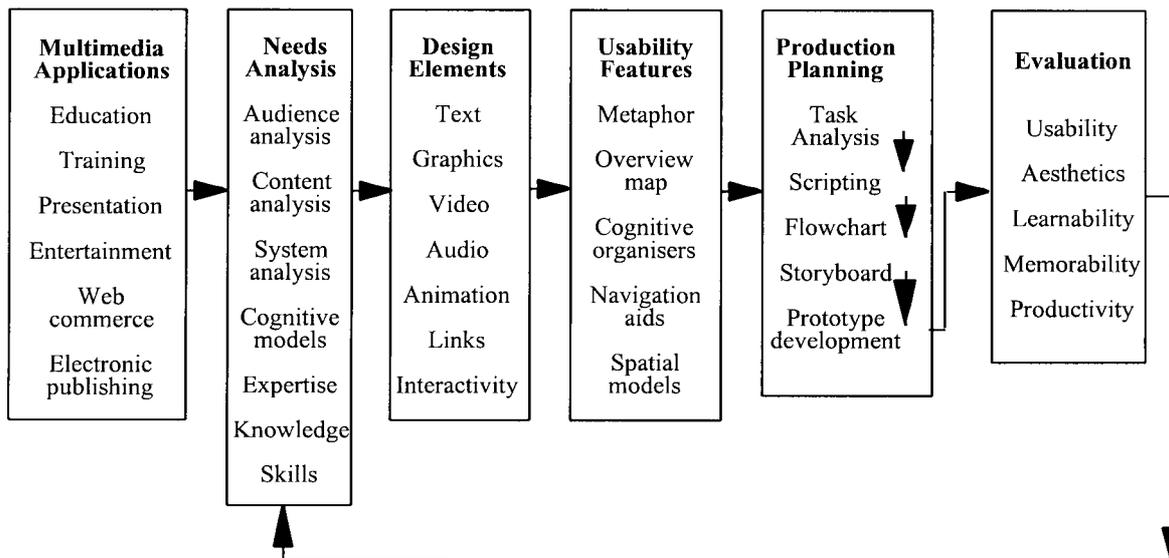
Multimedia typically provides many alternative links and pathways, and users are often "lost in hyperspace." Thereby navigation becomes an important issue. The user must understand how to get back to the origin. A navigation map is helpful. It outlines the links or connections between various areas and helps the user to organize the content, and plan how to move around. There are many types of navigation structures:


Figure 2. Ergonomics framework for multimedia development.

- *Linear* — users navigate sequentially from one frame to another.
- *Hierarchical* — users navigate along the branches of a tree structure that is shaped by the natural logic of the content.
- *Nonlinear* — users navigate freely through the content of the project, unbound by predetermined routes.
- *Composite* — users may navigate freely (nonlinear) but are occasionally forced to attend to linear presentations of critical information.

Navigation can also be improved by organization of information and by spatial representation:

- *Organization of information.* Global coherence in multimedia applications is an important ergonomic issue. The use of cognitive organizer tools, such as overview, maps, table of contents, and linking paths, can support organization and coherence of the information structure. Another issue is when and how to use hyperlinking. It is often claimed that nonlinearity of hypertext is especially suited to effective browsing, suggesting that hyperlinking should be used whenever possible.
- *Spatial representation.* The use of mnemonic systems, and a familiar spatial structure (e.g. the interior of a house) may increase the memorability of multimedia. They help to organize arbitrary sets of objects, concepts or events that can then be remembered easily. The Book House project, for example, is an interesting spatial illustration for finding books in a library (Pejtersen and Rasmussen 1997). Different rooms are used for different types of books, and by clicking on them, the library reference is presented. Providing spatial models of information structure can function as cognitive "prostheses" to multimedia users.

4. GUIDELINES FOR DESIGN OF MULTIMEDIA INTERFACES

Just as there is no standard definition of multimedia, little is also known about how to design usable multimedia interfaces. This is a difficult task since the time-varying nature of multimedia

interfaces demands new design principles. While not much empirical research exists that can support the many design guidelines found in the literature, the need to apply a certain structure seems inevitable for the design of multimedia.

To date, there are relatively few guidelines that can be shared among multimedia developers. Various ergonomic strategies can be used to address particular properties of multimedia. One strategy is to use a design team comprising engineers, computer scientists, ergonomists, industrial designers, graphics artist and application specialists. The use of design teams will see methodologies emerge specifically geared towards multimedia interface design, using the talents of all disciplines.

To help enhance the usability and ergonomics of multimedia, authoring and design guidelines have expressed the need to consider guidelines at several levels: conceptual (e.g. developing good metaphors), linking (e.g. creating dynamic links), prostethics (e.g. using navigational tools such as overviews and organizers), and structural (e.g. specifying appropriate network and spatial structures). Some design guidelines express the need to provide information in small chunks, reveal increasing levels of detail, not inundate the user but to focus on substance, provide an overview of the contents, and index the information. At the current state of knowledge about interface guidelines for multimedia, developers are cautioned to treat guidelines with a grain of salt, to realize that effectiveness may be "hit" or "miss," and to test the interface guidelines thoroughly with the help of the test audience.

Navigation is an important and difficult issue. The central problem is to let the user freely explore the data space, yet to provide guidance in the process. Overview diagrams, fisheye views, embedded menus, guides and a visual cache of previously examined nodes will all help in navigation. Users have to make decisions as to which links to follow and which to abandon. Given a large number of choices, links therefore induce a cognitive overhead.

The design of the multimedia interface must support flexible interaction. This requires the ability to structure material

hierarchically. Thereby users will understand how the system is designed and they will be free to navigate either in a depth-first or breadth-first strategy. Designers can also provide annotation techniques (e.g. keywords) to assist user navigation, browsing and retrieval of information.

Another type of navigation simulates the spatial properties of the world around us, in particular navigating and manipulating in 3D multimedia world. The "walking" metaphor is used to simulate the motion of a human body through 3D scenes. However, it may not be a desirable metaphor because of tethers, obstructions, and the slowness of physical movement (Blattner and Dannenberg 1992).

A common difficulty experienced by multimedia users is disorientation. The problem arises from the need to know where one is in the network, where one came from, and how to get to another place in the network. A similar problem is multithreaded navigation. Each navigation thread requires its own sense of orientation, and the user's overall sense of disorientation is multiplied unless effective orienting support is provided. This type of navigation pushes the limits on working memory and attention.

To reduce disorientation, Nielsen (1990) proposed to:
- create a straightforward and usable organization of the content material;
- make the structure apparent;
- provide maps and overviews;
- use annotation to increase rhetorical structure;
- create paths and hotlists; and
- add search tools to provide alternate means of "getting around."

Guidelines on multimedia design have focused on ways to facilitate learning, including the need to organize and display databases of various types; and to provide links to information sources in a logical and consistent manner. Interface design heuristics, commonly used for HCI design, can be applied to multimedia, such as: use simple and natural dialogue; speak the user's language; minimize the memory load; be consistent; provide feedback; provide clearly marked exits; provide shortcuts; prevent errors; provide good error messages (Nielsen 1990).

5. MULTIMEDIA USABILITY

There is no standard method for evaluating multimedia usability. Its evaluation is inherently more difficult than evaluation of software usability because there is hardly a notion of a standard task in multimedia applications, nor are there obvious measures of task performance using multimedia (Khalid 1998). Instead, one has to rely on subjective ratings of quality and usability of the multimedia, along with tests of comprehension of its content after the multimedia has been used. Global measures obtained from questionnaires and other subjective ratings must be supplemented with diagnostic measures. In addition to these evaluations one could also evaluate the overall information design — that it does not confuse, distract or annoy a significant number of users. The learnability and usability of navigation tools should also be tested, particularly those that are innovative or unusual.

Chignell and Waterworth (1997) proposed four empirical measures of usability that may be diagnostic of structural properties of usable multimedia: node accessibility, link recognizability, landmark recognition and convergence of conceptual structure. In usable multimedia linking paths should be clear and available for selection, and links for each node should be recognizable and make sense to the user. Also, the user's model of the structure should converge toward the system's representation of structure after a certain period of usage.

Nielsen (1990) identified four categories for the evaluation of hypertext documents which can also be applied to multimedia documents. Utility — a measure of whether the document actually helps a user perform the intended task; integrity — a measure of the completeness of the document; aesthetics — a measure of how pleasing the system is to the user; usability — a measure of the effectiveness of communication on five usability parameters: learnability (of the interface), efficiency, memorability, errors and satisfaction. The first experience most people have with a new system is learning to use it. Learnability is, therefore, considered the most fundamental usability attribute. A memorable system enables users to remember how to use and navigate in multimedia after some period of not having used it.

In multimedia, there are two common types of errors: failure to complete the navigation or search task, and deviations from the ideal path, such as when users have to backtrack. Both of these errors are indications that users have difficulties finding what they are looking for, and the designer should consider redesigning the links or improving the navigation by providing appropriate navigational aids.

6. FUTURE RESEARCH

We need human factors knowledge of *users* (e.g. psychology of multimedia users), *tasks* (e.g. standard models of multimedia for different tasks), *technology* (e.g. tools for constructing multimedia), and *environment* (e.g. multimedia in virtual environments). Multimedia has for many years been technology driven. There is a complex array of technological artifacts and computers. To design an educational courseware or entertainment, or an amalgam of both — "edutainment" — there are numerous options for selecting media, mixing and timing them, and for providing user feedback. Hardly any of these issues has been subjected to rigorous research in ergonomics. Perhaps the lack of interest has been because multimedia at present time is viewed more as an art than as a science.

We need new models of browsing that allow constrained exploration within a topic, and usability studies to evaluate the various maps and overviews that have been developed for visualizing multimedia structure.

We also need guidelines for adopting common rules in movie making (e.g. camera angle, panning, zooming) to multimedia. Experience rather than research guided these rules. In addition, we need guidelines to enhance spatial models of information to make them more usable and effective.

7. CONCLUSION

Recent developments in Web presentation technology imply that multimedia will continue to expand in importance. New media concepts, such as streaming of audio and video, demand new approaches to multimedia development; how they are conceived, designed, and implemented. This requires the skills of usability experts and designers who can develop tools and techniques that can assist in the coordination and presentation of media.

Ergonomics should support multimedia designers — the real users of human factors data, principles and tools — by packaging information and guidelines in a usable and meaningful form for direct application. To this end, much research will be necessary to support multimedia production.

Natural Language Communication

V. Raskin

Department of English and Interdepartmental Program in Linguistics, 324 Heavilon Hall, Purdue University, West Lafayette, IN 47907-1356, USA

1. INTRODUCTION

"Natural language" is the term used to denote all human languages that have evolved in the course of human history and been used monolingually to serve fully the needs of the communities that employ them. There are ~5600 extant natural languages, e.g. live languages and dead languages, for which there are records and/or descriptions (e.g. Sanskrit, Latin, Old English).

Natural languages are distinct from such artificial languages as specially designed international languages for human use (e.g. Esperanto, Ido, Volapük) or programming languages for computer use (e.g. Fortran, C++, Java) in many ways but, most significantly, in the manner they are acquired rather than learned by the users. A live natural language is seemingly effortlessly acquired by the native members of its speech community, often after a pretty minimal exposure to it, by the age of ~30 months. This natural language acquisition faculty remains active for a few years and starts fading to disappear entirely in most individuals by the end of their pre-teen years. Artificial languages, along with foreign natural languages to which an individual may be exposed later in life, have to be learned at a significant cognitive and temporal expenditure; in the case of foreign language, a foreign accent is a sure give-away sign of the language having been learned rather than natively acquired.

Natural language is the basis of all human activity and, therefore, an important component of many fields of study. The main discipline, however, which studies natural language as a universal human faculty and the most observable function of the human mind is linguistics.

2. LINGUISTICS

One of the most ancient academic disciplines, dating back several millennia and associated closely, in antiquity, with the study of foreign languages and preservation of dying languages and sacred texts in them, linguistics finally won its independence from such related fields as philosophy, theology, and philology in the early 19th century by developing a particular historical domain that was of little interest to other fields, namely the study of language families and, later in the century, reconstruction of ancestor languages, such as proto-Info-European, with the help of a well-defined methodology based on a systematic comparison of germane words in descendant languages.

This emphasis on precise methodologies served linguistics well in the 20th century when a momentum for an algorithmic, mathematicalized study of language developed in the 1920s, with the advent of structuralism and the subsequent emphasis on synchronic description of language, largely at the expense of its historical exploration. The American branch of structural linguistics, Leonard Bloomfield's descriptive linguistics, became most influential in the 1940–50s after introducing a near-algorithmic procedure for a field description of an unknown language, starting with the collection of a corpus and continuing with the recursive application of the segmentation and distribution procedures from the lower to higher levels of language structure.

These levels define the central subdisciplines of linguistics. Phonetics and phonology study the sound of language: the former empirically so and the latter theoretically. Morphology studies such parts of the words as the root, prefix, suffix and infix, as well as the words themselves and their groupings into parts of speech, such as nouns, verbs, prepositions, etc. Syntax is concerned with the complex organization of words into phrases, clauses, and sentences. Semantics deals with the meaning in natural language; pragmatics with meaning in context. The so-called hyphenated disciplines, socio-linguistics, psycho-linguistics and neuro-linguistics deal with the functioning of language in society, the relations of language to human psychology, and the place of language in the study of the brain respectively.

The mathematicalization, or more accurately, formalization of linguistics was institutionalized by Noam Chomsky in the late 1950s, whose twofold contribution included the development of the theory of formal grammars as a branch of mathematical logic and of transformational generative grammar as an implementation of a formal grammar. A finite set of several types of grammatical rules is postulated as the syntax of a language, and the syntactic structure of each sentence in the language is a formal derivation resulting from a consecutive application of a subset of these rules to the initial symbol S (sentence). The phonological and semantic components, developed a little later, complement the dominant syntactic module of the Chomskian edifice for linguistics.

The conception of language which has emerged from this approach and dominated linguistics ever since, even though most contemporary linguists deviate from some of Chomsky's more specific claims, is that of an algorithmic rule-governed mechanism, internalized in the minds of the native speakers. Many linguists agree with Chomsky that there exists an innate predisposition for natural language acquisition, which is what makes native language acquisition so ostensibly easy and painless. Because such a predisposition cannot be designed for any specific natural language (because, of course, a baby may be exposed to any natural language and acquire it the same as it would any other language), it is concluded that such a faculty contains the rules of "universal grammar," i.e., the foundational features that are common to all natural languages. The search for language universals and their principles and parameters has been the declared goal of contemporary linguistics, even though, in practice, as in many other disciplines, most work is done on the technical aspects of the proposed formalisms and their numerous modifications.

3. NATURAL LANGUAGE AND ERGONOMICS
3.1. Human–Human Communication

All human activity is based on language, most of it on the natural language of the community or the chosen common natural language of a multilingual community, increasingly so English,

in the last decades. All activities, such as manufacturing, services, communication, etc. that are served by ergonomics are no exception, so natural language, its nature and rules, and the body of knowledge accumulated about natural language in linguistics and its applications are all essential for ergonomics.

The primary function of natural language is communication among humans. There are several different modes of human–human communication. It is customary, after Paul Grice's influential work in the 1950–70s, to think of the fact-conveying, *bona fide* mode of communication as primary. In this mode, the speaker and hearer are committed to the literal truth of what is said. A slight and necessary extension of the mode allows such non-literal devices as metaphors and implicatures as long as the speaker makes it clear to the hearer how the utterance is to be understood. This mode is based on complete linguistic cooperation — and trust — between the speaker and hearer. Other, non-*bona fide* modes of communication, such as humor, play-acting, advertising, propaganda and lying, have their own principles of cooperation but none of the modes implies a commitment to the truth of what is being said.

All of these modes have to contend with two essential characteristics of natural language that complicate human–human communication, namely, underspecification, sometimes rather misleadingly referred to as "vagueness," and ambiguity. Underspecification of reality by language means simply that no utterance is capable of containing all the details of the situation it attends to describe. Thus, when the speaker says, "John was late for the calculus class this morning," those hearers who know who John is and what calculus class is meant will have a feeling of complete understanding. The sentence, however, leaves an infinite number of questions unanswered.

Some of them are obvious and may actually be asked by some hearers as a follow-up of their understanding of the sentences. These are such questions as, Why was he late? or How late was he? Others are much less obvious and, correspondingly, rather unlikely to be asked: What was he wearing? Which of the two doors did he use? Did he have a large red plastic diamond-shaped box in his hands? What had he eaten before coming to class and when? Does he know Amy? Has he ever heard of Jack London? These examples are suggested in the increasing order of remoteness and even absurdity but each of the answers may become imminently important a second later if the conversation goes that way.

Underspecification is accepted by native speakers (and hearers) as a fact of life and is rarely commented upon or much researched. (The computer, however, cannot, accepted it.) Ambiguity is a different matter: much of what native speakers do with language is a pretty sophisticated and almost entirely unconscious procedure of disambiguation. The fact is that just about every word in a natural language has multiple meaning, many syntactic structures can be analyzed in two or more ways, and as an obvious result of that, sentences, which are made up of words put together by syntactic structures, tend to be at least potentially many ways ambiguous. Thus, the much-analyzed sentence "The man hit the colorful ball" is believed to be four-way ambiguous; the specially concocted of hackneyed semantic examples "The paralyzed bachelor hit the colorful ball" is 25-way ambiguous.

Native speakers negotiate this potentially disastrous situation skillfully by using sentences in disambiguating contexts and by providing to the hearers the extra information needed to understand each sentence in the intended meaning. Sure enough, this sometimes falls through and misunderstandings occur, but because these are unacceptable to speakers, every effort is made, in the process of Gricean cooperation, to prevent ambiguity from affecting comprehension. (Ambiguity is allowed and even expected in humor, poetry, fiction, advertising, and some religious practices, and the speakers and hearers handle it according to a different principle of cooperation.)

Obviously, then, underspecification and ambiguity in human–human communication in natural language has to be taken into account in ergonomic studies. The efficiency of human–human communication affects all aspects of productivity. The most standard commands, requests, and other constantly recurring messages must be kept as short, precise, and contrastive with regard to each other, as possible: a good example of an ergonomic change to increase contrastivity was the decision to introduce the non-existent word *zwo* instead of the regular *zwei* for "two" into the German dialect of soccer stadium announcers because, in the noisy channel of stadium public address communication, *zwei* could be mistaken for the rhyming *drei* "three," and a dangerous confusion about the score of the game might ensue.

Standard situations require standard contexts, and the effects of underspecification and ambiguity are skillfully minimized by such practices, whether the originators of the established procedure are aware of these language phenomena or not. Non-standard emergency situations have been known to produce uncontrolled and unintended ambiguity resulting in disasters. Rule changes often have the same effect. This affects public address announcements, posters, the adoption of new formulaic commands, messages, and exchanges over communication media, etc. There is a growing realization of these dangers in the areas of ergonomics and industrial engineering and an increasing number of linguistically trained experts.

3.2. Human–Computer Communication

Much, if not already most human productive activity is conducted now with the help of computers. Human–computer interaction and the human factors aspect of computer development and use have, therefore, achieved paramount importance. Linguistics has contributed crucially to the study of these phenomena through its application, computational linguistics, or natural language processing (NLP), often seen also as the natural-language branch of artificial intelligence (AI).

NLP designs and implements automatic systems that, typically, take text in a natural language as input, process it according to the predefined tasks, and then generate output, which may be in the same or another natural language or in some other stipulated format, such as, for instance, a database report or a chart.

Historically, the first task, for which NLP was used in the early 1950s, was machine translation (MT) between pairs of such best-known and -described languages as English and Russian or English and French. While realizing the impossibility of simple word-for-word translation and devising an ingenious system of overcoming this difficulty syntactically, MT soon ran into the "semantic barrier": it became clear to the MT pioneers that no high-quality fully automatic translation was possible without

building the understanding of the text into the system, and this was not considered feasible at the time — to some extent, because of ambiguity and underspecification. As a result, MT degraded to human-assisted post-editor based systems, some of which were found to be practically useful enough to last for decades, and even to machine-aided translation systems, in which humans performed all the intellectual tasks and computers performed simple but time-consuming tasks, such as dictionary look-ups. This temporary collapse of MT as a naive ambitious goal of replacing a huge army of expensive human translators and interpreters with machines gave both MT and NLP a bad name in engineering fields in the 1960–70s, which persisted longer than it should have in spite of the crucial changes in NLP.

In the mid-1980s, MT started making a spectacular comeback as a knowledge-based, meaning-oriented application. This was due partly to progress in general AI and partly to the increasing role of computational semantics, which has moved from the fledgling efforts of its pioneers in the 1970s to the breakthrough developments of the early 1990s in handling ambiguity and underspecification and on to its currently dominant position in NLP. Contrary to the prevalent NLP ideology of the late 1960s–late 1980s, when an enormous amount of talent, effort, and funds were invested in avoiding computational semantics, usually through increasingly detailed syntactic parsing, the current state of the art easily assumes the necessity for the computer to understand the meaning of the text it processes. This makes it possible to diversify NLP applications to intelligent information retrieval and Web searches, automatic abstracting, summarization, etc. In computational semantics, input text is converted into its meaning representation at the required level of granularity, the system manipulates these representations according to the prescribed task and then converts them into natural language text or any other format.

Throughout the brief history of NLP, this representation-based approach, whether syntax- or semantics-based, has had competition in the statistics-based approach, involving no representation of the text in any form or shape but rather trying to achieve the system task on the basis of word lists, frequency counts, etc. Conceptually simpler and lower in cost, the statistical approach has a lower limit on accuracy and on the range of possible applications but it has frequently been opted for commercially if accuracy is less important than cost. There is a healthy division of labor between the representative and statistical approaches, however, with some simpler tasks delegated to the latter and the more intellectually demanding tasks handled by the former, with the statistical output often providing valuable help.

One obvious ergonomic application of NLP has been in the development of user-friendly computer interfaces. A low-cost and accurate NLP interface would allow the human user to interact with the computer in the native natural language without any training in the computer's operating system or a programming language. An additional speech recognition module, translating sounds into spelling, would make the typing of input optional, and these modules have been steadily improving in quality and decreasing in cost and training time as well as making a natural pace of speech more acceptable to them. Optimum interface solutions are apparently of hybrid types, combining the most effective GUI and menu-based interfaces with the more accessible and lower-cost NLP ones.

Product Sensorial Quality

L. Bandini Buti

Società di Ergonomia Applicata, Milan, Italy

1. INTRODUCTION

Usability is defined by the International Standard Organisation as "the effectiveness, efficiency, and *satisfaction* with which specific users obtain specific results in specific environments" (ISO DIS 9241-11). It introduces the concept of "satisfaction," which refers to the sphere of sensations. The sensorial quality of a product is, therefore, a conceptual category linked to the concept of usability.

Jordan (1997) suggests that products can be classified with respect to the user on three levels. The first is that of functionality. A product will result as useless if it does not have an adequate functionality. A product cannot be used or useful if it does not possess the functions necessary to the performance of the tasks for which it was designed. If a product does not possess the correct functionality it will render the user unsatisfied. To satisfy the needs of the user at this level, the ergonomic specialist must understand the destination of use of the product and the context and environment in which it will be used.

The second level is that of usability. When users are used to an adequate functionality they will want a product that is easy to use. An appropriate functionality is a prerequisite of usability, but does not guarantee it.

The third level is that of pleasure. After becoming used to a product, users will quite quickly want something more, a product that provides not only functional benefits, but also emotional benefits. The agreeability of a product represents a new challenge for ergonomics, a challenge that requires a comprehension of the intended user not only as a physical and cognitive processor, but also as a rational and emotional being, with values, tastes, hopes and fears. It is a challenge that requires a deep understanding of the product–person relationship: what will the properties of a product if it is to arouse and provoke certain emotional responses in the user? And how can a product convey a particular group of values? This is a challenge that requires the capture of the ephemeral — formulating methods and systems of investigation for the study and quantification of emotional responses.

2. SENSORIAL QUALITIES

Schopenhaur says (1819), "Primitive matter had to go through a decidedly long series of transformations before the first eye opened … this eye is the indispensable intermediary of consciousness, for which and in which only, the world can have a reality, and without which it is absurd to even think of such a thing, since the world is nothing other than representation, and as such needs a conscious subject to sustain its existence."

We can, therefore, consider the world as a provider of stimuli that, by means of the sensory canals (principally sight, hearing, touch), allow us to perceive the world and make us aware of our surrounding environment. This does not as yet regard the qualities that the stimuli possess. In fact, perception can be activated with equal intensity by effective but unpleasant stimuli or by equally effective but pleasant stimuli. This is the aspect that concerns the sensation of well-being.

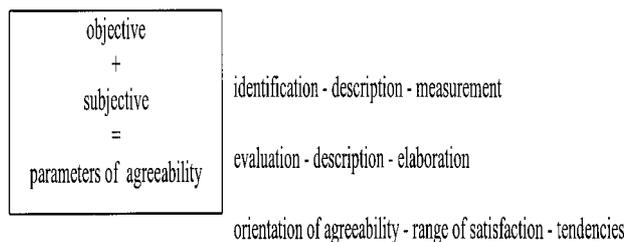
Studies of safety, well-being, and comfort do not allow us to evaluate the sensations experienced by an individual when confronted with an object, a situation or an environment. In other words, subjects express satisfaction and pleasure for various solutions in relation to the sensations that the object transmits to them through their senses as much as in relation to efficiency and effectiveness. This leads us to think that the pleasantness transmitted to an individual by an object is, together with comfort, an aspect relevant to quality research. This is valid for every object we come into contact with. When examining a product for the first time, we unconsciously effect a synthesis of the sensations the product communicates to us and which manifest themselves as a sense of pleasure, indifference or repulsion. When one then experiments by touching the product, feeling its weight, using it, other stimuli are received and the sensations become more precise. Before being able to judge the product on its real characteristics, a judgement of "pleasantness" has already been made, and this will heavily condition any opinion of the product.

The responsibility for reaching high levels of aesthetic quality in products has traditionally been assigned to sensibilities of the designer, as decreed by the current success of the work of creative people such as fashion stylists and industrial designers. But such intuition is no longer sufficient for the introduction of high levels of quality in complex, mass-produced, industrial products, which require, as well as creative work, specific methods for the analysis and application of the sensorial qualities.

The market for durable goods, in particular for electro-domestics, other electrical appliances, and motor vehicles, is becoming ever more interested in quality with the aim of providing an answer to buyers who demand comfort and usability from systems, and comprehensibility of informative means and instructions. One needs not only to identify the sensations perceived as agreeable by the user, but to be able to evaluate them rigorously, propose them in the context of design projects, describe them in the specifications, reproduce them in the product, and to hone them by comparing proposals with results. Sensorial qualities (such as, for example, the tactility of a control unit and the sensory characteristics of its functioning) cannot, in fact, be developed by basing the relevant work exclusively on the individual capabilities and sensibilities of the designer. If they themselves are the only instrument for the evaluation of quality, they become a limiting factor, as they are the only "measurer" of the phenomenon.

2.1. Subjective Sensations

Some product characteristics (material, dimensional aspects, efforts required in use, contact surface characteristics, etc.) can be measured with instruments, and qualified numerically with values valid for time and space (objective data), while the



objective
+
subjective

identification - description - measurement

evaluation - description - elaboration

orientation of agreeability - range of satisfaction - tendencies

Figure 1. Parameters of agreeability.

sensations they produce in those who enter into contact with them (tactile sensations, perceptions concerning ease of use, significance of colors, etc.) are linked to the complex interaction between product, use, and individual (subjective data).

The analysis of product agreeability must, therefore, regard both the measurable aspects of the product (objective parameters) and individual reactions to use (subjective sensations).

The objective of the analysis of sensorial characteristics is the evaluation of aspects of product agreeability, in order to be able to reproduce them and make them the object of specification, not differently from how the technical performance of materials and artifacts (design specifications, contract and supply specifications) are defined.

The subjective sensations felt by humans when they come into contact with objects are linked to the senses:

- tactile sensations: the form, dimensions, and weight of the product;
- prehensile sensations: the quality, softness, grip of surfaces;
- functional sensations: modes of use and operation;
- thermal sensations: conductibility and thermal capacity;
- chromatic sensations: the colors and finishes of the surfaces and the chromatism of the product; and
- acoustic sensations: the resonance of the material, the action, alarms and acoustic feedbacks.

There are also sensations linked to taste and smell, which, however, are to be considered as secondary in the evaluation of the sensorial characteristics of the product.

2.2. Sensorial Variables

Subjective "agreeability" or "pleasantness" is strongly linked to variable individual, cultural, sensorial, and temporal aspects:

- the *social or ethnic group culture* to which the subject belongs, is a cause of individual differences in the perception of quality in a product, as this depends on the history and experiences of the relevant group (e.g. in many parts of the Orient, white is the color of mourning, while in the West it is black), on modes of living (living in a town or city rather than in the country, etc.), on one's occupation, and so on.
- the *sensorial aspects* represent an element of differentiation in the perception of quality, since each individual has his or her own characteristics, which can derive from congenitive or acquired functional reductions (e.g. linked to age), or which derive from activities the subject carries out, such as the difference in tactile perception between a subject who performs heavy manual tasks (e.g. a builder) and another who, on the other hand, performs refined activities (e.g. a computer operator).
- the *temporal aspects* regard the alteration of the evaluation of sensations perceived over time. Certain color combinations that were judged by our fathers as vulgar and gaudy, are now normally appreciated; this is not to mention the evolution in the acceptance of different types of music in recent generations, etc.

3. AGREEABILITY

The evaluation of the emotional aspects of products requires specific study methodologies with the collection of objective data on products and the evaluation of sensations experienced by representative subjects in the direct contact of using products.

The evaluation of emotional aspects has required the development of a specific methodology for the study and introduction of the concepts of agreeability into product conception. The SEQUAM methodology (Sensorial Quality Assessment Method) was applied for the first time in 1992, to the internal components of motor vehicles. (The applications, beginning in 1992, have been effected by the Società di Ergonomia Applicata di Milano (Italy) on behalf of Fiat Auto (Turin), on those motor vehicle components in most direct contact with users.) It has as its objectives:

- The creation of scales of product satisfaction that, when associated with objective aspects, can highlight ranges of satisfaction (a satisfaction index of the products compared).
- The formulation of project specifications for the agreeability of the various product aspects (the most suitable and acceptable characteristics for surfaces, handle forms, softness, noise, etc.).
- The definition of orientations of agreeability that must guide designers.
- The effecting of predictive evaluations (that is, the projection of evaluations in the future).
- The elaboration of transmissible and comparable data on solid bases which may be applied during projection.

The theme for study can be one product or a collection of products dedicated to a specific function (e.g. a steering wheel, an environmental thermostat, a CD player, etc.). Experience tells us that studies of generic products, homogenous only in their functional typology (e.g. levers or push-buttons, leaving their function out of consideration) are to be avoided, as agreeability can never be disassociated from the modality and purpose of contact. Studies of products dedicated to the same function but with differing modes of operation/use (e.g. manual and automatic gear-boxes, or driver's and front passenger's seats in motor vehicles) are also to be avoided.

3.1. Methods of Testing

The evaluation of emotional aspects is divided into tests that allow us to evaluate the sensation of agreeability perceived by the individual:

1. *Laboratory tests* with products isolated from their context of use (e.g. steering wheels, gear-knobs, washing-machine controls presented on panels). Carrying out a test in a laboratory with an isolated product, allows one to use a relatively high number of samples, and to render the tests quicker with optimum time management, but it does not allow one to evaluate sensations linked to use.

2. *Simulation tests in a "natural" context* (electro-domestics fitted in experimental kitchens, motor vehicle parts fitted to simulatory models). These tests are carried using conditions that are close to those of real use, even if bringing subjects to the place of testing already creates conditions with a certain degree of artificiality. Compared with laboratory tests these are more realistic, but they are also more demanding in terms of time and cost.

3. *Tests in real conditions* are the closest to reality and consist of observations of individuals' behavior in their usual place of work/activity. They are onerous as it is the laboratory that comes to the subject and they can be limited by the fact that often it is only possible to test products that the subject

actually owns (e.g. in the study of electro-domestics in the home).

3.2. Operative Flow–chart

Studies carried out with subjects are very effective at describing how much is accepted and requested in a specific moment, but are, on the other hand, very ineffective in the evaluation of predictive situations. They give a good picture of today, not of tomorrow. But any action that has planning as its objective must first of all be concerned with tomorrow, since that which is analyzed has without doubt been designed a few years before, and that which is being designed will be on the market in a few years' time (with a gap that can be as large as 5 + 5 years in the case of motor vehicles). As a result of this, a design methodology that is content with studying the present runs the risk of staying in and consolidating the past, of becoming, in effect, an obstacle to evolution. For these reasons the SEQUAM methodology foresees that the operative plan is repeated during three sequential moments of study:

- study of the present;
- study of innovation; and
- verification with prototypes as a support to the development phase.

3.2.1. First phase – study of the present

This study is executed on products selected from among those on the market, chosen as being particularly interesting in relation to the various aspects of agreeability in such a way as to dispose of the widest possible range of components of the stimuli. The aim of this first phase is to obtain quantitative evaluations of the appreciation of the components of the stimuli and to orientate the design of mock-ups, necessary for the systematic study of agreeability. The study of the present develops through:

- the definition of the sensorial parameters that characterize

the product under examination (e.g. touch, rotation, opening, closing, etc.) and the identification of the qualities one wishes and is able to study (e.g. dimensions, weight, finishes of surfaces, etc.);

- the selection of products already manufactured that possess various gradations of the qualities one wishes to study. Every product will be defined by its measurable characteristics (dimensions, hardness, weight, resonance, range of movement delta, etc.), or its qualitative characteristics (genre of form, set of forms, surface characteristics, chromatic aspects, characteristics of operation, noise characteristics, etc.);

- the choice of subjects representative of the end-user. Subjects must not be specialists in the sector to which the product belongs (such as testers, maintenance workers, employees of the producing company), as they might be conditioned by familiarity with the product or by company loyalties. Subjects must be able to simulate the experience of using the product in real-life even though they are performing under laboratory conditions which differ from those of operating in real-life;

- the execution of analyses for the characterization of the parameters that have been the object of subjective analysis with numerical values;

- the execution of the study in a laboratory where conditions as close to real conditions of use as possible have been reconstructed. The test foresees that subjects will be observed (filmed) while they see/try products and they respond to open or specific (multiple choice etc.) questions; and

- the elaboration of data and the correlation of subjective data (scales of satisfaction) with objective data (measurement of parameters of agreeability of products) in order to define the satisfaction value of the various parameters tested. Data

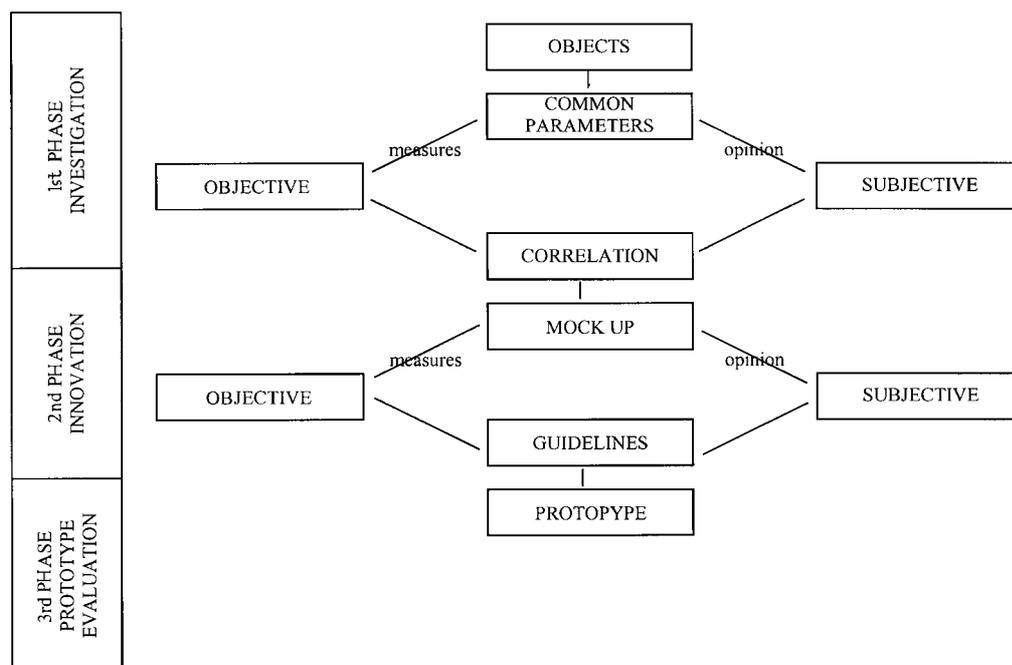

Figure 2. SEQUAM methodology foresees that the operative plan is repeated during three sequential phases of study.

will be continuously confirmed and enriched by the impressions collected, by suggestions, and by analysis of the filming of the tests.

3.2.2. Second phase — study of innovation

The study of the present gives an indication of the agreeability of those products already in production and, therefore, whilst significant for today, it tells us little about innovative trends. Thus, it is necessary to introduce into the study, a phase in which products created specifically for research purposes are analyzed. This phase foresees that the planning and realization of homogenous series of mock-ups, on which to conduct a study of the subjective response to the varying of individual components in situations of "low noise," that is, not 'polluted' by previous preconceptions. Models must allow us to:

- study parameters that in the first phase showed tendencies worthy of further investigation;
- analyze products that respond completely to the preferences emerging from the preceding phase;
- analyze the tendencies emerging from the study but not verified because of a lack of suitable products; and
- study innovative tendencies and trends.

The study methodology is the same as that applied to the first phase and, generally speaking, is executed with the same subjects. The questions are derived from those asked in the first phase, but are enriched by developments made during the planning phase and by the adaptations required by the technical characteristics of the models.

The results of these first two phases consist of project guidelines concerning the agreeability of the typologies studied. They must be considered as valid here and now, and thus to be re-verified in the course of time with the evolution of expectations of use and its characteristics.

3.2.3. Third phase — verification with prototype

Projects elaborated during research must not be intended as design projects in as much as they have not been conceived as integrated in an organic planning context, but, rather, have been elaborated for the specific ends of research and are often proposed for the study of limits of condition (e.g. grips or handles that are excessively large or small). Planning results obtained in the first two phases must be considered as a stimulus and means of orientation for the whole design process and as a means of rigorously evaluating aspects of agreeability and of rendering them easily transmissible.

The first two phases allow one to obtain the maximum amount of information within a reasonable period of time, as required by large industries. These conditions must be defined as "laboratory" conditions even in the most favorable of cases, in which functional products are available, as the studies take place in conditions more or less distant from real conditions of use. In fact, under experimental conditions, subjects tend to pay attention to the product itself, whereas in everyday use they are interested only in the results of their actions.

The final verification of the characteristics of a product's agreeability requires the carrying out of research with functional prototypes that possess all the characteristics of the finished product and that have been installed in coherent surroundings, both from the functional and formal point of view, and that can be used under real conditions by the generality of potential users.

