Socio-technically inspired production philosophies played an important role in major manufacturing sectors in Northern Europe in the 1970s and 1980s, especially in the automotive industry. New techniques and systems for materials handling were developed to support individualized and parallel work stations in high-volume production, and innovative ergonomics aids were introduced to solve problems of difficult posture and static loads. To assist workers in learning longer and more complex work cycles, new principles of occupational training were developed around principles of functional understanding and combination of mental maps and manual skills. Socio-technical systems significantly ameliorated the problems of Fordist working conditions, but sometimes led to difficulties in achieving sustained levels of higher production performance. Also, this approach did not focus how to integrate customer focus in operations and work organization (Pasmore 1988, Berggren 1992).

3. TOYODISM AND LEAN PRODUCTION

When the Japanese auto industry began to expand under heavy state protection after the war, the production system of the American Fordist car industry was taken as the reference point. Both the product and the labor market conditions in Japan were very different, however. Volumes were radically lower: in 1950, for instance, only 30 000 vehicles were produced in Japan, equal to 1.5 day's production in the USA. Furthermore, the Japanese companies had a wide product spread, indeed the auto firms had begun as light truck manufacturers. It was therefore necessary to adapt US methods to fit the efficient manufacture of lower volumes and, despite limited resources, to expand. The decisive defeat of independent Japanese labor unions in the early 1950s

gave the auto companies the opportunity to develop precisely these forms of low-cost rationalization. First, companies got a free hand in matters of shop floor organization and labor deployment. Second, the defeat resulted in a development of enterprise unions and corporate welfare systems, which linked workers' interests closely to the future of their company. The restricted product market and the new managerial opportunities formed the basis for the Toyota Revolution of the 1950s and 1960s. As at Ford, the Toyota system developed through a process of trial and error. Small-lot manufacturing replaced the Fordist philosophy of maximal batch sizes. One consequence was that setup times in press shops and welding lines had to be reduced dramatically. Buffers and inventory were squeezed out of the system, which made the process very sensitive to disruptions. Thus, manufacturing quality, "right the first time," acquired prime importance. Furthermore, small-batch manufacture led to the need for a highly flexible workforce. Toyota emphasized minute standardization and visual control of every operation, at the same time as workers were trained in several different tasks in order to make it easy to shift between various standardized jobs. Routine inspection was integrated with the production line as the responsibility of lead hands and operators. After work, they were mobilized in various small group activities such as quality control circles. In this respect, the problem-solving capacity of workers was effectively utilized. However, cycle-time rationalization, multi-machine tending and the integration of inspection work also contributed to considerable increases in work intensity. In summary, four specific features distinguished Toyodism from the Fordist production philosophy (Monden 1994):

- *Flexible mass production.* Instead of one standard product and dedicated lines, several products were integrated in a continuous flow, making use of quick die changes, Kanban systems for materials control and in-line inspection of quality.
- *Modification of narrowly defined job roles.* Rotation of workers through several standardized routine jobs and transfer between different sections to accommodate demand changes.
- *Continuous improvement* activities directed at reduction of all types of waste (defects, idle time, inventories, etc.).
- *Employee involvement* through quality movements and emphasis on customer satisfaction.

4. COMPARISON WITH SURVIVING FORMS OF MODERN CRAFT PRODUCTION

The three production philosophies reviewed are all basically concerned with high-volume production, Fordism especially so. However, in various industry niches producing sophisticated products for exclusive markets, or customized capital equipment for industrial customers, modern forms of craft production survive. This production philosophy is typically characterized by long work cycles at stationary objects (in contrast to the moving conveyor belt of Fordism and Toyodism), considerable worker skills and a high degree of autonomy on the shop-floor. In contrast to traditional, pre-industrial forms of craft work, the modern forms make use of high-precision tools, standardized parts and elaborate quality control and documentation systems. Furthermore, modern craft production borrows the Toyodist practice of involving workers in continuous improvement activities — as compared with the more static nature of traditional craft forms. Thus, the imprint of the individual on the end

product, so typical of older forms, is reduced in modern craft production.

Below, the four different production philosophies are compared, in terms of technological and organizational characteristics and ergonomics consequences in a broad sense.

When comparing the criteria of rewarding work with the production philosophies discussed here, it can be seen that there are agreements and disagreements within all philosophies. Since hardly any company is strictly organized according to one generic production philosophy, and most companies develop a mixture between several philosophies, there is room for changes and improvements. The above classification may be used as a tool when evaluating existing and planned production systems. Also, it allows a more conscious choice and enables consideration of ergonomics aspects as well as economics and production aspects. In this way, ergonomics may contribute to improving the production systems of the futu

Table 1. A comparison of various characteristics for four production philosophies, referring to production work.

	Fordism	Sociotechnical	Toyodism	Modern Craft
Volume	High	Medium-high	High	Low
Production control	Volume Cost	Volume, Quality Inventory, Cost	Volume, Quality Customization Continuous improvement	Quality Quality
Type of production equipment	Dedicated & rigid Mechanical flow systems	Modified human interface Operator control of production pace Parallel flows and buffers	Flexible machines Tightly controlled flow system, Zero buffers	Versatile machines Stationary production
Technical autonomy	production	Very low- Machine paced and machinery	Medium Decoupling of workers production	Very low High Machine paced
Administrative control	Tight supervision	Several responsibilities delegated to groups	A few responsibilities delegated by external goals	Self regulation
Cycle time	Short, one minute or less	Enlarge, one hour or more	Short, one minute or less	Long, days or weeks
Job content	One repetitve task	Several manufacturing and administrative tasks	Multi-tasking	Highly varied
Individual/group	Individual	(Semi-) autonomous group	Production team	Individual craftsmen or team
Skill requirements	Low	Medium	Low to medium	High and manifold
Feedback	Little	Medium	Medium	High
Responsibility/authority	Low	Medium	Medium	High
Physical work load	High repetitive strains Fatigue	Medium repetitive strains	Repetitive strain Time pressure Fatigue	High workload Accidents Long hours
Participative problem solving	Very low	Medium-high	Medium-high	High
Labor relations	Bad	Aims at improving	Aims at improving	Varied

Ergonomics/Human Factors Audits

C. G. Drury

Department of Industrial Engineering, University at Buffalo, 342 Bell Hall, Buffalo, NY 14260, USA

1. WHAT IS A HUMAN FACTORS/ERGONOMICS AUDIT?

Auditing is "testing and checking the records of an enterprise to be certain that acceptable policies and practices have been consistently followed" (Carson and Carlson 1977). The "acceptable policies and practices" can be interpreted as to ergonomics/human factors just as well as the more usual financial interpretation. Quantitative measurement is implied by "testing and checking," while emphasis on "consistently followed" implies that the measurement is relative to some standard of perfection or close to it. In ergonomics much of the auditing takes the form of measuring the characteristics of a sample of jobs or workplaces to determine what fraction meet ergonomic criteria. In the end, an audit must make an informed statement about how closely a company's jobs or workplaces adhere to good ergonomic practice.

To meet this goal of auditing, many questions must be answered about when to use audits, what audit tools to use and how to analyze and interpret the audit data to make this informed statement.

2. WHEN TO USE AN AUDIT

Although much auditing activity focuses on measuring workplaces, an audit should not be used when the issue is "how well does an individual workplace meet ergonomic criteria." For this case ergonomists have many measurement tools and methodologies which can examine in detail human/workplace fit. Rather, an audit is designed to answer questions that go beyond the individual workplaces, and draw conclusions about a *set* of workplaces.

The need for ergonomics audit programs has arisen as ergonomics has moved from a workplace level activity (e.g. design a better job or workplace for *this* task) to a systems-level activity (e.g. design an ergonomics program to improve safety/quality/productivity/operator well-being throughout the organization). Thus, the audit must measure many units (jobs or workplaces) to draw valid conclusions at the systems level. In a typical application an ergonomics audit is used to measure the on-the-ground achievements of an on-going ergonomics initiative, for the purpose of evaluating that initiative at a specified point in time.

An audit typically supplements rather than replaces outcome measures. Many outcome measures for ergonomics/human factors programs are long-term, for example industrial injuries or airline accidents. As with quality programs (see Quality entries), the aim of audits is to measure the precursors of major problems rather than the problems themselves. We can measure outcomes, such as reduced errors in aviation maintenance following a human factors training program (Taylor and Christensen 1998), but

should not have to wait for such rare events before evaluating our program. In another example, Drury *et al.* (1998) audited a multi-plant ergonomics program early in program implementation to make recommendations for program changes. Only later were data available to show that the injury rates that the program was designed to address were reduced by ~50%.

3. HOW TO SELECT AUDIT TOOLS

The tools used in human factors/ergonomics audits vary widely depending upon the audit requirements. Some are one-page checklists, others are checklists the length of a booklet, while yet others are structured interviews. An audit tool can be classified by breadth, depth and application time. Breadth indicates the number of aspects of ergonomics covered, ranging from single topics such as thermal audits to wide-ranging job audits. Depth is a function of how fully each aspect is audited. A topic may be covered by a single question (e.g. "Is lighting adequate for the task?") or at the other extreme by a detailed set of measurements (e.g. a complete analysis of task visual aspects from color temperatures of light sources to calculation of the glare index). Clearly, application time is a function of both breadth and depth, growing longer as either or both increase. In a real sense, you get what you are prepared to pay for. Some applications need a rapid evaluation of many ergonomics topics, while others need more depth and focus.

An audit tool can be applied to a workplace, to a job or to a specific personnel within an organization. Sampling workplaces is appropriate where people spend most of their time at one workplace, for example a data entry clerk at a computer workplace or a garment worker at a sewing machine. Measuring aspects of the workplace automatically gathers data to show how well the job fits the incumbent. Where one job involves many workplaces, such as a maintenance task or an order picker in a distribution center, we must sample the job, usually at a number of times throughout the shift, to find similar information. Finally, looking only at worker/workplace fit will not help us much with system issues, such as how an ergonomics program is utilized by management. Here, the appropriate tool would be structured interviews with a sample of management personnel.

Examples of these different audit tools, with various levels of breadth and depth, are available in the literature. A comprehensive listing, with many examples, is given in Drury (1997). Two examples of the structure of such audits are given. Table 1 shows the structure and typical points from Ergonomic Checkpoints, a checklist developed for the IEA by Kogi (1994). The whole list covers 128 points (called "checkpoints"), in areas from Materials Handling to Work Organization, with each checkpoint having a structure which allows the analyst to see possible improvements. While Ergonomic Checkpoints audits workplaces, ERNAP (Table 2) uses the job as the unit. ERNAP was developed for aviation inspection and maintenance functions where technicians perform many different tasks (Koli *et al.* 1998) and is in the form of a computer program. (Note: the sponsors of ERNAP, the Federal Aviation Authority, have made this tool available at http://www.hfskyway.com). ERNAP was formed by combining two earlier checklists (ERGO and EEAM), both of which had their reliability measured, and were validated against the findings of ergonomics/human actors professionals viewing videotapes of audited workplaces.

4. CONDUCTING THE AUDIT

At this point we have established the purpose of the audit, what units we are measuring (workplace, job, personnel) and what tool to use. In carrying out the audit we must now determine how to sample the available units, i.e. which workplace? which job? which manager? Choice will depend upon the objective. Do we need to make pronouncements about the whole organization, a specific factory, all inspection jobs, the new production line, or what? The answer determines our sampling frame, i.e. the set of all units we *could* choose.