When the development of a project allows for the production of prototypes that are, in terms of finish and function, fairly close to the finished product, the results of the first two phases may be the object of verification under real conditions of use on the part of a large sample of subjects.

During the project development of a product, in which ergonomics must form part of the planning group, verifications can be carried out on the various stages of the product comparing tests with the data collected in the two phases.

4. CONCLUSIONS

Studies of sensorial quality provide objective data (scales of values), subjective data on products (scales of satisfaction) and the comparison of objective and subjective data. The data as a whole enables us to formulate planning specifications for the agreeability of products, expressed as:

- optimum and/or maximum and/or minimum numerical values;
- trends and tendencies;
- values or tendencies that have specific validity for determined categories of products and/or users (e.g., sports cars, older users, etc.); and
- arguments that are not easily definable or that are heavily influenced by the immediate surroundings, but which must be taken into consideration and evaluated during the evolution of planning.

Studies do not produce design plans, but rather specifications for agreeability planning. In order to be effective they must be diffused as a systematic and transmissible approach to sensorial aspects and as a means of orientation that does not, however, limit the creative freedom of planners and designers. The application of the SEQUAM method permits dialogue on sensorial quality between planners, designers, and suppliers, based on objective data.

In fact, industries that produce on a large scale are characterized by an ever more complex organizational system, huge investments, and the pressing demands of the market, for which reason they need the concepts of ergonomy and agreeability to be able to enter into the normal flow of procedures so as to be then introduced into product development with the smallest margin of uncertainty.

In companies, studies carried out for the introduction of ergonomics into design projects can be directed towards a specific product in the course of its development or the generality of present and future models. When the objective is the development of a specific product, a work group is formed in which ergonomics researchers maintain a close contact with managers in charge of the planning and formal development of the model, with marketing services, suppliers, and purchasing departments. This renders the communication of results from studies easier, even if they are not expressed in a strictly formal way.

Formality, however, becomes indispensable when research studies have to be able to make use of the generality of present and future products, for which reason, the results of the studies, the principals and techniques of ergonomics and agreeability must be rapidly and effectively diffused at all levels of the company concerned. In other words, one must stimulate an orientation towards these themes of the structures that go to make up the complex system of planning, and which have to be able to gain

access to information in real time and with ease, in as much as few potential users (of whom there are a great number and who cannot really be predicted) have been able to have direct experience of research.

Data extrapolated form studies must be produced in a format that can be entered onto an Intranet site and available for all company operations interested in planning and design.

The system must enable:

- the transmission of data in a synthetic form that is easy for users with differing backgrounds to read (technicians, designers, stylists and administrators);
- the use of a graphic form adequate for rapid consultation; and
- the obtaining of more levels of reading with different degrees

of definition, facilitating reference to research literature in its entirety for the acquisition of details of research carried out and the justification of results obtained.

Speech-based Alarm displays

N. A. Stanton

Department of Psychology, University of Southampton, SO17 1BJ, UK

1. INTRODUCTION

Speech synthesis is receiving increasing attention as a potentially valuable medium for a variety of applications of information display. This paper addresses the use of speech as a means of displaying alarm information in "process control" type tasks. Typically the operator of a control desk will monitor the state of a process from a room that is sited remotely from the plant. Therefore, the operator's main source of information about the plant status is via process page displays presented on Visual Display Units (VDUs), which may contain up to 800 pages of information. Further, the process plant is controlled by a team of operators and a supervisor who are in contact, either face-to-face or via telephone, with plant engineers.

A speech-based display medium might have potential benefits to offer control room operation. Benefits that are often associated with speech displays include: breaking through attention, eyes-free—hands-free operation, omnidirectionality, no learning required, reduction in visual clutter, and public display. It has also been suggested that the auditory channel is particularly well suited to the transmission of warnings (Stokes, Wickens, and Kite 1990). Given the demands placed upon the operator in the control room, communication of alarm information using the auditory channel might therefore present a way in which better use might be made of their limited attentional resources.

The use of auditory displays in control rooms is not a new idea; in fact most control rooms employ non-speech auditory displays in conjunction with visual displays for conveying alarm information. However, non-speech warnings are clearly limited in terms of the amount of information that can be transmitted and the number of different types of signal that a human can discern (Stanton 1994). It is relatively easy to discriminate between up to seven different tone-based auditory warnings, but beyond this number it becomes much more difficult. Thus speech might be a more flexible and informative medium than tone warnings as this can be used to alert the operators to the problem, inform them of the nature of the problem, and cue the required response. However, Baber (1991) warns that although synthesized speech appears to be an attractive display medium for the presentation of warnings in control rooms, one needs to consider the appropriateness of speech for the tasks performed in the application domain before it is recommended. Baber (1991) also presents some design considerations regarding warning systems — for example, he suggests that the warning should sound distinct from human speech and that the message should be worded as a short phase containing a minimum of five syllables. These recommendations are intended to increase intelligibility and inform the operator that the message is from the machine and not from another human operator.

2. HUMAN VERSUS SYNTHESIZED SPEECH

In an experimental study reported by Baber, Stanton, and Stockley (1992), it was suggested that there might be a place for speech-based alarm displays in control room activities. In particular, they pointed out that a major benefit of speech in information-processing terms is that it can be used to relieve the visual channel. This was illustrated by introducing Wickens' (1984) model of information processing which suggests that visual–spatial information and auditory–verbal information draw on separate "pools" of attentional resources. Therefore transferring the alarm system's information from the visual display to an auditory channel might provide the human operator with greater capacity to deal with the incoming information and handle it appropriately. This could be seen as a possible solution in attempting to spread the mental workload demands of the task. Thus, in information processing terms, speech-based alarm systems might reduce the attentional demands on the visual channel. By comparing human and synthesized speech-based alarms, Baber *et al.* (1992) proposed that speech-based alarm displays need to be considered in terms of the tasks that operators are required to perform. For this purpose a model of alarm handling (Stanton, Booth, and Stammers 1992) was taken into the experimental laboratory so that the medium could be investigated in a more rigorous manner. From this study it was proposed that, in order to maintain a distinct difference between information communicated from the displays and information communicated between operators, synthesized speech was more appropriate than "human-like" speech. It was also suggested that speech might be suited to only a limited range of display information.

3. SYNTHESISED SPEECH VERSUS TEXT

Stanton and Baber (1997) investigated the operational performance differences in an experimental "process control" task by comparing speech and traditional scrolling text alarm displays. It was proposed that speech-based displays would be superior for attracting attention and single fault management (i.e. one alarm connected to one event), whereas scrolling text displays would be superior for more complex multi-alarm problems (i.e. many alarms connected to one event). The combination of speech and text should therefore lead to superior performance overall. Synthesis-by-rule was chosen over prerecorded messages for two main reasons. First, the alarm messages should be distinct from human speech. Second, in a real human supervisory control task there could be up to 20,000 alarms (such as in a nuclear power station). It would be a daunting task to prerecord all 20,000 messages, whereas synthesis-by-rule offers a practical solution. The surprise recall task used a pencil and paper so that participants could record the alarms they recalled.

Briefly, the experimental task required participants to conduct a planned activity in a simulated "process" plant. They had control over valves (open or close) and boiler heating (off, low, medium, high, or very high). They could also inspect the status of the plant elements — for example, tank levels, valve positions, and boiler temperature. Using this information, they were required to heat up a liquid until it was within predefined thresholds,

then they had to condense it whilst it was inside these thresholds. Several elements of the process could go wrong. For example, the source liquid could run out, the supply pipe could crack, the temperature of the boiler could be too hot or too cold, or the coolant tank could run out. Each of these problems had an associated alarm. The subject's goal was to "process" as much liquid as possible to achieve the maximum "output". In addition, the participant was requested to attend to a spatial secondary task when the workload on the primary "process" task permitted. The results generally suggested that performance was better in the text and speech and text (SandT) conditions when compared with the speech only condition. No statistical differences were found between the text and speech and text conditions. Interestingly, participants' performance in the speech only condition was generally significantly worse than that of participants in the other two conditions. This effect appeared to be reduced substantially when speech was combined with a scrolling text alarm display. Thus, one must consider why speech-based alarm displays appear to be detrimental to performance in a "process control" task.

4. DISCUSSION AND CONCLUSIONS

It has been suggested that the presentation of verbal information is inappropriate for fault diagnosis (Robinson and Eberts 1987). The suggestion is that the operator isolates the plant component in terms of its spatial reference rather than its verbal reference. Alarm information in the experimental task described within the second study was verbal in all three conditions, but the duration of the information was much shorter in the speech-based alarm condition. This is a more likely explanation of the findings, as all conditions were equally disadvantaged in "spatial reference" terms, i.e. in all of the conditions alarm information was presented verbally, as speech, scrolling text, or both. Baber (1991) also pointed out that poor quality synthesized speech and the resulting high memory demands this makes on operators could degrade performance. The latter of these probably had the greatest effect.

The results from the surprise recall task show quite clearly that participants in the speech-only condition were unable to recall as many alarm messages as participants in the other two conditions. This supports the findings of the first study that report recall performance for a synthesized speech condition was very poor. This suggests that synthesized speech is processed at a surface level, rather than at a semantic level, and could account for the poor recall performance. Thus, one could surmise that synthesized speech is inappropriate for tasks that involve a memory component.

Speech also has a "durational" component, which may lock people out of the interaction until the message is complete. This would occur even if the speech is of a high quality, whereas visual displays can be sampled at the operator's pace and are permanently displayed. Speech presents a paradox of operation: participants are required to respond immediately or the message will be lost, but have to wait until the message has ended before responding.

Stokes *et al.* (1990) suggest that speech-based warnings serve as both an attention attractor and as a channel for transmitting information about the failure. Although the synthesized speech used in both studies was distinct from human speech, participants in the speech-only condition were significantly slower to accept alarms than participants in the other two conditions. Participants

in the speech-only condition must have either ignored the message or failed to realize that the spoken alarm required an immediate manual response. Following a series of experiments examining fault management in process control environments, Moray and Rotenberg (1989) claimed that operators might observe abnormal values, but fail to act because they are already busy dealing with another fault and may wish to finish that problem before turning to a new one. They term this phenomenon "cognitive lock-up", and note that human operators have a preference for serial, rather than concurrent, fault management. Therefore, new alarm information is likely to be ignored until the operator is free to deal with it. If this alarm information is presented through a transitory medium, then it will be lost. This explanation of fault management suggests that synthesized speech-based alarm display systems are not appropriate for process control tasks. There is some evidence to suggest that irrelevant speech may have adverse effects upon performance (Smith 1990). The effects appear to occur independently of intensity. This could also lend some explanation to the study in this paper. Consider the participant working to maintain the process whilst speech alarms are being presented: the alarm information may be described as "irrelevant" if it does not relate to the particular task in hand, and performance is disrupted.

In conclusion, it is suggested that speech alone as a medium for alarm displays cannot be recommended for tasks where there is: (a) a memory component; (b) likely to be some delay before the fault is attended to; and (c) likely to be more than one alarm presented at a time, and the operator is required to assimilate information from a variety of sources using spatial reference. If speech is to be incorporated into the alarm system for "process control" tasks, it is recommended that it is paired with other media such as a text-based display. However, speech-based alarms might be appropriate for tasks where: an immediate response is required; the "operator" is away from the control desk; the situation is typically one-alarm to one-event and fault management is serial in nature.

Structured Integration of Human Factors and Software Engineering Methods

K. Y. Lim

Nanyang Technological University, School of Mechanical and Production Engineering, Nanyang Avenue, Singapore 639798

1. INTRODUCTION

A perennially reported problem of human factors input to interactive systems development is that its contributions are often requested late. In particular, human factors inputs are frequently excluded from design specification and its involvement is confined mainly to late evaluation. Design inputs (human factors or otherwise) at this late stage of system development are difficult and costly to implement and thus are less likely to be realized in full. Here, the design of the system would have been more or less fully developed, with interlocking dependencies that would imply wide ranging design disruption if modifications were to be implemented. In addition, affective considerations may complicate matters. For instance, proposed design changes might violate feelings relating to design "ownership" (leading to undue defensiveness on the part of the system designer and avoidance of potential offense or "stepping on toes" on the part of the ergonomist). Further, design modifications proposed at this late stage tend to be subjugated by other more pressing concerns relating to project budget and schedule. The result is thus a resistance to design modifications, manifested as the "too-little-too-late" problem of human factors input (Lim and Long 1994).

This poor state of human factors input may have arisen paradoxically, from too rapid a recognition of its importance around the time of the personal computer (PC) revolution. At this time (1980s), the scope of human factors input to interactive systems development was poorly defined. Human factors became a victim of its own success, as the development of its methods could not keep pace with the rapid increase in demand for a wider scope of design contribution. Human factors methods then comprised largely of an incomplete collection of disparate techniques, traditionally focused on design evaluation as opposed to design specification (Lim 1996). The scope of its methods (such as task analysis) was thus found to be limited and incomplete in the coverage of the system design cycle. Further, the human factors design process was criticized as largely implicit, and consequently impossible to time or intersect with the design activities and contributions from other disciplines. Worse, since the scope and process of human factors design were incomplete and implicit, its project resource demands could not be anticipated and planned for. The result was a lack of management support and commitment, and the prolonged exclusion of human factors from the project budgeting and planning agenda. In the absence of an explicit allocation of resources, human factors considerations were observed to be accommodated only opportunistically and sacrificed first (when needed most) when

a project hitch arose. In these circumstances, even when project resources were allocated to human factors design, they were encroached upon as managers could not support their retention on the basis of its implicit design scope and process requirements. In an attempt to cope with these difficult constraints, the human factors inputs that could be proffered were found to be inadequately explicit, or worse no more than advice. Consequently, in the late 1980s, it became clear that existing human factors design processes and methods had to develop in earnest.

2. TWO PROMISING SOLUTION APPROACHES: RAPID PROTOTYPING AND STRUCTURED ANALYSIS AND DESIGN METHODS

To advance the methodological foundation of human factors design, and so counter the "too-little-too-late" problem of its input to interactive systems development, the design framework offered by two key system development approaches were examined; namely rapid prototyping and structured analysis and design methods. The objective was to assess their potential to support the location and specification of more explicit processes and methods for human factors design. These system development approaches will now be considered briefly in turn.

First, rapid prototyping that advocates the rapid construction of a design artifact was developed to facilitate the iterative cycle of design modification and test. Although the approach offered many advantages and solved a number of problems of human factors input, some key concerns remained unaddressed; in particular the following:

- A rapid prototyping approach usually generated little or no design documentation. This is due to its emphasis on the construction of a design artifact directly on a computer.
- The emphasis of rapid prototyping on the fast generation of an artifact is predisposed towards inadequate requirements analysis and design.
- A rapid prototyping approach may relegate human factors input to prototype evaluation as opposed to active involvement in design specification. Poor designs may thus be discovered late.
- Although rapid prototyping was originally equivalent to throwaway prototyping, it was not always the case in reality. Instead, there was considerable resistance to discard a prototype since considerable effort was usually invested in its construction. The practice may be attributed to the reluctance of designers to show crude prototypes to clients and end-users, due either to professional pride or the fear of losing credibility. The result may be premature commitment to a design. Late discovery of a poor design may again arise.

Structured analysis and design methods, in contrast, advocate comprehensive design analysis and specification before the undertaking of any design implementation. Examples of such methods include Structured Systems Analysis and Design Method (SSADM), Structured Analysis and Structured Design (SASD) Method, Yourdon and Constantine Method, and Jackson System Development (JSD) Method, to name a few. This class of methods was developed with the key objective on ensuring the design of a correct system (this may be contrasted with formal methods which exploit algebraic descriptions to ensure "correct"

development of a system). Structured analysis and design methods are promising as they provide the following:

- Complete and comprehensive life-cycle support for system development.
- Explicit methodological characteristics with well-defined scope, process and documentation/notation, for each stage of system development. Project planning and quality audit are, therefore, well supported.

The explicit methodological characteristics of structured analysis and design methods afforded the following advantages:

- A well-developed framework that facilitates the definition or identification of more specific intersections and timing of cross-disciplinary design activities and contributions, including those of human factors design.
- Explicit intermediate design descriptions that support design communication among designers, end users and managers.
- A set of comprehensive design notations which may be exploited by human factors to enhance the specificity of its design descriptions, and hence the potential of a common language across contributing disciplines.

Although structured analysis and design methods showed promise, they were targeted at addressing Software Engineering design concerns only. In particular, a survey undertaken in 1987 revealed that user requirements analysis and specification and user interface design, were excluded from their design scope. Thus, these human factors design processes had to be incorporated into the methods. Unfortunately, existing human factors design methods were inadequately explicit, and direct incorporation into existing structured analysis and design methods could not be achieved. Further, to specify appropriate intersections and timing of cross-disciplinary design activities and contributions, an explicit and complete human factors design method would be required. Since such a structured human factors method did not exist in the late 1980s, it would have to be developed. In this respect, the framework offered by software engineering structured analysis and design methods could be used to guide the development of a structured human factors method. The latter may then be integrated explicitly with structured software engineering methods to ensure more efficient system development. Work in this direction began in earnest at this time, as evidenced by the work of Walsh *et al.* (1988), Sutcliffe (1988), Damodaran *et al.* (1988) and Blyth and Hakiel (1989). A brief account of the resulting conceptions of cross-disciplinary methodological integration follows.

3. EXEMPLARS OF STRUCTURED INTEGRATION OF HUMAN FACTORS AND SOFTWARE ENGINEERING METHODS: AN OVERVIEW

Here, published work on the structured integration of human factors with leading software-engineering methods is briefly reviewed. In particular, conceptions of methodological integration of human factors with the JSD, SASD and SSADM methods are examined.

3.1. Integration of Human Factors with the JSD Method

The structured integration of human factors and JSD methods was the most actively pursued in the late 1980s, as JSD was the preferred method for real-time systems development. Besides Lim *et al.*'s (1990) work on integrating MUSE with JSD (named MUSE–JSD), a second conception of such an integration was also published by Sutcliffe and Wang (1991).

MUSE–JSD is the result of a project commissioned specifically to develop an explicitly integrated human factors and software engineering method. From the outset, JSD was targeted as the software engineering method for integration. As a similarly structured human factors method did not exist, the initial work of Walsh *et al.* (1988) was focused on the development of a structured human factors method. Several versions of such a method was developed, culminating in a generic structured human factors method named MUSE. As the scope, process, products, procedures and notation of each design stage are defined explicitly in MUSE, specific intersections and timing of human factors activities and contributions could be identified with respect to specific JSD design stages. Obligatory cross-disciplinary reference or contact points are thus specified to ensure a common design basis and information pool. These contact points help to ensure the development of a consistent and convergent system design. As MUSE recruits the structured diagram notation from the JSD method, the potential of a common notation is exploited to facilitate cross-disciplinary design communication. From the literature, it would appear that MUSE–JSD offers the most explicit and developed conception of methodological integration. For a detailed account of MUSE–JSD, the reader is referred to a related article included in this encyclopaedia, and to Lim and Long (1994).

Sutcliffe and Wang's (1991) work on methodological integration was directed at recruiting existing human factors techniques to extend the scope of the JSD method. Their main concern was to locate task analysis and user–computer dialogue specification against pertinent JSD design stages. In particular, they suggested that descriptions of user task activities may be linked to the JSD model by extending the scope of JSD interactive function specification. Further, as in MUSE–JSD, Sutcliffe and Wang (1991) also supported the use of JSD structured diagrams as a common notation for cross-disciplinary design specifications. Concerning user–computer dialogue specification, three intersections were proposed between human factors and JSD design specifications:

- Actions of JSD entities should be mapped onto actions of user interface objects. Their argument for this mapping was that the JSD model is essentially an object and event model. For instance, they suggested that user inputs and errors may be related to the system context defined by the JSD model.
- User–computer dialogue specification should be based on the functional supports required by the user's task.
- User–computer dialogue specifications should be linked to JSD input subsystem specifications. Sutcliffe and Wang proposed that dialogue control requirements for error recovery, and prompts and feedback messages, may be specified as simple JSD filter processes. To avoid segmentation of the user task description into incoherent units scattered across JSD filter process specifications, they reasoned that the latter specifications would have to be modified.

Although Sutcliffe and Wang proposed some interesting ideas for integrating human factors and JSD methods, their conception

did not include the development of a structured human factors method. Thus, it is unclear from the literature whether their proposed methodological integration could be achieved.

3.2. Integration of Human Factors with the Structured Analysis and Structured Design (SASD) Method

In response to in-house demands, Blyth and Hakiel (1989) took up the challenge of integrating human factors design with SASD, their in-house software engineering method. Their efforts involved incorporating task analysis as a basic activity within the SASD specification of an Essential System Model. Function allocation activities were also intersected with the SASD specification of a System Function Model. With these extensions, the existing machine-oriented perspective of the Essential System Model may be tempered with a user-oriented perspective. Further, to extend the scope of SASD to include the specification of human–computer interactions, Blyth and Hakiel conducted a review of existing human factors techniques. On the basis of the review, they constructed an eight-level conception of system specification as follows:

1. Goal and Task Levels: detailed analysis of goals, tasks and function allocation. A set of task models is thus derived from domain abstraction.
2. Conceptual Level: definition of conceptual objects to be represented at the user interface.
3. Semantic, Syntactic, Lexical, Alphabetic and Physical Levels: top-down specification of human–computer interactions.

These levels of system specification are supported by five sequential steps to advance human factors design concerns; namely analysis of extant systems; user characterization; task analysis; function allocation; conceptual model specification.

In summary, the work of Blyth and Hakiel (1989) addressed the much-needed extension of early stages of the SASD method, to include human factors design concerns and activities. However, the potential of a common notation to facilitate cross-disciplinary design specification, was not exploited.

3.3. Integration of Human Factors with the Structured System Analysis and Design Method (SSADM)

The integration of human factors with SSADM was undertaken by Damodaran *et al*. (1988) as part of a consultancy project. Their objective was to incorporate into SSADM four areas of human factors design; namely user analysis, job design, task allocation and prototyping. Strangely, user interface specification was excluded from their scope of integration. Since the scope of human factors design addressed was incomplete, it is unclear how high level descriptions of task allocation and job design

could be translated into system specifications. In particular, procedural details of their integrated method were obscure. It seems that Damodaran *et al*. were only concerned with locating modules of declarative human factors knowledge (e.g. checklists, design guidelines) against specific stages of SSADM. This limited focus could be attributed to a key requirement of their project; namely that the integrated method must support application by a designer without formal human factors training. The aim of the project is, therefore, rather ambitious. However, there is no evidence from the literature that this requirement has been met. Similarly, it is doubtful that methodological integration was achieved. From the evidence, it can only be concluded that their work achieved a loose or high level mapping of a limited set of existing human factors techniques and concerns, onto specific design stages of SSADM.

This account completes an overview of the integration of human factors with specific software engineering methods.

Top Ten Mistakes in Web Design

J. Nielsen

Nielsen Norman Group, 2704 Fairbrook Drive, Mountain View, CA 94040, USA

1. INTRODUCTION

Design of home pages on the World-Wide Web is very challenging. Some of the common mistakes that designers make are discussed below and include:

- Using frames.
- Gratuitous use of bleeding-edge technology.
- Scrolling text, marquees, and constantly running animations.
- Complex URL.
- Orphan pages.
- Long scrolling pages.
- Lack of navigation support.
- Non-standard link colors.
- Outdated information.
- Overly long download times.

2. TOP TEN MISTAKES IN WEB DESIGN

2.1. Using Frames

Splitting a page into frames is very confusing for users since frames break the fundamental user model of the web page. All of a sudden, you cannot bookmark the current page and return to it (the bookmark points to another version of the frameset), URL stop working, and printouts become difficult. Even worse, the predictability of user actions goes out the door: who knows what information will appear where when you click on a link?

2.2. Gratuitous Use of Bleeding-edge Technology

Do not try to attract users to your site by bragging about use of the latest web technology. You may attract a few nerds, but mainstream users will care more about useful content and your ability to offer good customer service. Using the latest and greatest before it is even out of beta is a sure way to discourage users: if their system crashes while visiting your site, you can bet that many of them will not be back. Unless you are in the business of selling Internet products or services, it is better to wait until some experience has been gained with respect to the appropriate ways of using new techniques. When desktop publishing was young, people put twenty fonts in their documents: let's avoid similar design bloat on the Web.

As an example: use VRML if you actually have information that maps naturally onto a three-dimensional space (e.g. architectural design, shoot-them-up games, surgery planning). Do not use VRML if your data are N-dimensional since it is usually better to produce two-dimensional overviews that fit with the actual display and input hardware available to the user.

2.3. Scrolling Text, Marquees, and Constantly Running Animations

Never include page elements that move incessantly. Moving images have an overpowering effect on the human peripheral vision. A web page should not emulate Times Square in New York City in its constant attack on the human senses: give your user some peace and quiet actually to read the text. Of course, <BLINK> is simply evil. Enough said.

2.4. Complex URL

Even though machine-level addressing like the URL should never have been exposed in the user interface, it is there and it has been found that users actually try to decode the URL of pages to infer the structure of web sites. Users do this because of the horrifying lack of support for navigation and sense of location in current web browsers. Thus, a URL should contain human-readable directory and file names that reflect the nature of the information space.

Also, users sometimes need to type in a URL, so try to minimize the risk of typos by using short names with all lower-case characters and no special characters (many people do not know how to type a '~').

2.5. Orphan Pages

Make sure that all pages include a clear indication of what web site they belong to since users may access pages directly without coming in through your home page. For the same reason, every page should have a link up to your home page as well as some indication of where they fit within the structure of your information space.

2.6. Long Scrolling Pages

Only 10% of users scroll beyond the information that is visible on the screen when a page comes up. All critical content and navigation options should be on the top part of the page. More recent studies show that users are more willing to scroll now than they were in the early years of the Web. It is still recommend to minimize scrolling on navigation pages, but it is no longer an absolute ban.

2.7. Lack of Navigation Support

Do not assume that users know as much about your site as you do. They always have difficulty finding information, so they need support in the form of a strong sense of structure and place. Start your design with a good understanding of the structure of the information space and communicate this structure explicitly to the user. Provide a site map and let users know where they are and where they can go. Also, you will need a good search feature since even the best navigation support will never be enough.

2.8. Non-standard Link Colors

Links to pages that have not been seen by the user are blue; links to previously seen pages are purple or red. Do not mess with these colors since the ability to understand what links have been followed is one of the few navigational aides that is standard in most web browsers. Consistency is key to teaching users what the link colors mean.

2.9. Outdated Information

Budget to hire a web gardener as part of your team. You need somebody to root out the weeds and replant the flowers as the website changes but most people would rather spend their time creating new content than on maintenance. In practice, maintenance is a cheap way of enhancing the content on your

website since many old pages keep their relevance and should be linked into the new pages. Of course, some pages are better off being removed completely from the server after their expiration date.

2.10. Overly Long Download Times

This issue is placed last because most people already know about it; not because it is the least important. Traditional human factors guidelines indicate 10 s as the maximum response time before users lose interest. On the web, users have been trained to endure so much suffering that it may be acceptable to increase this limit to 15 s for a few pages.

Even websites with high-end users need to consider download times: it has been found that many customers access Sun's website from home computers in the evening because they are too busy to surf the web during working hours. Bandwidth is getting worse, not better, as the Internet adds users faster than the infrastructure can keep up.

3. TOP TEN MISTAKES REVISITED 3 YEARS LATER

My paper from May 1996, 'Top ten mistakes in Web design' is still surprisingly relevant today, 4 years later. The paper has become a minor Web classic with ~400 000 page views so far. It is still read 17 000 times per month. Even discounting the possibility that some people have read the article more than once, a readership of 400 000 means that the 'top ten mistakes' have been read by < 10% of the people responsible for the world's 5 million websites. So most of these mistakes are still being made and I still recommend that new Web designers read the older article.

4. ARE THE MISTAKES STILL WRONG?

4.1. Frames

Frames are no longer the disaster they were in 1995 and early 1996 due to some advances in browser technology: Netscape fixed the Back button with version 3, and since virtually nobody uses version 1 and 2 any more, this means that users can now navigate through frames with fewer problems. Version 4 reduced the problems printing frames (though users still often get a different printout than they expected), and Internet Explorer 5 has finally regained the ability to bookmark pages despite the use of frames. Frames still prevent users from e-mailing a recommended URL to other users and they also make the page clumsier to interact with.

4.2. Bleeding-edge Technology

If anything, users have less patience for bleeding-edge technology these days as the Web gets dominated by later adopters and the upgrade speeds for new browsers and plug-ins slow down. Users who encounter as much as a single JavaScript error usually leave a site immediately. It is just not worth the time to figure out how to make something work when there are 5 million other sites to go to.

4.3. Scrolling Text and Looping Animations

It is as hard as ever to read scrolling text, but aggressive use of distracting animation now causes even more problems than in 1996: users have started equating such designs with advertising which they routinely ignore. These days, it is extremely important for any content and navigation elements to look very different than prevailing advertising designs since users tune out anything that they do not think will be relevant to their task. Very severe

4.4. Complex URL

Users pay less attention to URL these days than they did in the early days of the Web. Since most sites now have navigation support, users are also relying less on the URL to tell them about their location on the site. But long URL still cause problems when users e-mail page recommendations to each other.

4.5. Orphan Pages

Less likely to make users stuck since most people have learned the trick to get to the home page of a site by 'hacking' the end off the URL. Still a disaster for novice users; still annoying for experienced users.

4.6. Scrolling Navigation Pages

Of users, 90% used not to scroll navigation pages but simply pick from the visible options. This has changed since most Web users now know that pages scroll and that important links sometimes are not visible 'above the fold.' Even so, the visible options still dominate and users sometimes overlook alternatives lower down the page. This is particularly bad if the visible part of the page seems to clearly communicate a certain purpose or a certain best approach: users may then happily conclude that they know what to do and not bother spending time on the rest of the page.

4.7. Lack of Navigation Support

Rarely seen, but a problem when it occurs. People are now getting used to certain canonical navigation elements such as a site logo in the upper left corner (linked to the home page) or a clear indication of what part of the site the current page belongs to (linked to the main page for that section). So if these elements are missing, users feel lost. Severe

4.8. Non-standard Link Colors

Continues to be a problem since users rely on the link colors to understand what parts of the site they have visited. I often see users bounce repeatedly among a small set of pages, not knowing that they are going back to the same page again and again. (Also, because non-standard link colors are unpleasantly frequent, users are now getting confused by any underlining of text that is not a link.)

4.9. Outdated Information

Worse now since so many other sites on the Web are continuously updated. Also, with the growth in e-commerce, trust is getting increasingly important, and outdated content is a sure way to lose credibility. (Note that archival information and information about old products are plusses and very different from outdated information.)

4.10. Slow Download Times

Contrary to many Internet pundits' pronouncements, the bandwidth problem has not been solved during the past 3 years; nor will it be solved during the next 3 years. Not until 2003 will high-end users have sufficient bandwidth for acceptable Web

response times. Low-end users have to wait until about 2008. I conclude that:

- All 10 mistakes from 1996 are still mistakes in 2000.
- Nine of the 10 mistakes still cause significant usability problems and should be avoided in modern websites

Scrolling navigation pages cause fewer usability problems these days and can be allowed if caution is taken in their design (any time you have overly long navigation pages, I would take it as a warning signal and as a requirement for usability testing).

Universal Design in Human–Computer Interaction

C. Stephanidis, D. Akoumianakis and A. Savidis

Institute of Computer Science, Foundation for Research and Technology-Hellas, Science and Technology Park of Crete, Heraklion, Crete, GR-71110, Greece

1. INTRODUCTION

In the past, accessibility in Human–Computer Interaction (HCI) was primarily concerned with the selection of suitable equipment to enable alternative computer access for people with disabilities. As a result, it was mainly considered as an afterthought and reflected a *reactive* approach, whereby Assistive Technology solutions addressed problems introduced by a previous generation of technology (Savidis and Stephanidis 1995, Stephanidis 1995, Akoumianakis and Stephanidis 1999). This reactive approach entails primarily *adaptations*. Adaptations facilitate access to the interface via suitable mechanisms, such as filtering, dedicated interaction techniques, such as scanning and specialized input/output devices (e.g. Braille displays, switches, eye-gaze systems). Typically, the result of adaptations includes the reconfiguration of the physical layer of interaction, and, when necessary, the translation of the visual interface manifestation to an alternative modality. For example, access to a graphical user interface (GUI) by a blind user requires "filtering" of the contents of the screen, using appropriate software (e.g. screen reader), so as to present them in an alternative modality (e.g. tactile, audio).

Despite the short-term benefits that such *a posteriori* adaptations may bring about, it is important to mention that there are serious shortcomings that render this approach inadequate in the long run. Some of these shortcomings have been identified in the relevant HCI literature. For the purposes of this chapter, it is important to add the following: first, adaptations introduce a programming-intensive approach towards accessibility, which increases the cost of implementing and maintaining accessible software. Second, technological progress may render adaptations harder to implement; there may be restrictions imposed either by the target application or by the operating system. Finally, it is increasingly recognized that, in the context of the emerging Information Society, accessibility should no longer be considered as mere translation of visual interface manifestations to alternative modalities (e.g. *a posteriori* adaptations), but as a requirement demanding a generic solution (Mueller *et al.* 1997, Stephanidis *et al.* 1998, 1999). As a result, there have been several efforts in the direction of advancing and articulating the principles of universal design to address a range of quality attributes, including accessibility, in the context of the emerging Information Society.

2. UNIVERSAL DESIGN

2.1. Definitions

Universal design or *design for all* (the two terms are used interchangeably) is frequently associated with different connotations. Some consider it as a new, politically correct term, referring to efforts to introduce "special features" for "special users" in the design of a product. To others, universal design is a deeply meaningful and rich topic that elevates what designers like to call "good user-based design" to a more encompassing concept of addressing the needs of all potential users.

Here (see also Stephanidis *et al.* 1998), the term is used to reflect a new concept or philosophy for design that recognizes, respects, values and attempts to accommodate the broadest possible range of human abilities, requirements and preferences in the design of all computer-based products and environments. Thus, it promotes a design perspective that eliminates the need for "special features" and fosters individualization and end-user acceptability. As already pointed out, the term is used interchangeably with the term *design for all* users. This does not imply a single design solution suitable for all users. Instead, it should be interpreted as an effort to design products and services in such a way so as to suit the broadest possible end-user population. In doing this, it is more than likely that there will be different solutions for different contexts of use.

Thus, universal design in the context of HCI is the conscious and systematic effort to proactively apply principles, methods and tools, in order to develop Information Technology and Telecommunications (IT&T) products and services, which are accessible and usable by all citizens, avoiding the need for *a posteriori* adaptations or specialized design. The rationale for universal design is grounded on the claim that designing for the average user, as the case has been with traditional design, leads to exclusionary designs and does not provide for the needs of the broadest possible population. As a result, the normative perspective of universal design is that there is no average user and consequently design should be targeted towards the broadest possible population.

In this context, universal accessibility implies the global requirement for access to information by individuals with different abilities, requirements and preferences, in a variety of contexts of use; the meaning of the term is intentionally broad to encompass accessibility challenges as posed by diversity in: (1) the target user population (including people with special needs) and their individual and cultural differences; (2) the scope and nature of tasks (especially as related to the shift from business tasks to communication and collaboration intensive computer-mediated human activities); as well as (3) the variety of technological platforms and associated devices through which information is accessed.

2.2. The State of the Art

Until recently, accessibility was technically supported through programming intensive efforts which relied on intuition and non-standardized techniques to allow assistive devices to obtain information possessed only by a particular platform (e.g. Windows), or a target application. By nature, therefore, these techniques are very specific to each application and each operating system. As a result, it is hard for them to handle upgrades, foreign versions, any applications they were not originally tested with, and it is also hard for them to migrate to new platforms such as Windows NT.

In the past few years, there have been a number of initiatives by mainstream actors (e.g. Microsoft, Sun, IBM, Apple) aiming to shift the focus of accessibility from the level of the application to the level of the overall interactive environment. Such efforts

seek to overcome the problems identified with contemporary practices by providing accessibility tools as integral components of mainstream interaction platforms and environments. Some of the promising alternatives, which have been developed, include the *Active Accessibility* initiative by Microsoft and the *Java Accessibility* by Sun. There have also been research projects aiming to provide architectural guidance and high-level tools for designing and implementing accessible user interface software. Indicative examples include the *FRIEND21* project (IPIE 1995) funded by Japan's MITI and the *Unified user interface development* platform (Stephanidis 1995, Stephanidis *et al.* 1997) developed in the context of the ACCESS project of the Commission of the European Union.

In addition to the above technological developments, and in line with a broadened notion of accessibility as postulated by universal design, there have been attempts to provide a critical mass of knowledge in the form of universal design recommendations. The existing corpus includes either general principles (i.e. Story 1998) or platform specific guidelines (i.e. HFES/ANSI 1997, W3C-WAI).

It should be noted that recent efforts towards universal design have met the wider appreciation of an increasing proportion of the research community (e.g. research consortia in the context of various Programmes of the European Commission), industry (e.g. the USA Telecommunications Policy Roundtable, Microsoft Active Accessibility, Java Accessibility), scientific and technical committees (e.g. USACM — the ACM public policy committee), legislative acts (e.g. Americans with Disabilities Act 1993; USA Telecommunications Act 1996 — sect. 255), as well as the United Nations General Assembly Standard Rules (1995).

In contrast to the above supporting initiatives and efforts, there have been claims debating the practicality and cost justification of universal design. In particular, there is a line of argumentation raising the concern that "many ideas that are supposed to be good for everybody aren't good for anybody" (Lewis and Rieman 1994). In spite of the truth behind this argument, universal design should not be conceived as an effort to advance a single solution for every body, but as an approach to provide environments that are designed in such a way that suit the broadest possible end-user needs, requirements and preferences. Another common argument is that universal design is too costly for the benefits it offers. Though the field lacks any real data and comparative assessments as to the costs of designing for the broadest possible population, it is felt that the cost of inaccessible systems is comparatively much higher and is likely to increase even more, given the current statistics classifying the demand for accessible products. It is important, however, to underline that any particular technology (in the broad sense of the term) towards universal design should satisfy much more than mere demonstration of technical feasibility, in order to be acceptable. Strictly speaking, even technical efficiency, which presupposes both technical feasibility and technical reliability, would still be an inefficient attribute. What is really needed is economic feasibility in the long run, leading to versatility and economic efficiency.

3. SKETCHING THE HCI CHALLENGES

To address universal accessibility in HCI in the context of the emerging Information Society, several obstacles need to be alleviated, including (1) the lack of a consolidated theory to guide and facilitate universal access, and (2) the intuitive and ad hoc character of the majority of recent development efforts in the field of Assistive Technology. These two shortcomings give rise to a wide range of issues, which for the purposes here, will be classified into design and development challenges.

3.1. Design Challenge

The lack of consolidated theories to guide and facilitate universal access is evident from the limited input and impact that prominent HCI design strands, namely *Human Factors evaluation* and *Cognitive Science*, have had on the study of (universal) accessibility.

In particular, Human Factors evaluation has delivered a wide range of general and platform specific guidelines for HCI design, as well as a rigorous scientific approach to system's evaluation. The available collections of guidelines cover a variety of topics and application domains. Some of them provide insights and recommendations towards accessible design of computer-based equipment (e.g. Thoren 1993, HFES/ANSI 1997), while others offer principles of good practice and examples of universal design (Story 1998). However, such accessibility guidelines, though useful to start with (when applied), suffer from well-known shortcomings, related both to the relevance of their actual human factors input to universal design, as well as to their practical use by designers (Akoumianakis and Stephanidis 1999).

Similarly, cognitive models, such as GOMS, have had minor impact, both on the design of systems accessible by people with disabilities, as well as the study of universal access. One study, by Horstman and Levine (1990), concentrated upon a word prediction task in an augmentative communication system. Their work, however, has come under fire by Newell and colleagues which has resulted in a lively exchange (Horstman and Levine 1992, Newell *et al.* 1992a, b), regarding the suitability of cognitive user modeling in augmentative and alternative communication.

In general, the models produced by cognitive science are designed to capture the generalities of a population rather than individual differences, or the requirements of small groups of specialized users. This is due to the need for collecting statistically valid data to justify the models. On the other hand, universal access stresses the importance of individual differences and seeks to develop models and tools for accommodating them throughout a product's life cycle.

3.2. Development Challenge

The above picture is further complicated by the lack of practical means to guide developments towards universal access systems. In the past, the issue of accessibility has been primarily addressed through programming-intensive efforts resulting in re-engineering or re-implementation of the user interface. In the field of HCI, part of the problem is attributed to the lack of tools to ease the task of creating accessible interactive software, which in turn, resurfaces one of the issues that has long been of concern to the HCI community, namely the user interface architecture (Mueller *et al.* 1997, Stephanidis *et al.* 1998).

In particular, existing architectural abstractions for user interface software, such as the Seeheim meta-model (Ten Hagen 1990), the Arch meta-model (UIMS Tool Developers Workshop 1992) or the PAC model (Coutaz 1990) fail to provide sufficient guidance towards building universally accessible applications.

First of all, they do not provide any guidance as to how to design and implement user interface adaptation, which is a central theme in universal access. More importantly, however, such models offer implementation-oriented views of user interface architectures, thus delimiting the role of design and not addressing how design knowledge can be propagated to development and implementation phases. As a result, they implicitly lead to re-implementations (reactive approach) rather than instantiation of an alternative design (proactive approach).

4. NEW RESEARCH AGENDA

Having pointed out the constraints that undermine the choice of a scientific and technological base for studying (universal) access, we now briefly outline a tentative research agenda for meeting the challenge. This agenda was developed in the first meeting of the International Scientific Forum (ISF) "Towards a Information Society for All" (Stephanidis *et al.* 1998) and it was subsequently refined specifically in the context of HCI (Stephanidis *et al.* 1999).

The agenda points out a broad range of required actions relevant to three main themes, namely technology and user-oriented issues, critical application domains and services, and support measures. Under the theme of technology and user-oriented issues, the agenda highlights the need for additional work covering the development of critical technologies, the advancement of suitable design frameworks and the evolution of powerful user interface architectures. Critical application domains and services include life-long learning, public information systems, terminals and information appliances, transactions services, social services and electronic commerce, as well as global issues, such as security, reliability, etc. Support measures that would facilitate a favorable environment towards an Information Society for *all* should cover the articulation of demand for universal design, support to industry, awareness raising and knowledge dissemination, and technology transfer.

In a subsequent effort, the above main themes were further elaborated to provide a roadmap for HCI research activities. Four main research clusters have been identified; the first three are proposed as Research and Technological Development (RTD) topics whereas the fourth is proposed as a support measure, or "horizontal" activity: (1) promote the development of environments of use; (2) support communities of users; (3) extend user-centered design to support new virtualities (and novel usage contexts); and (4) establish suitable accompanying measures. The four topics are interrelated. Thus, recommendations under one topic link with recommendations under a different topic. The type of actions envisaged, with the exception of the accompanying measures cluster, cover of all phases of technological development, ranging from feasibility studies, to basic and applied research, and demonstration. In what follows, we present a brief description of the meaning and rationale for each one of the four high-level recommendations, while below we elaborate on specific recommended RTD activities.

4.1. Promote the Development of Environments of Use

Environments of use imply integrated systems sharable by communities of users. They should, in contrast to the traditional notion of computers as productivity tools, allow for richer communications and signifying the progressive integration of the

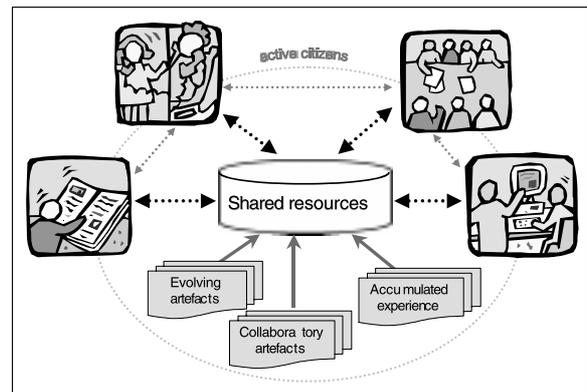

Figure 1. From productivity tools to environments of use.

computing environment with the physical environment (Figure 1). Moreover, in contrast to tools, which enhance the productivity of individuals, environments of use would promote the concept of loveable systems suitable for a broad range of communication and collaboration intensive activities among groups of people. Such environments should be characterized by sympathy and care for users and non-users and should be accessible by anyone, anytime, anywhere. (The term "non-user" is used to refer to members of a community who, though not interacting with the environment themselves at a particular point in time, are being affected by this environment, or its use by other active users.) Finally, they should provide unobtrusive means for supporting social activities.

As depicted in Figure 1, environments of use are likely to become integral components of daily activities among communities of users and facilitate the establishment of new forms of social endeavors. Consequently, they should be conceived and designed as community-centered, sharable, expandable, cooperative, collaborative and responsive media, catering through user and environment monitoring, for a broad range of human needs for both users and non-users. Additionally, they should offer voluntary and context-specific user support, and facilitate error tolerant behavior and preventive actions against unforeseen circumstances and/or misuse.

4.2. Support Communities of Users

Another critical trajectory en route to an Information Society is the one that progressively shifts the focus of attention from individual users to communities of users. The important element in this trajectory is the emphasis on social interaction in virtual spaces. To design interactions in such virtual worlds, it is pertinent to enhance the currently prevailing interaction paradigms (e.g. GUI and the World Wide Web) to support the broad range of group-centric and communication-intensive computer-mediated human activities (Figure 2).

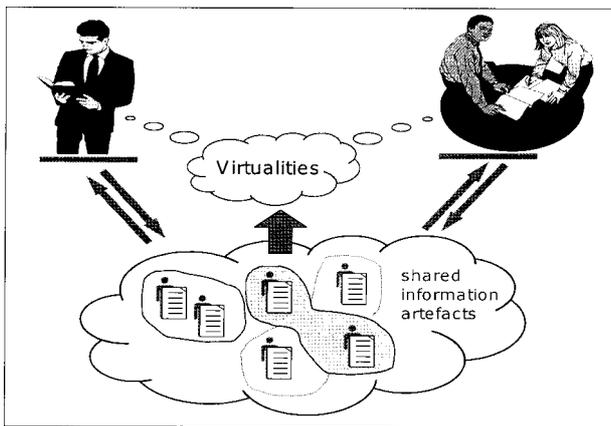
Such a community-wide design perspective, requires that activities among members of communities of users become the primary unit of analysis, as opposed to an individual's keystrokes or performance measures. Moreover, the design focus should be on the cumulative experiences of the community's users with the shared resources, as well as on the way in which communities move from early formation to maturity. To this end, there is a compelling need to study and understand how such communities (e.g. the virtual city) are formed, evolve, grow and intra-/


Figure 2. Supporting community-wide experiences.

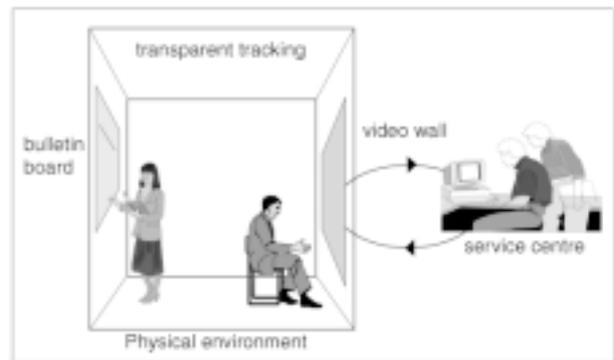
Figure 3. New virtual spaces for individual and collective experience.

interoperate to synthesize methods that facilitate the design of suitable virtualities and computer-mediated activities for all potential community users.

4.3. Extend User–centered Design to Support New Virtualities

To facilitate the design of new virtualities likely to be encountered in the Information Age, the existing inventory of methods, techniques and tools for user-centered design should be suitably applied and enhanced (Figure 3). To this end, attention should be drawn upon the accumulated knowledge and results in the social sciences (e.g. human communication theories, language theories, action theories, etc), to promote and facilitate the use of more developmental approaches to the study of computer-mediated human activities. (The term *developmental approach* to studying computer-mediated human activities is used to refer to various established theoretical strands within the social sciences and/or psychology that take explicit account of and model development in human behavior and capability. Such developmental approaches have recently started to progressively find their way into HCI. Examples include *activity theory* (Bødker 1989, 1991, Nardi 1996), *situated action plans* (Suchman 1987), *distributed cognition* (Hutchins 1995), *language/action theory* (Winograd 1988), etc.) In all cases, the tight evaluation-feedback loop advocated by user-centered design should provide the primary channel for timely input into design processes, so as to ensure that deficiencies are corrected at an early stage, while updates are less costly to make.

4.4. Establish Suitable Accompanying Measures

Support measures cover a whole range of multidisciplinary and cross-sector actions needed to facilitate the development of an industrial environment favorable to an Information Society for the broadest possible end-user population. Actions are needed to promote and facilitate the adoption and diffusion of good practice in the areas of accessibility and usability to ensure quality in the use of products and services. To this end, it is important that accompanying measures are initiated to articulate demand (Kodama 1992) for universal design, support the industry in adopting novel methods and practices, raise awareness, promote knowledge dissemination, and transfer technology in the form of know-how and know-why.


5. DISCUSSION AND CONCLUSION

The above are only some of the goals of international collaboration aiming to promote universal access in the Information Society. They demonstrate the benefits resulting from an international, multidisciplinary effort to advance the concepts and principles of universal design in the context of Information Society technologies, as well as the added value of undertaking this effort through a network of partners cooperating and collaborating towards a shared vision.

One possible option regarding the implementation of such an agenda is that national governments fund the required RTD policy mechanisms. However, many of the items and recommendations of the Research and Development (R&D) agenda have either an explicit international dimension, or can be more effectively addressed at an international level. As a result, what is needed is international collaboration and cooperation, which, in any case, would provide the necessary input to national and transnational RTD policy forums. In this direction, the ISF has initiated, and is planning to define activities aiming to consolidate current practice and experience in the area of universal design, and make it widely available as reference material, or provide contributions to on-going national and international standardization activities. Similarly, in the short- to medium-term, work can be directed towards the identification of key accessibility criteria or requirements to be met by products and services. These efforts can be consolidated into an appropriate form (e.g. accreditation scheme) that would guide subsequent efforts by both industry and academia, towards information products and services accessible and usable by the broadest possible end-user population. Furthermore, such activities can help industry to gain a renewed focus on the issue of universal design, and facilitate justification for the costs and benefits of alternative technologies. Additionally, it can stimulate new developments, and establish the ground whereby universal design informs and improves practice.

Use of Modern Chinese Language

B. Han and L. Luo

Institute of Psychology, Chinese Academy of Sciences, Beijing 100101, China

ABSTRACT

Statistical research on modern Chinese has produced a great number of results in the form of articles and dictionaries, as well as offering a significant platform for psychological, ergonomic, and linguistic research on Chinese information processing, from both a theoretical and a technical aspect. This contribution is profound, given that many of the results have been adopted as international and domestic standards. Three statistical studies on character/word frequency of modern Chinese are briefly reviewed, together with an introduction to four representative dictionaries on Chinese features for presenting basic achievements of research on Chinese information processing. Furthermore, related international and domestic standards of Chinese information processing are introduced. For the sake of application, in particular for ergonomic research, it is of utmost importance to understand the fundamental issues in this field.

1. INTRODUCTION

Chinese has been regarded as the oldest language, used for more than 3,500 years, and currently with more than 1.3 billion users. It is one of the easiest languages to learn because there are no morphological changes in the sentences, and yet it is one of the most difficult in that so many characters which cannot be pronounced directly must be learned. Although Zhong Hua Zi Hai collected 85,568 characters, most of them were used in ancient times. Only a few thousand are used in modern Chinese literature.

The application of information technology in China always has to do with language-specific problems — a typical example is, how can a computer process Chinese information? This question involves technical issues such as how many characters (or words) are necessary for an information exchange in modern society, and how to transfer these characters into binary information in order for it to be processed by computer. It is also related with psychological or ergonomic issues such as how to design and improve the usability of the Chinese information processing system. Therefore, statistical study on the frequency of Chinese characters/words and related features, as well as ergonomic research, is needed.

More than two decades of research have produced many results, in the form of articles, dictionaries, databases, national standards, Chinese keyboard input systems, Chinese word-processing systems, desktop publishing systems, etc. However, human–computer interface research is relatively rare compared to statistical and technical research (Zhu and Xu 1990).

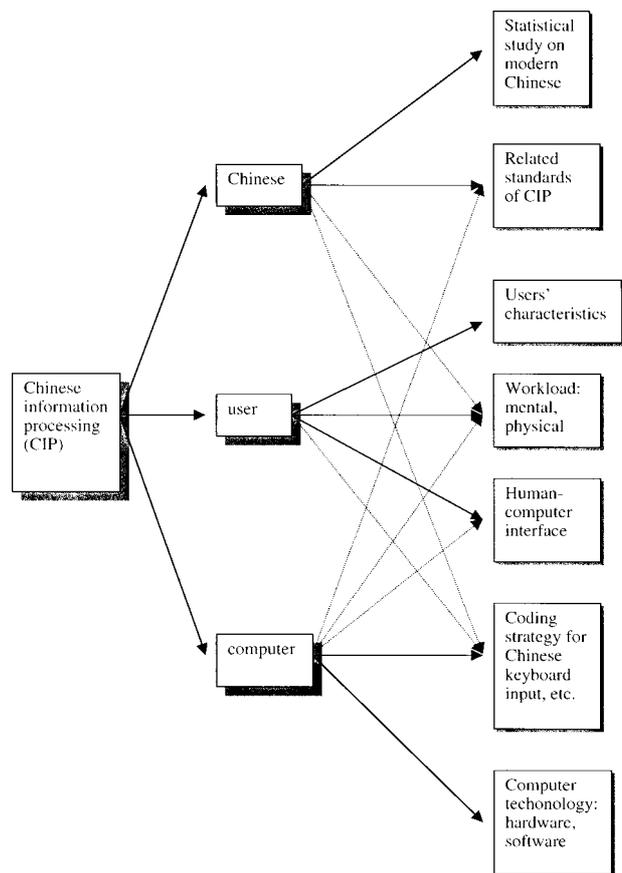

Figure 1. Research subjects related to Chinese information processing

Furthermore, most of these studies have been introduced in Chinese with only a few published in English, thus making them difficult to retrieve. This has had an adverse effect on Western colleagues' comprehension of the progress in related fields, as well as on communication between Chinese researchers and their Western colleagues. There is an increasing need for mutual communication in this net-wise world. Comparative studies on Chinese and Western languages, from information processing techniques to human cognition, will promote the process of global information from academic, cultural, and economic perspectives.

Figure 1 show the related study subjects for Chinese information processing (CIP). Please note the horizontal and vertical relationship between different subjects. This study reviews related statistical research on, as well as international and domestic standards of modern Chinese for, information interchange.

2. STATISTICAL RESEARCH ON, AND DICTIONARIES OF, CHINESE INFORMATION

Statistical research on modern Chinese has aimed at constructing databases for information exchange. The research can be divided into two stages chronologically, as is shown in the following three examples.

The first stage (1974–82) was characterized by three nationwide statistical studies on modern Chinese printed material. Some dictionaries were published and the first national standard of CIP (GB 2312-80) was issued, based on this research. Meanwhile, various Chinese keyboard input coding systems were

developed. The second stage (1983–98) was characterized by the publishing of more dictionaries, and the issuing of new standards, based on the basic research of the first stage. During this time, theoretical and technical developments had also made great progress, both quantitatively and qualitatively.

The second stage is also characterized with studies on micro-features of Chinese characters — for example, stroke order, components, components' combination, etc. Han (1994) studied the frequency of component combination and developed related databases. Two national standards, "Regular stoke order in modern Chinese" and "Chinese character component standard of GB 13000.1 character set for information processing" were also issued in 1997.

2.1. Statistical Study of Chinese Character Frequency (1974–79)

This is the first study to chart statistics on the utility frequency of modern Chinese — the study was known as the 748 project after its commencement date of August 1974 (it was finished in 1979). During this study some 21.65 million printed Chinese items were collected, showing the use of 5,991 characters and, for the first time in history, much first-hand data about the distribution of Chinese orthographic, semantic, and phonological features (Bei and Zhang 1988).

Based on these results, the first national standards of Chinese information processing were produced. *The Code of Chinese Graphic Character Set for Information Exchange: Primary Set* (GB 2312-80) was issued and *The Chinese Information Dictionary* (Li and Liu *et al.* 1988), which includes more than 30 entries of different features such as the radical, stroke number, component sequence, frequency, etc. of 11,254 characters, was also published. A database in disk format, called "The Database of Chinese Character Features" with the same indexes for 6,763 characters, was also open to public use (Shanghai Jiao Tong University 1985).

2.2. Frequency Statistics of Modern Chinese (1979–85)

From November 1979 until July 1985, 1.8 million samples of printed Chinese material were collected from different types of literature. In total, 31,159 words were found, together with 4,574 characters used. *The Modern Chinese Frequency Dictionary* (Wang *et al.* 1986) was published, based on these results. It includes eight tables listing characters or words according to frequency, usage, and distribution in different types of literature, as well as some analysis.

2.3. Word Frequency Statistical Studies on Modern Chinese (1981–86)

This is the largest study in this field to date, based on 25 million samples of printed Chinese, randomly and/or regularly collected from social science and natural science literature (about 0.3 billion printed characters), covering the years 1919 to 1981. The study began in 1981, and was concluded in 1986, during which a frequency statistical system as well as automatic recognition technology were developed. In total, 130,691 words, combined with 7,611 characters, were found.

As a result of this study, *The Frequency Dictionary of Common Words in Chinese* (Liu *et al.* 1990) was published. This dictionary lists 130,691 words, combined with 1-7 characters in phonetic order, according to the Chinese *pinyin* system. Each word was shown with its pronunciation, token frequency, percentage of frequency, accumulated frequency, etc.

2.4. International Standard Chinese Dictionary (1998)

The International Standard Chinese Dictionary (Fu *et al.* 1998) is the most recent of a number of dictionaries on Chinese information, published simultaneously in both book format and as a CD-ROM. It describes 20,902 characters (defined by ISO 10646) in a way that corresponds to all related standards already issued. Entries of each character include character form, stroke number and order, number and sequence of components, pronunciation (provided by a professional reader in the CD-ROM), definition, utility frequency, radicals, the 15 codes for international or domestic information exchange, and help functions. This dictionary represents the latest development of Chinese information processing.

3. INTERNATIONAL AND DOMESTIC STANDARDS OF CHINESE INFORMATION PROCESSING

Since the first national standards of Chinese information processing (GB 2312-80) were issued in 1982, many other related international and domestic standards have also been issued, as is showed in table 1. Most of the standards on Chinese information processing have been issued in Mainland China, while others were issued in Taiwan, Japan, or Korea. Some of them were adopted by the International Standards Organization as official international standards. Due to limited space, technical details of each standard cannot be described in this article. Please refer to the Internet resources listed in the references section, or to the original copy of a specific standard.

As was shown by earlier studies, several thousands of characters is enough for daily usage. Hence GB 2312-80 defined 6,763 characters. However, it is neither enough for special usage involving traditional Chinese documents (e.g. ancient literary or medical literatures), nor for international information interchange between China and Asian countries and areas, therefore ISO 10646 was issued after several years of preparation as a subset (Ideograph zone) of "The UCS Universal Multiple-Octet Coded Character Set". Table 2 shows the character sources in ISO 10646.

It is helpful to clarify the internal relationship between these standards, since some of them refer to the same thing, or cover similar character sets although they were issued in different countries or areas. Six standards issued in Mainland China were for 21,039 simplified characters and 21,142 corresponding traditional characters. These offer a basic platform for the information processing of Chinese documents. Table 3 shows the correspondence between the six standards.

Most of the standards describe only the form of single characters. This is because the single character is the basic element of Chinese words; statistical studies on characters are independent of cultural differences, while the single character is widely used in China, Japan, and Korea. However, more research is needed on components and stroke level in order to develop related standards. This will be useful to the evaluation of CKI methods, and to the Chinese information interchange at language level.

Table 1. International and Domestic Standards of Chinese Information Processing issued in recent years

Title of Standards	Issuer	Issued and time	Sample	Entries and Remarks
Scheme of the Chinese Phonetic Alphabet, Pinyin	SCRWS	1958		ISO adopted it as International Standard for spelling and marking Chinese in 1982.
GB2312-1980 Code of Chinese graphic character set for information interchange (CCCSII) – Primary set	SBS	1982.3.9	7445 graphic symbals included 6763 simplified characters	Binary code of QuWei and National Standard Code for Information interchange
Unitary Radical List of Chinese Characters (Draft)	SCRWS, PPA	1983	201	
GB/T 7589-1987 CCISII – The 2nd supplementary set	SBS	1987.3.27 1987.12.1	7237 simplified characters	Identical document: ISO 2022-86, REF
GB/T 7590-1987 CCISII – The 4th supplementary set	SBS	1987.3.27 1987.12.1	7039 simplified characters	Identical document: ISO 2022-86, REF
GB12345-1990 Code of Chinese ideogram set for information interchange (CCISII) – The 1st supplementary set	SBTS	1990.6.3	7583 graphic symbals included 6866 unsimplified characters	Correspondent with GB2312-80, included some punctuation used in upright typesetting, and 35 national phonetic alphabet. Some simplified characters match several unsimplifed characters
GB13131-1991 CCISII – The 3rd supplementary set	SBTS	1991.8.15	7237 unsimplified characters	Correspondent with GB7589-87
GB13132-1991 CCISII – The 5th supplementary set	SBTS	1991.8.15	7039 unsimplified characters	Correspondent with GB7590-87
ISO/IEC 10646-93	ISO	1992	20902	Subset of UCS universal multiple – octet coded character set
GB/T 13000.1-1993	SLWC, SBTS	1993.12.30	20902	Included characters proposed by China Mainland (17124), China Taiwan (17258), Japan (12157), Korea (7478). Identical document: ISO/IEC 10646-93, IDT
GF 3001-1997 Chinese Character Component Standard of GB13000.1 character Set for Information Processing	SLWC	1997.12.1; 1998.5.1	560 (disassemplied from 20902 characters)	
Regular Stroke Order in Modern Chinese	SLWC, SBNB	1997.4		

Note: Abbreviations used in the table stand for what shown as follows:
SCRWS = State Commission for Reformation of Writing System
SLWC = State Language Work Committee
SEC = State Education Commission, named as Ministry of Education— since 1998)
SBTS = State Bureau of Technological Supervision
ISO = International Standard Organisation
SBNB = State Bureau for News and Publishing
PPA = Press and Publication Administration of the PRC
MRFT = Ministry of Radio, Film and Television
SBS = State Bureau of Standards

Table 2. Character source of ISO 10646

Sources	Number of characters	References
Mainland China	17124	GB 2312-80 (GB 12345-90) GB/T 7589-87 (GB 13131-91) GB/T 7590-87 (GB 13132-91)
China, Taiwan	17258	CCCII CNS 11643-1992 Big Five
Japan	12157	JIS X 0208-1990 JIS X 0121-1990
Korea	7478	KS C 5601-1992 KS C 5657-1991

Note: Total number of characters in ISO (CJK Unified Chinese Coded Character Set) 10646 is 20902.

Table 3. Correspondent relationship between 6 standards issued in Mainland China

	Simplified characters	Traditional characters
	GB 2312-80 (0: 6763)	GB 12345-90 (1: 6866)
Standards (Set No.: Character number)	GB/T 7589-87 (2: 7237)	GB 13131-91 (3: 7237)
	GB/T 7590-87 (4: 7039)	GB 13132-91 (5: 7039)

Note: Set number and number of characters was shown in brackets. There are several situations in GB12345-90 where more than one old characters were simplified so correspondent to 1 character, hence total number of characters (6866) is more than 6763.

4. DISCUSSION

4.1. Some Basic Results of Modern Chinese Research

Statistical studies figured out the outline of Chinese character features which form the basis of designing CKI methods. For example, in 6,763 characters defined in GB 2312-80, the average number of stroke components are 10 and 3 respectively. In the ISO 10646 character set, 560 components are used. There are a total of 417 initial–final syllables used as phonological elements in Chinese. Of the characters commonly used in modern Chinese, 18.16% can be read with differing pronunciations.

4.2. Possible Application of Statistical Results of an Ergonomic/Psychological Study

Statistical research on modern Chinese offers basic data for constructing related standards, and has also been a prerequisite for the design, development, and application of the CKI method. These three aspects simultaneously complement each other, having developed on the increasing platform of computer technology. Still more are needed for research on ancient books, information retrieval, and indexes.

Such achievements have been very helpful to linguistic and psychological research, machine translations, artificial intelligence, language reform, character font design, as well as Chinese information processing. In particular, these achievements can be a good resource for ergonomists in such fields as human–computer interfaces and network communication (information exchanges via the Internet).

User Requirements in Information Technology

I. Vasmatzidis

iNautix Technologies Inc., Jersey City, NJ, 07399, USA

1. INTRODUCTION

Building information technology (IT) systems require a user-centered design approach. The core of such an approach is studying, understanding, and meeting user needs. In addition, user interaction with IT systems is subject to characteristics and limitations imposed by the *human information processing* system. Consequently, designers of IT systems should have a good understanding and knowledge of the users:

- information processing system
- target audience
- jobs and tasks
- knowledge and experience
- physical characteristics and cultural characteristics
- physical environment

User requirements are defined by all these factors. Requirements reflecting the information processing system are relatively constant across individuals. Requirements reflecting the rest of the factors should be determined for each IT project separately. The goal of an IT system designer should be to develop systems which meet user requirements to ensure system usefulness and usability and an error-free and efficient user-performance.

2. THE HUMAN INFORMATION PROCESSING SYSTEM

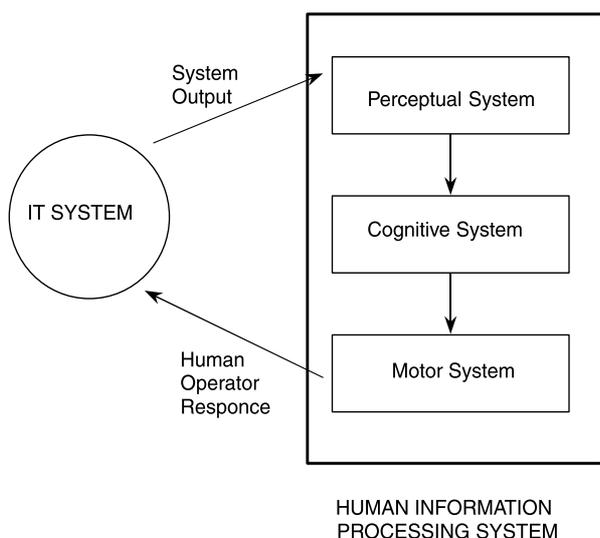
A tremendous amount of research has been conducted on how humans' process information (see Ellis and Hunt 1993 for an overview). In this article, we summarize these aspects that are most important to IT systems designers. The human information processing system can be divided into three subsystems:


Figure 1. The three human information processing subsystems in a typical human operator–IT system interaction.

- the perceptual system
- the cognitive system
- the motor system

When interacting with IT systems, the system's output is sensed and recognized by the human operator's perceptual system. This information is then processed further by the cognitive system. As a result, a decision is being made, which is executed by the motor system (see Figure 1).

2.1 The Perceptual System

Information processing begins by the activation of the receptor cells. Receptor cells are specialized cells located in the eyes, ears, nose, tongue, and skin that sense the physical energy of the environment (light, sound, vibration, etc.), and initiate the processes of sight, hearing, smell, taste, and feeling. Energy received by the receptor cells is temporarily stored in the memory system known as the *sensory register* or the *sensory buffer*. The stored record is known as the *sensory trace*. The sensory buffer has a large capacity for storing information, but a very short duration. For example, visual sensory traces last for up to only 300 milliseconds. The role of the sensory buffer is to temporarily hold information so the processes of pattern recognition and memory can further process it.

Information in the sensory buffer is meaningless. It becomes meaningful only after pattern recognition has been activated. During this process, the sensory trace is contrasted against knowledge stored in the long-term memory. How exactly this contrasting takes place is not clear, and certainly is much more complex than a simple "pattern matching". In any case, it involves the long-term memory, which is the knowledge depository necessary for supplying meaning into the sensory trace. Furthermore, it appears that pattern recognition is based on an analysis of the features of the information retained in the sensory register. Finally, pattern recognition depends on the context in which information is received.

2.2 The Cognitive System

There are two memory structures within the human cognitive system:

- Short-term memory (STM)
- Long-term memory (LTM)

STM is where we temporarily store information that has been recognized. To store information in the STM, we need to pay attention to it by invoking the process of *selective attention*. STM has a limited capacity and a limited duration. We can retain a very small number of information items in STM (7 ± 2) for a period of few seconds only. In order to retain information in our LTM we need to rehearse; by rehearsing, information remains in the LTM longer and eventually is transferred to the LTM.

STM is not only a storage buffer, but also a cognitive processor. STM is where we perform conscious mental operations such as arithmetic calculations and thinking. Thus, STM is also known as *working memory*. The limited capacity of STM is the major bottleneck in the human information processing. To offset this limitation we use the technique known as *chunking*. By chunking information we devise rules to organize information into meaningful groups. For example, it is much easier to remember the phone number 123-1234 than the phone number 472-8175. The first number consists of two "chunks" combined in a

meaningful way: they are two groups of numbers generated by a simple rule.

Information rehearsed long enough in STM is eventually transferred to LTM. LTM is unlimited both in capacity and duration. Information in LTM is coded semantically (at the level of meaning), in contrast with coding in STM which is acoustic or phonetic. Despite the unlimited capacity of LTM, storing and retrieving information from it is unreliable and slow. For example, consider how often we failed to remember a familiar name when needed, only to recall it at a later time!

Registering information in our STM requires selective attention. The process of selective attention prevents STM from being overloaded. It enables us to selectively focus our attention on the stimuli relevant to the problem at hand. However, attention also occurs involuntarily. For example, while carrying out a conversation in a crowded room, we can detect our names spoken from a third person, a phenomenon known as the "cocktail party phenomenon". Such involuntary attention occurs at the semantic level. Attention can also be *divided*, or *time-shared*. Divided attention refers to paying attention to two or more tasks simultaneously. Divided attention has a detrimental effect on operator performance.

Another process of the cognitive system of great importance to IT system designers is learning. The following characteristics of learning are of practical significance:

- Learning is faster when the material to be learned is analogous to material already learned;
- Learning is facilitated when the material to be learned is well organized;
- Learning is more effective when information is presented in incremental units.

2.3 The Motor System

User decisions and thoughts are transformed into actions through a series of discrete micromovements. In rapid movements (for example, in skilled typing), the micromovements reflect motor instructions that are preprogrammed. These instructions are subject to modification, depending on the visual and tactile feedback. Execution of fine motor movements involves different muscles than execution of gross motor movements.

2.4 The Cognitive System: Design Implications

This section discusses implications for IT system design based on the knowledge of the human cognitive system.

Implications from the perceptual system:
- Present information in a clear way to facilitate its recognition and analysis;
- Match information with expectations from the LTM;
- Avoid overloading the sensory system.

Implications from the cognitive system:
- Do not overload the working memory with excessive information;
- Design so as information is recognized rather than remembered;
- Design tutorials in interactive, incremental ways;
- Minimize tasks that require divided attention. Implement design techniques (e.g. blinking fields) that enhance the mechanism of selective attention;
- Organize information in meaningful groups.

Implications from the motor system:
- Minimize gross motor movements;
- Require users to exert different fine motor movements to accomplish different operations (e.g. in the Windows operating system, require single clicking for selecting a document icon versus double-clicking for opening and viewing the contents of the document).

3. USER–CENTERED DESIGN: THE USER REQUIREMENTS PERSPECTIVE

Designing successful IT systems requires much more than a good understanding of the user cognitive system. It requires a knowledge and understanding of whom the users are (target audience) and of the users' jobs and tasks, knowledge and experience and physical environment. In other words, IT design should be conducted within the context of the user–work domain. This concept is similar to the concept of ecological design (Rasmussen and Vicente 1989), or use-centered design (Flach and Dominguez 1995).

3.1 Target Audience

The first step in developing IT systems is to determine the target audience. The target audience can be very specialized (for example, pilots or air-traffic controllers for aviation IT systems) or very generic (for example, the general public for recreational IT systems). Knowledge of the target audience will guide the subsequent steps of determining the user requirements as discussed below.

3.2 Users' Jobs and Tasks

Defining the users' jobs and tasks is very critical. IT systems are built for a purpose: to enable users perform their jobs in an efficient and safe way with a high degree of satisfaction. Therefore, a good understanding of their jobs and tasks is necessary for meeting these objectives. Job and task analyses are the techniques used to determine the users' jobs and tasks. A problem with these techniques lies in their very basics: how are jobs and tasks defined? Here, we provide the following definitions:

Job: The process through which the goal of one's work is accomplished.
Task: The *constituent elements* of a job.

Job analysis is conducted in order to determine:
- The goals of the users doing the job.
- The job workflow: how various people and subsystems are involved in the job process. What their roles and their responsibilities are.
- A list of the tasks involved in completing the job. The output of such an analysis should be:
  A *comprehensive list* of the tasks
  Frequency of task performance
  Criticality of task performance
  Time to complete each task
  Difficulty of task performance

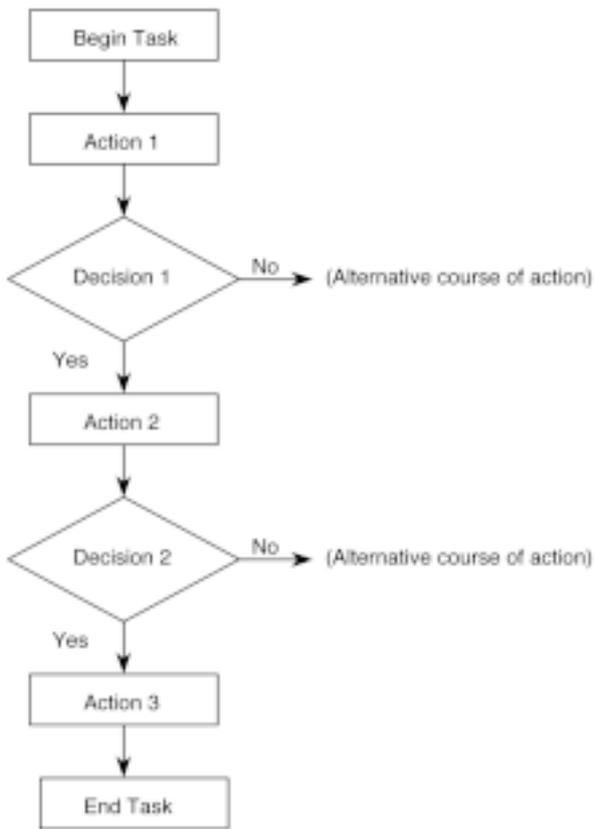
There are various task analysis techniques (see Hackos and Redish 1998). Here, we discuss the procedural analysis technique. This technique can be used not only for developing new IT systems, but also in evaluating existing ones. Procedural analysis describes the actions taken and the decisions made during task


Figure 2. A procedural analysis diagram.

performance. A diagram illustrating procedural analysis is shown in Figure 2.

Procedural analysis requires direct observation of the users; it identifies the actions and decisions of the tasks currently performed by the users. As such, procedural analysis can be used for:

- Identifying user requirements in terms of actions and decisions for building new or improving existing IT systems;
- Developing more efficient ways of satisfying user requirements by deciding which of the actions should be left to the IT system, and which should be left to the user/human operator.

3.3 Users' Knowledge and Experience

User knowledge and experience can be *domain-specific (semantic)* or *system-specific (syntactic)*. Domain-specific experience refers to experience with the tasks and functions the IT system is designed to support. System-specific experience refers to experience with operating other IT systems. An understanding of the users' knowledge and experience assists in classifying users along the following dimensions:

- domain novice users
- domain intermediate users
- domain expert users
- system novice users
- system intermediate users
- system experienced users

When designing IT systems, the target audience should be analyzed in terms of domain and system experience. To satisfy the various types of users, various design approaches can be taken:

- Provide domain explanation and instructions for the IT system operation, and good error prevention and recovery procedures for users who are both domain and system novices;
- Minimize such explanation and instructions and provide efficient methods of system operation (for example, command languages) for users who are both domain and system experts;
- Provide domain explanation and efficient methods of system operation for users who are domain novices and system experts;
- Provide instructions for the IT system behavior, but very limited domain explanation for users who are system novices and domain experts.

Another aspect of user experience reflects the concept of *mental or conceptual models*. A mental model is the internal understanding users have of how the visible and invisible parts of a system interact in order to bring about the observed system behavior. Users develop mental models over time drawing upon their experiences with system interaction. Mental models help users to remember and predict system behavior, and may or may not be accurate. When learning new systems, users will attempt to transfer knowledge from existing mental models. Therefore, IT designers should:

- facilitate the development of an accurate mental model
- take advantage of existing user mental models

To meet these goals, the following guidelines are recommended:

- Provide consistency in IT system interface design: same user actions should result in similar system responses
- Make system processes visible to the users
- Provide descriptive and informative messages
- Use familiar metaphors in the system design

3.4 Users' Physical and Cultural Characteristics

The physical characteristics of the users play an important role in the design of IT systems. In general, the following physical characteristics should be studied:

- age
- gender
- handedness
- color deficiency
- physical handicaps

3.4.1 Age

In many countries, the elderly represent the fastest growing segment of the population. For example, it is estimated that in the US 50 million people will be over the age of 65 by the year 2010. It is known that cognitive and motor skills are diminished in elderly people. Designers of IT systems should make the appropriate design accommodations for elderly users (for example, increased font size).