From this sampling frame we must then sample the individual units in a logical manner. This could be random sampling, where all units in the sampling frame are equally likely to be chosen. It could also be stratified sampling where we sample randomly from particular subsets (production, shipping, office, etc.) and later combine the results into a single audit sample. Or we could use cluster sampling where we choose clusters (new production line, old production line, etc.) and sample randomly within clusters. All are logical sampling plans, with particular uses, and are usually covered in detail under survey research methods.

An audit as we have defined it measures on-going activities, but we can supplement it with archival data to obtain a more longitudinal view of the organization's ergonomic effectiveness. Thus, audits of workplaces can be combined with analysis of records such as scrap, injuries, errors or employee turnover. Often the two sources can be mutually supportive, for example in an aviation maintenance environment both audits and error analysis can lead the auditor to the same problems with job instruction design.

Finally, in conducting an audit it should be standard operating procedure to use good ergonomic practice. Ensure that job incumbents are informed of the purpose of the audit and the anticipated uses of the data. Ensure too that where job incumbents must give responses, the auditor does not bias or lead the respondent.

5. DATA ANALYSIS AND PRESENTATION

Ergonomics is design for the user, so that a well-designed audit outcome should be designed to fit the user's needs. Of course, there may be multiple users with varying needs. The Chief Operating Officer may only need overall evaluation of the results (is the ergonomics program working adequately?) while the plant manager may need much more specific information (is the ergonomics program concentrating on reduction of errors in shipping? Is the new warehouse ergonomically better than the old one? Do we need to install task lighting throughout?). The most specific questions are the easiest to answer. We can tell the plant manager about the visual characteristics of the workplaces with statistical summaries of light levels, luminance values, glare indices and so on directly from the audit data. We can even break these distributions down by production lines or by job.

At the higher level there can be potential problems. Higher levels of management need to make programmatic decisions involving resource allocation between competing initiatives. We can answer questions such as "Is the ergonomics program working well in the men's apparel divisions?" or "should next year's budget cuts come from ergonomics or quality programs?," but the answers require that we use our ergonomics expertise in a managerial rather than strictly technical context. The issues

involve combining data from different aspects of human factors into higher-level indices of performance. Instead of showing the distribution of illuminance levels, or WBGT indices, we need to establish standards or criteria so that we can combine data in a meaningful way. The only way we can combine, for example, visual and thermal data is to classify each data point as either meeting or not meeting ergonomic criteria. We can then count the fractions of workplaces where specific criteria are met (e.g. 47% meet visual standards), and overall fractions of workplaces meeting all ergonomic criteria (e.g. overall, 17% of workplaces were free from ergonomic problems). To do this we have to assume that all failures to meet ergonomic criteria are equally bad, or provide some weighting scheme. Any choice of weights would be difficult to justify, so the assumption of equality is usually the most practical one.

A useful technique is to provide an overall index of ergonomic effectiveness with some qualifier about its constituents. For example, "38% of the workplaces in this division were ergonomically acceptable. The most frequent cause of non-acceptable workplace was poor posture caused by ill-designed conveyors."

This gives the decision-maker an assessment of the gravity of the situation, and an idea of what might be required (e.g. redesigned conveyors) to make improvements.

Percentage of ergonomically acceptable workplaces (or jobs) is a useful measure of overall ergonomic effectiveness, but it does presuppose ergonomics standards. We can collect data on jobs and workplaces, but eventually we must compare what is measured with what is appropriate for human use. Audit tools must do this either in the data collection or the data analysis: At times, the standard is built into the tool, for example by asking whether illuminance is greater than 500 lux for moderately difficult visual tasks. But measurements can be difficult to make reliably, especially when a standard of acceptability is implied. At many workplaces, careful placement of the light meter can be used to miss or achieve the 500 lux standard. It is usually preferable to write specific instructions for data collection, e.g. "record illuminance in horizontal plane at four points within the central 10∞ field of view." Data can later be compared with standards during analysis, particularly computer analysis.

Having decided what data to present, the report (or other presentation) should use human factors good practice to format graphs and figures for user comprehension. Suitable guidelines are given in Gillan *et al.* (1998). The most effective case is made when the report is written to address the user's issues rather than the writer's issues. An example is the ERNAP output (Koli *et al.* 1998) which is in the form of a memo to a Quality Assurance Manager listing overall findings for each aspect measured, and specific requirements for those places where ergonomic criteria were not met.

6. BEYOND THE AUDIT

Use of an audit tool and sampling plan can address the specific objectives used audit design. But the same data are also available for later use. Data at one location and one time can be extended across locations to make plant comparisons possible. They can also be extended over time to provide a time history or trajectory of ergonomic effectiveness. Specific measures can be analyzed

statistically to determine when plants or times differ significantly. By counting the reasons for workplaces not meeting human factors criteria, we can assess whether the same problems occur at all plants or whether different plants have different unmet ergonomic needs. Thus, Drury *et al.* (1998) found that most measures were consistent across plants and jobs, although postural and lighting problems were significantly job-specific.

Finally, as noted earlier, audit information can be combined with other data, often archival, to obtain a more complete understanding of the human factors issues. For example, Simpson (1994) and Fox (1992) used an error-based audit to improve many aspects of safety in coalmines. The error analysis prompted measurements (audits) of specific aspects of mine activity, such as locomotive design.

The subject of ergonomists in a design engineering environment is discussed. This chapter presents a short overview of the contributions and difficulties faced by ergonomists in an engineering design environment. The following chapter illustrates and further describes some of the concepts covered here. Both chapters are concerned primarily with the design of manufacturing or industrial production systems (MIPS).

1. APPLICATIONS OF ERGONOMICS IN ENGINEERING DESIGN

1.1. Value of Ergonomics

MIPS are becoming more complex as technology evolves, but the presence of human operators and workers remains a constant in every system. Humans implement, operate, reprogram and maintain the systems. Hence, MIPS should be designed to accommodate human characteristics. The system designer is expected to optimize system performance by giving proper consideration to human and technical components. The discipline of ergonomics encompasses the knowledge, tools and methods used to fulfill the human aspect of the system optimization task.

The reported benefits of considering ergonomics in the system design process include increased product quality, system reliability and productivity. Such increases can be achieved through reductions in human error, production time, time lost, product reworks and rejects, workforce turnover and absenteeism, the duration and complexity of worker training, start-up time and cost, and other factors. It should be remembered, however, that in most MIPS it is difficult to translate many of these advantages into financial terms, mainly because of a lack of accurate and reliable data. Incomplete or absent a priori financial justification weakens the arguments that might convince decision makers and key players in the system design process to accept the extra expense generated by the addition of an ergonomist to the design team. On the other hand, health, safety and human performance concerns are taken into account more systematically in industries where the costs or consequences of design errors are high or obvious (e.g. the atomic industry, continuous processes, aviation). In such industries, failure to consider the human aspects during system engineering design can have a significant impact on future insurance claims, for instance. Thus, the benefits of ergonomics are real, but are often difficult to express in financial terms.

1.2. Use of Ergonomics Knowledge and Tools In Engineering Design

For a number of reasons, ergonomics knowledge and tools are not used as extensively by system designers as might be expected (Campbell 1996), a community largely represented by engineers. In fact, Daniellou (1988) reported the existence of a significant gap between the availability of ergonomics knowledge and the actual application of this knowledge in engineering design.

First, most engineering training programs do not include formal and comprehensive training in ergonomics and safety aspects. Comparatively few engineers are aware of the existence of this field of knowledge, and those who are aware of it often do not know it well. To them, ergonomics boils down to table heights and selecting suitable chairs in the office environment, or to eye-catching automobile instrument panels. At the other end of the scale, most ergonomists have non-engineering or non-technical background training. As a result, they generally have a poor understanding of the technical requirements associated with engineering design.

Second, ergonomics analysis methods and tools are reported to produce output results that are difficult to incorporate in traditional engineering design methods. They are often too time-consuming for the fast pace and short deadlines that are typical of MIPS design projects. Also, designers with little training in ergonomics often find it difficult to implement the recommendations made by ergonomists and to apply the abundant information on human characteristics made available by the ergonomics community. Many guidelines and recommendations are said to be too vague to be usable, or in need of conversion to system-specific design specifications. This would be the case in particular for guidelines concerning the specifications of products or equipment in order to match or compensate for human cognitive or task performance abilities and limitations.

Third, ergonomics tools and methods are often perceived as more suited to the evaluation of a prototype or candidate system rather than to the initial design process. Moreover, there is no systematic approach to help designers incorporate ergonomics and safety considerations at the various steps of the engineering design process. Many methods and tools exist, including methods for risk analysis, task analysis, severity of consequences analysis and reliability analysis. However, they have never been integrated to form a unified design engineering framework. Designers are left with a plethora of methods and tools but there is nothing to help them select and apply the most effective and efficient methods for their particular design needs.

Despite these problems, experience indicates that considerable benefits can be achieved by applying ergonomics knowledge in MIPS design. Ergonomists who have been involved in MIPS design can confirm that transferring ergonomics and safety knowledge to designers through training and participatory approaches is an effective way of communicating ergonomics knowledge and fostering its use in the design process. Given the current state of tools, methods and knowledge in ergonomics and engineering, the successful design of a MIPS requires the contribution of an ergonomist. Meanwhile, initiatives aimed at increasing the utility and actual use of ergonomics information and methods by designers must continue.

2. DESIGN PROCESS AND ITS DIFFICULTIES FOR THE ERGONOMIST

2.1. From Problem to Solution

In industrial production systems, engineering design is generally concerned either with re-design (e.g. integration of new technology) or with improvement (e.g. correction) of existing and operational systems. The designer's task is therefore to define the problem space and develop solution alternatives. Definition of the problem space entails documenting the existing problem dimensions and the new opportunities presented by the design project. Problem space definition will usually begin with the problem definition provided by either the design project sponsor or client (or both), and the end user of the system (e.g. operators). Problem space definition is generally achieved gradually by developing solutions, and thus spans several stages of the design process. The problem is seldom defined in its entirety before the search for solutions begins, since the data required for complete problem definition is often lacking. Each new element of solution developed solves part of the problem, and at the same time introduces new aspects of the problem.

If different designers begin with the same problem statement but use different sets of criteria and work at different levels of detail, they will arrive at different feasible solutions. Indeed, the development of solutions will depend largely on the criteria used by the designers to define and tackle the problem, as well as on the importance given to these criteria. If the designers have a predominantly technical background, then the design process will emphasize technical criteria, and this will have an impact on both the data collected and the solutions developed. Level of design detail is also important. In MIPS design, the effort will necessarily focus on the highest level, represented by production means (e.g. building, machines, robots, conveyors), and to a lesser extent on the intermediate level, represented by workstation design (e.g. bench, hand tools, jigs). In many situations, the design effort will focus little if at all on the lower level, represented by work activities (i.e. how end users will actually interact with the workstations and production means to achieve expected production goals). Studies report that different designers within the same design team generally have partial and different views about the work activities being performed in an existing system and in a future system. This is even more the case when collective work is involved. For a design to be successful, the different views must be reconciled. Where work activities are concerned, this usually proves to be both time consuming and resource consuming.

The engineering design process is often described as opportunistic and intuitive. Iterations to earlier stages (i.e. redefinition of portions of the problem space) may be frequent, and changing goals are commonplace. In fact, the MIPS engineering design process is seldom purely sequential, well organized, preplanned, and totally controlled in nature. It is subject to many constraints, since it involves different people with different backgrounds and objectives who interact to achieve a common goal.