3.4.2 Gender

Physical gender characteristics that are important to IT system designers are anthropometric in nature. The anthropometric characteristics of female populations are smaller than those of male populations. Such differences are critical when deciding on the dimensions of hardware devices.

3.4.3 Handedness

A relatively large percentage of the users are left-handed (11% in the

US). The design of IT system hardware (keyboards, computer mice, etc.) should be optimized for both right- and left-handed users.

3.4.4 Color deficiency

A significant percentage of the users (8% in the US) have some form of color deficiency. In addition, fewer women are color deficient than man. To accommodate color deficient populations, color should not be used as the only way for information coding. Other visual cues (such as underlining) should be used in a redundant manner to convey the same meaning as color coding.

3.4.5 Physical handicaps

Physically challenged users (impaired vision, impaired motor skills, deafness, etc.) may not be able to use existing IT systems. Specialized technologies are necessary to allow accessibility of IT systems by such users. Such technologies include text-to-speech screen readers for blind people, which convert text into voice output, and voice recognition input devices for users with impaired motor skills.

3.4.6 Cultural characteristics

With the globalization of information technology, the cultural characteristics of users gain more and more importance. This is especially true in the dissemination of information through the Internet where the target audience is literally global. When building IT systems for national, specific or international audiences the culture of the potential users should be well understood and accommodated in the design.

3.5 Users' Physical Environment

Poor environmental conditions will render IT systems useless no matter how well user requirements have been understood. Consequently, efficient and error-free use of IT systems should take place in environments optimized for user performance.

When considering the physical environment the following issues emerge:

- *Lighting.* Poor lighting may cause visual fatigue or glare on computer monitors.
- *Noise.* A noisy environment can mask auditory warnings and message provided by the IT system.
- *Work space.* Limited or poorly designed workspace will impede users' work while interacting with the IT system.
- *Temperature and humidity.* Temperature and humidity extremes have an adverse impact on user information-processing capabilities. Such extremes should be controlled to ensure error-free user performance.

User-centered Graphic Design

J. Frascara

Department of Art and Design, University of Alberta, Edmonton, Alberta T6G 2C9, Canada

1. INTRODUCTION

User-centered graphic design or human-centered graphic design refers to a design approach that considers the final user as the departure point, in contrast to other approaches that seek economic efficiency, aesthetic currency, personal expression of the designer or technological improvement as their main concern. "User"-centered, instead of "receiver"-centered graphic design refers to a position in communication theory that rejects the traditional terminology coined by Shannon and Weaver (1949), who defined the three elements of the communication chain as transmitter–message–receiver. These terms reduce people's behaviors to those of electronic devices, and do not recognize cognitive styles, cultural differences, expectations, feelings, intentions, value systems and levels of intelligence as dimensions that contribute to the construction of a communication situation. The messages produced are not received, but interpreted by people (Frascara 1997).

2. HISTORICAL REVIEW

A concern for the user of designed products has existed for a long time; different periods attended to different perceptions of what was seen as adapting the design of objects and information to the characteristics, needs and abilities of people. These concerns, however, were initially more connected to the design of objects than to the design of information. The industrial revolution generated different reactions from designers in the 19th century, the most famous of which was the Arts and Crafts Movement. It was opposed to mechanized manufacturing and proposed a revival of the handicrafts and of the value of aesthetics for daily use objects. These concerns were further developed in the 1920s around the Bauhaus School in Weimar (1919–33) and the European avant-garde. At that time, the main objective, rather than to oppose technology, was to integrate it with art to educate the designer and to design modern products. Artists and craftsmen were brought together to create the ideal 20th-century designer, exemplified by Herbert Bayer, Max Bill and other Bauhaus graduates. The designer was very much seen as a person who conceived functional and beautiful objects for the benefit of the public. The public, however, was not part of the conception and production processes, and from today's vantagepoint one can see that certain dimensions of what today is defined as user-centered design were still missing.

The Ulm design school (1955–68) added an interesting dimension to the knowledge of the user in the communications field by developing a theory of communication based on semiotics, pioneered by Tomás Maldonado. This approach emphasized the possibility to analyze messages according to semiological structures, adapting to visual communications the ideas proposed by Ferdinand de Saussure in the field of linguistics at the beginning of the 20th century. While semiology includes the problems of syntactics (the organization of stimuli), semantics (the organization of meaning) and pragmatics (the particularities of communicational situations), in practice the central concern of design theory in the 1950s and 1960s was on the first two dimensions.

Over the past 20 years it has become apparent that, in addition to the general structure of human cognition, individual differences are substantial enough between human groups to require that we adapt messages to different users. The awareness of differences between individuals within any human group has resulted in the development of the notion of "market mix", as a supplement to the notion of "market segment" that dominated marketing strategies in the 1950s and 1960s. This notion permits a better consideration of the users of information, since it considers the individual differences that are found in any human group.

3. PEOPLE, NOT GRAPHICS

The notion of user-centered graphic design becomes more complex when one acknowledges that design is not really concerned with objects, but with the impact that those objects have on people. The central problem of the designer is not the construction of graphics, products, services, systems or environments, but the creation of means for people to act, to interact, to realize their wishes and satisfy their needs. It is the needs and the wishes of people that design have to serve; the objects of design are, fundamentally, means. This requires a better understanding of people, of society and of the ecosystem.

When looking at design as centered on people, one should look at the operational impact, the cultural impact and the ecological impact objects have. Every design project has an operational objective: it is supposed to affect the knowledge, the attitudes or the behavior of people in a desired way. But any object deployed in the public space – be it communicational or physical – has a cultural and a physical impact or side-effect. The cultural impact affects the way people operate with other people and with things, and creates cultural consensus. More has to be done to understand this cultural impact so that designers can operate more responsibly in society. It is in connection with the study of both the operational impact and the cultural impact of objects and information where design becomes strongly connected to the social sciences. The physical impact of artificial objects affects the ecology of materials and energy (Papanek 1985), conditions our lives and may have positive or negative effects on our well-being.

4. INTERDISCIPLINE

Product development is now far from being conceived as the province of the individual designer, craftsman, manager or manufacturer: the conception, production, distribution and use of products have become complex parts of corporate strategies, and include not only extensive research based on marketing, but also rely on anthropology, psychology and sociology. The same could be said of the design of instructional and educational materials: this is not any longer the terrain of teachers specialized in specific content areas.

The evaluation of the effectiveness of any design product or idea requires the contribution of several fields in the social

sciences. Leading advertising agencies, manufacturers and institutions such as the International Standards Organization (ISO) have for over 20 years gathered together designers and social scientists around the challenges posed by the design of products and communications, with the purpose of ensuring that the driving criteria of any design decision are based on a knowledge of the capacities and conceptions of the users.

5. LEARNING ABOUT THE USER

The variety of objects and user group profiles that the discipline of design has to address today, makes it impossible to predict with certainty the reaction of a specific group of people to a specific object or communication. The effectiveness of a design product derives from a good fit in this relation user-product. This implies a change from the notion of the user as receiver to that of the user as partner, and looks at communication as an act of negotiation, where the position of the originator of the information and that of the interpreter enter in contact searching for a common terrain. This has placed more emphasis on the need to study every case, and has given birth to the concepts of user-testing and iterative design (MacKenzie 1993, Penman and Sless 1994). Iterative design is based on the production of working prototypes, their testing and evaluation, the incorporation of adjustments, and the development of new testing until the product appears to have been developed to a satisfactory level of performance. Norman (1990) has been an intense advocate of products that match users' needs, motivations and abilities, and his writings are rich in analyses of specific cases. Communication design that is not centered on the user is inefficient, and promotes a passivity in the public that in the long run weakens the possibilities to create a strong society, based on conscious choices and on a sense of sharing.

Several strategies assist the user-centered approach in its commitment to include the user in the design process. These include focus groups, interviews, surveys and user testing. Focus groups are semi-structured meetings with small groups of representatives of user populations aimed at collecting qualitative information about issues and perceptions surrounding a given design problem. Interviews are one-on-one conversations that lead also to qualitative information. Surveys intend to obtain quantitative information concerning the frequency of a given perception in a given population, or the percentage of people in a given population that coincide on a given issue. User testing refers to the production of prototypes of a given product and the systematic study of its actual use by a sample of the user population. The intention in this case is to observe the effectiveness of different aspects of a given product in order to correct its design before mass production and distribution take place.

The conception of user-centered design has resulted in what can be recognized as the "softening of design." Upon adopting the observation and analysis of the user as central elements of the design process, the design of workstations, for instance, has been changed to the design of work. It is not possible to invent and design the perfect chair on which a person could be sitting for 8 h everyday without becoming physically fatigued. It is necessary to see the design problem not only as the ergonomic design of the furniture and other elements operators have to use, but also as the design of the activities to be performed by a person.

The same applies to the evolution of design for education: it has changed from the design of teaching aids to the design of teaching/learning situations. The success of a learning experience cannot be trusted to the design of a teaching aid. The whole activity has to be planned so that the teaching aid contributes its best to the experience. Many details enter this terrain, but certainly the teacher's actions, the student's actions and the environment in which the intervention occurs, all contribute to the learning event, and must be seen as part of the design problem. In education, actually, the notion of paying attention to the receiving side goes back to the 18th century with J.J. Rousseau (1712–78) and continues with J.H. Pestalozzi (1746–1827) and M. Montessori (1870–1952), among others. They saw childhood as a distinct cognitive and emotional stage, rather than as an imperfect adulthood, and proposed the need to adapt the educational tasks to the intellectual and psychological characteristics of children. Their learning theories developed as attempts to look at education not as a process of transmission of information but as a process of development of capacities. This was done on the basis of taking cognizance of child development and of strategies believed to be most effective for the fostering of maturation.

6. USER–CENTERED DESIGN AS A CONSCIOUS NOTION

User-centered design began with the application of physical ergonomics to the design of objects. Intuitive at first, as in the medieval shoemaker that measured the clients' feet, and systematic later, as in the production of mass-made clothing, passenger vehicles or workstations. The conscious notion of user-centered design began with the ergonomic studies of Alphonse Chapanis during World War II, and then moved onto the cognitive, the emotive and the cultural, including today ecological and health issues.

It could be argued that commercial advertising has for the past 50 years been user-centered, in that, rather than being centered on descriptions of the virtues of the products (as it was at the beginning of the 20th century) it has been centered on desires and values of people. Unlike education and ergonomics, however, the main purpose of advertising is not to benefit the public, but to benefit the business that produces the advertised goods. User-centered design in all its implications not only intends to attend to the characteristics of the public to be addressed in order to reach it, but also it attends to the needs and the welfare of that public. This is the case in urban design that improves the quality of living, or in computer interface design that facilitates the tasks of the user (Pradeep 1998).

The aim of user-centered design that takes all dimensions into account is to benefit the user. This concern does not end with the user's wishes and capacities but it extends to the users' physical and psychological health and well-being. This is the point at which user-centered design touches on science and culture, becoming contextualized in knowledge and value systems. User-centered design is, therefore, culture and knowledge dependent, and conceptions of it will vary from culture to culture and from time to time, but the common element is that user-centered design attends to the needs and the capacities of the user, including physical and non-physical considerations of people as biological, social and cultural beings.

7. CONCLUSION

User-centered graphic design is based on an understanding of design as a problem-oriented, interdisciplinary, creative action, in which the nature of the problem – normally an active relation between a user and a product (information, object or environment) resulting in an effect – defines the set of disciplines that must contribute to the creation of a design response. These disciplines frequently include several branches of psychology (perception, cognition, development, behavior and emotion), some aspects of sociology (statistics, survey design, culture, demographics), and anthropology (ethnographic observation or cultural theory).

To summarize, user-centered graphic design places significant emphasis on users' needs, abilities and well-being; it does so aided by scientific research; it includes user-testing and applies an iterative design process; and it includes systematic evaluation of outcomes directly and indirectly connected to the design brief.

1. INTRODUCTION

Video telephony (VTP) is a method of telecommunication, which makes possible on-line interactive contact using both audio and video information links. The remotely sited parties can see and hear each other synchronously from different geographical locations, replicating face-to-face contact. VTP is typically one form of multimedia technology, which includes pictorial representations and written and spoken language. For humans, the eyes constitute a "information highway," and VTP is an extension to it.

VTP is based on hardware, software and netware. The nets utilized nowadays are most often wired, but more wireless mobile possibilities will be available in the future. In the past, VTP was generally expected replace the normal audio telephone in personal use. Later, professional applications, especially videoconferencing, have been used in business and education. Face-to-face communication is not the only form. It is possible to arrange group meetings and give education showing many things other than only the people who are lecturing and, vice versa. Via VTP, many actions, objects and places can be seen along with the participants.

VTP can be utilized in various remote expert and diagnostics applications. Many new approaches are possible. For example, a system with good image quality and motion reproduction enables sign language communication for deaf people. For them, VTP is an essential (assistive) technology for everyday life.

Also, paradoxically, VTP can benefit the blind. The EU project PROMISE emphasizes the use of the videophone as a remote eye for blind people living alone: letters and other documents can be shown to distant parties who can then read them aloud.

Today, VTP is developing towards a wider diversity of professional applications, e.g. desktop or portable videophones, partly usable as extensions of PCs. These scenarios are often equally well suited to home use, as they mostly utilize commercially available hardware. They are based on special software and the Internet. In 1999, the Internet does not routinely provide high-quality full-scale VTP.

VTP means more possibilities, but simultaneously also more demanding cognitive tasks. For instance, the transmission of both image and sound must be controlled during the communication. New ergonomic methods must to be developed to prevent shortcomings: constrained postures, discomfort in the neck–shoulder area, poor photometric and acoustic conditions, sustained visual load, rapid, demanding stimuli through both the eyes and the ears, and the mental load of being filmed all the time.

On the other hand, the VTP situation is natural; you can see and hear your partner remotely as in real life when you are together. Partly this still feels quite abstract: one must be able to handle virtual features, i.e. telepresence.

This article addresses the essential viewpoints of VTP ergonomics and future developments, covering both design and use perspectives.

2. BALANCED ERGONOMICS

Products cannot be used or designed in isolation. This article takes as a basis the model of a system consisting of five components: user, videophone, task, context, and environment (cf. Table 1)

2.1. Model Component: User

The users consist of very different individuals or groups ranging from an individual user of a customized unique videophone to all the potential users of ordinary videophones, i.e. consumers of high-tech and high-volume electronics. Hence, the whole range of principles, i.e. design for all or for one, such as a disabled person or a professional expert, may be applicable to VTP.

Providing a summary of the characteristics of the product's intended users should be one of the first steps in the design (Cushman and Rosenberg 1991). The user profile should include:

- age;
- gender;
- nationality;
- education;
- previous experiences with similar products;
- native language, including culture-dependent body language, e.g. the hands;
- reading skills in native and foreign language;
- mobility, sensory or cognitive impairments;
- occupation;
- skills; and
- motivation.

Figure 1. Typical (roll-about) VTP system is comprised of the following subsystems/components: (1) video input (camera), (2) video output (VDU), (3) auditory output (loudspeakers), (4) display of transmitted picture (PIP "viewfinder" feedback), (5) input device (mouse), (6) codec and connections to ISDN network in roll-about rack/housing, and (7) auditory input (microphone), input device for VDU (remote control) and another video input (document camera) on desk. System is in telemedical use by virtual team of three physicians. Photo: courtesy Videra Ltd.

Table 1. Guidelines (GI) by main headings. All the essential ergonomic interactions of VTP, called main headings, are presented as gray boxes. Each box indicates the place of one or more GI in the user-technology field. The last three GI are only described.

INTERACTION USER AND USING VS.	VIDEO TELEPHONY VTP					
	video input and output	auditory input and output	input devices i.e. controls	user-interface software	system configuration	
					terminal - specific	work station -specific
USER • eyes (seeing, showing) • ears (hearing, speaking) • head, neck and shoulders • upper limb • other body parts, body as whole • perception, memory • decision	13th GI 14th GI 15th GI 1st GI 2nd GI 3rd GI, 16th GI	17th GI 4th GI,	20th GI 6th GI 7th GI 5th GI 21st GI 22nd GI	18th GI 19th GI	11th GI 12th GI	8th GI 9th GI 10th GI
TASK AND CONTEXT	23rd GI:	Understand first deeply users' and organisations' interaction with and utilisation of VTP, utilise user-involvement, and look later for that VTP system will be systematically demonstrated, verified and validated				
ENVIRONMENT	24th GI: 25th GI:	Plan carefully and adjust properly as far as lighting conditions are concerned Remember that acoustic conditions and characteristics are very essential to VTP				

2.2. Model Component: Videophone

The generic key factors at the background of VTP systems are:

- networks (telephone, leased lines, local area networks, Internet, wireless, others); and
- connection to a network via a *co*der and *deco*der (*codec*) or corresponding software for digitizing and compressing image and voice signals, and vice versa.

Figure 1 shows a typical system configuration of commercial VTP in 1999 (cf. Table 1).

The major videophony systems are:

- Roll-about systems (Figure 1).
- Large wall panel systems (cf. information panels in public buildings).
- Desktop systems (often resembling multimedia PC).
- Portable systems (often resembling laptop PC).
- Handheld compact systems (features of mobile phones; see Chapter 5).

2.3. Model Component: Task

The tasks are two-fold: the tasks needed to operate the videophone and the tasks done by the videophone. The "substance tasks"

(VTP as a tool) range from a gentle, even "accidental," informal face-to-face discussions to urgent, complex tasks done between many geographical places. Such examples include telemedicine, engineering design, maintenance of machinery, etc., where remotely, transmitted, real-time, visual, high definition live and still information is the most significant value-added feature of VTP (cf. Kautto *et al.* 1997).

At the end of the 1990's, the most typical application is VTP for business meetings and distance learning. Travelling and travel costs can be decreased by multimedia on-line telecommunication, by the substitution of physical commuting with electronic commuting VTP may be feasible. Even between places not so remote, e.g. sections of a big building or different sites of a decentralized company.

One important type of communication is that between colleagues or peers. There may be two or more geographically distant designers who need to communicate in real time via an eye-to-eye or at least face-to-face video link with an audio link and a shared drawing surface, i.e. an electronic whiteboard equipped with a telepointer.

2.4. Model Component: Context

Private persons mainly use computer-based VTP models. It is expected that, in the future, there will be available a variety of handy mobile videophones for private use as well as for domestic, leisure and business purposes (see Chapter 5).

Most of the VTP end-users are professional employees in enterprises and the public sector. Various special groups of citizens, e.g. elderly or disabled people, are served remotely using home videophones. The reasons for using VTP for telework vary, including a desire to live in the country or a need to be near one's elderly parents or children. Virtual teams can be built: employees are connected via telematics interactively to the physical workplace, colleagues and the management.

2.5. Model Component: Environment

When used for videoconferencing, the videophone is typically placed in a normal meeting room, auditorium or small classroom. PC-based videophones are typically placed in an office, on management or technical help-desks, or on shop floors in industrial plants. Portable and future mobile VTP terminals can be moved from place to place in factories, offices or hospitals, or even be used outdoors and in vehicles.

3. INTERACTION–BASED ERGONOMIC CRITERIA: ELEMENTS FOR EVALUATION

3.1. User–Product Interface

VTP systems are analyzed in the light of human characteristics (Table 1). Interactions are characterized by a total of 25 heuristic Guidelines (Gl). More specific single points are also listed in the text, giving design rules and solutions developed for and applied to VTP by the authors and based generally or partly on the papers by Ivergård (1989), Shneiderman (1992), Dul and Weerdmeester (1993), Helander (1995) and Kroemer and Grandjean (1997).

3.2. Main Headings on Material Interaction

3.2.1. Video input and output versus head, neck and shoulders

1st Guideline: *Try to arrange VDU(s) and camera(s) so as to prevent unnecessary static load, fatigue and discomfort in the neck and shoulder*
- by preferring low enough placement: if the object of focus is close (up to 1 m) and the back posture is fairly erect, the optimal line-of-sight angle is ~30° below horizontal, and the maximal angle is 60° (Kroemer and Grandjean 1997);
- by preferring a horizontal or slightly lower line-of-sight for average-sized persons, which allows them to keep their trunk and head erect if the visual target is far away(>1 m); and
- by locating the built-in camera below rather than above the screen.

2nd Guideline: *Try to minimize the need to twist the head and trunk when looking at the VDU(s) and camera(s)*

3.2.2. Subsystems of VTP versus body as a whole

3rd Guideline: *Guarantee optimal body (-part) positions during the session*
- by ensuring that the joints are mostly in a neutral position;
- by locating all essential system components so as to minimize the need to twist the body;
- by preventing other constraints and/or static postures whether due to any subsystem; and
- by preventing poor hearing or vision that may cause poor posture, e.g. for elderly persons, with a limited range of clear vision, it is necessary to place the items in the system at a distance where they are clearly visible (cf. 14th Guideline).

4th Guideline: *Ensure that all subsystems are within easy and functional reach*
- by keeping the number of items that have to be touched minimal;
- by organizing well the VTP system, distinguishing between primary and secondary items, and giving the primary ones optimal accessibility; and
- by guaranteeing that the primary items are located within the reach of the 5th percentile.

5th Guideline: *Pay enough attention to the user profile*
- by taking into account specific user groups, e.g. the disabled and elderly;
- by supporting the diversity of human characteristics, e.g. left-handed and right-handed users; and
- by adapting to individual features affecting vision, e.g. eyeglasses and color blindness.

3.2.3. Input devices versus the upper limbs and the head, neck and shoulders

6th Guideline: *Optimize the functions of the input devices*
- by taking into account the importance, order and frequency of use of the different controls;
- by adjusting the C/R ratio optimally (Sanders and McCormick 1993);
- by avoiding cumulative repetitive movements of the mouse button or any key and awkward key combinations (the operation of several controls is only recommended to prevent unintentional touching);
- by employing the smallest, quickest and most accurate body

motions (response time is the sum of reaction time and motion time); and

- by considering remote controls which give the user more freedom.

7th Guideline: *Consider care of the anthropometrics and optimal postures when placing the input devices*

- by determining the distance between the controls anthropometrically. Cushman and Rosenberg (1991) recommend that the center to center spacing between any two buttons of a keypad or a touch-screen should be 19 mm, while the key size recommendation is 13 _ 13 mm);
- by allowing the wrist be mostly in a straight, neutral posture, especially if one has to move simultaneously or repetitively a hand or a finger;
- by remembering that wrist supports reduce the static load on the shoulders and arms, but the improper ones many contribute to some repetitive strain injuries; and
- by allowing the forearms to be supported on the chair or the work surface or in some other way.

3.2.4. Workstation versus whole body

8th Guideline: *Ensure care of proper dimensioning as far as different body sizes are concerned*

- by considering that the small person gives the measure for reach and the large for fit;
- by providing enough space for all the essential activities on surfaces;
- by reserving enough space for the thighs, knees, legs and feet;
- by allowing the feet to be firmly supported on the floor or a foot-rest; and
- by applying the recommendations for VDU workstations if feasible.

9th Guideline: *Give adjustability, support and variability a high priority when designing a workstation*

- by determining the adjustability range according to the user profile;
- by avoiding a work station without an adjustable keyboard or work surface height and adjustable height and distance of the screen meant for continuous use;
- by considering alternatives for the keyboard and mouse;
- by providing the chair with armrests when possible/desirable, and with a backrest with lumbar support up to 50 mm; and
- by increasing the degrees of freedom, e.g. by allowing a choice between different postures, by allowing easy adjustment, and by permitting natural movements;

10th Guideline: *Think carefully about all the essential joint angles of a sitting body*

- by remembering the pros and cons of the all proper sitting postures as far as VTP is concerned; and
- by realizing that the sitting posture makes it possible to focus one's attention better than the standing posture (Helander 1997): a lot of attention is needed in VTP, which favors classical and armchair sitting to sit–standing and standing.

3.2.5. Terminal versus whole body

11th Guideline: *Recognize essential system-specific key factors and take them into account ergonomically*

- by considering for weight, size and shape;

- by not accepting components that are unwieldy, unstable or difficult to grasp or handle (cf. center of gravity);
- by remembering the easy positioning of items if they are required to be held or manipulated at a distance from the trunk; and
- by benchmarking usability with successful known designs.

12th Guideline: *Remember safety, aesthetics and comfort characteristics*

- by analyzing kinetic, mechanical (sharp edges and protruding parts), chemical, electrical, thermal, pressure, radiation, EMC and software hazards;
- by noting the lifting, pushing or pulling characteristics/limits; and
- by giving comfort, appearance and physical degrees of freedom high priority.

3.3. Main Headings on Immaterial Interaction

3.3.1. Video input and output versus eyes

13th Guideline: *Make alphanumeric characters easy to read and understand*

- by paying attention to the demands set by screen and paper documents;
- by preferring a white-dominated screen with black letters if documents are frequently needed;
- by using text with familiar typeface and not consisting entirely of capitals;
- by using the common rule of thumb for character height h: h = 1/200th of viewing distance, which means a visual angle of 17 minutes of arc (capitals on a typical close VDU = 3 mm);
- by remembering that in a high-resolution display with good contrast, 9- or 10-minute characters may be legible enough;
- by recognizing that characters > 24–25 minutes of arc are inappropriate;
- by considering that the elderly, at least without glasses, can see precisely only so distant characters that are then at too small visual angle;
- by remembering the recommendations for "easy" line length, one of the most common being one-third of viewing distance; and
- by forcing the line spacing to be at least 1/30 of the line length.

14th Guideline: *Optimize watching conditions for vision, perception, fidelity and comfort*

- by using familiar symbols, pictograms and icons;
- by remembering that, for easy and quick eye movements, the regular viewing tasks should be within a 30° cone around the (principal, central) line of sight (cf. 1st Guideline); it means the following diagonals of the screen at different viewing distance:

Distance (cm)

	30	50	70		90	150	250	400
in inches	6.3	10.5	14.7(≈A4)		18.9	31.7	52.7	84.4
in cms	16	27	37		48	81	134	214

- by trying to minimize the number of items to be watched and focused on, e.g. the viewing distances to the screen, to the documents and to the keyboard should be as identical as possible because of productivity in general and for older users" eyes (Helander 1997);
- by weighting to allow for significant relationships between the photometric characteristics of the computer display and visual discomfort;
- by eliminating the effects of disturbances caused by mechanical shocks or vibrations affecting the camera; and
- by keeping in mind that, for special purposes, there are combinations of the screen and the camera that give the impression of being in direct eye-to-eye contact, and stereoscopic displays for enhanced fidelity.

15th Guideline: *Guarantee hi-fi quality of the transmitted image*
- by making the focusing of the camera easy during viewing;
- by ensuring optimal camera placement for unconstrained and realistic video communication, e.g. by utilizing voice-directed camera;
- by providing feedback helping to control the camera and to direct the behavior of the persons in front of the camera (e.g. PIP and possibly others corresponding viewfinder systems that guarantee properly placed and sized feedback of the transmitted image); and
- by providing clear status indication of whether the camera and transmission are switched on.

3.3.2. Video input and output versus perception and memory

16th Guideline: *Get acquainted with the basics of cognitive ergonomics related to display design*
- by considering the possibilities to strengthen signals due to the environment or the user's age (brightness, display time);
- by considering about information density and format on the video display; and
- by keeping in mind the 7 ± 2 rule, which gives the typical range of identifications people can make (Sanders and McCormick 1993).

3.3.3. Auditory input and output versus user in general

17th Guideline: *Try to find means, including noise control, to enhance the quality of audition in VTP*
- by noticing that auditory display is a challenge for VTP: provide directional accuracy and cues as to where to look on the VDU, and try to enhance situational awareness through the auditory sense when using VTP;
- by utilizing stereophony, which improves the listener's ability to localize the direction of sound;
- by applying echo cancellation;
- by utilizing a headset with a combined micro- and earphone;
- by attenuating the noise from the system, e.g. a noisy fan cooling the components;
- by preventing confusion which the synthesized speech or speech-based input the devices may generate (spoken messages); and
- by providing clear on/off indication of mute of auditory input or output.

3.3.4. User-interface software versus sensing

18th Guideline: *Emphasize the possibilities of software approaches when developing VTP further*
- by preferring software control that accounts for usability and such things as localization needs, elderly users and users with disabilities, i.e. a customized user interface;
- by consulting the standards before designing new pictographic symbols for the user interface software or other parts in the product; and
- by developing new symbols by selecting from several symbols the one that appears most effective in tests.

3.3.5. User-interface software versus perception, memory and decision

19th Guideline: *See that the general principles of human information processing and good practices are observed in the software*
- by preferring consistency in action sequences, terms, layouts, colors, etc.;
- by considering a direct-manipulation interaction style of the kind used in word processors, video games or CAD programs, which are transparent and concrete;
- by considering direct manipulation as a good way to master cameras, their sequence, focusing and zooming;
- by considering remote direct manipulation (e.g. using a keypad with arrow and function keys) as a useful possibility to be linked with VTP;
- by remembering that icons on the screen allow of recognition instead of recall and often provide spatial representations of the commands, which helps to make abstract concepts more concrete, especially for novice users (Majchrzak *et al.* 1987);
- by ensuring help and memory aid (user assistance);
- by designing the system so that operation involves a moderate rather than high short-term memory load;
- by designing the symbols and icons to be readily understandable, i.e. easy to decode by the user;
- by ensuring that operator errors can be easily corrected; and
- by utilizing standardization which refers to the common and familiar user-interface practices across the operation system.

3.3.6. Input devices versus eyes

20th Guideline: *Plan carefully in accordance with the established principles and standardized practices of cognitive ergonomics of controls*
- by keeping the use of colors limited because colors strongly affect attention;
- by designing the relative location of the cursor key on the keyboard so that it corresponds to the direction of movement (compatibility);
- by supporting blind orientation to the different keys on the numeric pad even by providing key 5 with a tactile cue;
- by making the minimum height of the lettering on the keys 2.5 mm;
- by using a standard layout for the keyboard, though a split and tilted version may be preferable; and
- by selecting one of the standard layouts for the numerical keypad, probably the one used in push-button telephones.

3.3.7. Input devices versus perception, memory and decision

21st Guideline: *Look for the recognized ergonomic design principles of input devices to enhance perception*

- by making operation easier by (1) anticipating the user's expectations concerning compatibility and standardization, (2) combining display and control, or (3) dialogue and anticipation between the user and the system;
- by promoting spatial compatibility, i.e. controls that follow the same layout as the system or displays; and
- by providing enough time between the execution of a response and the signal for the next response, whenever possible, let the user set the pace.

22nd Guideline: *Consider carefully the pros and cons of remote controls, touch-screens or speech control as well as other non-frequent possibilities*

- by designing the remote control so that the way is should be held is evident;
- by locating the important function keys of the remote controls consistently; and
- by remembering that as far as inexperienced users are concerned touch-screens have the advantage of providing

direct, concrete relationship between what the eyes see and what the hands do.

4. ERGONOMIC EVALUATION

A VTP system is subject to numerous and often contradictory requirements. Special attention should, therefore, be given to tradeoffs during the design or purchasing. In any case, the demands related to "the eyes and upper limbs up to the shoulders" are of great importance. These must be given enough weight when using multi-criteria decision aiding procedures for making tradeoffs (e.g. use value analysis; Figure 2). These two are though not only centers when designing VTP ergonomics. The key principle of effective design might be a balanced compromise in ergonomic specification.

5. EVOLUTION TOWARDS WIRELESS HAND–HELD MEDIAPHONE SYSTEMS

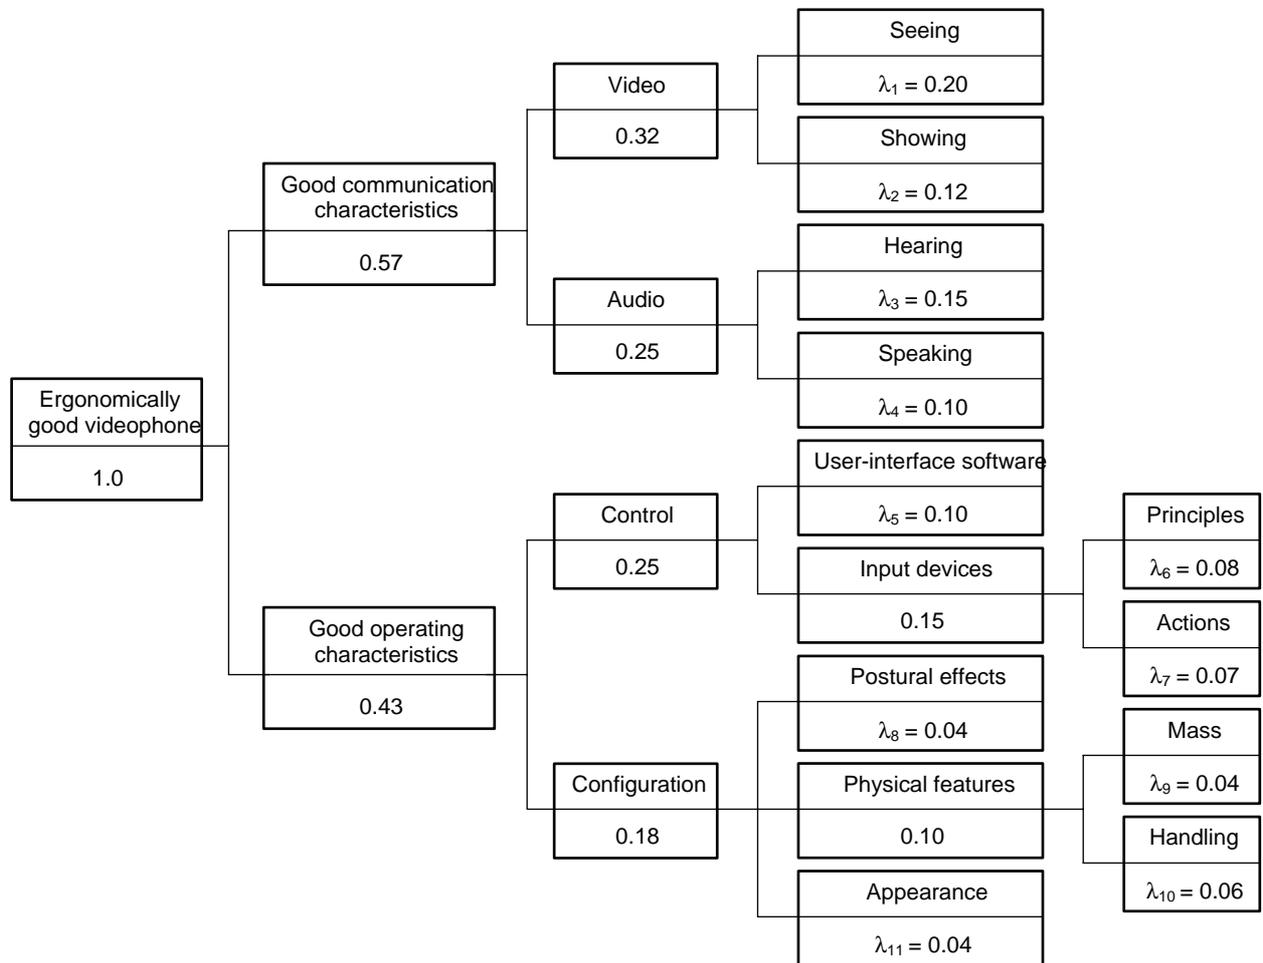
Developments in the wireless communication technology open up new possibilities in the implementation of the videophone as


Figure 2. Example of one possible ergonomic objectives tree model for evaluating videophones. This model enables a multi-criteria tradeoff based on 11 final objectives, i.e. criteria ($j = 11$). Each criterion has a weight factor l_j corresponding to the relative importance the criterion, e.g. $l_1 = 0.20$ means that the proportional effect of good visual output characteristics on the total goodness is 20%. Optional i alternatives can be score-rated for each criterion (e_{ij}), e.g. on a five-point scale, from 0 = unsatisfactory to 4 = very good (Pahl and Beitz 1988). Total ergonomic goodness EG of each VTP alternative can be calculated as a weighted average ($EG_i = \hat{A} l_j e_{ij}$), expressed on the same scale. The cumulative sum of the hierarchic and subtractive shared weights is hence a total of one ($\hat{A} l_j = 1.00$).

an extension of the current cellular phone. Especially the broadband digital wireless networks that will emerge ~2001–05 hold promise for the widespread use of media phones, e.g. cellular phones with VTP characteristics. Mobility adds a completely new dimension to the basic videophone characteristics: telepresence and augmented reality. Telepresence is enabled by a "carry along" arrangement, where the videophone is stereoscopic and follows the movement of the users' head. Augmented reality is a further extension of telepresence, where synthetic, i.e. computer-generated, information is added to the telepresence image to convey some meaningful additional information belonging to the context, such as navigational information, personal identities, etc.

Telepresence and augmented reality bring in new requirements in addition to the videophone requirements: field of vision, registration accuracy and real-time responsiveness. Visual field involves the question of how many degrees of the normal viewing range of humans need to be covered? Increasing the visual field improves the telepresence effect, i.e. immersion, but at the same time detracts from resolution. Registration accuracy is defined for the accuracy of positioning annotations (graphical symbols, alphanumeric characters) on top of a stereoscopic video telephone image. Real-time responsiveness refers to the dynamic aspect of registration accuracy, i.e. how well the annotations are able to follow the respective objects in the image when the user moves.

Figure 3 presents the Cyphone Mediaphone, which was designed to study portable real-time stereoscopic video input and output enabling telepresence. The receiver is able to see the same view as the transmitter. The problem of different user sizes has been solved by a binocular-like mechanism. The technology of miniature displays is expected to reach a level sufficient for high quality and resolution of image viewing.

The user interface has been kept as simple as possible by eliminating the conventional numeric keypad. Instead, a numbering input device has been integrated in a touch-sensitive surface, which also serves as a touch-pad. Cyphone has a transparent and logically intuitive user interface, because the touch-pad and the screen have the same size. This gives a realistic feeling to the menus. The shape of the left side has been designed to bring the mini-displays near the eyes and also to support grip. The microphone has been placed at the edge of the touch-pad and the loudspeaker on the upper side of the display.

Cyphone has two cylindrical shapes going through it. There is no need for a physical connection between the cameras and the mini-displays, but a binocular impression has been wanted to create in order to give the users intuitive help on how to use the mediaphone. The shape also gives good support for grip. For some applications, such as personal navigation, a head-mounted display in the form of intelligent eyeglasses or sunglasses is foreseen, although the technology may only become mature somewhat later.

6. CONCLUSION

VTP in its different forms is a technology of today, which becomes more feasible every day. Ergonomics, e.g. usability, and various contextual factors, e.g. organization of jobs, are crucial as far its success is concerned. It remains to be seen what kind of physical systems are most effective and best preferred by the end-users.