2.2. Contribution of an Ergonomist

The role of the ergonomist in an engineering design environment is usually threefold. First, s/he is an expert in human characteristics. The ergonomist can tap into a considerable amount of literature pertaining to human behavior and characteristics in various contexts, and then extract pertinent information from which to formulate recommendations for the systems designers to use in their work. Second, the ergonomist is an expert in the activities of end users (e.g. operators and maintenance workers). Access to methodological tools designed specifically to analyze work activities and interact with end users, often coupled with extensive experience in particular work settings, means that the ergonomist becomes very knowledgeable about the work performed in a variety of production system implementations. S/he is therefore a valuable resource when different design solutions must be considered. In these two roles, the ergonomist is somewhat passive, providing input only when asked.

The third role of the economist is as an active member of the design team, whose participation can influence both the design process and the design itself. Part of this role will certainly consist in ensuring that other designers listen to the opinions of end users in the design process.

2.3. Difficulties for the Ergonomist

One of the main difficulties faced by ergonomists is that their contribution is generally solicited too late in the design process, i.e. when technological choices have already been made (Oland 1991). Since these choices probably did not take the human component into consideration, new constraints are added to the ergonomist's own problem space, making the task even more difficult and less effective in the end. This situation may be due to the fact that designers are often skeptical about the usefulness of the ergonomist's contribution to the design process, or do not understand the importance of including the ergonomist at a very early stage of the process. The fact that ergonomists and designers have different formal background training may exacerbate an already difficult situation, often plagued with communications problems, preventing the ergonomics specialist from making an active and effective contribution to the design process. Case studies report that where the contribution of the ergonomist is clearly understood and accepted through adequate communication, the design process usually proceeds well.

In manufacturing systems, an error in the design of a system may result in the system being inoperable because of technical problems. The result of such an error sends immediate feedback to the designer, so that s/he can correct it. However, if the design error relates to an ergonomics aspect, then the system will probably still be operable because of the unique and formidable ability of humans to compensate. However, this type of error usually leads to dysfunctional states of the system, degrading the working conditions of the employees. Degraded working conditions have been linked to productivity losses, including occupational accidents and diseases.

An illustration of this situation, and of the sometimes conflicting objectives of designers, is the use of the Pareto distribution, which virtually all engineers are taught. The Pareto concept is used by engineers to help focus on important aspects of a problem. The bulk of a problem can be solved with a comparatively small investment of effort (e.g. a 20% effort can solve 80% of a problem) (Konz 1990). Working on the most important problems or aspects of a problem leads to a more efficient use of engineering resources. Engineers apply this basic

concept to a variety of problems. Thus, an engineer designer will usually be content with an operational design that is stable (or works well or is within specified parameters). S/he has little incentive to spend valuable resources in order to achieve a near perfect system, since at a certain level the effort required to further improve performance greatly outweighs the gains that can be expected. Besides, the engineer knows that the end user will compensate in any case for the few remaining system inefficiencies. In contrast, the ergonomist is interested in the sources of variability in the system, because they cause dysfunctions that render the end users' work activities and lives more difficult. It is precisely the variability, which is not considered by the designer because it occurs in a comparatively small portion of cases, that forces human interventions. The ergonomist is aware that these dysfunctions will probably generate costs in the long-term. Unfortunately, such costs are very difficult to estimate at the design stage. It follows that, in the engineer's mind, the ergonomist is spending, not to say wasting, time and valuable resources on aspects or conditions of the system that are not worth the effort.

The ergonomist is often included in a design team in the hope that his or her contribution will help reduce occupational accidents and diseases. In the long-term, this type of contribution is hard to sell, since its main pitfall is that resources will be invested for "non-events", i.e. events that are expected not to materialize (e.g. occupational accidents and diseases). This is counter-intuitive, in the sense that humans usually expect an investment in resources to produce some form of result, not the absence of something. Hence, the contribution of the ergonomist will not be observed or measured unless a similar and comparable existing system can be used to benchmark the new system. In theory, both the old and the new systems should be operated together long enough to allow for accidents and diseases to materialize in the new system - a situation that is rarely possible in reality. Hence, the ergonomist's contribution should not be tied solely to health and safety questions, but also to productivity, quality and reliability issues.

Design problems are often complex and are divided into subproblems, each of which is assigned to a different design team. Since it is common practice to have one ergonomist for the whole project, this person has to cope with the burden of interfacing and dealing with several teams at once, because ergonomics issues will sometimes cut across several subproblems. This may help make the ergonomist's task more difficult.

3. CONDITIONS TO FACILITATE THE WORK OF AN ERGONOMIST

The literature suggests that the following five conditions should be present if an ergonomist is to be successful in an engineering design environment. First, the ergonomist must convince the other technically oriented designers of the importance of the field of ergonomics. This ongoing effort is important, since the ergonomist's participation in the design project is bound to generate new problems for the other members of the team - problems that would otherwise have gone unnoticed. Top management in particular must be convinced of the value of ergonomics from the outset. Second, the ergonomist must play an active role in the very early stages of the design process, so that the human side of the system to be designed is addressed adequately. Third, the ergonomist must constantly describe the human aspects to the other members of the design team, and link them to the other technical components of the system. This is necessary, since the other members of the design team, owing to their predominantly technical background, will often unconsciously evacuate the human aspects to focus on technology. Fourth, since the choices made throughout the design process predetermine the work activities of the future system's end users, the ergonomist must constantly help the other designers to anticipate those activities, so that they can orient their design choices accordingly. Finally, ergonomists must adapt. On the one hand, they must adapt to the constant changes imposed by new technologies, which more than ever before are placing emphasis on the cognitive rather than the physical aspects of work activities. On the other hand, they must adapt to the constant changes that occur in the design process environment (e.g. changes of objectives, changes of design team members).

1. INTRODUCTION

The return to the workplace of individuals affected by work-related musculoskeletal disorders (WMSDs) of the upper limbs, represents a critical problem in work settings which feature a multitude of tasks liable to biomechanically strain the upper limbs. Workers suffering from disorders are largely considered to be temporarily or permanently unfit for the jobs which are likely to have caused or aggravated the disorder. Some relevant criteria, procedures, and solutions for returning workers with limited fitness to tasks and jobs with lower exposure will be described. For successful reintegration we suggest an intensely participatory approach involving technical staff, medical staff, and affected workers. This should allow the affected workers to remain productive, at least to some extent, while safeguarding their health.

2. PROCEDURES AND CRITERIA

2.1. Involvement of Technical Staff in Redesigning Jobs

The technical staff should be trained to submit the relevant jobs to the specific risk assessment procedure, so as to more effectively redesign tasks for both "healthy" and diseased workers. The training should cover aspects such as definition of repetition injuries of the upper limbs and their relationship to work stresses; introduction to the pathogenesis of the principal upper limb disorders related to repetitive movements; methods and criteria for rating occupational risk; techniques for measuring action frequency by analyzing slow-motion films, methods of applying an upper limb strain index using the Borg scale, criteria for detecting awkward postures and evaluating recovery times, identification and measurement of additional risk factors.

The technical staff should be asked to inspect their departments and single out jobs and duties that would be immediately suitable for WMSD-affected workers, or could be adapted with minimal changes. When jobs are not entirely suitable for affected workers, job redesign recommendations should be drafted. Any jobs or tasks that would be too expensive or too slow to modify should be rejected. An ergonomic supervisor should carry out a final check on the task analysis and evaluation performed by the technical staff and a final check on the jobs they have selected.

2.2. Criteria for Locating Suitable Tasks and Jobs for Affected Workers

The recommendations for redesigning jobs for affected workers could be based on the following criteria: frequency should be less than 20 actions per minute; minimal upper limb exertion (less than 5% of the maximal voluntary contraction, or a score of 0.5 on the Borg scale); posture and movements not requiring "intense involvement" of the main joints; adequate recovery times during each shift. If tasks already include adequate recovery times, no further allowances are added.

If posture is not optimal, the recommendation is to slow down the frequency of the actions, with special attention devoted to the clinical findings of the worker involved. If the job involves occasional manual material handling, the following weights should be considered, assuming the handling is carried out with the correct posture:

- For 4–5 kg loads, lifted alone, lift no more than 2–3 times every 30 minutes.
- For the occasional 7–10 kg load, lifted by 2 workers, lift no more than once every 30 minutes.
- For the occasional 14–15 kg load, lifted by 2 workers, lift no more than once every 60 minutes.
- Avoid lifting loads of more than 15 kg.

2.3. Matching Tasks and Jobs with Disorders

To facilitate communications between the technical staff and the medical staff within the factory, the results of the analysis of the various jobs and tasks should be classified. It is also useful to classify upper extremity disorders in relation to degree and severity. This makes it easier to match the affected workers with the most appropriate jobs.

The following ratings are suggested for the task: excellent with no limitations (no modifications needed, suitable for all affected workers); excellent with some limitations (no modifications needed, but not suited to all affected workers); excellent with modifications (suitable for all affected workers, even the most severe, provided that the recommended modifications are adopted); very good with modifications (suitable for workers with a moderately severe condition, provided the recommended modifications are adopted); unsuitable (job difficult to adapt, therefore not suitable for affected workers).

The following ratings are suggested for disease degree: severe (only one part of the upper limb affected severely, or several parts affected moderately); moderate (only one part of the upper limb affected moderately, or several parts affected mildly); anamnestic (only suspect symptoms detected, with no clinical or instrumental findings). It is also important to check the sequence of the upper limb involved — scapulohumeral joint (shoulder), elbow, wrist, hand/finger.

2.4. Timetable for Returning WMSD-affected Workers to the Workforce

The principal aim of reassigning workers with upper limbs disorders to new or redesigned jobs or tasks is to alleviate the clinical signs and symptoms associated with the disorder while maintaining the worker's productivity. To ensure the results of the various decisions could be monitored continuously, it was essential to have close cooperation between the technical staff,

the plant medical staff, and above all the workers themselves. Here is a recommended schedule.

2.4.1 Medical history

Workers known to have work-related disorders should be interviewed by medical staff regarding their symptoms upon starting the redesigned job. The interview should be carried out using a clinical questionnaire in order to standardize the data collection.

2.4.2 Enhancing worker awareness

Meetings should be arranged between the medical staff and the workers involved in the study. The meetings should be designed to make the workers more aware of how best to cooperate with the medical and technical staff in verifying how successfully the jobs are redesigned and allocated. During the meetings (for groups of up to 10 workers), the following points should be discussed:

- Type and pathogenesis of the most common biomechanical strain disorders affecting the upper limbs; reasons for changing and shifting workers to new or redesigned tasks and jobs.
- Correct use of the modified job, particularly the correct use of recovery times; importance of maintaining a regular pace without accelerating the frequency of the actions; importance of avoiding the needless lifting of harmfully heavy loads.
- Need to pay careful attention to any disorders affecting the upper limbs, and in particular to any flare-up of existing symptoms (if symptoms worsen, the worker is invited to notify the plant physician, even between regularly scheduled follow-up appointments).
- Need to pay careful attention to the new method adopted for performing the job, and inform the supervisor whenever any unforeseen problem arises (use of excessive force, inability to keep up with required speeds, etc.).

2.4.3 Supply and use of orthopedic orthesis

During the meeting to discuss the worker's medical history, the medical staff should recommend the use of specific orthopedic ortheses whenever they are appropriate. The ortheses are recommended primarily for workers with carpal tunnel syndrome; initially they should be worn only at night.

3. HEALTH CARE MONITORING

Close monitoring is required every time jobs and tasks are redesigned; this should be carried out almost continuously, so that any technical and organizational modifications can be made promptly. A special health care program is used to validate the decisions made about the various diseases that are present; this aims to monitor (at close intervals) the clinical condition of the workers in their newly designed jobs, as well as their degree of acceptance of the jobs.