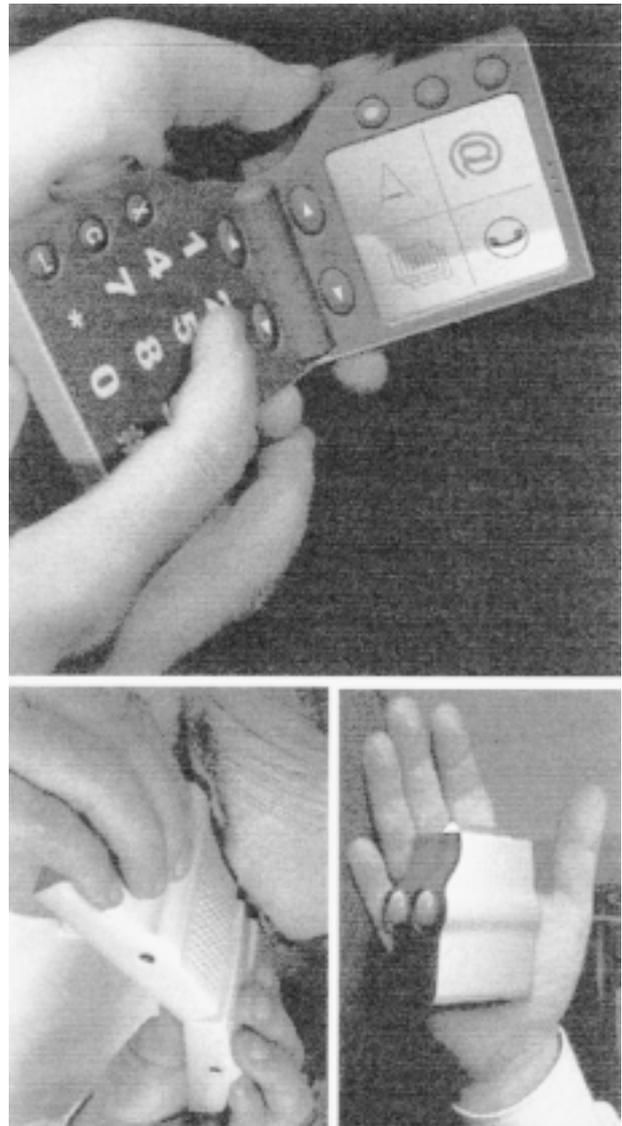

Figure 3. Cyphone, a mobile mediaphone developed at the University of Oulu. Telepresence and augmented reality applications are supported by the stereoscopic image input and output.

Various all-in-one systems will obviously become more common, among them hand-held compact systems, which have a high priority in the plans of telecommunication companies in 1999.

VTP normally causes an increased level of alertness, which further demands the user to have corresponding vigilance abilities. It also means that the user must have an adequate mental model of the devices and the whole system. The human stereotypes, if they are taken into account in a VTP system, can support in demanding using situations. The user interface software meets many challenges. So do for instance augmented reality and annotations.

It is evident that the users must put enough weight on the ergonomic characteristics of VTP. It is therefore possible to gain benefits both at utilitarian and subjective, i.e. hedonic, experiential and emotional, levels. To meet the expectations of the users of this demanding hybrid product, laborious design tradeoffs are needed by manufacturers. Most probably,

increasingly diverse VTP solutions will be needed in the future to satisfy the growing number of users and ergonomically challenging applications.

Virtual Environments

W. Barfield† and E. B. Nash

Virtual Environment Laboratory, Department of Industrial and Systems Engineering, Virginia Tech, Blacksburg, VA 24060, USA

1. INTRODUCTION

Virtual environments are interactive, multisensory, three-dimensional computer-synthesized environments that can be manipulated by virtual environment participants (Barfield *et al*. 1995b, Furness and Barfield 1995). By providing an egocentric frame-of-reference, virtual environments let the user be immersed within the computer simulation, resulting in a suspension of disbelief in which the participants feel like they are actually present in the virtual environment. This chapter discusses the visual, auditory, haptic and olfactory components of virtual environments, and the concept of presence in virtual environments.

2. COMPONENTS OF VIRTUAL ENVIRONMENTS

The sensory representations that characterize virtual environments are typically conveyed to participants using several different types of virtual environment display technology. Using virtual environment display technology, combinations of visual, auditory and/or haptic stimuli are displayed to the senses at sufficient fidelity such that they appear to originate from within the three-dimensional space surrounding the user. This chapter will briefly discuss the features of such displays and how they convey information to the visual, haptic and olfactory modalities.

2.1. Visual Display Technology

The visual component of virtual environments typically consists of a stereoscopic, computer-generated image viewed using an opaque head-mounted display (HMD) or a stereoscopic image viewed using time multiplexed shutter glasses (Figure 1).

Using a HMD, a virtual environment is created using two separate displays (e.g. nominally 1 inch^2) which provide two slightly offset views of the same scene. The magnitude of the lateral disparity provided by the two images is dependent on the interocular distance between the viewer's eyes. Through the use of optical elements that magnify, collimate and project the images via a mirror combiner, the computer-generated image appears as a large picture or full-scale three-dimensional scene suspended in the world. Furthermore, a scene viewed using a head-tracked HMD will provide the user an egocentric frame of reference, where objects are viewed from the perspective of the user's position in the three-dimensional space provided by the virtual environment.

Interactivity within the virtual environment is achieved when the psychomotor (and in some cases, physiological) behavior of the user can be monitored by the system and used as input to manipulate the virtual display. Physical movements of the user can be integrated with visual display information when a position sensor system is used. Such a system will typically track the user's head and hand positions. With these types of direct physical mappings, the user can control the virtual environment within natural visual and motor skills, providing a display that is "visually coupled" to the user (Kocian and Task 1995). It is important to note that coupling is an important concern when interactivity is desired, regardless of the type of display.

Figure 1. A virtual environment viewed through an opaque head-mounted display (HMD). Also shown is a glove with a 6° of freedom position sensor allowing the user to manipulate virtual objects.

2.2. Auditory Display Technology

For virtual environments, the goal of auditory display technology is to manipulate sound sources so that they assume localized positions within the virtual environment, mapping the source channel into the three-dimensional space of the user (Cohen and Wenzel 1995). The most conventional approach to spatial sound generation employs a hardware- or software-based convolution engine that convolves a monaural input signal with pairs of digital audio filters to produce output signals for presentation over stereo loudspeakers or headphones.

2.3. Haptic Display Technology

Haptic displays can be classified into two groups: tactile displays, which provide sensations of shape and texture on the surface of the skin, and kinesthetic displays, which provide the sensations of position and force in muscles and joints. The goal of haptic displays when used with virtual environments is to persuade the user to attribute haptic sensations to the parameters of the virtual objects rather than to the immediate location of the sensation (i.e. the haptic display's contact with the skin). This psychological phenomenon is referred to as distal attribution (Loomis 1992).

2.3.1. Tactile displays

The three primary tactile display technologies associated with virtual environments are static mechanical tactile stimulation, vibrotactile stimulation and electrotactile stimulation. Although the former would readily provide the means necessary to produce the sensation of skin deformation at the exact moment of touch with a virtual object, these types of displays are not regularly used due to high power consumption and the rapid adaptation to static stimuli (Kaczmarek and Bach-y-Rita 1995).

2.3.2. Kinesthetic displays

Kinesthetic displays used in virtual environments operate to produce sensations of mechanical energy flow. Specifically, electric motors provide force feedback against the limbs of the body to mimic the forces of physical interaction experienced while interacting with real world objects. Coupled with the actions of the virtual environment participant, kinesthetic displays can model energy flow relationships bi-directionally. This entails both sensing the parameters of the virtual objects and their actions and reproducing these as physical forces to the user, and sensing forces input by the user and reproducing these as actions within the virtual environment.

2.4. Olfactory Displays

Other senses are not exempt from application within virtual display technology. Though olfaction has received relatively little attention among researchers (and gustatory none at all), the olfactory modality provides a potentially rich source of information to users in virtual environments. Potential applications include training for the recognition of hazardous materials, room identification by odor and the demarcation of exit pathways (Cater 1992). In practice, virtual olfaction displays can be created for use with virtual environments using a system of hardware, software and chemicals to deliver the olfactory stimulus. However, before they can be of use, psychophysical issues such as detection thresholds, accuracy of odor recognition, odor localization, odor discrimination and channel capacity must be fully understood (Barfield and Danas 1996).

3. SELECTED HUMAN FACTORS ISSUES IN VIRTUAL ENVIRONMENT TECHNOLOGY

3.1. Perceptual Capabilities and Limitations of Humans

It is understood that human senses have certain capabilities and limitations. Thus, the capabilities and limitations of the senses can be used to provide guidelines for the design of virtual environment display technology (Barfield *et al*. 1995a). For example, visual, haptic or olfactory displays need not be designed with a resolution that exceeds the capabilities of the human's senses to perceive the presented information. In the context of vision, because the retina contains fewer cones towards the periphery compared with the fovea, it is relevant to ask whether visual display resolution should also decrease toward the periphery of the display and how realistic color should be represented in the periphery.

At present, the full integration of human sensing and manipulation capabilities with current display technologies is impeded by either the lack of knowledge of human capabilities or by limitations in technology. With haptic displays, this means that there are human movements that cannot be adequately sensed, or, more importantly, human senses that are under-utilized. The present disparity between rate of task performance in teleoperated or virtual environments, compared with real ones, is the net result of such disparity. If we can completely match the specifications of human sensing with virtual environment display characteristics, then it may reduce this disparity to zero. This will not likely happen in the near future.

3.2. Relevance of the Task

The optimal coupling of display fidelity with human's sensory capacities will also be task-dependent. That is, not all tasks will require the largest field of view, the most realistic tactile feedback, or the most realistic spatialized sound technically possible. In this regard, Barfield et al. (1995a, b) have discussed the tradeoff between field of view and display resolution in the context of the required application and task. If the task is to navigate through a virtual environment, then a HMD with a wide field of view may be necessary. However, if the task is to control a slave manipulator at a remote site, then a HMD providing a smaller field of view with higher resolution may suffice.

3.3. Prolonged Exposure to Virtual Environments

Before the use of virtual environments will gain widespread prevalence, researchers must address the question of the effect of prolonged exposure to virtual environments on the human's ability to re-adapt spatially and cognitively to the real world. This consideration becomes especially important when the stabilization of the virtual environment is poor. In such cases, exposure may lead to symptoms of simulator sickness, manifested as general discomfort, apathy, drowsiness, headache disorientation, fatigue, pallor, sweating, salivation, stomach awareness, nausea and vomiting after or during a session with a virtual environment. Isolation of these causal factors must occur before prevention techniques can exist.

4. PRESENCE IN VIRTUAL ENVIRONMENTS

Because virtual environment display technology has the capacity to surround the user with three-dimensional stimuli from multiple sensory modalities, under ideal conditions these components may interact to provide the viewer with a sense of presence within the virtual world (Barfield and Hendrix 1995). In our view, presence is not a physical but rather it is a cognitive state that emerges from the information the human sensory organs collect and convey to the brain. Presence is a desirable effect of a participant's interaction with a virtual environment. In fact, most virtual world applications are designed with the objective of creating an environment that will engage and lure the participant into "feeling" present in the environment.

Hendrix and Barfield (1996) have shown that presence in virtual environments is dependent on the type of input device, display characteristics (such as stereopsis and field of view [FOV]), and the presence or absence of head tracking. Among input devices, these include the nature of the input device itself, the ease of input control and how well the input device allows the participant to move within the virtual space of the virtual environment. Among display characteristics, these include the level of engagement of the displayed environment, geometric field of view and stereoscopic cues (Hendrix and Barfield 1996). In addition, researchers have postulated that an increase in display fidelity will influence the level of presence in a virtual environment (Hendrix and Barfield 1995) and that other display variables, such as scene update rate, will influence the fidelity of the scene and, hence, the sense of presence (Sheridan 1992).

5. CONCLUSIONS

In this chapter is presented the display components and interface concepts related to virtual environments. Once the gamut of available display technologies become more fully developed, these must be integrated into the virtual environment such that optimal combinations are provided to fit the capabilities and limitations of humans and the tasks they perform. In the future this strategy may serve to provide users with minimal disparity between sensations experienced during tasks performed in virtual environments and those experienced during tasks in the real world.

Virtual Reality

R. C. Williges

Department of Industrial and Systems Engineering, Virginia Polytechnic Institute and State University, Blacksburg VA 24061, USA

1. INTRODUCTION

Virtual reality (VR) is a term that describes a variety of computer-mediated techniques that are used to represent various aspects of the physical world to the user. Although most of the current techniques deal with representations of the visual environment, consideration has also been given to representing the entire human sensory environment including visual, auditory, touch, and motion domains. Consequently, virtual environment (VE) is often used as the more descriptive term of this family of computer-augmented techniques.

1.1. Degree of Virtuality

A more comprehensive view of the VE is to consider a reality-virtuality (R-V) continuum. For example, Milgram and Drascic (1997) describe an R-V continuum from the real world to a VE created totally with computer modeling. In between these two extremes various forms of mixed reality can exist. If the environment is primarily the real world with aspects of the VE superimposed on it, then one has an augmented reality environment. On the other hand, if the environment is primarily a VE with aspects of the real world included within it, then one has an augmented virtuality representation.

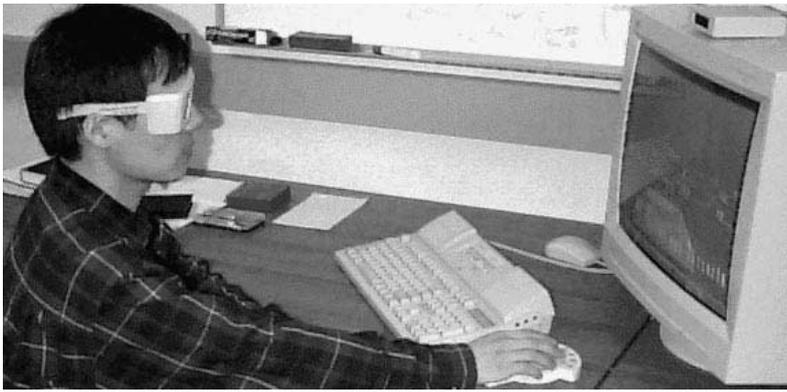
Representing the VE along this R-V continuum allows the designer to consider a variety of mixed reality alternatives for design application rather than just a pure real world or completely modeled VE. For example, augmented reality can be used to enhance or highlight aspects of the real world such as guiding industrial quality control inspection through computer augmentation. Alternatively, augmented virtuality can be used to enhance the VE by depicting a picture of the user's real hand pointing at or grasping an object in the VE so that the user has a higher degree of perceived presence and sensory immersion in the VE.

1.2. Telepresence

One of the most important considerations in the design and use of VR is to facilitate the user's perceived presence of actually being in the VE. Draper, Kaber, and Usher (1998) provide a comprehensive review of various parameters involved in the perception of presence in a physically remote or computer-simulated site as characterized by VR systems, telecommunications, and teleoperations. They describe simple, cybernetic, and experiential telepresence. Simple telepresence is the user's ability to operate the computer-augmented environment. Cybernetic telepresence is a quality index of the human–machine interface itself based on the compatibility of human performance with the computer-mediated environment. Experiential telepresence refers to the mental state of the user who feels physically present in the synthetic environment.

Draper, Kaber, and Usher (1998) review both technology-based and psychologically-based explanations of telepresence. Technology-based explanations relate factors such as sensory feedback, fidelity of sensory information, control dexterity, display quality and consistency, and degree of sensory immersion to telepresence. Psychological explanations of telepresence, on the other hand, involve characteristics such as task flow, self-attribution of presence in the VE, situation awareness, and cognitive factors related to information processing and decision making that affect perceived presence in the VE. They proposed a structured attention resource model as a means of describing and predicting the degree of telepresence.

2. DESIGN ISSUES

The human factors specialist must consider a variety of design issues when using VR. Stanney, Mourant, and Kennedy (1998) provide a comprehensive review of over 150 scientific articles related to human factors issues in the VE. They organized their review around three major issues including human performance efficiency, health and safety issues, and the social impact of technology. Human performance efficiency included issues pertaining to task characteristics, user characteristics, human sensory and motor physiology, multi-mode interaction, and design metaphors. Health and safety issues included cybersickness and deleterious physiological after-effects. Social issues deal with the negative impact of user's misuse of VE technology such as excessive exposure to violence in VR gaming applications. Based on this review and current research in VEs, one must consider several critical issues when designing applications of VR.


2.1. Display Alternatives

Visual displays need to be considered carefully when developing VR applications especially in augmented reality displays that combine real and virtual objects in the same field of view. Localization of these objects, superimposing images, and aligning virtual and real three-dimensional (3D) objects are critical for user acceptance and performance.

Current VR display technology allows several alternatives for presenting the computer-mediated visual scene. Figure 1 depicts three of the most common classes of visual display of the VE. Desktop VR can be used to present either perspective 3D scenes on the display screen or true stereoscopic 3D images by viewing the display screen through shutter glasses as shown in Figure 1a. A head-mounted display (HMD) can be used to provide a more immersive visual environment with a limited field of view (FOV). The HMD can be an augmented reality display as shown in Figure 1b in which the user can see through the HMD to superimpose the virtual image on the real world. The visual display can also incorporate head tracking shown in Figure 1c to adjust the visual scene depicted on the HMD according to head movements of the user. The most immersive VE visual scene uses full wall projections providing a large FOV shown on one to six screens in a completely enclosed VR room as shown in Figure 1d.

2.2. Control Alternatives

Various control alternatives are available for users of VEs. Four commonly used controllers used in VR are a 3D ball, 3D puck, wand, and dataglove as depicted from left to right in figure 2.

Figure 1. Display alternatives for virtual environments; a. Desktop display; b. Augmented reality display; c. Head tracking display; d. Room display.

Figure 2. Four control alternatives for virtual environments.

Most often these controllers are used to control visual orientation and locomotion within the visual scene in the VE. A certain amount of training and practice is required to achieve proficiency in the use of these controllers. Care must be taken to chose the appropriate controller for the specific application so as not to interfere with task performance.

2.3. Perceived Presence

Instilling a feeling of presence in the VE as compared to simply viewing the VE from an outside real-world perspective is often a design goal in VR applications. The feeling of presence is an evaluation made by the user and measured by subjective opinions, surveys, and rating scales. However, perceived presence does not have a perfect positive correlation with performance in the VE, and it depends upon a variety of design parameters. For example, Snow and Williges (1998) isolated seven parameters that significantly influenced perceived presence. They found that FOV,

sound, and head tracking, had almost three times more influence on presence than visual display resolution, texture mapping, stereopsis, and scene update rate.

2.4. Cybersickness

Negative side effects ranging from mild discomfort, to headaches, to nausea can occur in VR. This type of discomfort is somewhat similar to motion sickness and is generally referred to as cybersickness. Individuals differ in terms of their susceptibility and severity of exhibited symptoms, but usually their discomfort is short lived after exiting the VE. Several parameters of the visual scene including limited FOV, visual vection or flow in peripheral vision, sensory cue conflicts, lags, etc. need to be considered by the human factors engineer as ways of minimizing potential health and safety risks related to cybersickness.

2.5. Orientation and Navigation

Navigation throughout the VE can be problematic for new users and can hamper their performance. Human factors issues include both features that affect orientation and aids to improve navigation. Many factors related to the design and representation of features such as the number of edges used graphically to depict an object in the VE affect user orientation and navigation. Understanding the influence of these factors is a critical to fostering effective use of the VE. Navigational aids such as visual movement or momentum, maps, visual portals or doorways, and 3D representations can be used to improve navigation in the VE.

2.6. Sensory Modality

Although the primary focus has been on the visual display of the VE, other sensory modalities have been considered. Three other prominent sensory channels include auditory, motion, and touch modalities. Alternative devices are also available for special applications such as speakers for 3D spatialized sound, force sensitive controllers for providing haptic feedback, and treadmills to allow locomotion. Both the primary effects of each sensory modality and the interaction of various multiple sensory inputs need to be considered in designing the VE.

2.7. Individual Differences

Individual differences among users also influence the design and use of VR. Two important classes of users that require special consideration are children and the elderly. Most VR equipment is designed to be used by young adults, but there are age differences in the use of this equipment. As children begin to use VR more often in educational and leisure activities, the equipment needs to be designed to fit their physical capabilities, to minimize their discomfort and cybersickness, and to foster their spatial orientation in the VE. Additionally, the reduction in physical as well as sensory capabilities of vision and hearing need to be considered by the human factors engineer when using VR devices with the elderly.

3. APPLICATION AREAS

The use of VR technology has been expanding rapidly. Different application areas often raise unique human factors and ergonomic issues that need to be considered in order to facilitate appropriate use of this emerging technology.

3.1. Entertainment

Probably the first use of VR was computer games in which the player is immersed into the VE. The popularity of these games is growing and has a large economic impact in our society. Additionally, VR has been used extensively in the motion picture industry as a means of providing realistic animation and representation of environments, characters, and objects that do not exist in the real world but are critical components of the fantasy world depicted on film. Given the commercial market potential, entertainment will continue to be a leading application for VR. Little human factors attention has been given to determining the characteristics of the virtual representation that is engaging and provides the greatest entertainment for the user.

3.2. Design

Applications of VR have been useful in design applications. Specifically, in architectural design, 3D representations and virtual walkthroughs of structures during various phases of design have proven useful in facilitating design decisions, isolating design problems, and promoting user acceptance. The exact nature of the role of visualization and the level of visualization required in various stages of architectural design is still an unresolved human factors engineering issue.

Engineering design applications of VR have proven to be a valuable aid to workers in manufacturing systems. In particular, augmented reality is useful as an aid to workers in the assembly of complex components in aircraft systems and in the reduction of visual inspection time while maintaining inspection accuracy as compared to purely manual inspection. By superimposing a virtual projection of instructions, measurement points, etc. in the physical manufacturing process, the augmented reality display provides valuable guidance to the worker. Likewise, VR applications can be made to the design of workplace layout and ergonomic analysis of workstations.

3.2. Conferencing

An emerging application area is the use of VR to facilitate group and team work through computer conferencing using a VE. For example, conferences of distributed team members could be accomplished through networked, fully immersive VEs. The degree of virtuality on the R-V continuum needed to facilitate team communications, techniques to coordinate task performance, and improved decision making procedures are examples of macroergonomic issues that need to be considered.

3.4. Education

Educational use of VR is rapidly increasing. For example, scientific visualization of complex mathematical and chemical structure using VR technology can lead to improved understanding and new insights. Likewise, many areas of medical science related medical diagnosis and surgical treatment could be demonstrated and practiced in a VE without danger to live patients. The necessary and sufficient level of telepresence in the VE visualization required to promote learning still needs to be specified.

3.5. Simulators

The area of application of VR that provides the most important set of human factors issues is the design and use of VEs as a

synthetic training devices. The visual display and multisensory feedback provided by VR technology is ideally suited for use in training simulators of space, air, land, and naval transportation vehicles. Simulation training can improve operator safety and reduce operational costs as compared to real-world training in these vehicles. The VE can be used both in part-task and whole-task training environments. However, issues related to the effect of perceived presence on transfer of training and the minimization of cybersickness need to be addressed by human factors engineers when using VR simulators.

4. AREAS OF DEVELOPMENT

Although applications of VR have increased tremendously, several areas of development are being addressed by current research in order to facilitate further improvements. Most of these developments are methodological.

4.1. Metrics

Standard evaluation metrics are used in order to facilitate comparison of various alternatives of VR. Rating scales of discomfort and perceived presence in VE have been developed. One example of specifically defined metrics in VE is the use of free modulus magnitude estimation as a convenient psychophysical technique for assessing a user's perceived presence in VE.

4.2. Integrated Database

The results of empirical studies in VR need to be integrated into a database that includes the results of several studies. Both a common set of tasks and a procedure for representing and interrogating the integrated VR database need to be developed before integrated databases can be built.

Lampton, Kneer, Goldberg, Bliss, Moshell, and Blau (1994) developed a battery of generic VE tasks to support training applications of VR. Their battery includes five task categories and several subtasks within each category. The visual task includes subtasks related to acuity, color, object recognition, size estimation, distance estimation, and search. The locomotion task has both walking and flying components. The walking components include straightaway, backup, turns, figure eight, and doorway subtasks; whereas, the flying category includes window and elevator subtasks. The manipulation task includes slide, dial, and bins subtasks that involve various ways of grasping objects in the VE. The tracking task includes both head and device control in regard to stationary and moving targets. Their fifth task is a reaction time task including simple and choice reaction times. Developers of a VE application can choose the appropriate set

of tasks and subtasks from this battery for their application and, thereby, have a common baseline for comparing alternative designs of the VE application.

Sequential experimentation can be used as a mechanism for combining data across several experiments into an integrated database using a common subset of this VE task battery. Fractional-factorial designs and central-composite designs along with a common data point and data bridging can be used to collect data in an efficient manner on a large set of factors affecting VE performance. Empirical models based on polynomial regression can subsequently be generated from the resulting integrated database. Snow and Williges (1998) demonstrated the use of these techniques as a means of predicting the effect of several system factors and their interaction on perceived presence in a VE.

4.3. Design Guidelines

Little guidance exists for the appropriate user-centered design and application of VR. As more research is conducted, as case studies of applications increase and as integrated databases are developed, empirically-based human factors and ergonomic design guidelines and standards will develop for the use of VEs.

5. CONCLUSIONS

The technology involved in generating VR systems is advancing rapidly, and applications of this technology are escalating. Because VR is still an emerging technology, this area offers exciting and challenging issues for human factors engineers to address in order to harness the potential of this technology for human use.

Virtual Reality: Virtual and Synthetic Environments – Technologies and Applications

R.J. Stone

Virtual Presence Ltd, Chester House, 79 Dane Road, Sale M33 7BP, UK

1. INTRODUCTION AND DEFINITION

With most new and exciting technologies, there is often an early tendency for the pioneers and "evangelists" to become preoccupied with novel hardware and software and divorced from the requirements of commercial applications and user needs. Typically the result is a painfully slow and often costly uptake process on the part of industry and commerce. "Technology push" outweighs both "market pull" and sensible implementation based on sound ergonomics principles. So it was in the past with speech recognition, robotics, artificial intelligence and neural networks. So it was with Virtual Reality (VR). That is, until quite recently. Since 1997, and after an incubation period lasting some 6–7 years, VR has experienced something of a massive revival. A revival that has taken the form of a number of important developments that have helped VR to become an *accessible*, usable and justifiable technology for many industrial, commercial, educational and public sectors.

To appreciate the reasons for this revival, one has to understand what VR actually is: "Virtual Reality refers to a suite of technologies which permit intuitive, real-time interaction with three-dimensional databases …" (Stone 1996a). Absent from this definition are what many still believe are the two most important features of VR (prerequisites, almost): computer graphics and *"immersion"*. The term immersion (or "inclusion") describes the situation where users experience a strong sense of presence in a virtual world, typically having donned a head-mounted, stereoscopic display and special forms of clothing, such as instrumented gloves, suits, even mechanical exoskeletons. It will be seen later that what is referred to today as "wearable computing" is but one item in an ever-increasing catalogue of data input and output technologies for VR. Returning to the definition, the four key issues are:

- *Suite of technologies*. This recognizes the fact that VR is a convergence of technologies from a much wider range of disciplines — telerobotics, multimedia, computer-aided design (CAD), process simulation, computer-generated imagery (CGI), animation and, of course, human factors and ergonomics. Nowhere has this been demonstrated to better effect than in the exemplary historical and ongoing efforts of the human factors teams at NASA's Ames Research Center in California. Their early Virtual Environment Workstation (VIEW) project, described below, paid full attention to the human factors issues associated with VR and associated interface technologies, including the integration of auditory cueing, multi-sensory data representation and speech recognition. Today, similar attention is paid to other safety-

Figure 1. NASA air traffic tower simulator. Courtesy National Aeronautics and Space Administration.

critical applications of virtual environment technology, such as NASA's Air Traffic Control Simulator (Figure 1).

- *Intuitive interaction*. The term "intuitive" reflects an ambition of VR to provide users with a *transparent* interface which makes navigation through, and interaction with virtual environments as "natural" as possible, thereby avoiding lengthy and costly training in specific computing skills. In the recent past, it was assumed that intuitive interaction could only be provided by immersing the VR user within a virtual environment. Today, there is a variety of highly usable multi-function display and control devices on the market. There are also many other products that lay claim to an ergonomics quality but leave a lot to be desired when they are used.

- *Real-time*. This important feature of VR relates to the importance of allowing users the freedom to explore and interact with virtual objects and environments without incurring disruptive time delays between their actions (e.g. head or hand movement) and the result of those actions within the virtual environment. Often one comes across a tendency for VR to be compared with many of the CGI and computer-animated films one can experience at the cinema. While these productions capture the attention of their audiences with their advanced graphics, they are nothing more than cartoons — highly detailed graphics which are drawn, or "rendered," frame-by-frame over very lengthy periods and, where necessary, superimposed on live action. In other words, they are *scripted* computerized sequences which, while visually impressive, cannot be interacted with in real time. Unlike VR, users are not free to choose where they can move next, or which object they will grasp and manipulate next.

- *Databases*. The significance of VR lies not in the nature of the sensory experience *per se* (with vision typically providing the dominant channel), but in the structure and behaviour of the data underpinning the sensory experience. The software qualities and "intelligence" endowed to objects in a virtual environment, together with their geometric and behavioural relationship with other objects, permit an

approximation to the nature of their real-life counterparts. Alternatively, in cases where such objects or processes do not exist in reality or are not visible to the naked eye (e.g. financial records, molecular structures and fluid dynamics), such features of VR make those objects and their behaviours more accessible and understandable to the human user. Some examples of these features will be illustrated below.

2. A BRIEF HISTORY

Without doubt, the USA played a significant and formative rôle in the establishment of a global VR market and community (Moody 1999). Many researchers will acknowledge the 1950s' contributions of such pioneers as the late Morton Heilig with his *Sensorama* entertainment system — the "forerunner" of the single-person virtual arcade system (http://www.telepresence.com/org/ sensorama/index.html). However, the first concrete example of a concept involving an immersive VR system is attributed to the 1960s' work of Ivan Sutherland. His experimental system, called *Sketchpad*, was a computerized design tool that allowed users to design and manipulate graphical objects on a screen using a light pen. Sketchpad ran on a TX-2, the most powerful computer available at the time. It was not only a tool for visualization, it was an operating environment in its own right. Sutherland's later work, described in 'The ultimate display' (Sutherland 1965), was based on research for the Advanced Research Projects Agency. Using a ceiling-mounted, cantilevered stereoscopic display headset boasting a 40° field of view — the *Sword of Damocles* — primitive 3D wire frame graphics with hidden line removal could be inspected from numerous direction by the user.

In the 1960s, an alternative form of VR had been the subject of much research by Myron Krueger, who had been investigating the human–computer interaction aspects of what he called "artificial realities" (Krueger 1991). In 1969 Krueger became involved in a project known as *Glowflow*, creating illusions of perspective and slope by fitting out normal, darkened rooms with tubular lighting at various orientations. Through other, more interactive projects, Krueger's research led to the development of the *Videoplace* or *Videodesk* System. By backlighting a translucent screen behind the participant (or participants, in the case of a networked system), body form could be distinguished from the background by video digitizers. A special executive computer processor translated the digitized "behavior" of the participant into silhouette form which could interact with the graphical world and its constituent objects appropriately (including some early forms of "artificial life").

However, the VR technologies being marketed today have only been under development since the early 1980s, through pioneering ergonomics research into the natural human control of space robots ("telepresence") at NASA Ames, and in the development of the *SuperCockpit* concept at the Wright Patterson Air Force Base in Dayton, Ohio. The goal of the *SuperCockpit* work was to develop advanced avionics and cockpit management systems to enhance information transfer and to protect pilots' eyes from the dazzle threat from laser weapons and nuclear airbursts. Instead, virtual representations of the environment external to the cockpit were generated from airborne sensors and reconnaissance data for presentation using large screens or sophisticated helmet-mounted displays (HMD), such as the *VCASS* System (Visually-Coupled Airborne Systems Simulator;

Harvey 1987). In stark contrast, NASA's VIEW System, mentioned above (http://telepresence.com/org/nasa/index.html), combined a low-cost HMD with an interactive glove equipped with magnetic spatial hand tracker and fiberoptic finger flexion/extension transducers (the *DataGlove*, one of the products from the late VPL, Inc.; Fisher *et al.* 1988).

In the UK, the other country accredited with major innovations in the field, VR first came to the notice of the British public late in the late 1980s. Commercial research teams who had been involved in developing the technology presented their work for the first time at the 1990 London Computer Graphics Conference. Even before then VR projects had been under way, the first notable instance being in the early 1980s. The *Spatial Workstation*, a mobile television, displaying simple 3D wire frame images to the wearer of shuttered glasses, was developed by Jonathan Waldern, who went on to establish the VR games company W Industries (later Virtuality Plc). In 1989, a VR and telepresence research program was started at the recently opened National Advanced Robotics Research Centre in the North of England. Following a period of some 4 years (during which time the now-familiar corporate names of Division and Superscape had emerged from embryonic teams of hardware and software specialists), the center launched the first collaborative industrial VR initiative called *VRS* (Virtual Reality & Simulation; Stone 1994). *VRS* brought together organizations from such market sectors as defence, medical, retail, utilities, aerospace and petrochemical. The legacy of *VRS* can still be seen today in the existence of some quite prestigious corporate VR facilities and projects throughout the country.

3. VR TECHNOLOGIES

Over the 3 years that *VRS* was striving to introduce companies to the concept of VR, one witnessed a considerable upturn in the development of new human–system interface technologies, particularly from the USA. Some of these developments were stimulated by a marketing drive that required many defence-related companies to become more open and competitive with their products. To do this, they had to target new markets and "down-grade" their display and control technologies from the restrictive and costly requirements of military standards. Predictably, however, most of the developments were stimulated by an almost obsessive need for all manner of companies across the globe to become involved in the VR market in one way or another. New peripherals, many of which were being launched even before the first prototype had been completed, were featuring in catalogues with implicit claims that each would solve the outstanding problems associated with immersing a human being into a computer-generated world, or with controlling sophisticated robots at a distance. However, these claims proved to be "flights of fancy," with potential purchasers of new display and control devices experiencing first hand the problem of placing orders for "vapourware." For a time, the VR hardware and software supply community began to lose face. Another factor contributing to the problems of a technology desperately striving to acquire credibility was the absence of any serious applications for the technology — games and entertainment systems were still seen to dominate the market. Of those products that did eventually reach the customer, many were considered to be no more than expensive and none-too-reliable toys, with no evidence of an

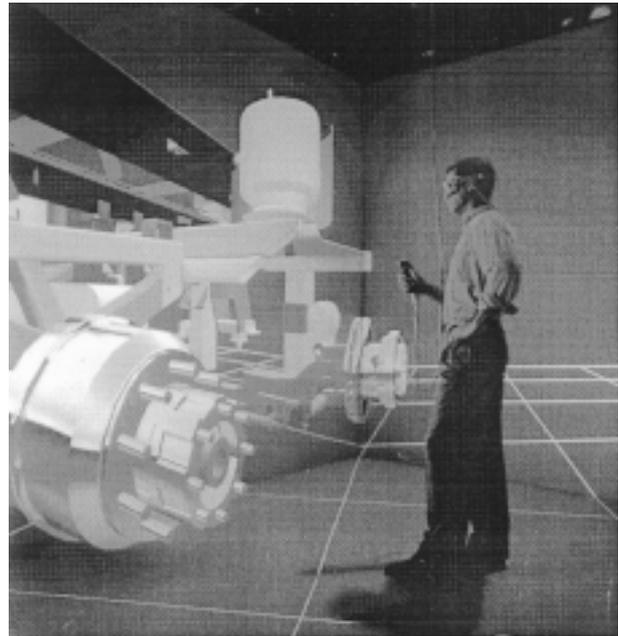
Figure 2. Example of an immersive virtual reality. Courtesy Virtual Presence.

Figure 3. Example of a CAVE virtual environment system. Courtesy Silicon Graphics, Inc. (UK).

ergonomics input to their design and little prospect of being used in anger in real industrial applications. Fortunately, the situation has changed for the better. Robustness, reliability and value for money are the norm in today's VR hardware and software rather than the exception.

As mentioned above, in some cases, the exploration of, and interaction with virtual environments or CGI requires the use of special peripheral devices to create a sense of presence, or immersion, within the virtual environment. In one form of immersive VR (Figure 2), users don a stereoscopic head-mounted audio-visual display (HMD) and can interact with the environment in real time using such devices as an instrumented glove (e.g. Virtual Technologies' *CyberGlove*), hand controller ("wand") or even complete body suits. The HMD and other peripherals are tracked in real time, for example using a proprietary electromagnetic tracking system (Stone 1996b). Movements and control actuations of the users in real space are transformed by the computer to update their position and orientation within the virtual space. The computer then renders the 3D virtual scene for display to the user, adding other appropriately transformed sensory data as necessary, such as 3D sound, touch and even smell.

Immersive VR was first commercially demonstrated on 7 June 1989 when the American company VPL, Inc. launched their RB2 system (Reality Built for 2). RB2 featured such revered product names as the *EyePhone* HMD, based on liquid crystal displays (cannibalized pocket televisions) with a special optical assembly and the VPL *DataGlove*, as described above.

Yet, total immersion in VR, using head-mounted displays and other bodily-worn equipment, still remains VR's "Holy Grail. The actual need for immersive VR accounts for no more than 15–


20% of the real applications evident throughout industry. Nevertheless, the quest for lighter weight and lower cost devices, such as the Sony Glasstron and Olympus personal information displays, continues unabated, fuelled with hopes of a lucrative domestic or mobile business market. Proponents of total immersion have many technical hurdles to overcome before their users can freely explore and interact with a computer-generated world they inherently feel part of, using the skills they were born with — walking, looking, grasping, listening, speaking, smelling. There are other equally important variants of VR, most of which tend to be based around the method by which information is presented visually to the user(s).

For example, an impressive, although expensive alternative to the HMD approach is the CAVE (Cave Automatic Virtual Environment — the trade name applied by the University of Illinois; Figure 3).

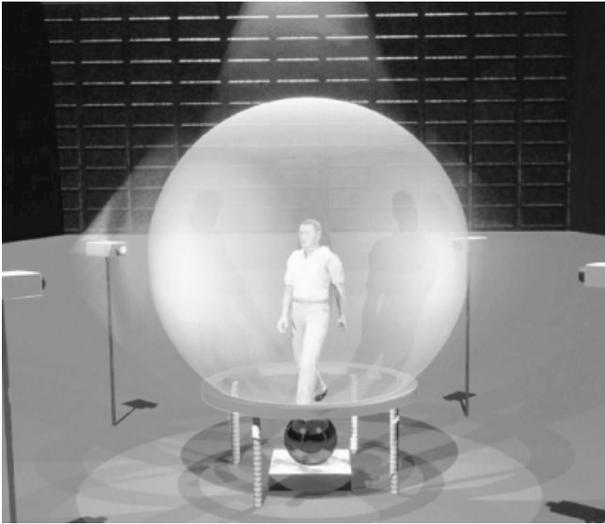
A CAVE is, in effect, a small room within which a small number of users are surrounded by whole-wall displays onto which the virtual images are back-projected using high quality video projectors. CAVE users may be provided with special liquid crystal "shutter" glasses, synchronized with the projectors, so that each alternate scan line of the display triggers one of the shutters, presenting left-eye or right-eye images only, thus creating a 3D effect ("active stereo"). A variation on the CAVE concept is the immersive projection sphere, one example of which has been developed by VR Systems in Southampton. This system consists of an acrylic sphere, 3.5m in diameter, into which the user stands (Figure 4). The sphere is supported by bearings mounted within a large horizontal ring. Within the area of the ring is a smaller sphere surrounded by rotational sensors. By walking within the main sphere, the user can explore virtual environments, displayed on its translucent surface by means of a series of high power projectors.


Figure 4. VR Systems' immersive projection sphere. Courtesy VR Systems Ltd.

"Partial" immersion can be achieved by means of what is popularly known as a BOOM mechanism. BOOM is actually a trade name of a device developed by Fake Space Labs in the USA, and stands for Binocular Omni-Orientable Monitor. BOOM users do not have to "wear" the display housing, as with HMD. Rather, they simply pull a counterbalanced stereoscopic display module towards their faces on demand and interact with the virtual environment by means of small buttons located at the side of the optical enclosure (or other means).

Desktop VR is a term applied to standard computer terminals, such as PCs or more sophisticated Microsoft Windows-based workstations. The virtual environment is presented to the user via a conventional monitor (sometimes modified to display stereoscopic images using optical assemblies or LCD shutter glasses, as described above). Movement through, and interaction with the environment can be achieved using a range of devices, from the conventional mouse and multi-axis isometric joysticks, such as the Spacetec IMC Spaceball or LogiCAD3D's Spacemouse/Magellan, to novel finger-mounted systems such as the Spectrum Ring Mouse.

Projection VR (Figure 5) is a display technique whereby individuals or groups of viewers sit in front of a single wall-mounted screen, multiple "wrap-around" screens or look down onto a special desk-or bench-mounted display. The virtual imagery is projected onto these screens using conventional three-tube video projectors. Again, LCD shutter glasses can be used to achieve a stereoscopic effect, although pairs of projectors with polarizing filters may also be used, so that viewers (wearing low-cost spectacles with complementary polarizing filters) can experience a "passive stereo" effect.

On a smaller scale, 3D virtual images can be created for single users, or small groups of users, by projecting the output of two liquid crystal or cathode ray tube displays onto screens of various sizes. One method of achieving such projection involves the use of (for example) holographic optical elements, with a resulting stereoscopic effect that avoids the need for users to wear cumbersome headsets or special glasses (autostereopsis). Another, more advanced form of projection — the Volumetric Display — offers 3D images that literally "float" in space (apparently occupying a real volume) and is viewable from many different angles by many observers.

A version of VR which has found popularity in the medical and surgical arena is referred to as Augmented Reality (AR). AR makes use of special headgear, or modified optical instruments (such as microscopes), and superimposes virtual images onto the user's view of the real world. AR requires careful attention to the accuracy of head tracking, to avoid disruptive visual problems caused by poor registration of the virtual and real images.

Other, more speculative systems, such as direct neural interfaces for widespread human use in VR, despite their "popularization" on TV programs, remain a science fiction dream, although this could easily change within the next 10 years. Less intrusive technologies exploiting human physiological and sensori-motor systems (e.g. eye tracking, laser retinal scanning, electromyography) may well develop over the next few years to the point when the need to don cumbersome and expensive VR headsets gloves or suits will become unnecessary. Sound generation for virtual environments is quite a mature subject and,

Figure 5. Example of a large-scale projection display. Courtesy CADCentre.

Figure 6. *PHANToM* haptic interface. Courtesy Sensable Technologies.

while the cost–benefit of adopting full 3D sound has yet to be proved (as opposed to straightforward mono or stereo), there is no doubt that the incorporation of sound in even the simplest virtual world adds immensely to the user's experience. Other forms of feedback to the human VR user — haptic (touch/force) and olfactory (smell) — are still the subject of international R&D programs (one impressive olfactory project being undertaken in the US, funded by the Advanced Research Projects Agency, ARPA). Some of these developments have yielded impressive results. Some are even mainstream products, such as Sensable Technologies' *PHANToM* haptic feedback systems (Figure 6).

A final and very important point to bear in mind is that VR is no longer the sole province of the so-called and expensive graphics "supercomputer." There is a relentless quest for faster, higher quality and more interactive virtual worlds to be deliverable on industry-standard Windows NT/95 workstations (e.g. Intergraph, Silicon Graphics), even multimedia PCs using high-performance graphics accelerators (witness the pervasion of low-cost Open GL/Direct 3D boards). Software packages for building and distributing 3D and digital panoramic virtual worlds on CDs (e.g. Superscape's VRT Visualiser/Viscape, Apple's QuickTime VR, Black Diamond's Surround Video, Live Picture's Reality Studio, Infinite Picture's SmoothMove, etc.) are readily available. In fact, access to quite sophisticated demonstrations, model libraries and low-cost, even free modeling and run-time software over the Internet for non-commercial use (e.g. AC3D modeling package: http://www.comp.lancs.ac.uk/computing/users/andy/ac3d.html; Swedish Institute of Computer Science DIVE — Distributed Interactive Virtual Environment: http://www.sics.se/dive; Manchester University, UK; Maverik GNU License: http://hegel.cs.man.ac.uk/systems/Maverik) are also contributing to a more widespread uptake of VR than was the case 2 years ago.

4. APPLICATIONS

Since 1997 it has been recognized that the key to the future of VR lies in the uptake of the technology by industrial and commercial organizations. Space does not permit a complete review of where the successful applications can be found. However, those interested in pursuing the subject can find a wealth of information on a Web site dedicated to improving VR awareness in the UK (UK VR Forum: http://www.ukvrforum.org.uk). Also available from this site is a 1998 report prepared for the UK VR Forum (Cydata 1998) which looks at the future of the VR market and presents trends for uptake within certain key sectors. Right at the outset, the report concludes: "the research results provide clear evidence that VR technology and implementation expertise have advanced sufficiently for a wide range of commercial applications to be possible, some of which seem now to be showing the prospect of substantial business benefits." There are other encouraging messages. For example, one well-known international telecommunications company has been exploiting VR for some time now. The results, insofar as their business is concerned, are well worth mentioning:

- 1168 days have been saved per year over three projects in just 6 months.
- VR models were derived from original engineering CAD data.
- Models were not just geometric in nature, but included version control, associated text and picking lists.

- VR is today hosted on an organization-wide Intranet.
- VR has stimulated a 97% reduction in requests for hard-copy material.
- Technical authors derived pictorial information from the VR model, reducing the need for camera crews and video by four sessions per year.
- Electronic access to the VR models generated savings on overseas visits by 25%.

Other applications areas are summarized below.

4.1. Large-scale Engineering

The ability to convert otherwise computer memory-intensive CAD data into visually acceptable, real-time interactive models is a feature of engineering VR that is now well established. Endowing those models with behavioral capabilities culled from associated engineering databases is also becoming an accepted and proven process (as will be seen in the sections dealing with scientific simulation and defence). The applications covered by the term "large-scale engineering" are many and varied, from petrochemical plant design or construction sites in general, to the ergonomic and aesthetic evaluation of automobile and civil aircraft interiors; from the verification of maintenance strategies for aircraft engines (Figure 7) to the prototyping of nuclear control rooms (UK VR Forum: http://www.ukvrforum.org.uk). Ergonomics is playing an ever-increasing rôle in engineering VR and simulation. For example, there has been a marked rise of recent years in the number of commercial human mannequin packages, themselves endowed with anthropometric and biomechanic data, not to mention physiological libraries encompassing energy expenditure, clothing effects, psychomotor parameters and so on. Not only do these packages provide the VR and human factors practitioner with a cost-effective assessment technique for engineering assessments, they also enable new industrial users of VR to do away with antiquated (and highly inaccurate) forms of "ergonomic" assessment based on toy figures, such as "GI Joe" or "Action Man!"

4.2. Physical/Scientific Simulation and Micro-engineering

This category is one of great promise for VR in the mid-to-far term future. VR has always held the potential to unlock the

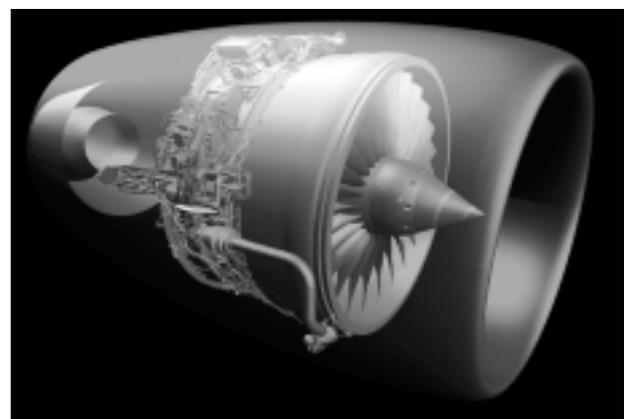

Figure 7. Virtual Rolls-Royce Trent 800 aero engine. Courtesy Virtual Presence.

Figure 8. Virtual computational fluid dynamics process, as displayed using VR techniques. Courtesy Virtual Presence and UK Health & Safety Laboratory.

"snapshot" and rather static world of the optical, electronic or digital microscope, to bring to the human eye minute features of living and inanimate material which would otherwise be invisible — and certainly inaccessible. Similarly, VR can help scientists to visualize all manner of complex artifacts and processes, be they new protein chains, viral compositions, chemical drug concepts or gaseous particles in motion (i.e. computational fluid dynamics, or CFD).

As an example of VR used for CFD visualization, NASA Ames Research Center's Numerical Aerospace Simulation Facility has developed a highly impressive facility based on VR technologies to allow users to explore numerically generated, three-dimensional unsteady flow fields. The project allows users, equipped with a BOOM stereoscopic display and *DataGlove* (described above), to view and inject smoke-like virtual tracers in and around aerospace vehicles. One of NASA's sister sites (Langley) has, for international research and education purposes, now ported the concept of the Virtual Wind Tunnel on to the World Wide Web. Another example of using low-cost (PC) computing technologies to deliver fully interactive VR representations of CFD processes was supported by the UK's Health & Safety Executive. This project assessed the design of chemistry laboratory fume cupboard handles and their effect on the propagation of potentially harmful particles back into the laboratory and towards the working scientists (Figure 8).

As with large-scale engineering today, ongoing developments in micro-, even nano-engineering will establish VR as a *de facto* standard in the provision of advanced interfaces for scientists and engineers, delivering a new form of telepresence for the manufacture, inspection, assembly and operation of miniature systems for such pioneering applications as microsurgery and biotechnology.

4.3. Defence

Defence establishments and military forces across the globe — already home to many of the world's human factors specialists — have long been exploiters of VR technology (or "synthetic environments," to use military phraseology), primarily in large-scale simulators designed for such activities as operations planning, war gaming, command–control–communications and intelligence (C^3I) and, of course, tri-service pilot, navigator and driver training. However, this exploitation has, of recent years, extended to part-task or "off-mission" activities, such as those military trainers which endow basic CAD or VR models of military platform subsystems with realistic behaviors, thereby enhancing the training of such procedures as maintenance, fault-finding and refit. VR has been developed to create realistic military environments for such tasks as helicopter machine gun training, parachuting experience, explosive ordnance disposal, naval helicopter deck landing, submarine and surface ship blind piloting, officer of the watch training, etc. Also, as weapons platforms become more advanced, the inevitable reduction in real systems available for training means that computer-based lessons, many featuring VR, will become an essential tool of the military classroom. Nowhere is this problem more acute than is the case with future submarines. Here, smaller fleets will spend much more time at sea and less time in dock at the disposal of the inexperienced naval rating. The need for VR classroom trainers to familiarize the incoming ratings with submarine systems and layouts is incontestable. Furthermore, the success of networked simulators, courtesy of pioneering initiatives such as distributed interactive simulation (DIS; Smart 1998), brings a major new dimension to military VR trainers. For example, networked VR allows geographically remote infantry personnel to train together in a shared virtual theatre of campaign, acting as a single, coordinated battalion, complete with fighting vehicle back-up and other hardware support. It also provides the classroom educator with an important practical tool for assigning tasks and responsibilities to individual or collaborating trainees, not to mention providing a more quantifiable method of assessing the extent of trainees' learning.

Figure 9. Minimally invasive surgical trainer (MIST) in use. Courtesy Virtual Presence.

Figure 10. VR for retail space planning and consumer behavior assessment. Courtesy Virtual Presence and Nestlé.

4.4. Medical and Surgical Applications

The recent major advances in computing technology have delivered the means to construct sophisticated and comprehensive anatomical and physiological simulations of the human body. From the digital reconstruction of microtomed bodies of executed convicts (e.g. the Visible Human Project: http://www.nlm.nih.gov/pubs/factsheets/ visible_human.html) to speculative deformable models of various organs and vascular systems, the quest to deliver comprehensive "virtual humans" using dynamic visual, tactile, auditory and even olfactory data goes on and on. Yet, with one or two exceptions, the uptake of these simulations by surgical research and teaching organizations has been poor. One cannot attribute this failure to a lack of technological appreciation or foresight on the part of individual specialists or administrators within the target user organizations. The poor uptake actually stems from an equally poor understanding — sometimes on the part of simulation developers — of the medical needs and ergonomic requirements of the surgical users and trainees. Furthermore, it is all to often easy to forget that most medical organizations simply cannot justify the excessive initial costs of so-called graphics "supercomputers" — not to mention crippling annual maintenance charges, depreciation and, in today's rapidly changing IT world, rapid technological redundancy.

Figure 11. Sunrise over a virtual Stonehenge. Courtesy Virtual Presence and English Heritage.

The prohibitive costs and technological difficulties of implementing a surgical trainer based on comprehensive virtual humans using dynamic visual, tactile, auditory and even olfactory data have prompted a number of VR proponents to carry out a radical rethink of their methodological approaches. One example of such a rethink, MIST (Minimally Invasive Surgical Trainer), evolved from a comprehensive in-theatre task analysis. MIST is a British PC-based "keyhole" surgical trainer that uses commercial VR and database software to foster and document trainees' acquisition of minimally invasive surgery skills (Gallagher *et al.* 1998, Taffinder *et al.* 1998). In stark contrast to those expensive simulators that attempt to generate high-fidelity anatomical images, MIST (Figure 9) presents the trainees with simple geometric tasks that extrapolate to those surgical procedures evident in theatre (e.g. clamping, diathermy, tissue sectioning, etc.).

At the time of writing, numerous medical and academic institutions are revisiting the controversial topic of surgical training and assessment. It will not be long before the VR and human factors communities witness an influx of training and evaluation systems, each claiming to be able to deliver objective measures of surgeons' dexterity performance and skill levels. Each claim will need to be assessed on its own merits and care will need to be taken in defining exactly *what* is being measured. The issue of transfer of training (from the virtual to the real), as discussed below, is one of the major research opportunities for human factors and VR specialists alike, especially in the demanding arena of medicine and surgery. Human factors specialists interested in researching these opportunities are recommended to read the excellent collections of papers in Westwood *et al.* (1998, 1999).

4.5. Retail

In the retail arena, it is now accepted that VR is totally capable of eliminating the need to build full- or part-scale models for ergonomic, "visual impact" and usability assessment, be they models of individual products, concept shelf and storage designs, or even complete stores (Figure 10). By avoiding the wasteful use of materials in the iterative construction, modification and reconstruction of product and packaging examples, VR has, unintentionally, become an environmentally friendly technology — one that some market research organizations and many leading retail and "brand name" companies are keen to exploit. For example, studies have already shown the cost-effective nature of VR in assessing consumer behavior in immersive supermarket and domestic settings. Unlike conventional assessment practice, whereby supermarket areas have to be cordoned off (a very costly practice), or cumbersome eye tracking equipment has to be deployed in-store, VR trials can be set up almost anywhere.

4.6. Heritage

There has been a strong international growth of interest in the prospect of using VR to recreate historic sites and events for such purposes as education, special project commissions and showcase features at national and World Heritage visitor centers (Figure 12; Virtual Heritage: http://www.geocities.com/Athens/Acropolis/5014/vh-6.html). To use just some of the words put forward in the early 1990s by two Nynex researchers — Rory Stuart and John Thomas — VR can give the general public access to places

and things not normally accessible, to explore objects and experience events that could not normally be explored without "alterations of scale or time," to interact with remote communities and to interact with virtual (historical) actors. In the context of heritage, VR goes much further, however, in that it offers a means of protecting the fragile state of some sites and can help educate visitors not so much about their history, but in how to explore, interpret and *respect* them. For example, VR can display the potential damage caused by the ravages of human intervention and pollution by accelerating the simulated destructive effects to monuments, even large areas of land and sea, over short periods.

5. THE FUTURE FOR VR AND ERGONOMICS

It should be appreciated that VR is not just a suite of tools capable of delivering radically new design and evaluation techniques to the engineering, design or human factors practitioners involved in projects such as those presented above. It is also a technology with its own genre of ergonomics *needs*. At the outset the need for sensible implementation of VR facilities based on sound ergonomics principles was stressed. However, therein lies a problem.

Apart from one specific public domain summary publication by Wickens *et al.* (1989), with some reference to 3D in the likes of Boff and Lincoln (1988) and Farrell and Booth (1984), there have been no serious attempts to produce practical guidelines — suitable for application in real industrial settings — for the design and assessment of VR or interactive 3D visualization systems. Most of the available books on VR are of little practical use and date very quickly. A substantial chapter (Chapter 52) exists in the well-known Salvendy *Handbook* (1997), although again one has to question the practical use of its contents. International efforts to develop a Handbook of Virtual Environments are, at the time of writing, being coordinated by the University of Central Florida, which will include quite an extensive coverage of usability issues.

As VR matures, so its accelerated uptake by industry and commerce will depend on the provision of hard (financially supported) case study material and the availability of practical guidelines and techniques for assessing user performance and application relevance. As far as the former issue (case study material) is concerned, there are now examples which can be used to help overcome the initial barriers to adopting VR by companies large and small. As far as the latter issue is concerned, in my view, there are three key areas (research opportunities, even) that are currently lacking in the pursuit of human factors excellence for the industrial and commercial application of VR.

5.1. Measures/Metrics of Situational Awareness

Situational Awareness (sometimes referred to as *spatial* awareness) is a general term that refers to several aspects of human performance in a real or synthetic environment. The key components contributing to a VR participant's awareness of a situation include:

- Judgement/perception of one's own position relative to the world and objects therein ("egocentricity").
- Overall comprehension of the current situation.
- Projection of future status.

As part of a methodological approach to assess operators'

performance and the transfer of training from the virtual to the real environment, situational awareness (SA) measures can be developed, based around reasonably established US and UK developments, such as the Situational Awareness Global Assessment Technique, SAGAT (Endsley 1995a, b), and the Situational Awareness Rating Technique, SART (Taylor 1990).

The SA measure development and test procedure should involve a classification of the tasks expected of the operators (e.g. based around Wehrend's task decomposition approach, as contained in Keller and Keller 1993) leading to a specification and application of:

- the most appropriate pretraining indices of trainees' propensities to adapt to VR, including cognitive style (e.g. Group Embedded Figures), mental rotation qualities (e.g. Shepard and Metzler 1971) and experiential factors. Note that Parker and Harm (1992) proposed that an individual's mental rotation capabilities are important for the reduction of motion sickness and for the fostering of competent performance (navigation and interaction) in and with virtual environments;
- within-training indices (cognitive mapping, spatial awareness, object-relation/path recall); and
- post-training validation of SA and adaptation techniques, correlated with standard acceptance test measures and mental workload (e.g. using the NASA Task Load Index, TLX).

5.2. Transfer of Training

"Attention comes first, learning after attention is focused. And learning is primarily action …." (Dewey *et al.*, in Bricken 1991)

"The most important principle of classroom activity design is that the students' actions determine what will be learned…." (Walker, in Bricken 1991)

The most important three words in these quotes are attention, action and learning. By its very nature, VR is an attention-grabbing medium. A VR stand at an exhibition, be it focused on engineering, heritage or education, attracts the interest of individuals of all ages and from all walks of life. The real-time nature of VR and its capability to represent aspects of real and conceptual worlds are appealing to many people, especially those who would not normally have the opportunity to experience such worlds. Again by its very nature, *VR demands interaction*. It is not a passive medium, as one might find with conventional learning and presentational media — "chalk-and-talk," slides, overheads, videos, etc. The user is, within certain constraints, free to explore and interact with objects in the virtual environment. This freedom is believed by many to help enhance trainees' *intrinsic motivation*, thereby improving their learning (retention) and subsequent real-world performance (see also the comments under situational awareness).

A classic example of the efficacy of VR in training future factory workers on manufacturing lines which use human operators in the supervision of industrial robots is a study carried out by Motorola, in conjunction with Adams Consulting Group in the USA. The production line in question, which was recreated in VR for both desktop and immersive presentation to test subjects, was Motorola's Pager Robotic Assembly Line. When

comparing the performance of those trainees who had exposure to the VR set-up with those who trained using real equipment in the laboratory, the results of the trials (while not subjected to any significance testing, due to the small sample sizes; seven in each group) suggest that VR trainees learn faster and make fewer errors.

Projects addressing the advantages of virtual environments in the human acquisition of spatial information are also a topic of study within the VR laboratories of the Massachusetts Institute of Technology. MIT's *SPLOC* (Spatial Location) program was designed to address the transfer of spatial knowledge from virtual to real spaces and to provide guidelines on stimulus simplification routines (to take account of real-time limitations of a variety of computer platforms) without incurring performance penalties in spatial navigation performance. In addition, *SPLOC* aims to advise on the augmentation of simplistic virtual worlds using other technologies (e.g. multimedia, basic audio-visual image inserts). One of the key applications generating information of use to the *SPLOC* program is a submarine Officer of the Deck (OOD) simulator which enables trainees to guide a submarine into dock using a range of display formats, from actual bridge views to plan position displays and virtual "binoculars."

It may be of interest to note here that specific experimental design guidelines for training effectiveness and training transfer have been attempted by Meister (1985, 1986, AIAA 1993).

5.3. Health and Safety Issues

Since the beginning of the spread in the uptake of VR technologies in the early 1990s, there have been anecdotal reports and limited academic research results which suggest the existence of serious side effects associated with prolonged immersion in a virtual environment. This, coupled with fierce debate on longer-term consequences, has captured the attention of potential VR users, not to mention the press. In a number of cases VR or "cyber-" sickness, as it has been called, has been listed as *the* major barrier to adoption for many commercial organizations. While the situation is still less than satisfactory — very few unambiguous or constructive guidelines have resulted from R&D programs — the quality of investigation has improved steadily since 1995.

One key issue is that there are significant individual differences in the nature of the symptom(s) reported, the severity of the report and the time of onset. The important work by Kolasinski (1995) summarizes many of these differences. For example, it is claimed that any symptom that is likely to occur will do so within 10 min from the start of immersion, with the severity increasing thereafter. It has sometimes been stated that individuals (e.g. pilots) with real-world experience of the tasks used in the design of simulators (for training, design, prototyping, etc.) are also those most susceptible to sickness when performing in the virtual "reconstruction." Some VR users who experience repeated exposure to virtual environments (an initial 15–30 min with a second exposure occurring within 2–3 days) adapt well to those environments, with an accompanying reduction in the incidence of sickness reports. Postural instability ("ataxia"), measured before and after an immersive VR experience is considered by some researchers to be one of the more important indicators of disorientation and possible malaise.

Human factors researchers intending to conduct experiments into VR-induced malaise should be aware that any observed or recorded effect can be caused by a combination of factors as well as those attributed to individual differences. These include how well the VR system has been set up, the content of the target virtual world, the degree of interaction expected of the subjects and the nature of the task being undertaken. Another frustrating problem is that *specific* conclusions drawn using a VR system procured today may well be of little value to industrial users. The results may well be invalidated with 2–3 months, typically as a result of the launch of new head-mounted displays (with higher resolution and wider-field optics), faster graphics cards supporting more photorealistic environments, higher-quality interactive control devices, etc.

The VR and human factors communities are still attempting to implement and validate both subjective *and* objective methods of recording VR users' performance, susceptibility to sickness and general well-being. Among the *objective* methods currently being researched are eye/head motion tracking and playback, brain activity (electroencephalography, EEG), muscle activity (electromyography, EMG) and gastric activity (using electrogastrograms, EGG). While many of these techniques are beginning to yield interesting results, they are not yet available in a form that supports their effective application in industrial settings. Among the more commonly referenced subjective measures available are pen-and-paper questionnaires, such as the Simulator Sickness Questionnaire (SSQ; Kennedy *et al.* 1993), the Motion Sickness Questionnaire (MSQ; Reason and Brand 1975), General/Specific "Self Efficacy" (G/SSE) Questionnaires, NASA's Task Load Index (TLX) measure of mental workload, and so on. Although a good number of these measures can be applied pre-, during and post-immersion in their "raw" form, it has to be recommended that they are reviewed before use, with the aim of tailoring their contents to the target VR application.

Until more in-depth and longitudinal studies of within or post-immersion effects are announced, one can only recommend caution (and, to a certain extent, common sense) when setting up an in-house VR facility, be it for academic or industrial use. Practical guidelines are available, such as those published by the author (Stone 1998) and by the naval Training Systems Center in Orlando (NAVTRASYSCEN 1988; Stanney *et al.* 1997). These go some way to helping VR-equipped organizations satisfy their in-house health and safety inspectors that the subject is being taken seriously.

There are those in the industrial and VR market sectors who may well be critical of research projects attempting to quantify the extent of VR-induced malaise. Nevertheless, academic researchers should take heart by the fact that, even though their objective and subjective measures of performance may not correlate well with symptoms or expressions of sickness, they are nonetheless contributing to an ever-growing library of good, basic applied psychology data and documented human factors experiences.

6. CONCLUSIONS

The successful adoption of VR technologies into organizations, be it for commercial gain, for streamlining operational procedures, or even basic education is not just a case of trying to impress potential users with the capabilities of an exciting technology. Understanding the needs and characteristics of the individual user and his or her organization is essential to the future development of VR as a stable form of information technology. It

is all-too-easy (even for qualified human factors specialists) to fall into the trap of striving for visual excellence at the expense of usability and content, not to mention losing sight of the needs of the user organization. For example:

many developers (especially in the human factors field) believe that one effect brought about by the existence of advanced [VR] hardware and software technologies has been a reduction in the application of scientific rigour to the design of human–system interfaces. Suddenly, reasonably user-friendly software tools have become readily available which have, in some cases, permitted the designers of information displays to "go to town" in their design approach. The result? "3D works of art" — visually impressive interface formats — but of questionable usability. The drive for visual impact appears to have over-shadowed the crucial issue of concentrating on the underpinning human factors issues surrounding the need for sophisticated 3D display formats …. (Stone 1997)

It should always be borne in mind that VR is, first and foremost, a suite of technologies which provides the ergonomics and human factors community with a "toolkit" for optimizing the design of the human–system interface for numerous applications. Ergonomics, sometimes (ignorantly) underrated as a technological field of endeavor, has a significant contribution to make to the development of VR into the next Millennium. Not just as a means of alerting VR users to negative and sometimes scare-mongering issues, such as the potential side effects of immersion, but in the development of methodologies to measure and report the positive effects of applying this exciting human-centered technology throughout industry. Human factors, or ergonomics, is often defined as the study of the relationship between the human and his or her working environment. It should make no difference whatsoever if that working environment is real or virtual.

VR Technology for Ergonomics Design

R.H.Y. So

Human Performance and Virtual Reality Laboratory, Department of
Industrial Engineering and Engineering Management, Hong Kong
University of Science and Technology, Kowloon, Hong Kong

1. INTRODUCTION

Here, a specific technology, namely virtual reality (VR), will be introduced with an emphasis on its applications in ergonomics design.

The word "ergonomics" has its roots in the Greek language and it can be defined as the "natural laws of work." For human beings the most natural way to select field-of-view is by turning our heads. When viewing conventional monitor displays, users cannot fully utilize this "natural" capability. When the displays are used to present two-dimensional (2D) materials such as text, graphs and charts, the loss of "head-pointing" capability does not affect the performance and the satisfaction levels of the viewers. However, when presenting three-dimensional (3D) graphics simulation, the lack of "head-pointing" can degrade the sense of realism and, hence, reduce the satisfaction levels of the viewers (e.g. in a driving simulator). Examples of applications with 3D graphics include computer-aided designs (CAD), interactive digital tours and training simulations. With VR display systems, the ability to select the field-of-view using head movements has been retained. A typical VR display system consists of a head-mounted display (HMD) and a head position tracking system. As the viewer turns his/her head, the orientation of the head is measured so that images presented on the HMD can be updated according to the head-pointing angle. In other words, the viewer can select the field-of-view by turning his/her head. This VR display enables the viewer to view and "immerse" into a visual environment generated by a computer. Not surprisingly, in the early days of VR displays, they have been referred to as "visually-coupled" displays. A user wearing a commercially available HMD is shown in Figure 1. With an HMD, stereoscopic images can also be presented. One of the earliest VR displays was developed in 1968 by I.E. Sunderlands in the USA.

Figure 1. A user wearing a head-mounted display.

Since then, the technology has advanced rapidly. Even as this chapter is being written, break-through in high-resolution displays, haptics interfaces and 3D audio interfaces are taking place. This chapter would be of limited use if the author focused only on the capability of the current VR technology. Therefore, the focus will be on the fundamental promises of VR technology and their contributions towards better tools for designers, ergonomists and engineers to design more user-friendly and safer products, equipment, workplaces and living environments.

Below will be explained the fundamentals of VR systems (Section 1.2) and ergonomics designs (Section 1.3) so that readers will have a clear picture about the needs and issues concerning ergonomics design and the capability of VR technology. A summary of typical procedures for conducting ergonomics design is then presented. This is then followed by a discussion on how VR technology can complement existing computer-aided tools and offer added values. Examples of current VR tools are sited and this chapter concludes with a suggested approach towards developing a comprehensive VR tool for ergonomics design.

2. FUNDAMENTALS OF VR SYSTEMS

2.1. Brief History of VR Technology

HMD technology was originally developed to improve interactions between US Air Force pilots and their flight control and weapon delivery systems. One of the earlier HMD prototypes, the Visually Coupled Air-borne Simulation System (VCASS), can be found in the Research Laboratory at the Wright-Patterson Air Force Base at Dayton, Ohio. This HMD used cathode ray tube (CRT) technology and is quite bulky. With the use of liquid crystal display (LCD) technology, the size and the weight of a HMD have been significantly reduced. Researchers at the NASA Ames Research Center in California were among the first to apply LCD technology to the construction of HMD. As the HMD technology becomes mature, VR displays find their way into the non-military market (e.g. the game and entertainment industry, and the engineering design industry).

2.2. Types of VR Systems

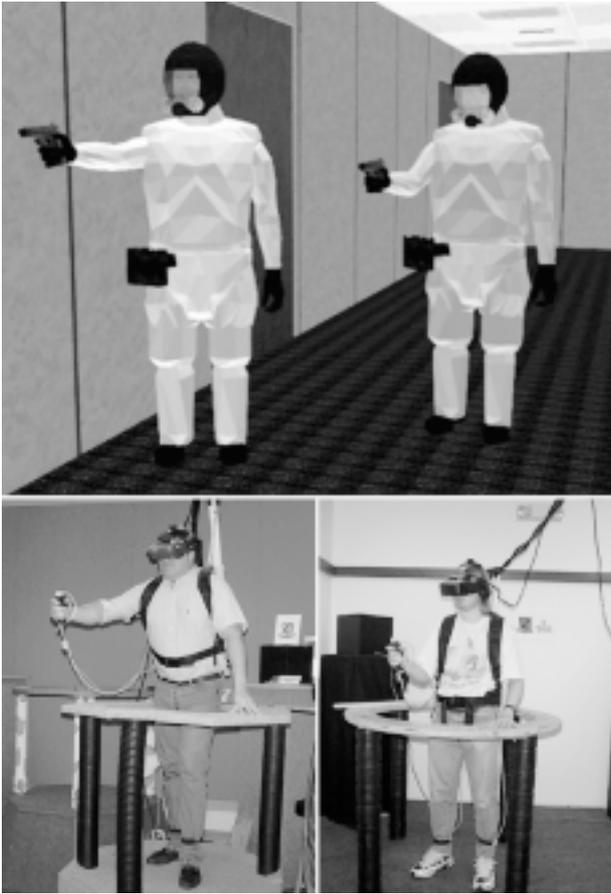
In general, VR systems can be classified into four categories: (1) immersive VR; (2) desktop VR; (3) augmented VR; and (4) quick-time VR systems. Although there are overlapping areas among these categories, each does have its own unique characteristics. Most VR flight simulators developed for the military belong to the category of immersive VR. This type of VR system requires some sort of surround displays such as a HMD or a CAVE™ (a surround projection system developed at the University of Illinois). Users can view computer-generated images appropriate to their head positions and orientations. In other words, head positions are tracked in immersive VR applications. Besides a head-tracking system, special input devices translate natural body movement into control commands. One example is the use of CyberGlove™ to measure and use the position and gesture of the hands to control the direction of navigation. Other examples include the use of a modified treadmill and hand-held joysticks with position sensors attached. Examples of immersive VR applications are found in many entertainment theme parks (e.g. Disney World). At the Institute of Simulation and Training, University of Central Florida, a multi-user immersive VR system with two HMD has been developed. Two users can "enter" the


Figure 2. Two physically separated trainees practicing team mission procedures in a shared VE using the Fully Immersive Team Training (FITT) research system. FITT was developed by the US Army Research Institute for the Behavioral and Social Sciences and the University of Central Florida's Institute for Simulation and Training (courtesy of the IST, UCF).

same computer-generated environment and interact with each other as well as with animated manikins. Magnetic position sensors are put on the users' bodies and limbs so that the computer can track the body movements and recreate them and their effects within the computer-generated virtual environment (VE). Also, by stepping on the same spot, users can instruct the computer-generated virtual bodies to walk. This system is used for training purposes and the Army Research Institute has been the sponsor of this project (Figure 2). In Stuttgart, Germany, a CAVE™ display presents actual sized computer models of motor proto-types so that designers can visualize their designs and make appropriate changes.

In desktop VR systems, graphics with 3D perspective cue are presented on a monitor display. Navigation is done through conventional computer input devices (e.g. a PC mouse). Examples of desktop VR applications written in Virtual Reality Mark-up Language (VRML) can be readily found on the Internet. With desktop VR systems, no head-tracking is involved and viewers cannot select their field-of-views with head movements. Figure 3 illustrates two viewers watching a desktop VR system in stereo through two pairs of shutter-glasses™. Graphic images for the

Figure 3. Two users viewing a desktop VR system in stereo, each wearing a pair of shutter-glasses™.

left and the right eyes are presented alternatively on the monitor and the shuttering filters on the shutter-glass™ are synchronized with the presentation so that appropriate images are shown to each eye alternately.

In immersive VR systems with HMD, HMD are usually non-see-through. In other words, users cannot view the outside world when they are watching images generated by the computers. In augmented VR applications, HMD with see-through capability are used. The working principle is similar to that of a head-up display in which computer-generated images are displayed on top of the outside world. This is a very specific application of VR technology and is mostly used in manufacturing industry where computer-generated markers are spatially over-laid on top of some real objects. Head-tracking is usually required to maintain the correct spatial positions of the computer-generated markers. Augmented VR has long been used in the military for target acquisition (Barfield and Furness 1995).

Quick-time VR, originally developed by the Apple Computer Ltd, refers to the use of digitized photographs to generate a VE in which users can select their field-of-views. Currently, head-tracking is not used in most quick-time VR systems. Navigation with the quick-time VR environment is normally performed using a PC mouse. Details of this technology are on the World Wide Web using quick-time VR as a search word. A series of pictures is taken from a set of predetermined viewpoints and a special browser allows users to navigate through the pictures as if they are watching a movie. Special technologies to compensate for the camera distortion and mismatches between consecutive photographs are applied so that the "movie" will appear smoothly. The quick-time VR technology is mostly used in 3D cataloging and Web-based advertisements.

In the following sections the author explores how immersive and desktop VR systems can help in ergonomics design.

2.3. Uniqueness of VR Systems

To explore how VR technology can help in ergonomics design, it would be helpful to understand the uniqueness of VR technology. As described above, one of the most powerful features of a VR system is its ability to surround users with a computer-generated 3D visual environment (VE) in which users can interact with images in real-time. This visual environment can be further

enhanced by the presentation of 3D audio information carrying the correct spatial characteristics. An example would be a virtual construction site in which users experience the visual environment of working at height and also relying on their hearing to detect any dangers around them. Besides visual and audio interfaces, the third useful interface in VR systems is the haptics and thermal display. Appropriate force, vibration and thermal energy can be applied to the users' bodies and limbs. Although the current technology for haptics interfaces has not matured yet, future VR systems will certainly have these capabilities. In recent years, research on computer-controlled olfactory interfaces has also been emerging.

3. FUNDAMENTALS OF ERGONOMICS DESIGN

3.1. Types of Ergonomics Design

Readers should find ample information concerning ergonomics design in the encyclopedia or in *Ergonomics Design for People at Work* (Eastman Kodak 1986). The author does not intend to duplicate the effort here. Rather, this section will classify the types of ergonomics design from a practitioner's point-of-view so that readers can appreciate the challenge of ergonomics design and how VR technology can help.

The aim of ergonomics design is to design products, equipment, workspaces, environments and tasks so that they will fit the users. In general, the focuses of ergonomics design can be divided into three main categories: (1) workspace and environment design; (2) task flow and equipment design; and (3) workload and work patterns design.