A simple questionnaire should be used to obtain information regarding changes in relevant symptoms (classified as symptoms completely disappeared, symptoms improved, situation unchanged, symptoms worse, appearance of new symptoms or disorders); use of the orthopedic appliance, in terms of compliance and degree of tolerance; assessment of acceptability of new job or task, with details concerning any inadequacies

deriving from awkward joint segment positions, excessive muscle force, etc.

Moreover, the questionnaire should provide a diagnostic link, perhaps for requesting further clinical or instrumental tests; and a useful operational link for the production engineers. Based on the results of the study, the physicians are able to provide the engineering staff with practical information, which may be summarized as follows: the worker need no longer be classed as "affected" (remission of disease); the worker may continue to perform his/her duties in the current job, even if not redesigned for affected workers (anamnestic case); the worker must remain in his/her current workstation redesigned for affected workers (clinical case); the worker must be transferred to a redesigned workstation (new case or worsening of anamnestic case); the workstation to which the worker has been assigned must be redesigned for diseases other than those related to repetitive movements. Checkups should be scheduled as follows:

- 2 weeks after changing jobs
- 3 months after changing jobs
- 6 months after changing jobs
- 12 months after changing jobs
- every 12 months thereafter

The checkup at 2 weeks is to give a rough assessment of whether or not the situation is satisfactory, and to reinforce the instructions given to the worker.

4. RESULTS OF THE HEALTH CARE MONITORING PROGRAM

Cross-tabulation is used to analyze the preliminary results of the monitoring program on workers affected by upper limb disorders who were transferred to a redesigned job or task one year earlier. The tables show disease, degree of severity, sex, location, bilateral location, multiple joints, relative complaints (improvement or worsening), appearance of new disorders, department and job redesign. To elucidate the most plausible phenomenon, it is usually advisable to evaluate the worst percentiles and the better percentiles.

Table 1 shows the trend for disorders affecting wrists analyzed in two different departments: the job in one department (assembly line) had been redesigned earlier than in the other department (electrical engines) due to technical problems. A large proportion of the workers in the second department were still performing jobs that were only partially redesigned. The table clearly illustrates the difference between the wrist symptoms in the two departments: the results are highly positive in the first area. Even without a thorough statistical analysis, there is no question the redesign has had positive effects. Special attention should be paid to carpal tunnel syndrome and the use of orthopedic ortheses; workers who wear an orthesis frequently report an improvement.

5. CONCLUSIONS

- It seems essential to reduce the amount of exposure to repetitive tasks of the upper limbs among workers with WMSDs.
- Reducing exposure to risk factors associated with repetitive tasks of the upper limbs would seem to be a sufficiently

Table 1. Condition of workers with specific wrist disorders 6 months and 1 year after starting re-designed job, in two different workstations.

WRIST SYMPTOMS	RIGHT WRIST					LEFT WRIST			
	ASSEMBLY BAY WORKSHOP		ELECTRICAL ENGINES			ASSEMBLY BAY WORKSHOP		ELECTRICAL ENGINES	
	No.	%	No.	%		No.	%	No.	%
Disappeared	10	33.3	2	11.1		5	20	3	18.7
Improved	8	26.6	4	22.2		8	32	4	25
Unchanged	10	33.3	7	38.9		9	36	5	31.2
Worsened	0	0	5	27.5		1	4	3	18.7
Onset of new symptoms	2	6.6	0	0		2	8	1	6.2
TOTAL POSITIVE CASES	30	100	18	100		25	100	16	100

adequate measure. In fact, it produces a distinct improvement in symptoms.

- The decision to allow workers to perform tasks with a frequency of less than 20 actions per minute, in the absence of any other risk factors, proved to be a good starting hypothesis which deserved to be further verified and, eventually, validated. This approach moreover preserves the WMSD-affected worker's residual productivity. Expressed as an OCRA exposure index (Occhipinti 1998), this decision would imply that workers with upper limb disorders are on the whole better suited to jobs and/or workstations with a strain index score less than or equal to 0.7.

- For the program to be successful, it is vital to ensure active participation and excellent communications between all those involved (technical staff, plant medical staff, workers).

Healthy Work Organization

D.M. DeJoy, M.G. Wilson, and C.S. Griffin-Blake

Workplace Health Group, Department of Health Promotion and Behavior, University of Georgia, Athens, GA 30602, USA

1. INTRODUCTION

Work organization refers to the way work processes are structured and managed, including scheduling, job design, interpersonal aspects, management style, organizational characteristics, and related topics. Healthy work organization is a logical outgrowth of work organization and represents the idea that (a) it should be possible to identify a set of job and organizational dimensions or factors that characterize the healthy organization, and (b) such workplaces should have safer, healthier, more productive workers, and superior profitability and market success. In most respects, the basic concept of healthy work organization falls within the scope of macroergonomics. Macroergonomics emphasizes a top-down sociotechnical systems approach to the overall design of organizations, work systems, jobs, and related human-environment interfaces (Hendrick 1991). Microergonomics, in contrast, focuses more on the immediate human-machine interface and the design of specific tasks, jobs, and workstations.

Part of the attractiveness of healthy work organization is that it represents the integration of research and practice in several areas, including human resources and organizational development, occupational stress, occupational safety and health management, and worksite health promotion. Each is discussed briefly below.

1.1 Human Resources and Organizational Development Perspective

Case studies of successful organizations suggest that healthy people and healthy relationships are at the very core of business, and that many business problems and failures to remain competitive can be traced to traditional, hierarchical forms of management and employee relations (Rosen and Berger 1991). From this perspective, creating healthy work organizations involves a redefinition of the relationships, expectations, obligations, and interactions between employees and organizations.

1.2 Occupational Stress Perspective

A number of prominent stress researchers have attempted to identify the job and organizational attributes or factors which characterize healthy or low stress work environments. Almost without exception, these authors emphasize the importance of organizational or contextual factors in diagnosing and remedying the causes of stress within organizations. For example, Cooper and Cartwright, in their "front-end" approach to addressing organizational stress (Cooper and Cartwright 1994) suggest a variety of organizational change interventions, in addition to the more traditional individual-oriented strategies typically used to manage job stress. Karasek and Theorell (1990) argue that a fundamental shift in the relative distribution of decision latitude or control is essential to creating healthy work organizations.

1.3 Occupational Safety and Health Management Perspective

Three areas of occupational safety and health research, in particular, underscore the breadth of interest in organizational or contextual factors. First, research on safety and health climate or culture points to the importance of the broader organizational context in shaping employee behaviors. Second, recent research on human error, most notably Reason's work on active and latent failures (Reason 1995), calls attention to the importance of organizational action or inaction in creating the substrate or backdrop for human error by frontline workers. And third, research on workplace self-protective behavior is consistent in highlighting organization-level factors as facilitating or hindering safe behavior in the workplace.

1.4 Health Promotion Perspective

Work in this area argues that worksite health promotion programs should be expanded to include interventions designed to improve organizational and environmental conditions. DeJoy and Southern (1993) have proposed an integrative model of workplace health promotion that features three interactive systems: job demands and worker characteristics, work environment, and extraorganizational influences. The basic architecture of this model suggests that attempts to preserve and enhance worker health should develop from a total work situation analysis.

1.5 Cross-cutting Themes

Viewed together, the four perspectives reveal three cross-cutting themes:
- The increased salience of organizational or contextual factors in the work-health relationship.
- The importance of organization-level action in producing positive change.
- The need for modification of the traditional employer-employee relationship in terms of increased opportunities for employee involvement and input.

2. DIMENSIONS OF HEALTHY WORK ORGANIZATION

Reviews of the literature cited earlier suggest that a set of dimensions of healthy work organization can be compiled and conveniently organized into three categories or domains: (1) job-related factors, (2) organizational structure or climate, and (3) career development (Figure 1). Although it is impossible to argue that the dimensions listed in Figure 1 represent a perfect or all-inclusive list, there is sufficient consistency across the literature to make a persuasive case for the importance of each dimension.

2.1 Job-related Factors

The rather extensive literature on job stress provides much of the foundation for a general agreement on the job factors that are most important in preserving or enhancing worker health and well-being. These factors include workload, autonomy and control, role clarity, job content, work scheduling, and environmental conditions.

Workload consists of the daily demands of the work situation or job design. Workload is associated with job satisfaction and an assortment of psychological, physiological, and behavioral strain symptoms. However, workload per se may not necessarily

Figure 1. The three domains of healthy work organization

be the defining factor in producing worker strain. Research on machine-paced and other externally controlled tasks indicates that strain may most likely occur when control is not commensurate with job demands.

Autonomy and control refers to the degree to which the job provides substantial freedom, independence, and discretion to the individual in scheduling the work and determining the procedures to be used in carrying it out. Employees who perceive relatively high levels of control at work have been associated with higher levels of motivation, performance, job satisfaction, involvement, and commitment, as well as lower levels of absenteeism, turnover, emotional distress, and physical symptoms and conditions, including exhaustion, headaches, and cardiovascular disease.

Role clarity involves the extent to which an employee's work goals and responsibilities are clearly communicated, and the degree to which the individual understands the actions and processes required to achieve these goals. Role ambiguity, the opposite of role clarity, exists when there is a high level of uncertainty about job expectations. It can lead to burnout, increased stress, work dissatisfaction, and decreased productivity and occupational commitment.

Job content involves the meaning, value, and worth that employees attach to their jobs. Jobs which are fragmented, highly repetitious, and monotonous, or that otherwise provide little stimulation or skill utilization have been linked to job dissatisfaction, worker strain, and poor mental health. Work scheduling encompasses a variety of options: full-time or part-time, fixed schedules or rotating schedules, and day work versus shift work. Employees who work their preferred schedule have increased job satisfaction, work commitment, and positive work-related attitudes. Rotating shifts and permanent night work appear to be most problematic in terms of psychological, social, and physical well-being.

Environmental conditions cover a variety of physical conditions and work requirements. They can affect the employee's well-being through exposure to factors such as loud noise, inadequate ventilation, bad lighting, variable temperatures and/

or smoke, toxic chemicals, and infectious diseases. Musculoskeletal symptoms and injuries have also been found in conjunction with various ergonomic hazards, such as highly repetitive tasks and frequent bending, twisting, and heavy lifting.

2.2 Organizational Structure and Climate

The dimensions within this domain emphasize the way in which the workplace is organized, particularly in terms of how it impacts interpersonal relations and the general social environment. They include organizational support, participation and worker involvement, and feedback and communication. Healthy work organizations should provide opportunities for meaningful interpersonal interaction and communication; this is because they give emotional support and they also give instrumental or tangible support in fulfilling job tasks and other assigned responsibilities.

Organizational support can be viewed as any action taken by the organization or its representatives that indicates a concern for the well-being of its employees. Employees' commitment to their organization and their job satisfaction, productivity, and morale are influenced by their perceptions of the organization's support and commitment to them. In addition, social support from supervisors and coworkers have significant effects on job stress and burnout.

Participation and worker involvement refer to situations in which employees have some meaningful input into job-related decision making. Considerable research indicates that increased levels of participation and worker involvement can increase job satisfaction, motivation, productivity, and mental health, and they can reduce job stress and role ambiguity.

Feedback and communication includes the degree to which employees receive direct, clear, and timely information about the effectiveness of their performance and the relative existence of ongoing and two-way communication within the organization. Having an effective two-way communication system may be one of the best methods to involve and empower employees, and it has shown positive effects on role ambiguity, job performance, job stress, worker satisfaction, safety and health program effectiveness, safety climate, and a variety of safety-related behaviors and outcomes.

2.3 Career Development

The third category shifts attention from the attributes of specific jobs and the characteristics of the organizational social environment to job security and career development considerations. In healthy work organizations, employees should be clearly informed about opportunities for improving their job skills and career opportunities, as well as about the organizational and economic developments that may alter their employment situation. The dimensions in this category include job security, advancement and learning opportunities, equitable pay and benefits, and flexible work arrangements.

Job security has been defined as an employee's perception of potential threat to continuity in his or her current job. Perceiving that one's job is secure has been consistently related to job satisfaction, work commitment, quality of life, and mental and physical health.

Advancement and continuous learning opportunities have assumed increasing importance in today's era of mergers, corporate downsizing, and rapid technological change. This

dimension involves opportunities for employees to broaden their job skills and knowledge, and to increase their resources and ability to cope with organizational change.

Equitable pay and benefits is a fundamental issue for employees and the organization. There are two important issues: the actual distribution of rewards and the perceived fairness of the procedures used to decide this distribution. Decreased job satisfaction, leadership, and working relations have been associated with inadequacies in the pay system.

Flexible work arrangements involve the extent to which job requirements allow employees the opportunity to accomplish tasks such as arranging childcare, shopping, scheduling appointments, and meeting other personal obligations and responsibilities. Positive relationships have been found between flexible work arrangements and depression, anxiety, job satisfaction, and work-family conflict for both men and women.

3. MODEL OF HEALTHY WORK ORGANIZATION

Figure 2 presents a conceptual model of healthy work organization that builds upon the dimensions presented earlier. A key aspect is that organization-level action is critical to creating and maintaining the healthy organization. The dimensions of healthy work organization may genuinely be considered as effects more than as causes; that is, well-designed jobs, supportive organizational climates, and positive career development options exist largely as a result of the policies established and actions taken by the leaders of the organization. So, in developing a workable conceptual model, there needs to be some entity, some construct, or some set of constructs that enable these effects to occur. The research literature which support the model provides ample evidence that organization-level support and action is fundamental to organizational effectiveness in terms of employee well-being and financial performance.

The *core organizational attributes* in the model include organizational values, beliefs, and behaviors. These three variables delve into the leadership resources of the organization at three different levels. Organizational values are defined as relatively enduring beliefs about what kinds of behaviors or end-states are preferable to others. Recent studies of successful organizations indicate that success typically comes from paying attention to all stakeholders. In terms of organizational values, healthy organizations and successful organizations should both show good balance between production and employee orientations. Organizational beliefs involve how the organization views its commitment to and responsibility for employee health and well-being.

Of central importance is the idea that employees represent more than units of cost in the business equation. Organizational

behaviors are managerial actions related to employee health and well-being, which essentially reflect how the organization's values and beliefs are translated into policies and programs. The inclusion of core organizational attributes in the model emphasizes the importance of organizational-level action as a leverage point for producing change in the workplace. The inclusion of the three levels (values, beliefs, and behaviors) is intended primarily to establish points of attachment for interventions designed to enable organizations to become healthier.

The job design, organizational climate, and job future components include many of the dimensions discussed earlier. The job design component refers to the dimensions related to job and task demands which consist of workload, control and autonomy, role clarity, job content, work scheduling, and environmental hazards.

The organizational climate component includes the dimensions of organizational support, coworker support, involvement, communication, and physical and psychological danger. Organizational support and coworker support are treated as separate variables in the model to reflect the importance of formal (organizational) and informal (coworker) social support in the workplace.

Feedback and communication are blended into one dimension, and as suggested by recent research on safety climate and culture, physical and psychological danger is included to represent the importance of personal safety and security on the job. The job future component consists of job security, equity, advancement and learning opportunities, and flexible work arrangements.

Figure 2 also features a component labeled *worker perceptions and expectations*. This component is defined as the beliefs, expectations, attitudes, and goals that employees have concerning the organization in which they work. It recognizes that the way in which workers perceive and evaluate events is important for understanding the impacts of various job and organizational factors. Four variables define this component of the model: job satisfaction, organizational commitment, empowerment and stress symptoms. They may also be viewed as intermediate outcomes that are ultimately linked to organizational effectiveness. These particular variables are included because of their demonstrated relevancy to the various dimensions of healthy work organization, and because satisfied, committed, empowered, and low stress employees contribute to organizational effectiveness.

Finally, the *organizational effectiveness* component includes financial and health-related outcome measures. The key to healthy work organization is that it impacts the financial performance of the organization as well as employee health and well-being. Financial measures might include outcomes such as return on equity, sales growth, absenteeism, and turnover. Health and well-being measures might include health care costs, health risk behaviors, loss prevention results, and work-related injuries and illnesses.

4. SUMMARY AND IMPLICATIONS

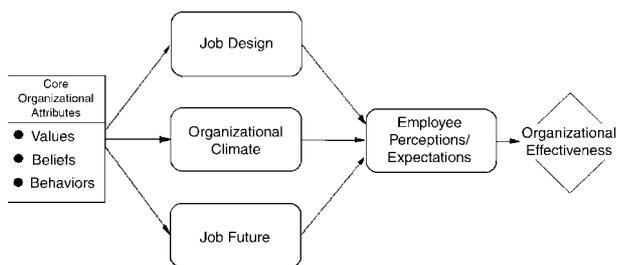
The idea of healthy work organization has come about largely as a logical extension of the interest in work organization within the field of occupational safety and health. Work organization sometimes means different things to different people, but the


Figure 2. Conceptual model of healthy work organization

basic theme is that in trying to make workplaces safer and healthier, it is important to examine contextual and organizational factors, particularly how work processes are structured and managed. Although its roots may be in occupational safety and health, the concept of healthy work organization also reflects a convergence of research and thinking in human resources and management, occupational stress, and worksite health promotion.

Review and synthesis of this literature suggest that a profile of healthy work organization can be derived in terms of a defined set of job and organizational characteristics or dimensions. The dimensions have each been linked to various health or behavioral outcomes in the workplace, and some of these outcomes, such as job satisfaction and absenteeism, have been linked to traditional indices of organizational effectiveness. Moreover, these dimensions can be organized into a conceptual framework that provides a workable blueprint for auditing workplaces and organizations and for designing healthier ones. This model makes a strong case for the criticality of organizational change in creating and maintaining healthy organizations.

However, in spite of progress in describing healthy work organization, the actual predictive or explanatory capacity of the healthy work organization model has not been comprehensively evaluated. The model is tentative in the sense that it remains to be determined whether the various elements are both necessary and sufficient to explain either health or financial outcomes in real-world organizations. The dual-benefits aspect of healthy work organization is also largely untested. Very few studies have examined worker well-being and organizational financial performance simultaneously, even with respect to single variables or dimensions.

Using autonomy and control, one of the job dimensions in the model, as a case in point, a number of studies show that jobs characterized by low levels of worker control are associated with a variety of adverse health and behavioral consequences. Interventions designed to increase worker control also have demonstrated beneficial effects in terms of worker well-being. But shifting to the financial side, traditional research on organizational effectiveness has paid relatively little attention to control and autonomy as a variable of interest in examining outcomes related to productivity, efficiency, and financial performance. Even fewer attempts have been made to examine both worker well-being and financial outcomes in the same study.

Many researchers and workplace advocates would argue that positive behavioral and health outcomes alone provide sufficient justification for organizational redesign efforts, but the importance of testing the parallel-benefits hypothesis should not be diminished. Positive findings would provide significant and much needed impetus for redesign efforts aimed at maximizing human capital and creating safer, healthier, and more fulfilling workplaces and organizations.

Historical Development of Macroergonomics: the Development of Human–Organization Interface Technology and its Application to Work System Design

H. W. Hendrick

Hendrick and Associates, Englewood, CO 80111, USA,

1. INTRODUCTION

Ergonomics, or human factors as it alternately is known in North America, is considered generally to have had its formal inception as an identifiable discipline in the late 1940s. From the beginning, ergonomics has been concerned with the design of sociotechnical systems to optimize human–system interfaces. For the first three decades of its formal existence, the focus of this design concern was on optimizing the interfaces between individual operators and their immediate work environment, or what today often is referred to as *microergonomics*. Initially this focus was labeled as *man–machine* interface design. In the 1970s, as industrialized cultures became more sensitive to gender issues, it became known as *human–machine* interface design. In general, the objective was to apply scientific knowledge about human capabilities, limitations, and other characteristics to the design of operator controls, displays, tools, workspace arrangements, and physical environments to enhance health, safety, comfort, and productivity, and to minimize human error via design.

Beginning with the development of the silicon chip, a subsequent rapid development of computers and automation occurred, bringing a whole new set of human–system interface problems to the ergonomics discipline. As a result, a new sub-discipline of ergonomics emerged which centered around software design and became known as *cognitive ergonomics*. The primary focus remained on the individual operator, but with an emphasis on how humans think and process information, and how to design software to dialog with humans in the same manner.

In the late 1970s, ergonomists began to realize that our traditional predominate focus on individual human–system interfaces, or what herein is referred to as micro-ergonomics, was not achieving the kinds of improvements in overall total system functioning that both managers and ergonomists felt should be possible. More specifically, ergonomists began to realize that they could effectively design human–machine and human–software interfaces, and still have a poorly designed work *system*. Out of this realization developed the sub-discipline of *macroergonomics*.

2. THE BEGINNING: SELECT COMMITTEE ON HUMAN FACTORS FUTURES, 1980–2000

Although one can identify a number of precursors, the most direct link leading to the formal development of macroergonomics as a distinct sub-discipline can be traced back to the US Human Factors Society's Select Committee on Human Factors Futures, 1980–2000.

In 1978, Arnold Small, Professor Emeritus of the University of Southern California (USC) and former President of The Human Factors Society, noted the many dramatic changes occurring in all aspects of industrialized societies and their built environments. He believed that traditional human factors/ergonomics would not be adequate to respond effectively to these trends. At Professor Small's urging, the Human Factors Society (now, the Human Factors and Ergonomics Society) formed a "Select Committee on Human Factors Futures, 1980-2000" to study these trends and determine their implications for the human factors discipline. Arnold Small was appointed chair of this select committee. One of those appointed to the committee, Professor Hal Hendrick of USC, was specifically charged to research trends related to the management and organization of work systems.

After several years of intensive study and analysis, the committee members reported on their findings in October 1980 at the HFS Annual Meeting in Los Angeles, California. Among other things, Hendrick noted the following six major trends as part of his report:

1. *Technology*. Recent breakthroughs in the development of new materials, micro-miniaturization of components, and the rapid development of new technology in the computer and telecommunications industries would fundamentally alter the nature of work in offices and factories during the 1980–2000 time-frame. In general, we were entering a true information age of automation that would profoundly affect work organization and related human–machine interfaces.

2. *Demographic shifts*. The average age of the work populations in the industrialized countries of the world will increase by approximately six months for each passing year during the 1980s and most of the 1990s. Two major factors account for this "graying" of the workforce. First, the aging of the post-World War II "baby boom" demographic bulge that now has entered the workforce. Second, the lengthening of the average productive lifespan of workers because of better nutrition and healthcare. In short, during the next two decades, the workforce will become progressively more mature, experienced, and professionalized.