3.2. Conventional and Computer-aided Methods for Ergonomics Design

In the first category, workspace and environmental design, the objectives are to keep (1) the users in comfortable body postures and (2) their sensory channels (e.g. vision and hearing) free from unnecessary and harmful disturbances. The conventional methods to achieve these objectives include the measurement of users' body dimensions (i.e. anthropometric data), application of workstation design guidelines, measurement of the environmental stressors (e.g. vibration, temperature, noise), and reduction of stressors if they exceed their relevant standards and limits. With the advances in computing technology, CAD packages for workspace design are available. Besides the general facility and product design tools like AutoCAD, 3D Studio and ArchiDesign, some software has built-in manikins that are sized according to an anthropometric database. Examples of such software include JACK, ManneQuin_Pro, SAFEWORK and MASoft. In designing a user-friendly product, the physical properties of the materials can be of importance. CAD packages that will simulate the physical properties of materials (e.g. Working Model 3D) and perform finite element analyses (e.g. ANSYS) are available. Concerning the reduction of environmental stressors, programs to compare the measured data with relevant standards and threshold limits are also readily available. At the Army Research Laboratory in the USA, a research group under Dr G.R. Price has developed a computer model of the ear to predict hazards from intense sound. With this program, animation of how a cochlea responds to a sound impulse can also be seen. At the Ruhr-Universitaet, Bochum, Germany, Professor J. Blauert has developed computer programs to simulate the acoustics properties of concert halls. Listeners can select the seating position and hear the simulated acoustic effect of an orchestra performing on the stage. In the Computer Aided Systems Human Engineering Performance Visualization System (CASHE) developed by the Crew System Ergonomics Information Analysis Center, Dayton, Ohio, a series of on-line test benches is available for users to see and hear simulated effects of display vibration, image flickering, speech degradation and hearing loss.

In the second category, task flow and equipment design, the objective is to optimize the logistics flow of information and materials so that a task can be completed efficiently and comfortably. Ergonomists have been tackling this problem by matching mental models of the operators with the actual workflow and patterns of equipment usage. In the field of work flow and work process optimization, the simple method and time study remains a popular technique. Computer simulation software such as ARENA, Pro-model, SimWork and Micro-Saints can identify the critical elements within a workflow that need attention. Currently, with the exception of Micro-Saints, neither ARENA nor Pro-model includes a database of predetermined human capability. To fill this gap, MODAPTS PLUS can be used to determine a reasonable cycle time for a given work sequence before conducting the work flow simulation.

In the third category, work load and work pattern design, the aim is to design the task requirement and schedule so that the persons involved can fulfill the task without hurting themselves. Specific objectives will depend on the exact nature of the tasks. For example, if the task is of a repetitive nature, one of the objectives must be to minimize the risk of cumulative trauma disorders (CTD) to the workers. If the task involves the handling of heavy materials, then the objective would be to minimize the risk of muscle and spine injury. Likewise, other objectives would include proper shift scheduling to maintain workers' vigilance and proper training so that the task requirement will be lower than the workers' capability. Conventional methods to conduct ergonomics assessment rely heavily on the expertise of the ergonomist and the published data concerning the physical and psychological limits of humans. Although computer programs are available for individual design procedures such as task analysis (e.g. Micro-Saint) and heart rate analysis (e.g. Polar software), the author has yet to find a comprehensive software that can assess multiple ergonomics risks involved in a given task. Currently, software is available to analyze and predict the loading on the spine as functions of weights and lifting postures (e.g. ManneQuin_Pro). Also, an extension of MODAPTS PLUS software can analyze the repetitive nature of a work sequence and offer predictions concerning potential muscle-skeletal injury.

4. PROMISES AND USES OF VR TOOLS IN ERGONOMICS DESIGN

4.1. Summary of the Current Process of Conducting Ergonomics Design

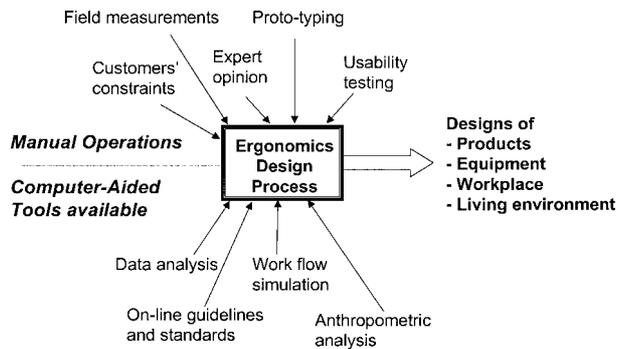
To assess and appreciate the benefits of VR technology for ergonomics design, the inadequacy of current computer-aided tools are explored. The current process of ergonomics design comprises field measurements, proto-typing, usability testing, expert opinion solicitation, guidelines and standards solicitation, computer simulation, and customer survey. An illustration of this


Figure 4. Information flow during a typical ergonomics design process.

process is shown in Figure 4. This generalized process applies to the design of products, equipment, workspaces and living environments. Currently, individual computer-aided tools can conduct simulation, on-line guidelines and standards search, and analyses of field data. Although some computer-aided tools have multiple functions (e.g. CASHE: both simulation and guideline search), comprehensive computer-aided tools for conducting ergonomics design are rare. The author believes that VR technology can help the integration of individual computer-aided ergonomics design tools. For a more academic examination of this subject, see Wilson (1997).

4.2. Benefits and Limitations of VR Technology

VR technology offers a natural way for designers, end-users and future maintenance workers to interact with designs of products, equipment and workplaces. However, the author would like to stress that VR alone could not and would not provide a comprehensive solution for ergonomics design. A combination of VR interfaces, existing knowledge databases, simulation algorithms and data analysis software is needed for the formulation of a comprehensive solution for ergonomists and designers. When this is achieved, computers would be able to perform design procedures that were previously labor intensive (e.g. the conventional procedure of physical proto-typing can be replaced by digital proto-typing). This is not to say that humans can be taken out of the design loop, but that humans can have more time to think creatively while the VR tools handle the more routine design procedures.

An inspection of Figure 4 shows that conventional use of computers in the design process has been biased towards mathematical computations (e.g. data analyses and simulation) and data storage and retrieval (e.g. guidelines and standards). Neither of those requires much real-time interactivity between humans and computers. This phenomenon is understandable since, traditionally, computers have always been used as number-crunching machines (e.g. mainframes and Cray supercomputers). Only in recent years has graphics simulation become important (e.g. Silicon Graphics workstation). As explained above, immersive VR technology offers a natural way for users to interact with computers through their visual, audio and tactile interfaces. As a result, design processes like proto-typing, usability testing and simulation of field data (e.g. noise) can now be implemented as part of an immersive VR simulation. When these previously non-computer-aided processes are featured in the same computer

application with conventional features like on-line ergonomics guidelines and workflow simulation, a comprehensive VR tool for ergonomics design is born. As one could easily imagine, the integration of all these features in a user friendly way is itself a huge ergonomics design challenge! However, positive steps have already been taken at many VR and ergonomics research laboratories throughout the world. In the next section, the author will browse through some examples of existing VR tools for ergonomics design.

4.3. Examples of VR Tools for Ergonomics Design

In the USA, a VR design tool for digital prototyping called "Working Model 3D" (from MCE software) has been developed on the Window 95/NT platform. This tool can simulate the physical properties of mechanical parts so that design engineers can test and visualize the mechanical properties of their prototypes (www.mcesoft.com). Within this VR simulation environment, computer-generated objects can move, slide and collide with each other. At the Department of Mechanical Engineering, University of Wisconsin-Madison, a desktop VR tool called "Virtual Design Studio, VDS" has been developed for the design of mechanical and electromechanical components (icarve.me.wisc.edu). This VDS uses shutter-glasses™ to present stereo images and can take voice commands from the designers. At the Bosch research laboratory in North America, a 3D graphical design tool called MASoft 3D has been developed for workspace design (www.boschautomation.com). This MASoft 3D is similar to the ManneQuin_Pro (www.nexgenergo.com) where scalable manikins can be inserted into a workspace design for anthropometric analyses. CadPLUS" Products Co. in the USA has a range of software products for facility layout, and mechanical system design. To benefit from desktop VR technology, a VR module called CadPLUS" VR Flyer™ has been developed. This module allows the viewers to navigate through the CAD models in real-time (www.cadplus.com). At the University of Alberta, Canada, a VR authoring tool called Minimal Reality (MR) is available at no cost to educational establishments so as to promote research and development in VR applications. A group of researchers at the Human Interface Laboratory, University of Washington, utilize augmented VR technology to assist patients of Parkinson's disease to walk normally (ww.hitl.washington.edu).

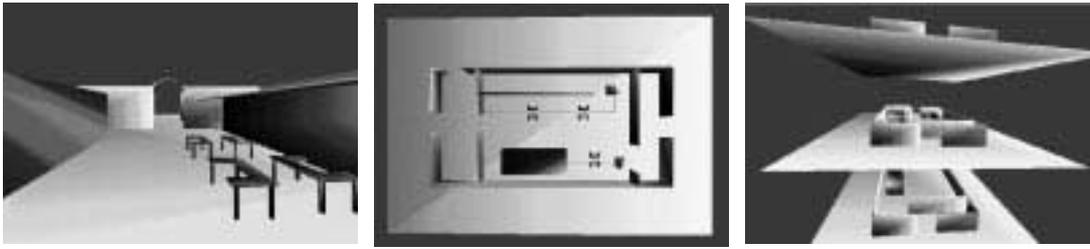
In Europe, the Engineering Link (formerly part of British Rail) at Derby, UK, has used Superscape (a PC-based VR authoring tool) to develop a desktop VR tool to design the interior carriages of a train (www.superscape.com). This tool enables engineers and designers to check the access for wheelchairs, and catering trolleys. At the VIRART center, University of Nottingham, UK, a VR design tool has been developed for the Nottinghamshire Social Services Department to assess houses and flats for their suitability for wheelchair access (www.nottingham.ac.uk/meom). Professor Robert Stone, based in Manchester, UK, has used immersive VR technology to help a company called Airline Services to visualize and market interior design of airplane cabins. As can be seen in ManneQuin_Pro, SAFEWORK and MASoft, the availability of scalable manikins enhances the usefulness of VR ergonomics tools. At the School of Psychology, Cardiff University, UK, research efforts have been focused on the development and use of virtual


Figure 5. VR computer-aided design tool for multi-floor factory design. The tool was developed at the Hong Kong University of Science and Technology.

manikins in VR design environments (www.cf.ac.uk). A series of case studies concerning how VR technology has helped the industry in the UK to design products and facilities can be found at www.ukvrforum.org.uk. Examples include the design of a nuclear plant control room and an offshore oil platform. In view of the needs for a more comprehensive VR tool for ergonomics design, the center for VE at the University of Salford, UK, has developed an Interactive Product Simulation Environment for Assessing Assembly and Maintainability Tasks (IPSAM). Details can be found at www.salford.ac.uk/cve. At the Department of Civil Engineering, University of Strathclyde, UK, VR technology has been applied to evaluate benefits of different construction equipment (www.strath.ac.uk). As mentioned above, motor designers in Stuttgart, Germany, are using immersive VR systems to visualize and evaluate their designs. In Sweden, researchers at the Division of Ergonomics and Aerosol Technology, University of Lund utilize VR technology to enhance the cooperation and communication among designers. Their progress can be viewed at www.cw.lu.se

At the Hong Kong University of Science and Technology, a VR CAD package based on the RENDERWARE library (a PC-based VR authoring tool) has been developed to enable designers to layout multi-floor factories (Figure 5). A VR training environment for operating computer numeric control (CNC) milling machines has also been developed to optimize the training procedures of workers (www.ieem.ust.hk). This application is developed using World-Tool-Kit software (a VR authoring tool) and runs on a Silicon Graphics workstation.

5. FINAL REMARKS: TOWARDS A COMPREHENSIVE VR TOOL FOR ERGONOMICS DESIGN

As seen from the examples described above, the scope and capabilities of individual VR tools tend to be limited and specific to one or two applications only. This may have been due to the complexity involved in simulating the real world properties of individual products and environments. For example, in VR tools for mechanical design, complex algorithms are needed to simulate the effects of physical interactions. In interior design applications, special attention is needed to simulate high quality graphics and effects of lighting. In addition, acoustics properties are also important for certain designs such as concert halls and noisy workplaces. In other words, it is difficult to develop a general purpose VR tool that enables users simultaneously to examine multiple ergonomics issues. An alternative and more realistic approach is to develop a base program on which additional testing modules can be added. This base simulation program should perform desktop VR simulation of objects and environments with engineering precision and with simulated Newtonian properties such as gravitational force, reaction force and friction. Examples of add-on modules include immersive VR module for usability testing, acoustics test modules, finite element analysis modules, aesthetic modules (with fine graphics and lighting effects), anthropometry modules and workflow modules. With advances in computational speed and VR technology, we can look forward to a VR tool that can significantly reduce the time taken to make prototypes and conduct usability tests.

Display and Control Design

Auditory Warnings and Displays: Issues Relating to Design and Selection

G. S. Robinson, S. E. Lee and J. G. Casali

Department of Industrial and Systems Engineering, Virginia Polytectonic Institute and State University, Blacksburg, VA 24061, USA

1. INTRODUCTION

Auditory displays, alarms and warnings are ubiquitous in our technologically advanced society. Buzzers in cars tell us that the seatbelt is not fastened or that the headlights are on, gas pumps beep to remind us to pay for our gasoline purchase, and computers prompt us whenever we make a mistake. Although auditory displays permeate nearly every aspect of our lives, few people, including those responsible for the design and selection of such displays, are aware of or consider the many factors that affect the utility of auditory displays and ultimately affect the usability of the systems in which they are implemented. This article will discuss some of the more important factors affecting the design and selection of auditory displays, alarms and warnings. The purpose is strictly introduction; topics will be introduced, and the importance of these issues within the context of system design will be briefly discussed. The discussion is not intended to represent a comprehensive review of the field or serve as a design guide. For more detailed discussions of these issues, see the references cited herein.

2. APPROPRIATENESS OF AUDITORY DISPLAYS

The first question that must be answered when contemplating the use of an auditory display is: "Is an auditory display appropriate for this application?" (as opposed to a visual display or perhaps a speech display). The answer can be complex and depends on several factors, including the message content and complexity, environmental conditions, and the expected workload of the message recipient(s). For example, in situations where lighting conditions are poor or unpredictable or where the operator's visual channel is already fully occupied, an auditory warning would probably be appropriate (Deatherage 1972). In general, an auditory display should be considered when: the message is short, simple and will not be referred to later; when the operator's visual channel is already (over)loaded; when immediate action is required; when the operator's location or the orientation of his/her head is unknown (auditory signals are omnidirectional and omnipresent) or when environmental conditions (darkness or glare) preclude the use of a visual display.

3. MASKING

Perhaps the most important issue related to the design and selection of auditory displays is masking. Even a well-designed auditory alarm, warning or display is useless if it cannot be heard. Masking is defined as an increase in the absolute threshold of one sound, the *masked* sound, caused by another, *masking*, sound (Gales 1979). In industrial situations, the masked sound might be an auditory alarm or warning, speech or a sound produced by a machine (e.g. the sound of a slipping drive belt or chipped gear teeth). Typical masking sounds include engine or motor noise, ventilation or fan noise, conveyor noise, and machine noise. It is also possible for one intentional signal to mask another intentional signal if both are active at the same time. Masking becomes a problem when an intentional or incidental sound conveying useful or important information is rendered inaudible by another sound. Several methods have been proposed for calculating masked thresholds in noise. Two of these methods are briefly described below.

3.1. Critical Band Method

The masked threshold for a tonal signal can be approximated using critical band theory (Fletcher 1940) if the spectrum of the masking noise is sufficiently flat. In many cases, this is a valid assumption and the masked threshold (L_T) can be expressed as:

$$L_T = L_S + 10 \log_{10}(BW),$$

where L_S is the spectrum level of the masking noise in the vicinity of the signal component being considered and BW is the width of the auditory filter centered around the signal component in question.

It is important to note that the spectrum level of the noise as presented in the equation above *is not* the same as the octave band or one-third octave band level measured using a spectrum analyzer. Spectrum level refers to the level per Hz or the level that would be measured if the noise were analyzed using a 1-Hz wide filter. If we assume that the noise is flat within the bandwidth of a one-third octave band filter, for example, then the spectrum level can be estimated using the following equation:

$$L_S = 10 \log \left(\frac{10^{BL/10}}{BW_{1/3}} \right)$$

where L_S is the spectrum level of the noise within the one-third octave band filter, $BW_{1/3}$ is the bandwidth of the one-third octave band filter, calculated by multiplying the center frequency (f_c) of the filter by 0.232 (Beranek 1988), and BL is the noise level measured in the one-third octave band in question.

The bandwidth of the auditory filter can be approximated simply by multiplying the frequency of the masked signal/tone by 0.15 (Patterson 1982, Sorkin 1987). Again, this procedure assumes that the signal being listened for is tonal or has strong tonal components. (If the calculations presented above are to be based on octave band analyses, $BW_{1/1}$ can be found by multiplying the center frequency of the octave band by 0.707.)

3.2. ISO 7731–1986(E)

International Standard 7731-1986(E) (1986) presents methods for calculating the masked threshold for a signal in noise based on broadband as well as octave-band and one-third octave band noise measurements. The general procedure for the full and one-third octave band measurements follow.

- Step 1: Starting at the lowest full or one-third octave band level available, the masked threshold (L_{T1}) for a signal in that band is:

$$L_{T1} = L_{N1},$$

where L_{N1} is the noise level measured in the full or one-third

octave band in question, referred to as *band level* (*BL*) in the preceding example.

- Step 2: For each successive full or one-third octave band filter *n*, the masked threshold ($L_{\mathrm{T}n}$) is the noise level in that band or the masked threshold in the preceding band, less a constant; whichever is *greater*:

$$L_{\mathrm{T}n} = \max (L_{\mathrm{N}n}; L_{\mathrm{T}n-1} - C),$$

where *C* = 7.5 dB for octave band data or 2.5 dB for one-third octave band data.

This procedure, unlike the earlier procedure, takes upward spread of masking into account by comparing the masked threshold in the band in question to the masked threshold in the preceding band. (Upward spread of masking is the phenomena wherein a tonal or band-limited noise will mask sounds at frequencies above the center frequency of the noise in addition to those sounds occurring at the center frequency of the noise.) It is also more adaptable to a wide variety of signals, both tonal and broadband, whereas the previous method assumes a tonal signal.

3.3. Ensuring Audibility

It is important to remember that these calculations represent threshold levels, not the level at which the signal can be reliably heard. It is generally agreed that a signal should be presented 6–15 dB above its masked threshold to ensure audibility (Wilkins and Martin 1982, Sorkin 1987). However, to avoid a startle response, the signal should not exceed its masked threshold by > 25 dB. Furthermore, when alarms are to be presented in high-noise environments, caution should be exercised to ensure that the signal level does not exceed 115 dB to minimize the potential for noise-induced hearing loss (OSHA 1989).

In general, the louder the background noise is relative to a signal, the more difficult it will be to hear the signal. Conversely, if the level of the background noise is reduced or the level of the signal is increased, the masked signal will be easier to hear. Whenever it is possible to do so, it is preferable to reduce the background noise level to reduce masking problems. If reducing the background noise is infeasible or impractical, it may be possible to increase the level of the signals, but close attention must be paid to the resulting sound pressure levels to avoid hearing loss for the listener. Although most off-the-shelf alarms and warning devices have a preset output level, it is possible to increase the effective level of such devices by placing multiple alarms or warning devices throughout the workplace instead of relying on a single centrally located device.

4. INATTENTION

Most laboratory-based masked-threshold experiments are conducted in a manner such that the experimental participants not only expect a specific signal, but are also listening intently for it. While such procedures are useful for determining true detection thresholds, they are not representative of the real world. Workers do not normally sit around waiting for an alarm; instead, they are doing their jobs, concentrating on the task at hand. It is intuitively obvious how someone engrossed in his/her job might fail to notice an auditory alarm that would otherwise be audible. Unfortunately, attention is an extremely difficult variable to

quantify and control in an empirical study. Typically, experimental participants are simply asked to perform some secondary task (e.g. playing a video game or driving a vehicle simulator) while simultaneously performing the listening/detection task. Few such studies have been performed, and the results are contradictory. Some researchers find no difference in detection thresholds (Wilkins and Martin 1982, 1985) while others find significant differences (Fidell 1978).

Some of the factors that can adversely affect the audibility of an auditory display (both in the laboratory and the real world) include the motivation of the listeners, the consequences of a false alarm, the benefits or rewards for a correct response, and fatigue. In laboratory experiments, it is very easy inadvertently to affect a test subject's criteria for deciding when to respond to a signal, thus biasing the results of the experiment. Such experimental artifacts are at least partially responsible for the contradictory results reported in the literature. On-site tests are even more difficult due to the researchers' nearly complete lack of control over the experimental conditions (noise and signal level, workload, etc.). Lacking any truly reliable, quantitative data, the best and most conservative course of action is to assume that workers may not notice an alarm or warning if they are engrossed in their jobs. The usual solution to this problem is to increase the sound pressure level at which the alarm is presented, staying within the guidelines presented earlier.

5. CONTRAST AND COMPLEXITY

In addition to manipulating the levels of the auditory displays, alarms, warnings, and background noise, it is also possible to increase the likelihood of detection of an auditory display or alarm by manipulating its spectrum so that it contrasts with the background noise and other common workplace sounds (Wilkins and Martin 1982). For example, in an environment characterized by high-frequency noise such as sawing or planing operations in a lumber mill, it might be best to select a warning signal with strong low-frequency components, perhaps in the 700–800 Hz range. On the other hand, for low-frequency noise such as might be encountered in the vicinity of large-capacity ventilation fans, the better choice would be an alarm with strong high-frequency components in the 2000–3000 Hz range. Unfortunately, there are no quantifiable guidelines on signal contrast to aid designers in this pursuit.

A concept intimately related to contrast is the spectral and temporal complexity of the signal itself. Simply put, complex signals are more easily detected in noisy environments than are simple tonal signals. There are several reasons why this is so. First, a complex signal with multiple fundamental frequency components and strong harmonic and inharmonic elements is more likely to have at least one component that exceeds the masked threshold in nearly any noise. Furthermore, a complex signal (i.e. a signal possessing multiple frequency components, a periodic or aperiodic temporal pattern, and with modulating frequency and/or amplitude envelopes) contains much more information than is contained in a simple pure tone. The brain can use this additional information in processing the auditory stimulus and will thus be better able to distinguish the desired signal from the background noise. Manipulation of the various acoustic characteristics of a complex auditory signal also allows

for the manipulation of the signal's perceived urgency (discussed below), its contrast with other signals and the background noise, and its attention-getting ability.

6. RECOGNITION AND IDENTIFICATION

Regardless of how well an auditory alarm or warning is designed or how well it contrasts with the background noise and other signals, humans have a limited ability to distinguish one item from a group of N similar items. A basic principle of ergonomics places this number between five and nine, depending on the stimulus (Miller 1956). Patterson (1982) found that individuals could quickly learn the first seven of a set of 10 auditory alarms and could learn the entire set with only 1 h of training. However, just 1 week later, the same individuals recognized, on average, only seven of the 10 alarms. Although recall improved after additional training, Patterson suggested that the number of auditory alarms be limited to seven or eight to avoid confusion and eliminate the need for constant retraining.

7. LOCALIZATION AND SPEED JUDGMENT

In addition to masking an auditory display, alarm or warning, elevated noise levels such as those encountered in typical industrial environments can have a detrimental impact on an individual's ability to localize sound. The brain localizes sounds in space by utilizing subtle phase and intensity differences between the sounds received in each ear (to judge azimuth) as well as the balance between the direct and reflected sound (to judge distance). Speed and movement are judged by changes in the sounds' position over time, the rate of change, and perceived pitch changes as the sound source approaches or recedes. As background noise levels increase, sound sources are judged to be closer to the observer than they actually are. This is because the noise masks the reflected component of the sound reaching the observers' ears (McMurtry and Mershon 1985). Localizing the sound's direction is less affected by the presence of noise. However, if the noise source and signal are co-located or the signal level is not sufficiently above its masked threshold (by ~10–15 dB), then problems in localizing high-frequency signals can occur (Small and Gales 1991).

Why is this important when considering auditory alarms and warnings? Consider the conditions encountered by someone working in a warehouse or factory. For safety reasons, that person must be able to hear an approaching forklift or automatic guided vehicle (AGV). While many such vehicles do have auditory warnings that function when the vehicles are in motion, they can also create considerable noise (an example of a moving alarm co-located with a noise source). The problem is exacerbated if additional background noise sources (e.g. machinery or HVAC noise) are present. Similar situations exist on loading docks. In both scenarios, workers must not only be able to hear the auditory warnings, but also must be able to pinpoint their location with a high degree of accuracy to avoid a potentially catastrophic accident.

8. PERCEIVED URGENCY

Another important factor in the design and selection of auditory warnings is their *perceived urgency*. Problems often arise when the reaction elicited by an alarm does not match the severity of the circumstances related to the alarm. Disruptive alarms can not only draw an operator's attention away from the task at hand, but can also divert attention from an emergency while the operator attends to the alarm. Conversely, disaster could result if an alarm warning of a critical situation were perceived to be routine or unimportant. To alleviate this problem, Patterson (1982) recommends that auditory alarms be differentiated by type: advisory alarms or "attensons," intended to draw the operators' attention to additional information explaining the situation, and immediate action alarms. Furthermore, he suggests that an alarm should be carefully designed or selected so that its perceived urgency matches the urgency of the situation responsible for the alarm.

The problem remains, however, as to which acoustic parameters can be manipulated and how they should be manipulated to achieve a desired level of perceived urgency. Edworthy *et al.* (1991) found that the perceived urgency of a warning signal could be varied in a predictable manner by manipulating signal characteristics such as fundamental frequency, amplitude envelope, harmonic delay, rhythm, speed, pitch range and pitch contour. Haas and Casali (1995) found that perceived urgency increased and reaction time decreased as pulse level increased and inter-pulse interval decreased.

Unfortunately, it is not yet possible to assign a quantitative value of urgency to a given situation and then specify signal parameters so that an appropriate alarm can be designed or an off-the-shelf unit selected (although with continued research, this scenario might someday become a reality). The important thing to remember is that it is not appropriate to use the loudest, most obnoxious alarm available for every situation. Each situation must be carefully considered and the alarm that will elicit the appropriate response selected; good judgment, common sense, and a thorough understanding of the situation should guide this process until quantitative guidelines are available.

9. DISPLAY SETS

In complex systems in which multiple alarms are implemented, the alarms should not be designed independently of one another. Instead, the alarms should designed *as an integrated set*. By doing so, the system designer can optimize, to the extent possible, the acoustic parameters which affect the audibility of the alarms, their perceived urgency, and the contrast of the alarms with one another and any background noise. In addition to optimizing the alarms to the environmental conditions, this approach, if implemented successfully, will have the added benefit of maximizing operator performance by reducing response times and minimizing the possibility of confusion between alarms.

10. AUDITORY ICONS – A NEW CLASS OF AUDITORY DISPLAY

Auditory icons are representational sounds in that they have specific, stereotypical meanings associated with their sound. While traditional auditory displays and alarms are typically defined by their acoustic parameters (e.g. a 1000 Hz tone with a 1 s period and a 50% duty cycle), auditory icons are defined by the objects or actions that created the sounds. (An example application is using the sound of a metal trash can being emptied to convey the action of discarding the items in the "Trash" folder

on a computer.) While auditory icons have been demonstrated to be superior to conventional signals in terms of recognition, there has been little success in implementing them in complex systems. This lack of success is often attributed to a mismatch between the operator's perception of the warning signal and the event the signal is intended to represent. Recent research (Belz *et al.* 1997) has attempted not only to formalize the auditory icon selection process, but also to determine if the use of auditory icons can actually reduce operator response time in critical situations. For example, in simulated driving tasks, auditory icons elicited significantly shorter response times and improved recognition compared to conventional auditory warnings for both front-to-rear and side collision scenarios.

Although auditory icons are promising, they are still a long way from being deployed as displays in real systems. Some of the questions still needing to be answered include: (1) how can the perceived urgency of such sounds be quantified and manipulated?; (2) how will the use of such sounds in "artificial" displays affect a listener's response in situations where the "real" sound occurs? (for example, if a tire skid is used as a collision-avoidance warning in a vehicle, will it have a long-term effect on a driver's reaction, in terms of response time and action taken, when a real tire skid is heard?); (3) will habituation occur and how will this affect a listener's response?; and (4) How will the occurrence of false alarms affect a listener's response and acceptance of the system in which the auditory icon(s) are implemented? These and other questions must be answered before auditory icons can be selected with confidence for use in complex, real-world systems.

11.   SUMMARY

The above discussion was intended to introduce the reader to the complex process of designing and selecting auditory displays. There is more to the process than simply picking a buzzer or horn from an industrial supply catalog. Briefly to recap, when contemplating or implementing auditory displays, warnings or alarms into a workplace or system, caution should be exercised to ensure that:

- an auditory display is appropriate for the application;
- the displays, alarms or warnings will be audible;
- the displays, alarms or warnings are presented at levels sufficiently above their masked threshold to command attention without provoking a startle response;
- the displays, alarms or warnings contrast sufficiently with the background noise and one another;
- the number of different auditory displays, alarms or warnings is appropriate;
- the perceived urgency of the display, alarm or warning is appropriate for the situation; and
- multiple alarms (when used) are designed as an integrated set rather than individually.

Finally, many industrial organizations and consortia have developed standards and/or design guidelines regarding implementation of auditory displays, alarms, and warnings in specific situations or for specific purposes. The American National Standards Institute (ANSI) and the International Standards Organization (ISO) publish many such standards. Whenever relevant standards or guidelines exist, they should be followed.

Calibration and Characterization of Color Displays

C. S. Calhoun† and D. L. Post‡

†Logicon Technical Services, Inc., Dayton OH, USA

‡Air Force Research Laboratory, Wright-Patterson Air Force Base OH, USA

1. INTRODUCTION

Visual information designers and researchers must sometimes specify, predict, or control the luminance and chromaticity of self-luminous displays. (Luminance is a measure of radiant energy, weighted according to its visibility for humans. The preferred units are candelas per m^2 (cd/m^2), as specified in the Standard International (SI) notational system, but foot-Lamberts (fL), from the English system, are still used sometimes; chromaticity is used to refer to those psychophysical measures of color that are independent of luminance.) Accurate image representation can be very important because the human visual system responds differently to different levels of light intensity, color, size, duration and other factors. Visual information designers attempt to exploit visual system characteristics through appropriate manipulation of light. For an information display design to produce a desired response consistent with population stereotypes, for example, or to avoid an undesired response such as a perceptual artifact, a display image's luminance and chromaticity may have to meet certain specifications.

For a color display, calibration consists mainly of setting the display's white point to specific chromaticity coordinates, although peak luminance, convergence, purity, and focus adjustments may also be necessary. (A display's white point is the color produced when all three RGB channels are driven equally.) Characterization is a measurement process yielding data that describe the input-voltage to luminance transfer functions of the display's red, green and blue (RGB) channels. Several good methods are available for using characterization data to predict a display's colorimetric behavior; the best choice for a given application depends on the desired prediction accuracy, one's tolerance for implementation difficulty and the available measurement equipment.

1.1. Color Perception

Color perception is a complicated process, affected by physical, psychophysical, and psychological variables. The Commission Internationale de l'Eclairage (CIE) developed a system in the early 1900s for converting measurements of light into psychophysical measures, e.g. luminance and chromaticity coordinates; however, the CIE system does not account for all phenomena that affect color perception. Walraven (1992), for example, details several interesting perceptual artifacts that can result from factors such as the observer's visual adaptation state, the image's spatial and temporal characteristics, surrounding lights and environmental influences such as ambient light. Therefore, although an image's luminance and chromaticity coordinates can be determined precisely using appropriate instruments, this information does not specify the resulting color perception, and if the perception is important it must be checked in the environment in which the display will be used.

1.2. Display System Fundamentals

A typical digital display system includes a computer, video-generating device, and display. Display output results when image-generating software on the computer sends appropriate digital values to the video-generating device, which converts them to analog voltages using a digital-to-analog converter (DAC) and sends the voltages to the display. The display generates images through spatial or temporal combination of the RGB channels. Most DAC parse their output voltage range into (2^8 =) 256 levels. This process is easily seen with computer software that permits user-adjustable colors in text or graphics. Generally, the user has access to 256 (0–255) adjustments per channel. Thus, (256^3 =) 16.7 million RGB combinations are possible. The goal in display system characterization is to select and measure a few well-chosen DAC that permit accurate predictions for any RGB DAC combination.

2. DISPLAY CALIBRATION

Display calibration is needed to ensure proper color rendition and has direct consequences on the subsequent characterization. Calibration parameters include contrast, brightness, individual channel gains, and white point. The contrast or cutoff control sets the maximum achievable luminance, whereas the brightness or gain control sets the background level. It is usually best to maximize the display's peak luminance while maintaining the ability to display a reasonable black. Many new monitors now include front-panel, electronic channel-gain controls. If available, these controls are adjusted such that the desired white point is achieved; otherwise, internal controls must be used. The display's white point is usually set equal to a standard white, such as CIE standard illuminant C or D$_{65}$, and confirmed using a colorimeter or spectroradiometer (see Section 3.4).

The brightness and contrast calibration procedure is (1) Make sure the display is located in its intended environment; (2) reduce brightness to its "off" state; (3) reduce contrast to a low level while maintaining a viewable image; (4) increase brightness until the background raster can be seen, then reduce brightness until the background just disappears; and (5) increase contrast until the image can be viewed comfortably. The process can be repeated if necessary, but generally yields a satisfactory result on the first iteration.

3. CHARACTERIZATION

Characterization is needed only when predictive equations are going to be used to either predict the luminances and chromaticity coordinates that will be produced by specified DAC, or to compute the DAC needed to produce desired luminances and chromaticity coordinates. Characterization consists usually of measuring the luminance of the RGB channels separately at several (usually equally spaced) DAC. The resulting data are then used to fit the predictive equations. An alternative characterization method, developed by Berns *et al.* (1993b), is to measure the display system's white point at several DAC triplets, and measure the chromaticity coordinates of the RGB channels. The chromaticity coordinates are then used to decompose each white measurement into its constituent RGB luminances, thus yielding three RGB luminances for each white measurement and reducing the required number of measurements.

3.1. Display Gamma

A display's voltage to luminance transfer function is often characterized by a power function, the exponent for which is called its gamma. One difference between CRT monitors and flat-panel displays is that CRT typically have a gamma ranging from 2–3, whereas flat panel displays have a gamma of ~1; this means that flat-panel display luminance changes fairly linearly with drive voltage. Therefore, to characterize a CRT adequately, it is especially important to sample each channel's transfer function at several DAC.

3.2. Display System Characteristics

CRT often exhibit a lack of independence among the RGB channels: The whole does not equal the sum of its parts. Channels interact due to circuit interference and power supply limitations. It is also possible to have interactions among different areas of the display, due either to electronic limitations or internal reflections off the display's faceplate, which cause light from one area on the display to exit at another. Therefore, when performing characterization measurements, it is best to display an image that is representative of those for which colorimetric predictions are desired. Non-uniformities in the display's temporal and spatial characteristics can also affect characterization. For example, Berns *et al.* (1993a) found that a CRT can take as long as three hours to warm up, and even then as much as 90 s may be needed before the image's luminance and chromaticity stabilize. Longer-term instabilities occur over a month or more. One must also be aware that luminance and chromaticity may vary across the display screen (for CRT, luminance is greatest at the center of the screen and decreases toward the sides and corners by as much as 25%), so a characterization performed at one location may not yield accurate predictions for others. Finally, viewing angle should be considered. Viewing angle does not usually have much effect for CRT, but can impact both luminance and chromaticity for flat panel displays—liquid-crystal displays, in particular.

3.3. Ambient Illumination

Ambient illumination affects image legibility and readability. It does this by adding luminance to the image, which reduces contrast and desaturates the colors. It can also create specular glare off the faceplate. If the display will be viewed under ambient illumination, characterization should be performed with the illumination present.

3.4. Photometric and Colorimetric Instruments

Three types of devices are used to characterize displays: photometers, colorimeters, and spectroradiometers. Photometers measure luminance. Colorimeters measure chromaticity coordinates and either luminance (if they have optics to gather light from a target) or illuminance (if they have an integrating diffuser instead). Properly calibrated devices are reliable to about ± 2% in luminance or illuminance and to within ± 0.005 in chromaticity coordinates. Spectroradiometers provide a color's spectral power distribution (SPD), which is the equivalent of a fingerprint for light. An SPD graphs radiant power as a function of wavelength. Given an SPD, the associated luminance and chromaticity coordinates can be computed using the appropriate CIE equations.

4. METHODS FOR ACHIEVING DESIRED COLORS ON A DISPLAY

There are essentially two ways to get predetermined luminances and chromaticity coordinates to appear on a display. The best choice depends mainly on the number of colors that are needed. If only a few colors are needed — for example during prototype evaluation — iterative manual search is best. If many colors are needed, display characterization and the use of predictive equations are usually more efficient in the long run.

4.1. Iterative Manual Search

Iterative manual search requires little knowledge about the display system. The operator simply adjusts DAC until the desired luminance and chromaticity coordinates are achieved. Before attempting this, it is a good idea to measure the peak luminances and chromaticity coordinates of the RGB channels and ensure that the colors one seeks lie within the display's color gamut. (See Post and Lloyd (1994) for a tutorial on color gamuts.) It is also helpful if the channels are monotonic, i.e. each increase in DAC produces an increase in luminance.

Iterative manual search involves: (1) presenting a color on the display; (2) measuring the color's luminance and chromaticity coordinates; (3) determining whether the measurement meets the desired specifications; (4) adjusting the color's RGB DAC if necessary; and (5) performing another measurement to determine whether the adjustments produced the desired color. This process repeats until the desired color is achieved. When performing the adjustments, it is useful to know that the R DAC affects mainly the CIE *x*-chromaticity coordinate, G affects mainly the *y*-coordinate, and B affects mainly the *z*-coordinate, which is to say it affects both *x* and *y*. All three DAC affect luminance, of course, although G usually has the greatest effect because the G channel typically has the greatest maximum luminance.

4.2. Predictive Methods

Predictive methods are used to identify either the DAC needed to produce a desired luminance and chromaticity coordinates, or conversely, the luminance and chromaticity coordinates resulting from a particular set of DAC. There are basically two approaches to predicting a display's colorimetric behavior: theory-based modeling and empirical modeling. Both approaches require fitting functions to the characterization data set.

To predict the luminance and chromaticity coordinates that will be produced by specified DAC, the first step is usually to use predictive equations to determine the RGB channel luminances that the DAC will produce. These luminances are converted to CIE XYZ-tristimulus and the tristimulus are then converted to luminance and chromaticity coordinates. The conversion from channel luminances to tristimulus is:

$$
\begin{bmatrix} X \\ Y \\ Z \end{bmatrix} = \begin{bmatrix} \dfrac{x_R}{y_R} & \dfrac{x_G}{y_G} & \dfrac{x_B}{y_B} \\ 1 & 1 & 1 \\ \dfrac{z_R}{y_R} & \dfrac{z_G}{y_G} & \dfrac{z_B}{y_B} \end{bmatrix} \begin{bmatrix} L_R \\ L_G \\ L_B \end{bmatrix}, \tag{1}
$$

where X, Y, Z are the desired CIE 1931 XYZ-tristimulus; x_R/y_R, x_G/y_G, etc. are the CIE 1931 x,y-chromaticity coordinates for the RGB channels and will be referred to here as the

transformation matrix; and L_R, L_G, L_B are the RGB channel luminances necessary to produce the desired tristimulus. Typically, the transformation matrix is determined at each channel's maximum DAC to maximize measurement signal-to-noise ratio. Colorimetric predictions need not use only a single transformation matrix, though. A separate matrix can be generated for each display parameter that affects predictive accuracy, such as location on the display, image size, number of images presented simultaneously and different ambient lighting conditions.

Sometimes, an instrument capable of measuring channel chromaticity is not available, so channel chromaticity must be estimated. The display's manual may contain values; if not, they can usually be obtained from the manufacturer. For CRT, the channels' chromaticity coordinates can also be guessed using published standards for phosphors.

To predict the DAC needed to produce a desired luminance and chromaticity coordinates, the inverse of equation (1) is used to compute the required RGB channel luminances. Predictive equations are then used to determine the RGB DAC that will produce those luminances.

4.2.1. Theory-based modeling

Berns *et al.* (1993b) presented a method for modeling the relationship between RGB DAC and RGB channel luminances that is based on theory of how CRT behave. (Actually, they modeled the CRT's output in units they called "monitor tristimulus values," which are more generic than luminance; however, their model is easier to understand and explain in terms of luminance.) The basic form of the equation they used is:

$$L_i = L_{i,max}[k_{g,i}(DAC_i/DAC_{i,max}) + k_{o,i}]^{i}, \qquad (2)$$

where L_i is channel i (R, G or B) luminance, $L_{i,max}$ is channel luminance at maximum DAC ($DAC_{i,max}$), $k_{g,i}$ is display system gain for channel i, DAC_i is DAC for channel i, $k_{o,i}$ is display system's or offset for channel i, and γ_i is the display system's gamma for channel i. Equation (2) can be inverted to compute DAC for a given luminance. The gain, offset and gamma terms are estimated for each channel using nonlinear regression, i.e. search techniques. The resulting power function provides accurate predictions and has been endorsed by the CIE (1996); however, special software is required to perform the nonlinear regressions, human intervention is required to ensure the solutions converge, and each solution requires multiple searches using different starting values for the parameters to assure optimality.

4.2.2. Empirical modeling

Empirical modeling seeks a function that minimizes prediction error without regard to whether the function corresponds with theory. Post and Calhoun (1989) found that the predictive accuracy of several empirical polynomial and logarithmic functions, assessed in terms of error in luminance and chromaticity coordinates, was generally poor. Post and Calhoun (1989) presented a better approach, termed piecewise linear interpolation assuming constant chromaticity coordinates (PLCC), that provides good predictions with minimal implementation

effort and no more than 16 characterization measurements per channel. Lucassen and Walraven (1990) found that a logarithmic version of PLCC also provides good predictive accuracy. PLCC can be used with the white-point decomposition method introduced by Berns *et al.* (1993b) to reduce the required number of characterization measurements.

The aforementioned methods provide good predictive accuracy, however improvements can be made. Post and Calhoun (1989) described a method they called piecewise linear interpolation assuming variable chromaticity coordinates (PLVC), which provides improved accuracy. PLVC incorporates measured changes in channel chromaticity at each measured DAC. The advantage is that variations in channel chromaticity are accounted for in the predictions. The disadvantage is increased implementation complexity.

4.3. Correcting for Faceplate Internal Reflections

Del Barco *et al.* (1995) showed the improvement in predictive accuracy that can be achieved by incorporating a correction for internal reflections at the faceplate. After performing a characterization, the display is measured at zero DAC. Next, the zero-DAC measurement is subtracted from each measurement in the characterization. Predictive equations are then fitted to the corrected characterization data set. To predict the luminance and chromaticity coordinates produced by given DAC, the calculation is made in the usual manner and the zero-DAC measurement is then added to the prediction. To predict the DAC needed to produce a given color, the zero-DAC measurement is first subtracted from the color's tristimulus and then the calculation is made in the usual manner.

Chinese Characters and Computer Input

B. HAN and J. LI

Institute of Psychology, Chinese Academy of Sciences, Beijing 100101, China

1. INTRODUCTION

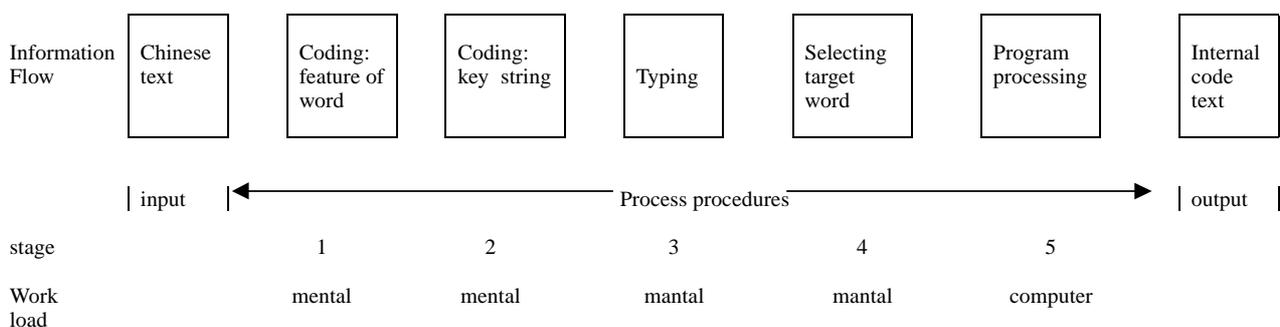
The past three generations of Chinese have had a tough but successful experience of processing their native language by computer. After the development of the English word-processing system of the 1960s, Japanese as well as Chinese scientists began designing the Chinese word-processing system (Ong and Shahnavaz 1987). Since the first Chinese keyboard input system (CKI) was produced in 1978 (Chen and Hu 1994), dozens of Chinese word-processing systems (CWPS) were developed. Some of them, e.g. CCDOS, UCDOS, CWPS, Xiao Jun 2.13 and WPS, became popular in the 1980s. In the 1999s, almost all the important international business programs have a Chinese equivalent, e.g. dBASE, FoxPro, SPSS, SAS, not to mention MS Office (Word, Power-Point, Excel).

CKI has been a bottleneck for Chinese information processing. Although the speed of CPUs and printers has increased, users must keep their typing at a relatively slow speed (50–300 characters/words per min for a normal/professional typist). Given the fact that the efficiency of CKI is already higher than that of English keyboard input (Chen and Hu 1994), and the successful design and marketing of the Chinese information processing system, one of the remaining problems is that each must include several CKI methods to obtain as many users as possible. On the one hand the user can choose the method he/she prefers, but on the other the system designer must offer several options, since no method can be regarded as superior over another. This is confusing for the beginner. Which method is the best and which is the most suitable for him/her? Although Chinese is not as difficult to input as may be imagined, the complexity of CKI can cause some initial fear or anxiety. In fact, even a skilled Chinese typist has a greater workload than the user who is typing English. This chapter will describe the causes of the workload of the CKI process, as well as the efforts to lighten this workload.

2. PHYSICAL/MENTAL DEMANDS OF CKI

2.1. General Workload

No matter what kind of features (orthographic, phonological, combination) a CKI method will take, all of them aimed to transfer the text to an internal binary code which can be processed by computer, according to specially designed rules, as shown by Figure 1, which depicts the flow chart of CKI. Note that compared with English keyboard input, stages 1, 2 and 4 are unique in CKI. Stage 5 is much more complex than the letter-internal code used for transforming the input of English, thus increasing the demands on both user and computer. As is shown, the types of workload differ between the initial stage of learning and the executive process, a fact which nearly all CKI users must deal with.

- Remembering the coding and mapping rules — each CKI method has at least two sets of rules (Han and Sun 1999). One is for encoding characters/words with a selected number of phonological or orthographic features as elements. The other is a set of mapping rules, whereby each element is allocated to one key on the board. It is the primary source of mental workload for the beginner of CKI. However, it is not always difficult since the coding method to some extent uses a rational code, which means that it is similar to a user's background knowledge. For example, the phonological coding method uses the Pinyin system (initials and finals) which most Chinese are familiar with from their early schooling. This makes it easier for users to learn, although they still have the coincident characters (those which share the same code) to deal with. Orthographic coding methods are difficult to remember but have far fewer coincident characters. For mapping rules, the phonological element (21 initials, 35 finals, four tones) is easy to map on the 26 keys of the keyboard, and is fairly simple to learn. However, orthographic elements (normally > 100 elements except for the stroke feature) are more difficult to remember and map. There are always some specific rules to balance the distribution of elements on keys, based on orthographic or phonological similarity between elements and keys. The user must simply learn these by heart.
- Encoding the characters/words — users encode the text manually, or mentally, according to the coding method used. This can be done one by one at stroke, component, character, word, phrase, or even sentence level. This will result in an elemental sequence or string for the basis of the next operation.


Information Flow	Chinese text	Coding: feature of word	Coding: key string	Typing	Selecting target word	Program processing	Internal code text
	input	← Process procedures →					output
stage		1	2	3	4	5	
Work load		mental	mental	mantal	mantal	computer	

**Figure 1. Flowchart, processing procedure, and workload of Chinese keyboard inputting.**

Figure 2. Cognitive model of Chinese keyboard input (adapted from Zhang and Chen 1991).

- Input of text by punching keys — the operator punches the keys along with the element sequence which is formed through encoding. Physical workload is the main characteristic of this step. There is also a certain degree of physical workload in connection with typing. For example, in typing from a written page, the operator must move his/her eyes back and forth between the screen and the text while typing. This causes tension in the ocular and neck muscles. However, the mental workload in this situation is relatively low if the typist uses an orthographic coding method, and need simply transcribe the text to an internal code. (The orthographic processing level in this situation infers a lower mental workload). Figure 2 shows the cognitive process along with different typing situations.

- Selecting the main character — one of the difficulties of CKI is that the user must select a main character from a number of coincident characters/words, especially regarding the phonological coding method (Han and Sun 1999). Occasionally it requires both time and effort since the user must turn over the small pages showing the coincident characters/words in the limited windows of the screen. The uncertainty of the result after keypunching produces some mental stress, which can only be eliminated by selecting the main character. It could even be disappointing if no matching character is produced after punching.

2.2. Specific Aspects of CKI Workload

The workload is also related to specific aspects, e.g. typing situations, coding methods, interface characteristics, and the users themselves.

- Input situations — CKI coding methods can be used daily for transcribing dictation, or for input from a written page, as well as mentally composed texts. Different situations involve different modalities. Whether the feature used in the coding method matches the modality involved decides how great the mental workload will be. For example, the auditory modality is involved in processing phonological information, so the phonological coding system is suitable for typing from dictation or mentally composed texts. If using the orthographic coding method in these two situations, the user must process the information by phonological modality, then encode it in a visual system, then transfer to auditory modality again in order to finish the input. This kind of transferring greatly increases the mental workload, not to mention the special rules that have to be referred to in some cases. In addition, the deep processing level (phonological and semantic process versus orthographic process; Craik and Lockhart 1972, Han and Lin 1998) involves more cognitive resources, hence the added mental workload.

- Coding methods — the degree of mental workload varies with the different coding methods, since the coding rules

do not always correspond with a user's background knowledge. As stated, the phonological code based on the Pinyin system is therefore easiest to remember, while the orthographic code normally uses components which the user is familiar with, but which nevertheless require some thought before using. As mentioned above, the greater the number of coincident characters, the greater the amount of eye and head movement, hence a greater physical workload. Although a combination of phonological and orthographic codes are used in most coding methods in order to obtain a balance of advantages/disadvantages, it is necessary to choose one of them as a main code, thus avoiding any confusion. Another aspect of the physical workload is the difference in code lengths, i.e. the difference in key punching time. For example, the character "jiang" by Pinyin has five letters, with only one initial (j) and one final (iang). This means that two punches are theoretically enough for inputting by initial (represented as j) and final (say, if represented by h), but at least five letters are needed if using the whole letter code (jiang). This is the reason for differences in movements and the amount of fatigue in muscles.

- Interface design — there has been very little research done at system level for interface designs; an important exception are the studies on Chinese character display (Zhu and Xu 1990). These are significant given the fact that most of the educated Chinese will have to use the CKI system sooner or later. This area contains much for ergonomic researchers to explore. Considering that there are several popular Chinese platforms to date, the availability of different CKI methods is not equal to users. Some of these methods are included as OEM programs (e.g. Biao-Xing-Ma, Wu-Bi-Zi-Xin), some often have to be installed by users themselves separately.

- The operator — the operator's characteristics, e.g., computer anxiety, background knowledge (composing, coding), personality, and movement/activity co-ordination, can affect the CKI efficiency. However, no research has been done on CKI users with respect to the above-mentioned variables. Psychologists have a great deal to explore in this area.

2.3. Other Related Problems

- Software design — Chinese version of many popular English information processing systems have been produced. Given the technical success of marketing the Chinese versions of software such as MS Office, SPSS, FoxPro, etc., more attention should be paid to the specific characteristics of Chinese information. Issues such as page layout, format, and document production/transferring need more research instead of just copying everything from the original foreign software. Nevertheless, several CIP systems (e.g. WPS, CCED, UCDOS, and Chinese Star) have a considerable number of users.

- Speed and memory of computer and printer — each Chinese character is saved and processed as a picture. The greater its discriminating rate, the greater the demand on the processing speed or memory of CPU and printer. Mismatching between input, processing, and printing often induces extra waiting time.

3. RELATED GROUPS FOR DECREASING THE WORKLOAD OF CKI

It has been a 20-year struggle for designers and operators to try to lower the demands of CKI. Achievements have been significant, in that more and more people use word processing daily, and many technical improvements have been made. However, there is still a long way to go. The participation of ergonomic researchers and psychologists will be helpful to both designers and users; these related groups can approach the problem from different angles.

3.1. The Designer

The designer always chooses a favorite feature, either orthographic or phonological, as a coding element. However, it is important to consider how to facilitate the use of the coding method. The first step, often taken instinctively, is that of making the coding element as rational as possible in order to match the user's background knowledge. The second step is to make the rules — coding as well as mapping — as simple as possible. However, the simplicity of these rules is often cancelled by the coincident code or the biased distribution of features among the keys on the board. Therefore, a certain number of special rules must be used as a control. This is an expedient measure for the programmer, although it results in a greater mental workload for the user. In short, it is not always possible for the programmer to make everything easy.

3.2. Users

Users must choose the best CKI method for his/her daily word-processing work, although this is not always a clear-cut choice to make. It is important to strike a balance between usability, ease of recall, and the individual's own language habits and profession.

Users in northern China who can speak Mandarin well often prefer phonological coding methods, while users in southern China often choose orthographic coding methods, and so avoid having to deal with the pronunciation of characters/words. Professional typists often prefer orthographic methods for higher speed and fewer coincident codes during inputting, while researchers and writers will most often choose phonological methods for the consistent auditory modality involved in thinking and encoding, and also for the ease of learning and remembering.

3.3. Ergonomic Researchers/Psychologists

The role of ergonomic researchers/psychologists in lowering the workload of CKI can be significant, with respect to the remaining human/computer interface issues. These issues have seldom been investigated; improved communication between researchers in different fields and between different countries is needed.

4. DISCUSSION
4.1. Workload and Evaluation of CKI

When we discuss the workload of CKI, we often refer to keyboard input of alphabetical languages, in particular that of English. However, no reasonable comparison on keyboard input between alphabetical languages and ideographic languages has been made to date, nor a cognitive process analysis or any experimental studies.

The key to decreasing the workload of CKI is to find suitable methods for evaluation and measurement, as well as effective methods for lowering the workload. This has, however, proven difficult because firstly, although earlier studies on evaluation realize the difficulties in copying variables related to users, further study is still needed, and secondly, more research is needed on ergonomic issues of CKI.

Han and Li (1998) have proposed a framework of CKI system evaluations, based on the cognitive process analysis and user-centred design strategy. It is argued that the "best" principle should be replaced by a "satisfying" principle in the design of a CKI method. Accordingly, the computer program strategy should be changed from "Chinese-centered" or "computer-centered" to "user-centered." A Chinese-centered strategy focuses on language attributes, while a computer-centered strategy focuses on the application of coding methods. The user-centered strategy focuses on the cognitive characteristics of different inputting situations as well as human/computer interface harmony.

4.2. Significance of Research on the Workload of CKI

It is, no doubt, very important to lower the workload of the CKI system. There are 1.3 billion people whose native language is Chinese, in addition to the increasing number of foreigners using the Chinese language to communicate with Chinese colleagues for business or academic reasons, plus Internet visitors of innumerable Chinese Web sites. This implies an increase in the use of CKI systems. Much time and effort could be saved through a decrease of workload in at least one aspect of CKI. Related topics, such as the limitation of Chinese attributes and coding designs, as well as user-training programs, need further study.

In addition, this is a promising field in which many areas remain unstudied and worthy of exploration by international ergonomic researchers, not only for the sake of technology itself, but also from the viewpoint of cross-cultural comparison.

1. INTRODUCTION

In the last decade visual display units (VDUs) have become widespread for routine use in almost all workplaces in offices and production units. Development of computer networks and software programs like Windows have given the operator the opportunity to obtain almost all information at the computer. Thus, the time per day spent using the computer and particularly the time spent using the mouse as an input device has been increasing. Johnson *et al.* (1993) found that mouse use can account for up to two-thirds of the computer operation time, depending on the task performed and the software used. However, mouse use is nearly always combined with keyboard work, therefore consideration should be given to optimize all aspects of VDU activities. Several studies have documented a relationship between VDU work, particularly mouse use, and musculoskeletal illness. Karlqvist *et al.* (1996) reported an odds ratio of 2.2 with prolonged mouse use for CAD operators regarding shoulder/upper arm, elbow, wrist, and hand/finger symptoms compared with telecommunication laboratory workers. Several studies have documented increasing risk of upper extremity symptoms in terms of an odds ratio of 2 comparing VDU work more than 4 hours per day with an operational time of less than 4 hours per day (Punnett and Berqvist, 1997).

An exposure-response relationship between VDU use of more than 2 hours versus less than 2 hours for hand/wrist problems was found by Oxenburgh (1987). Punnett and Berqvist (1997), in their review of epidemiological studies of VDU work, found that VDU work indicated higher risk of neck, shoulder, arm, wrist and hand musculoskeletal illness compared with non-VDU work. Bergqvist *et al.* (1995a) compared VDU work with non-VDU work. They found a cumulative incidence of 2.8 for discomfort in the forearm and hand compared with non-VDU workers. Furthermore, a dose-response relation between VDU work and hand/wrist problems was indicated (Bergqvist *et al.* 1992). Many factors are associated with musculoskeletal discomfort in the neck and shoulder: rapid work pace, stereotyped repetitive keyboard and mouse use. Other factors are stressful work posture resulting from poor workstation and input device design as well as insufficient recovery time in terms of limited opportunity for rest breaks (Punnett and Bergqvist 1997). Limitation of spontaneous rest breaks was found to be associated with neck and shoulder discomfort (Bergqvist *et al.* 1995b).

In addition to musculoskeletal illness, eye discomfort is the main problem reported by VDU operators. Aarås *et al.* (1998) found a relationship between visual discomfort and pain in the neck and shoulder for VDU workers. The correlation coefficient was between 0.3 and 0.4. In the same study, a significant reduction of visual discomfort was reported by the VDU workers after having increased the illuminance level from 300 lx to 600 lx with luminaires giving high luminance of the ceiling and walls (approx. 80 cd m^{-2}),

Optometric corrections for presbyopic operators have to consider the viewing distances, which for VDU work are normally longer than reading distances. Laboratory studies by Horgen *et al.* (1989, 1995) showed that single-vision lenses gave less muscle load in the neck and shoulder compared with multifocal lenses. The importance of having optimal corrections was shown in a study where two intervention groups received optometric correction if needed; these groups reported significant reduction of visual discomfort but the control group, who did not receive corrections, showed no significant changes (Aarås *et al.* 1998). The importance of using single-vision lenses, if possible, is also supported by Bergqvist *et al.* (1995b), who found that VDU operators wearing monofocal glasses had lower risk for tension neck syndrome compared with those wearing bifocals or progressive glasses.

2. WORK POSTURE

There is little knowledge about an optimal postural load which gives a training effect of the muscles and prevents musculoskeletal discomfort. However, there is a consensus that the static muscle load should be kept at a minimum while the dynamic work pattern should be increased (Kilbom *et al.* 1986). Based on this knowledge, the VDU workplace should enable the operator to adopt a reference work posture giving minimum static load, along with easy variation in work posture, thereby increasing the dynamic muscle work.

2.1 Postural Load of the Neck

The muscle activity of the neck, shoulder and back is influenced by the trunk posture along with the head, neck, and arm position. In addition, any external load in the hands will increase load in the musculoskeletal system. Using electromyography (EMG), Schüldt *et al.* (1986) measured the lowest static load in the neck and shoulder muscles when the trunk was leant backwards 10-15°. The muscle load is very low, even for an extremely flexed position of the cervical spina (Harms-Ringdahl 1986). These results are supported by the biomechanical analysis of Dul *et al.* (1982), who found that in 40-45° flexion of the cervical spina, the neck muscles are stretched more than 30% of their length, i.e., the passive muscle and ligament forces are almost sufficient to counterbalance the forward turning movement of the head. Aarås *et al.* (1997) compared directions of gaze below the horizontal of 15° and 30° to the centre of the screen for data entry work. No significant difference was found between the two positions regarding static trapezius load or the static load of the erector spina lumbalis (L3 level).

Epidemiological evidence supports the idea that great flexion of the head and neck does not increase the incidence of musculoskeletal illness in the neck and shoulder. Aarås (1994) found that in workers who flexed their head between 39° and 58° for the predominant work position, the development of sick leave was low for musculoskeletal illness in the neck and shoulder. These data indicate that even great flexion of the head and neck in the sagittal plane gives a small risk of development of musculoskeletal illness in the neck and shoulder areas. This knowledge seems important for reducing visual fatigue. Investigation of the resting states of the oculomotor systems in different directions of gaze suggests that work with downwards gaze could reduce visual fatigue. Lie *et al.* (1997) have reported that visual discomfort and musculoskele-

Figure 1. The physiometer records EMG on four channels; six channels are available for postural angles measurements. Inclinometers are attached to the upper arm, head and back

tal pain and stiffness were reduced in a one-year follow-up study when the position of the VDU screen was lowered from 15° to 30° downward gaze inclination to the centre of the screen.

2.2. Postural Load of the Shoulder

Flexion and abduction of the upper arm in the shoulder joint are much more important risk indicators for musculoskeletal illness in the neck and shoulder than flexion of the neck (Sigholm *et al.*

1984, Kadefors 1994, Aarås 1994). Sigholm concludes that the shoulder muscle load depends on the degree of flexion and abduction of the upper arm in the shoulder joint (glenohumeral joint) and the load in the hands. This means that flexion and abduction of the upper arm in the glenohumeral joint should be kept as low as possible. This is particularly important if the operators have no possibility of supporting the forearms on the tabletop in front of them (Aarås *et al.* 1997). A laboratory study was carried out to measure EMG (figure 1) from the upper part of the musculus trapezius and from the lumber part of the musculus erector spina (L3 level) during data entry work. The muscle load was significantly less in sitting with supported forearms compared to sitting and standing without forearm support (Aarås *et al.* 1997).

Similar results were also found when using a mouse as input device (figure 2). In this test, a computer version of the card game solitaire was chosen because of short cognitive decision making, leading to very frequent movement of the mouse.

The median trapezius load was reduced significantly from 3.2% maximum voluntary contraction (MVC) to 0.4% MVC. Corresponding values for the erector spina were 1.7% MVC and 1.0% MVC. The results from this laboratory study were confirmed in a real work situation. Two groups were given intervention in terms of new lighting, opportunity to support the forearms, and optometric corrections if needed. A third group acted as a control. According to Aarås *et al.* (1998), Shoulder pain was reported with no significant differences between the three groups before intervention ($p = 0.66$). The average intensity of shoulder pain during the last six months showed a significant reduction in one of the intervention group ($p = 0.02$) and a clear tendency to reduction in the other group ($p = 0.08$), while no significant changes were found in the control group ($p = 0.92$), when comparing before and after interventions. The intervention groups reported significantly lower intensity of shoulder pain compared with the control group after the interventions ($p = 0.02$).

Both the keyboard height and the VDU placement are associated with pain in the musculoskeletal system (Punnet and Berqvist 1997). Thus, the workstation should be adjustable to accommodate the anthropometric dimensions of the operators. Training in adjusting the table and chair is important in reducing

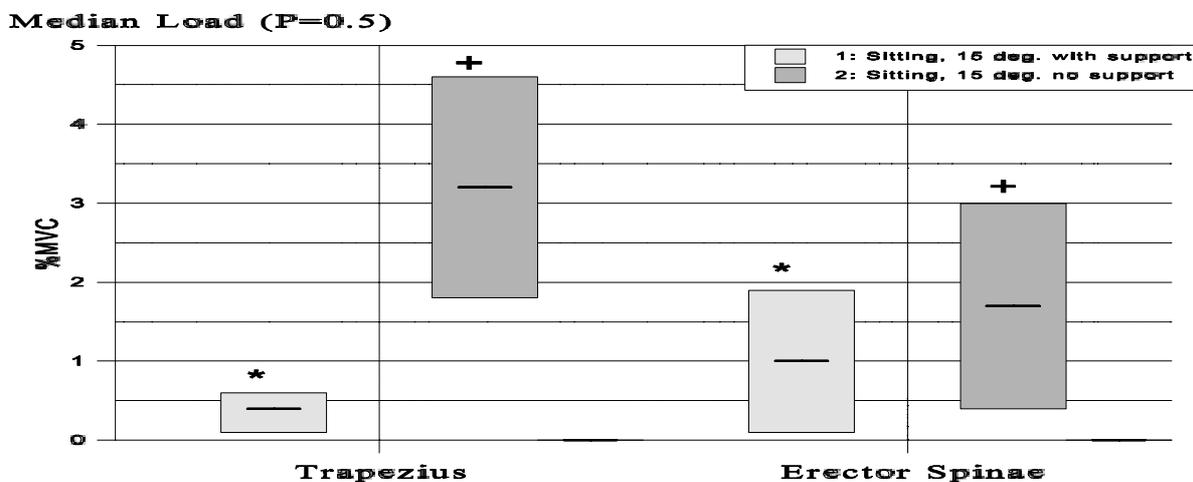

Figure 2. Group median values with 95% confidence interval for the two work postures; 20 subjets participated in the study

neck, shoulder, and forearm discomfort during VDU work (Lim and Carayon 1994).

2.3   Postural load of the forearms

Supporting the forearm on the tabletop did not affect the pain level in the forearm (Aarås *et al.* 1998). However, a relationship was found between the pain level in the forearm and the total time when the operators used the mouse. In a laboratory study, a mouse which gave the operator a more neutral forearm position was compared with a traditional mouse design. The muscle load of the forearm in terms of extensor digitorum communis and extensor carpi ulnaris was significantly less when using the mouse with the forearm in a more neutral position compared with the greater pronation of the forearm required for a mouse of traditional design (Aarås and Ro 1999).

The importance of the position of the upper arm and forearm is documented by Karlqvist *et al.* (1994). They found that mouse operators had a more outward rotated position of the upper arm in the shoulder joint compared with nonmouse users. For mouse operators the work posture and movements of the arm and hand were in the interval 15-30° ulnar deviation of the wrist as much as 34% of the working time. The corresponding percentage for those workers not using a mouse was 2%. Karlqvist *et al.* (1996) found an association of neck and upper extremity symptoms with hours per day of mouse use. The odds ratio with prolonged mouse use was 2.2 or higher for shoulder, upper arm, elbow, wrist, and hand/finger symptoms. Hünting *et al.* (1981) found that data entry work with more than 20° of ulnar abduction of the right wrist had an odds ration of 3 regarding pain in the right arm compared with those with less than 20°. They recommend that the ulnar deviation of the hand in the wrist should be less than 20°. Preferably, the hand should be held in the most neutral position possible at the wrist joint.

The importance of working with a neutral position of the wrist and hand is evident from several studies. A neutral position of the wrist may be important to prevent carpal tunnel syndrome (CTS) by giving low intracarpal tunnel pressure (ICP). The position of the wrist that creates the lowest ICP when the wrist has a flexion of 2.0-3.5° and ulnar deviation of 3-5° and a small pronation (Rempel and Horie 1994). Epidemiological studies support the importance of operating the keyboard and mouse with a more neutral position of the hand and wrist. Titteranonda *et al.* (1998) compared a keyboard of alternative design (splitting the keyboard in half and increasing the angle of the two halves from lateral to medial end) with a traditional keyboard. After six months the overall pain symptom severity of musculoskeletal illness (tendinitis) and functional status of the hand significantly improved while the operator using the traditional keyboard reported worsening of pain and discomfort.

It has also been suggested that changing the operation of the mouse between the right and left hand should be beneficial. Hoffmann *et al.* (1997) showed that VDU operators easily learn to change the mouse operation between their preferred hand and their nonpreferred hand, thereby reducing the period of activity in one hand. In a prospective epidemiological study, Aarås and Ro (1999) have documented the importance of operating the mouse with a neutral position of the wrist and hand compared with a more pronate forearm when using the traditional mouse design. Some 66 subjects suffering pain in the shoulder and fore-

arm with an intensity of at least 25 mm on a 100 mm Visual Analog Scale (VAS) were included in the study. The group was randomly divided into one intervention group and one control group. The intervention group got a new mouse, giving them the opportunity to work with the forearm in a neutral position; the control group continued with a traditional mouse design. After six months a significant reduction was reported in the intervention group regarding the pain intensity in the wrist/hand and forearm as well as the shoulder region and neck; no significant changes were observed in the control group. These results were valid for the average pain intensity as well as the frequency of pain.

3. CONCLUSION

The amount of knowledge already available should be applied to reduce the high prevalence of work-related musculoskeletal illness and visual discomfort for VDU workers. Primary prevention is of utmost importance, because when musculoskeletal illness has reached a chronic state, it seems very difficult to cure the disease, even if the most important risk factors are reduced to a minimum (Berg and Torell 1988). However, there is a clear indication that if the risk factors are abolished in the early stages of the musculoskeletal illness, the outcome will be promising (Jonsson and Persson 1988).

Design Issues: Action Research In Control Room Operations

N. A. Stanton, M. Ashleigh
Department of Psychology, University of Southampton, SO17 1BJ, UK
Tony Gale
University of Portsmouth, Portsmouth, UK

1. CHANGES IN CONTROL ROOM OPERATION

There is a tradition of research being conducted into control room operation to enhance our understanding of the role of the human operator and learn about new ways of supporting those activities. According to Kragt (1994) technological developments in process control have led to dramatic changes in the nature of work practices and behaviors. This development has gone through four generations of control systems: local manual control, local automatic control, centralized panel displays and SCADA (system control and data acquisition) systems. The first revolution was to automate parts of the process so that workers were able to supervise larger areas of plant. The second revolution was to centralize the controls and displays into a single control room, again enabling workers to supervise larger areas of plant. The third revolution was to put all the information at the workers' fingertips via information technology, further reducing the personnel requirements.

A review of research into human supervisory control reveals three distinct phases over the past three decades. Research in the 1970s may be characterized by interest in cognitive control. Interest in the individual shifted to interest in team structure and performance in the 1980s. More recently, in the 1990s, researchers have been focusing on human behavior in context. Zwaga and Hoonhout (1994) argue that all of the technological developments in supervisory control have been based upon the conception of the control room engineers' task of "operation-by-exception": control room engineers only intervening in the process when called to do so by the alarm system (Dallimonti 1972). However, Zwaga and Hoonhout (1994) argue that this conception is fundamentally flawed. Rather, they propose, control room engineers' behavior is better characterized by a "management-through-awareness" strategy: control room engineers are actively extracting information from their environment rather than passively reacting to alarms. The dichotomy of "active extraction" and "passive reception" was noted by Stanton and Baber (1995) in an analysis of alarm handling activities.

In a review of the impact of control room technology on the behavior of the operators it was apparent that three research approaches were dominant: the use of surveys and questionnaires, small-scale observational studies, and simulation of control room environments. Many of the questionnaire studies involved selected samples of employees, often at a time of introducing new technology. This meant that they were being surveyed under conditions of task restructuring, when they were ill-trained for the technology in question, fearful of redundancy, and motivated to a particular set of response biases. Observational studies, which appear on the face of it to offer ecological validity, are often of a very short duration so that they are likely to suffer from the Hawthorne effect. Social psychologists have drawn a distinction, in the context of observation, between acts and actions, the former relating to behaviors observed by an outsider, the latter to the layers of meaning which surround an act, from the viewpoint of the actual participant or indigenous person. Unless the outsider is au fait with the group's history, purposes, beliefs, and values, acts remain as acts. Laboratory studies, which offered more control, often involved relatively brief samples of behavior generated by unrepresentative samples of volunteer participants with little sense of continuity of employment or of the personal significance of the tasks they were required to perform. We know that workers, after extensive operations in a working context, develop subtle adaptations in their interaction with work interfaces, establishing idiosyncratic patterns and habits which simply cannot be captured in brief simulations. In the search for an alternative approach which yields veridical data, ecological validity and experimental control seem to be at odds with each other; yet without appropriate controls it is hard to plot true causal paths. This proposal offers to test a compromise research approach which seeks to combine ecological validity with control in a dynamic and developmental way.

2. RELATIVE BENEFITS AND PITFALLS OF EXISTING APPROACHES

Gale (1984) was quick to realize that the benefits of traditional approaches should be preserved, whilst the disadvantages should be overcome if at all possible. The recognized benefits of laboratory studies include: control over independent variables, limitation on the number of independent variables, control over environmental variables, control over participants' behavior, event sampling at choice, construction of complete experimental designs, choice of representative or random samples, systematic manipulation of variables, systematic development of a series of studies eliminating specified sources of variability, simplification of data to a level manageable by existing theoretical power, partitioning of subject effects, systematization of error, capacity for repeated longitudinal measurement over time, planning in advance and replication. However, there are several shortcomings: failure of a differential partitioning of *in vivo* influences, the generation of statistically significant effects rather than practically significant recommendations, an interest in effects greater than chance rather than effects which apply to large populations, a focus on contemporary theoretical ideas to the exclusion of potential or actual factors impacting on a working environment, theory-driven rather than problem-driven orientation, the use of inexperienced participants (often from an inappropriate background), and sampling which is far too brief to enable participants to develop their own coping strategies. Field studies, whilst being more realistic, typically suffer from: multivariate influences on participants, uncontrolled environmental contexts, uncontrolled and unpredictable disruptive events, restrictions on access for the duration of the study, restrictions on experimental power and status, the use of incomplete designs with incomplete cells, low cooperation and high suspicion by participants, biased samples, incomplete designs which restrain inference, and an inability to replicate.

3. THE CAFE OF EVE METHODOLOGY

In 1984, Gale presented an internal report to the Human Factors Technology Centre at ITT Europe, in which he proposed a new

research strategy for assessing the impact of new technology and for guiding design. In 1987, Gale and Christie set out a detailed blueprint for the approach. The project was called the CAFE OF EVE — a Controlled Adaptive and Flexible Experimental Office of the Future in an Ecologically Valid Environment. Whilst originally conceived as an approach for investigation of human behavior with office technology, the CAFE OF EVE approach may be equally successfully applied to investigations in control rooms. This requires the researcher to reconceptualize the research paradigm by applying an action research approach to the investigation of human activity.

The aim of the CAFE OF EVE project is to combine the advantages of both laboratory and field studies while minimizing the disadvantages. The proposal involves taking over a control room within a company in a way which allows for the day-to-day operational function, combined with a parallel set of research studies. Staff operating within the selected control room would be included in the research function. For the duration of the work, their job descriptions would alter officially to include reflection on their working situation and upon task demands. Their roles as experts in this regard would be recognized. In so doing, they would be invited into a partnership of equals with the researchers, thereby diffusing some of the suspicion which attaches to clever outsiders. In turn, the researchers would share some of the control room functions with the aim of understanding the meaning of events and activities for participants. At the same time, through daily exchanges with the permanent employees, the barriers between participants and experimenters would break down. As a conscious act the researchers would gently move conversation and interaction beyond the working context, to issues of family and other non-work concerns, thereby cementing affiliate relationships.

By addressing issues beyond the work barrier, the researcher who adopts a willingness to self-disclosure lowers within-work barriers to free communication. Thus the researcher take on the role of participant observer as developed in anthropology (Vetere and Gale 1987), living and working within the human system in question but also recording daily events. Researchers and participants share a social world. As researchers and participants share a social world the barriers between researcher and participant become more permeable and participants feel freer to express their opinions and reactions about their working environment. In daily debriefing sessions, participants interact with researchers, with the goal of identifying problems from the participants' perspectives. End-of-day briefings are part of the extended job description of the worker, and the employer formalizes the use of the last half hour of the day for the worker to reflect on system operation during the day, his or her reactions, and any other thoughts which come to mind. Because of the relationship which has been built up with the researcher, the end-of-day briefing is more akin to an after-work report to the worker's spouse or partner than to an alien researcher. Within this context, therefore, the expectation is that worker reactions will be more unabridged than would be the case in more typical research interviews. Thus, the research questions which are generated are not dictated by existing theories but by the actual perceived experience of control room engineers.

So far as possible, video observation and analysis, diary keeping, interactive recording of subjective responses would be carried out in the control room and integrated with everyday task functions. The aim of the CAFE OF EVE approach is to use a longitudinal and developmental technique to capture real experience and to shape new technological developments. The research questions are not imposed by prior conceptions but emerge from the working context and the views and analyses of participants. Thus it involves a partnership in exploration in which researcher and participant have equal status. It is argued that objectivity is retained because the researcher is still apart, but ecological validity is ensured by drawing on the participants' day-to-day experiences.

The key features of the approach are as follows:
1. Ecological validity is approximated;
2. All psychologically significant variables are likely to be identified;
3. Participants and researchers develop a partnership of exploration;
4. Sampling is flexible and by mutual consent;
5. Participants reveal and are able to reflect upon coping strategies developed over time;
6. Research studies emerge naturally;
7. Participants themselves will suggest studies or identify salient variables;
8. Participant loss will be minimal thereby allowing longitudinal studies;
9. Cooperation will affect broader organizational structures, such as new ways of working.

The CAFE OF EVE methodology offers an action research approach. There is obviously an element of risk associated with investing in such a long-term project. The researcher is likely to encounter unperfected events and difficulties, but this likely to be outweighed by the quality of the data and the insights gained through research of this nature.

4. CONCLUSIONS

The CAFE OF EVE approach seeks to draw together a normal working context and a controlled laboratory to create a special human factors environment, capitalizing on the benefits of ecological validity and experimental control, while seeking to avoid the disadvantages of the two contrasting approaches. In so doing, the research benefits should surpass the benefits typically yielded by either approach taken separately or sequentially. What we are proposing, and its emergent properties, could constitute a minor revolution in human factors research.