   As the organizational literature has shown (e.g. see Robbins 1983) as the level of professionalism (i.e. education, training, and experience) increases, it becomes important for work systems to become less formalized (i.e. less controlled by standardized procedures, rules, and detailed job descriptions), tactical decision-making to become decentralized (i.e. delegated to the lower-level supervisors and workers), and management systems to similarly accommodate. These requirements represent profound changes to traditional bureaucratic work systems and related human–system interfaces.

3. *Value Changes*. Beginning in the mid-1960s and progressing into the 1970s, a fundamental shift occurred in the value systems of workforces in the United States and Western

Europe. These value-system changes and their implications for work systems design were noted by a number of prominent organizational behavior researchers, and were summarized by Argyris (1971). In particular, Argyris noted that workers now both valued and expected to have greater control over the planning and pacing of their work, greater decision-making responsibility, and more broadly defined jobs that enable a greater sense of both responsibility and accomplishment. Argyis further noted that, to the extent organizations and work system designs do not accommodate to these values, organizational efficiency and quality of performance will deteriorate.

These value changes were further validated in the 1970s by Yankelovich (1979), based on extensive longitudinal studies of workforce attitudes and values in the United States. Yankelovich found these changes to be particularly dramatic and strong among those workers born after the World War II. Of particular note from his findings was the insistence that jobs become less depersonalized and more meaningful.

4. *World competition*. Progressively, US industry is being forced to compete with high quality products from Europe and Japan; and other countries, such as Taiwan and Korea, will soon follow. Put simply, the post-World War II dominance by US industry is gone. In the light of this increasingly competitive world market, the future survival of most companies will depend on their efficiency of operation and production of state-of-the-art products of high quality. In the final analysis, the primary difference between successful and unsuccessful competitors will be the quality of the *ergonomic* design of their products and of their total work organization, and the two are likely to be interrelated.

5. *Ergonomics-based litigation*. In the US, litigation based on the lack of ergonomic safety design of both consumer products and the workplace is increasing, and awards of juries have often been high. The message from this litigation is clear: managers *are* responsible for ensuring that adequate attention is given to the ergonomic design of both their products and their employees' work environments to ensure safety.

One impact of this message, as well as from the competition issue, noted above, is that ergonomists are likely to find themselves functioning as true management consultants. A related implication of equal importance is that ergonomics education programs will need to provide academic courses in organizational theory, behavior, and management to prepare their students for this consultant role.

6. *Failure of traditional (micro-) ergonomics*. Early attempts to incorporate ergonomics into the design of computer workstations and software have resulted in improvement, but have been disappointing in terms of (a) reducing the work system productivity costs of white collar jobs (b) improving intrinsic job satisfaction, and (c) reducing symptoms of high job stress.

As Hendrick noted several years later, we had begun to realize that it was entirely possible to do an outstanding job of ergonomically designing a system's components, modules, and subsystems, yet fail to reach relevant systems effectiveness goals because of inattention to the *macro*ergonomic design of the overall work *system*. Investigations by Meshkati (1986) and Meshkati and Robertson (1986) of failed technology transfer projects, and

by Meshkati (1990) of major system disasters (e.g. Three Mile Island and Chernobyl nuclear power plants, and the Bhopal chemical plant), have all led to similar conclusions.

Based on the above observations, Hendrick concluded in his 1980 report that, for the human factors/ergonomics profession to truly be effective and responsive to the foreseeable requirements of the next two decades and beyond, there is a strong need to integrate organizational design and management (ODAM) factors into our research and practice. It is interesting to note that all of these predictions from 1980 have come to pass, and are continuing. These needs would appear to account for the rapid growth and development of macroergonomics that since has occurred.

3. INTEGRATING ODAM WITH ERGONOMICS

As a direct response to Hendrick's report, an ODAM technical group was formed within the Human Factors Society in 1984, and similar groups were formed that year in both the Japan Ergonomics Research Society and the Hungarian society. Less formal interest groups were formed in other ergonomics societies internationally. In 1985, the International Ergonomics Association formed a Science and Technology Committee comprised of eight technical groups. The first eight groups formed were based on the input from the various federated societies as to what areas could most benefit from an international level technical group. One of those first eight was an ODAM Technical Group (TG). This TG has consistently been one of the IEA's most active groups. For example, the IEA ODAM TG has helped to organize six highly successful IEA international symposia on Human Factors in ODAM, with the proceedings of each being commercially published by North-Holland (Elsevier), and it is planned to continue this activity indefinitely on a biennial basis.

In 1988, in recognition of its importance to the discipline, ODAM was made one of the five major themes of the 10th IEA Triennial Congress in Sidney, Australia. In recognition of both its importance and rapid growth, it was one of twelve themes for the 11th Triennial Congress in Paris, France in 1990. At the 12th Triennial Congress in Toronto, Canada in 1994, and again at the 13th Congress in Tempare, Finland in 1997, a major multi-session symposium on Human Factors in ODAM was organized. For both of these congresses, more papers were received on macroergonomics and ODAM than on any other topic. A similar symposium is being planned for the 14th Triennial Congress in the year 2000.

4. THE CONCEPT OF MACROERGONOMICS

By 1986, sufficient conceptualization of the ergonomics of work systems had been developed to identify it as a separate sub-discipline, which became formally identified as *macroergonomics* (Hendrick 1986). In 1998, in response to the considerable methodology, research findings, and practice experience that had developed during the 1980s and 1990s, the Human Factors and Ergonomics Society's ODAM TG changed its name to the "Macroergonomics Technical Group" (ME TG).

Conceptually, Macroergonomics can be defined as a top-down, sociotechnical systems approach to work system design, and the carry through of that design to the design of jobs and related human–machine and human–software interfaces. Although top-down conceptually, in practice it is top-down,

middle-out, and bottom-up. The Macroergonomics design process tends to be non-linear and iterative, and usually involves extensive employee participation.

For an understanding of the sociotechnical systems approach, see *Sociotechnical systems theory* in this encyclopedia; for a better understanding of Macroergonomics and work system design, see *Sociotechnical analysis of work system structure* in this encyclopedia.

Human Factors and Total Quality Management

C. G. Drury

Department of Industrial Engineering, University at Buffalo, Buffalo, NY 14260, USA

1. INTRODUCTION

To understand and use the relationship between quality and ergonomics/human factors, the quality movement must first be reviewed, then where ergonomics and quality have worked together must be indicated and finally some prescriptions to enhance both disciplines must be provided. A fuller account of these relationships is found in Drury (1998).

2. THE QUALITY MOVEMENT

The quality movement began in the 1920s and 1930s with the application of statistical techniques to industrial operations. These included control charts for determining when a process had left its controlled state, sampling schemes for determining whether to accept a batch of product and industrial experiments to improve products and processes. Acceptance sampling is no longer used, but control charts have evolved into statistical process control (SPC) and industrial experiments into the Taguchi methods of robust design.

A major advance in the quality movement began when Japan began to develop quality techniques in the 1950s and 1960s to meet the challenges of producing quality goods with few natural or economic resources. Two themes characterize this movement: variance reduction and management. The first sees variation from all sources as a strong cost driver and therefore seeks to find, reduce and eliminate sources of variation in products. This has led to the redesign of products and processes using the philosophy of continuous improvement, i.e. continuous (often small) changes to reduce variance. Management's role in quality is now seen as a key to success. Quality has moved from being a technical discipline delegated to specialists to a managerial discipline of concern to the whole organization. The drive for continuous improvement is usually led by top management commitment, but implemented at much lower levels. Teams of employees, comprising operators, engineers and supervisors, are the preferred change agents. Underlying this management philosophy are the ideas that driving down variability will reduce costs as well as increase quality, and an emphasis on implementation rather than just statistical analysis (e.g. Evans and Lindsay 1995).

When these ideas were applied, quality moved from quality control, a largely on-line activity, through quality assurance to quality management, a largely off-line activity. Thus, the responsibility for quality moved both up and down within the organization, and (through robust design) backwards in the design/production/sales cycle. Quality management became an important tool throughout the world in the 1980s and 1990s with numerous successes claimed and many parallel activities, such as quality awards and international quality standards (e.g. the ISO-9000 series). "Successes" need to be treated with some caution, however, as isolating a single factor as causal in a complex, open system such as a manufacturing organization is logically quite difficult.

3. QUALITY AND ERGONOMICS

There are many sources of information on the quality movement, with an excellent overview and analysis provided by Hackman and Wageman (1995). Table 1 is adapted from their work to summarize the fundamental beliefs of the quality movement, particularly total quality management (TQM). The rest of this encyclopaedia provides equivalent summaries of the fundamental beliefs of the ergonomics movement, which has evolved over a similar time span into an industrially useful discipline. A summary of ergonomics/human factors tenets is given in Table 2. The parallelism between ergonomics and quality invites comparisons, which turn out to be useful in showing how these disciplines can work together more effectively.

Tenets of TQM parallel those of ergonomics/human factors in many ways. Both disciplines believe in the essential integrity of the human operator as a person who desires quality and avoids errors. Equally ergonomics and quality both rest on a foundation of measurement, with a belief in quantification rather than intuition. Finally, quality and ergonomics use teams and active operator participation as a way of finding problems and implementing change. However, ergonomics differs from TQM in some fundamental ways. It has often focused on the minutae of work design (microergonomics) whereas quality management has operated at a higher level. But microergonomics is not fundamental: ergonomics has at least as much to say about socio-technical systems as about biomechanics, and macroergonomics is now advocated as a higher-level approach.

The tools used by the quality movement, such as quality

Table 1. Tenets of TQM (adapted from Hackman and Wageman 1995)

Assumptions	1. Good quality is less costly to an organization than is poor workmanship
	2. Employees naturally care about quality and will take initiatives to improve it
	3. Organizations are systems of highly interdependent parts: problems cross functional lines
	4. Quality is viewed as ultimately the responsibility of top management
Change principles	1. Focus on the work processes
	2. Uncontrolled variability is the primary cause of quality problems: it must be analyzed and controlled
	3. Management by fact: use systematically collected data throughout the problem-solving cycle
	4. The long-term health of the organization depends upon learning and continuous improvement
Interventions	1. Explicit identification and measurement of customer requirements
	2. Creation of supplier partnerships
	3. Use of cross-functional teams to identify and solve quality problems
	4. Use scientific methods to monitor performance and identify points for process improvement
	5. Use process-management heuristics to enhance team effectiveness

Table 2. Tenets of ergonomics/human factors

Assumptions	1. Errors and stress arise when task demands are mismatched
	2. In any complex system, start with human needs and system needs, and allocate functions to meet these needs
	3. Honor thy user: use measurements and models to provide the detailed technical understanding of how people interact with systems
	4. Changing the system to fit the operator is usually preferable to changing the operator to fit the system. At least develop personnel criteria and training systems in parallel with equipment, environment and interface
	5. Design for a range of operators rather than an average; accommodate those beyond the design range by custom modifications to equipment
	6. Operators are typically trying to do a good job within the limitations of their equipment, environment, instructions and interfaces When errors occur, look beyond the operator for root causes
Change principles	1. Begin design with an analysis of system and human needs using function and task analysis
	2. Use the task analyses to discover potential as well as existing human/system mismatches
	3. Operators have an essential role in designing their own jobs and equipment, and are capable of contributing to the design process on equal terms with professional designers
	4. Optimize the job via equipment, environment and procedures design before optimizing the operator through selection, placement, motivation and training
	5. Use valid ergonomic techniques to measure human performance and well-being before and after the job change process
Interventions	1. Prepare well for any technical change, especially at the organizational level
	2. Involve operators throughout the change process even those in identical jobs and on other shifts
	3. Use teams comprising operators, managers and ergonomists (at least) to implement the change process

function deployment, design of experiments, statistical process control and cause-and-effect charts, focus on the technical processes. In contrast, the tools of ergonomics treat the human operator explicitly and centrally within a process context. Thus, function and task analysis goes beyond process description to discover potential human/system mismatches, which can lead to errors. To do this, ergonomics calls on explicit models of human functioning.

A final point of departure between ergonomics and quality is the consideration of the effect of the system and process on the operator. Ergonomics has operator well-being as a central concern, whereas this is only an implicit consideration in quality. The quality movement avoids errors, which can be logically extended to include injuries, stress and disease states as design errors. In practice, such extensions are rare. In contrast, ergonomics deals directly with questions of human injury, operator stress, job satisfaction and even industrial hygiene.

It is interesting that neither the quality movement nor ergonomics automation are the central issue, although automation is perhaps the most pervasive change agent in society. In quality, automation is treated, if at all, as an extension of mechanization, and thus as a way to reduce variability from human sources. In ergonomics, the design of automation plays an important, but hardly central, role, with function allocation seen as a way to make automation serve human needs. The effects of automation on healthy work design, stress and error rates are a specific area of ergonomics concern.

4. JOINT APPLICATIONS OF ERGONOMICS AND QUALITY

A number of case studies have been reported where ergonomics and quality were used jointly (for details, see Drury 1998). Two examples will be given to show that such joint activities can indeed be successful.

Eklund (1995) reported a major on-going study in automobile manufacturing where ergonomic and quality aspects were considered together. He showed a close correspondence between jobs with ergonomic problems and those with quality problems. This Quality, Working Environment and Productivity

(QPEP) project provided much evidence of the interrelationship between ergonomics and quality, and also questioned whether the quality movement alone could design healthy, safe and satisfying jobs.

In one of the USA's large mail-order companies, Rooney *et al.* (1993) started an ergonomics program under the auspices of an on-going TQM initiative. The focus was first on workplace design, but it later extended to include work organization and payment systems. Great reductions in workplace injuries and other measures of economic and ergonomic performance were reported.

There is clear evidence that ergonomics and quality can be implemented together with mutually beneficial results.

5. NINE PRESCRIPTIONS FOR COOPERATION

The following list of factors needed for joint ergonomics/quality efforts is modified from Drury (1998). It comes from a comparison of the tenets of quality and ergonomics (e.g. Tables 1 and 2) and a consideration of the literature in both disciplines. At first, similarities (points 1 and 2) where the movements are quite closely aligned are highlighted; then the focus is on areas where ergonomics can learn from quality (points 3–5), then ending with places where quality can learn from ergonomics (points 6–9).

5.1. Study and Measure the Process

Start from a systems focus rather than the current process, an approach also advocated in Business Process Reengineering. Use this as the basis for a detailed quantitative understanding of the process. Standard quality techniques should be used to measure process parameters, and models of human performance and well-being are used to measure and understand the role of the operator in the system. Use these measurements as the basis for directing and quantifying continuous improvement.

5.2. Honor Thy User

Respect the operator in the system as a person trying to do their best, and having an inherent stake in performing well. Do not necessarily blame the operator alone for poor quality/productivity/safety. Tap the potential for operator-empowered improvement by giving real power to small teams that include operators. The

rewards will be improvements in performance, safety and job satisfaction.

5.3. Consider the Strategic Level

Understand the forces beyond the process within the factory, such as requirements of the ultimate customer, and active management of the supply chain. Ensure that ergonomic interventions are truly customer-driven by explicitly measuring customer needs.

5.4. Understand Leadership

Any change activity needs responsibility of managers, up to the highest level. Do not take the mechanistic view of an organization that defines each manager by function. Understand the principles of leadership, recognize leaders and practice leadership. All change projects need a powerful champion.

5.5. Use Well-developed Team Skills

TQM, and many other change disciplines have standard methods of starting, organizing and running successful teams. Use these methods where appropriate. At least understand the methods so that the teamwork-training legacy within the organization from TQM programs can be built on.

5.6. Use Allocation of Function Techniques

A basic building block of human factors is the concept of function allocation, i.e. permanent or flexible assignment of logical functions between human and machine. This has been used by ergonomists at levels ranging from the whole complex system to a single human–machine system. Without an explicit treatment of function allocation, technology can easily fail.

5.7. Error-free Manufacturing/Service

While TQM is calling for drastic reductions in error rates, human factors is coming to grips with the causes of human error. Many military, industrial and service systems have classified errors and derived logical interventions, moving from a consideration only of the accident-precipitating event to a study of root causes and latent pathogens.

5.8. Interface Design

From the workplace layout to reducing injuries to the interface between software and user, human factors engineers have been designing less error-prone interfaces between people and systems. This set of techniques is largely ignored in the TQM literature, despite the latter's emphasis on error reduction, parts per million and six-sigma processes. Ensure that quality programs have access to, and actively use, human factors techniques.

5.9. Maximize Operator Well-being

Respect for the operator should lead to explicit use of operator well-being as a design criterion. System performance (quality, productivity) must not be achieved at the expense of human injury, disease, stress or dissatisfaction. Although designing for long-term performance should eventually ensure that these goals are met, they need to be a visible part of the criterion set if the short-term tradeoffs between the good of the organization and the good of the operator are to be avoided.

As can be seen, ergonomics and quality have enough points of similarity to ensure that they can work together successfully. Additionally, the strengths of each tend to compensate for specific weaknesses of the other. A joint approach should be, and has been measured to be, beneficial to the organization, its workforce and its customers.

Inspection

C. G. Drury, PhD, CPE
Department of Industrial Engineering, University at Buffalo, NY 14260, USA

1. THE ROLE OF INSPECTION

In manufacturing, inspection has traditionally been an activity associated with customer protection: the inspector protected the customer from defects in the product. This role has gradually changed as we move towards techniques of in-line quality assurance (QA), and, more recently, off-line QA. The aim now is to monitor the process, and its output, to determine whether it is in a state of control, i.e. will not produce defects (Vardeman and Jobe 1998). Inspection is now seen as a detection process within this QA system, so that the inspector is largely freed from ever seeing a defect. Indeed, if a production stream needs to be checked for defects, this is often performed automatically. Finally, any inspection activity has usually been reassigned to the production operator for the purpose of rapid control of the production process. Hence, there is unlikely to be a person with the title "inspector". The natural question is whether there is indeed any role for a human inspector?

Human inspectors have a natural role where the inspection task is complex — for example, finding one of a large number of possible visual defects in a casting, or when uniquely human sensing is required as in wine-making. They also have a role in hybrid inspection, where a display system presents manipulated images of objects so that human pattern-recognition and decision skills can be utilized. In addition, with the inspection functions now assigned to production operators more, not less, people are likely to be engaged in inspection activities. But manufacturing is not the only home of inspection. It is a feature of medical diagnostic techniques (X-rays, CAT scans), of continuing airworthiness of aircraft (crack detection, systems testing) and of many security systems, such as screening airline passenger baggage for weapons or explosives. If the inspector at the end of a production line has passed, the inspection activity in manufacturing is still a valuable asset, and the inspector in service functions is still very much a growth job.

Inspection as an activity should above all be accurate: a baggage screener who misses weapons is ineffective. Inspection should also be efficient in that it should take the minimum of resources, usually inspector time, to achieve the desired level of effectiveness. Finally, the inspection should be flexible, i.e. able to detect a variety of threats/defects/targets each with a high level of accuracy and efficiency. It should be noted that none of these attributes specifically imply human inspection.

2. THE FUNCTION OF INSPECTION

While we can specify the desired attributes of the inspection activity, we must examine the functions comprising inspection more closely if we are to understand and improve an inspection system. There have been a number of listings of the functions comprising inspection, but a generic list from Drury (1992) will be used here as it can apply to many different inspection systems. Table 1 shows the generic function list, with particular examples for industrial inspection, security screening and civil aircraft in-service inspection.

From Table 1, it is clear that inspection comprises some functions which are mainly mechanical (Access, Respond), some which have considerable cognitive components (Search, Description) and some which can include significant amounts of both (Initiate). The functions listed in Table 1 can be used to predict and classify the errors which can arise during inspection. Each function can fail in different ways, and for different underlying causes. While a complete analysis is not possible here (see e.g. Drury and Prabhu 1993 for more detail), typical errors and typical causes are presented in Table 2 for each function. Because the main objective of inspection is accuracy, the possible outcome errors at each function are also listed in Table 2.

At the most aggregated level, inspection errors can be classified as either a Miss or a False Alarm:

Miss — Error of failing to respond correctly to a true defect, i.e. concluding "No Defect" instead of "Defect".

False Alarm — Error of responding to an item without a defect as if it had a defect, i.e. concluding "Defect" instead of "No Defect".

Table 1. Generic inspection functions with examples

Generic function	Industrial inspection	Security screening	Civil aircraft inspection
1. INITIATE	Calibrate inspection equipment. Set up for specific product.	Calibrate X-ray screener. Run self-test of computer system.	Read work interruption card for particular area to be inspected. Obtain lighting equipment, etc.
2. ACCESS	Select item from production system. Bring item to inspection position.	Next bag passes through X-ray on conveyor.	Locate area to be inspected on aircraft. Position self and equipment so area is visible.
3. SEARCH	Move eyes across selected item. Move item if needed to ensure visual coverage. Stop if an indication is found.	Visually scan display of bag image. Stop if an indication is found.	Move eyes, flashlight, and mirror so as to cover area to be inspected. Stop if an indication is found.
4. DECISION	Compare indication to standards for rejection of item. Reject if indication beyond standard.	Manipulate image if needed to compare indication to memorized images of threat items. Decide 'threat' if indication exceeds standards.	Manipulate lighting, mirror and, if needed, indication itself to determine if it exceeds memorized or written standards.
5. RESPOND	Mark item as defective, and re-route from process. If item not defective, return to search or next item.	If threat item, invoke defined security procedures, e.g. hand search of bag or call for law enforcement personnel.	If defect found, mark defect location and write up repair order. If not a defect, return to searching area.

Table 2. Errors associated with each generic function for the example of industrial inspection

Generic function	Typical errors	Typical causes	Outcome errors	
			Miss	False alarm
1. INTITATE	Equipment not correctly calibrated	Poor procedures. Setup for wrong product.	Miss	False alarm
2. ACCESS	Wrong item selected for inspection.	Poor procedures. Correct item not immediately available.	Miss	False alarm
3. SEARCH	3.1 Fails to locate indication	Inadequate coverage indication not recognized	Miss	-----
	3.2 Locates false indication	Poor briefing on indications. Visual similarity to true indication	---	False alarm (if decision also incorrect)
4. DECISION	4.1 Accepts true defect	Poor briefing on standards. Visual difficulty of judgement.	Miss	---
	4.2 Rejects false indication	Poor briefing on standards. Visual difficulty of judgement.		False alarm
5. RESPOND	Makes response which does not correspond to decision	Skill-based slip. Interrupted task. Difficult to make one of the responses.	Miss	False alarm

These outcome defects usually have quite different consequences. For example in aircraft inspection a Miss can result in an in-flight failure while a False Alarm can result in unnecessary delay and cost, e.g. to replace an avionics unit. Clearly, misses are the more serious error, but false alarms are not without costs. It has been found in avionics inspection that about half of all units removed for repair have "No Fault Found" on later detailed testing and analysis. These were presumably false alarms which incurred unnecessary additional testing and replacement costs.

While logically false alarms and misses can arise at any of the listed functions, the evidence of many studies (Drury 1992) shows that the most error-prone functions are Search and Decision, i.e. the more cognitive functions. The Initiate function is largely procedural, while the Access and Respond are typically physically limited functions. Brief descriptions of the roles of search and decision in inspection are given here, while the entries on visual search and signal detection contain more detail.

Search in inspection is often visual, although examples of tactile search and procedural search can be found. Visual search proceeds as a sequence of eye movements between fixation points, with the aim of searching the whole required area. Around each fixation point is an area within which the target or indication can be seen: the visual lobe. This area depends upon the characteristics of the target and background, being small when they are similar and large where they are very different. Some target/background combinations may result in visual lobes so large that they effectively cover the whole search area. In these cases, there is no serial search process and the target appears to "pop-out" from the background. An example would be a target of a color substantially different from the background. Provided this effect does not occur, then the inspector must choose at each fixation whether an indication has been found or not. If so, the Decision function is invoked: if not, the inspector typically continues searching. To continue searching the inspector must have some strategy for choosing the next fixation location. This can range from highly systematic, where the inspector never returns to the same fixation point again to quite random, where the inspector may well-refixate an area. There has been much modeling activity of these strategies (e.g. Morawski, Drury, and Karwan 1980) but the effect of strategy on outcome may not be that large unless the task is very simple. Most skilled inspectors tend to have a repeated search pattern (e.g. Megaw and Richardson 1979), which is modified by what is found during the search.

The models of the search process noted above can be used to predict how the probability of detection (POD) changes with the time spent searching the area. Obviously, longer times will give more complete coverage, with a consequent increase in POD. Typical curves for a single task are shown in Figure 1. Because search performance depends on the time allocated, search is a Resource Limited task. A frequent cause of inspection failure is search failure (Sinclair and Drury 1979), often due to insufficient coverage of the area. As the inspector searches the area for longer and longer, there will come a time when he or she decides to stop searching and move on to the next area or item. Choice of stopping time in search can again be modeled (Morawski, Drury, and Karwan 1980), with the models appearing to predict search performance of human inspectors quite well (Chi and Drury 1995). If the inspector does stop searching without finding an indication, the Decision function is trivial: the item should be classified as "No Defect." If an indication *was* found, then decision needs more careful consideration.

The Decision function is a choice between alternatives: either the indication is judged to have exceeded the standard for a defect or it has not. Such decisions are often modeled using Signal Detection Theory, which considers an evidence variable to be generated proportional to the perceived severity of the indication. This evidence variable is typically subject to noise, so that whether a true signal was present or not cannot be uniquely determined. The best an inspector can do is to choose a fixed level of the evidence variable as a criterion, and always report "signal" (i.e. "Defect") if the evidence variable exceeds the criterion and "No Signal" (i.e. "No Defect") if it does not. Decision performance is a function of the signal-to-noise ratio (or detectability) of the defect and the choice of criterion position, which is based on the costs and probabilities of the outcomes in the Signal Detection Theory model (McNichol 1972). Typically inspectors choose a criterion related to these costs and probabilities, but not the same criterion as an economic maximizer would (Chi and Drury 1998).

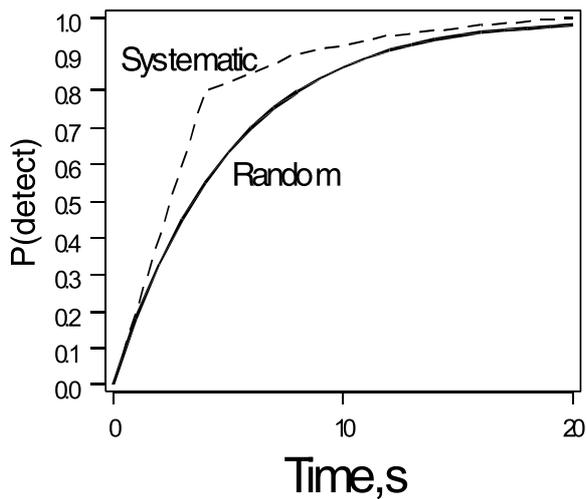
As the inspector's criterion is varied, so the balance between the two errors (miss and false alarm) changes. A low criterion will give few misses and many false alarms, while a high criterion will reduce false alarms at the expense of increased miss rate. Note that no signal detection issues can be invoked unless the search function succeeds in finding an indication to judge. Thus, it is important in understanding an inspection task to analyze


Figure 1. Probability of detection vs searching time.

only the Decision function in terms of theories such as Signal Detection Theory. If we use Signal Detection Theory on a task with a non-trivial Search function, factors affecting search will be wrongly interpreted as affecting decision. Because the overall wrong outcomes of inspection are "Misses" and "False Alarms", many have been tempted to apply decision theories such as Signal Detection Theory to the overall results of inspection performance measurements, with consequent misinterpretation of the findings.

The advantage of considering such models of search and decision in inspection is that they allow detailed quantitative modeling of the inspection task, and hence prediction of the variables affecting performance and the magnitude of the effects of these variables. For example in visual search, visual lobe size is proportional to the conspicuity of a target in a background, and mean search time is inversely proportional to visual lobe size. Hence the effect of enhanced conspicuity on inspection performance can be predicted, either as a known decrease in mean search time or a known increase in accuracy (POD) for any given search time. Similarly for decision, the Signal Detection Theory model shows that low defect probabilities tend to increase the chosen criterion, meaning that as product quality improves, the inspector can be expected to generate more misses and fewer false alarms.

3. ALLOCATION OF FUNCTION IN INSPECTION

With a listing of inspection's functions such as Table 1, it is possible, indeed inviting, to consider how these functions should be allocated between human and machine in an overall inspection activity. In this way, we can have a rational approach to inspection automation, replacing the currently practiced ad hoc approach. The primary determinant of function allocation in inspection is the outcome of the sensing element of search. If this sensing gives a continuous measurement, we have what is known in quality assurance as Variables Inspection. Examples would be measures of length, electrical resistance or color values. In contrast, the outcome can be sensing of discrete defects, such as scratches, rust, missing components or reversed assembly. This is known as Attributes Inspection.

Unless there are compelling reasons for including humans,

all functions in variables inspection are probably best allocated to machines. Computers can process continuous data easily, and produce reliable outcomes based on even complex rules and calculations. These outcomes can easily be coupled to the process itself to produce feedback control or even predictive control without human intervention.

Attributes inspection is where human inspectors prove their value. They can detect, perhaps with the aid of sensors, a wide variety of discrete defects, even those not considered by the inspection system's designers. Thus, security screeners can recognize as a "gun" a whole variety of firearms, most of which they have never seen before. A machine allocated the same function would perhaps test for the total projected area of some degree of X-ray opacity typical of gun material. Any area beyond some threshold would be flagged, missing very small guns or those with high plastic content, while alarming on metallic objects unrelated to weapons. Humans and machines will both generate misses and false alarms, but under particular circumstances humans can outperform machines.

Within attributes inspection, the relatively poor performance of people at visual search tasks suggests that the Search function be given primary consideration for machine allocation. The Decision function, in contrast, can often benefit from human pattern recognition abilities and human capability for responding to unprogrammed situations. In general, if only one or two well-characterized defects are possible, then machines can inspect well. Machines are, of course, constantly improving as computing power increases. There is a tendency among automation engineers to see their objective as ridding inspection of error-prone human inspectors. The result has often been highly automated devices which either do not perform even as well as the people they try to replace, or which are later found to need a human after all as the final decision-maker.

A better way is to choose between humans and machines for each separate function, and later combine the functions into an integrated, hybrid automation system. Often this means having an automated search function presenting displays of indications to a human decision-maker who is equipped with well-designed displays and job aids. Hou, Lin, and Drury (1993) show how such hybrid systems can out-perform either fully manual or fully automated systems.

4. DESIGNING INSPECTION JOBS

A system design must include specifications of those factors which control performance variability. For inspection, as for most systems, these can be classified under Task, Operator, Machine and Environment. In this entry they can only be outlined, but fuller treatments available, e.g. Drury (1992), a reference which also contains a systematic design procedure for inspection tasks based on the function list of Table 1 and a list of the attribute defects which must be detected. Here, an example of a listing of the factor affecting inspection performance is given in Table 3 for the example of baggage screening inspection. For each generic function factors are listed under the Task/Operator/Machine/ Environment headings.

From this list come some straightforward conclusions. First, there are large individual differences in the abilities necessary for inspection performance. These are unfortunately not constant across inspection tasks so that the attributes of a good circuit board inspector may not be those of a good X-ray technician.

Table 3: Factors affecting screener and system performance

Function	Task	Operator	Machine	Enviroment
Set-up	1. Calibration procedures 2. Maintenance procedures	1. Ability to follow procedures accurately 2. Training (quality and recency) for calibration and maintenance	1. Operator interface for calibration 2. Operator interface for maintenance	1. Management support to calibration and maintenance 2. Location of equipment 3. Availability of procedures, job aids
Present	1. Baggage selection procedure	1. Training (?)	1. Physical layout of equipment	1. Management control over baggage selected 2. Perceived and actual passenger pressure
Search*	1. Defined wand search pattern	1. Training (quality and recency) for search pattern 2. Operator dexterity	1. Human interface, e.g. wand, alarm indicator	1. Management support to ensure procedures are followed 2. Perceived and actual passenger pressure
Decision	1. p (true threat) 2. p (false alarm) 3. Time available	1. Knowledge of threats 2. Knowledge of potential false alarm items 3. Experience, overall and recent 4. Decision ability 5. Resistance to passenger pressure	1. Operator interface to display design 2. Operator interface to acquire additional information	1. Management support for following correct decision procedures 2. Perceived and actual passenger pressure
Response	1. Alarm resolution procedures 2. Management provision of adequate feedback	1. Knowledge of alarm resolution procedures 2. Resistance to passenger pressure	1. Interface to other systems (LEO, management, security)	1. Management support for alarm resolution procedures 2. Perceived and actual passenger pressure

Some individual difference measures do predict part of the performance variability across a number of tasks — for example, Field Dependency or Peripheral Visual Acuity. Despite considerable research, we still do not have universally effective selection tests for inspectors.

Training, however, is much better understood, and effective training procedures are available. These usually separate search and decision training (Gramopadhye, Drury, and Prabhu 1997) and go far beyond the simple lectures-plus-job experience found in most industries.

Task design must consider both the time allowed for inspection, which has a large effect on search, and the probabilities and costs of outcomes, which predict decision performance. Beyond these, factors such as time-on-task can play a role. Laboratory evidence shows that vigilance is difficult to sustain on repetitive tasks with low signal rates, similar to inspection tasks. There is not much evidence for such vigilance decrements in actual inspection tasks, but in fairness it should be noted that vigilance effects have not been sought in most inspection measurements in the field. At present, reasonable advice is that it would be prudent to allow for possible vigilance effects by using inspectors only for relatively short periods, perhaps up to 30 minutes, before they perform other duties.

Machine or equipment design can play a major role in inspection effectiveness. Workplace ergonomics do improve inspection performance. Also the design of the display of indications to the inspector can have a major effect. Now that we can manipulate images on a computer screen, we need to examine carefully how we manipulate them for maximum performance. This may not always be obvious to designers, as evidenced by the bizarre color mappings seen in inspection imaging equipment. Just because we *can* use hundreds of bright colors does not mean that this will enhance measured performance.

Finally, there is environmental design. In visual inspection the most obvious environmental influence is the provision of adequate lighting. However, not all lighting increases or "improvements" actually have an effect on measured performance. An example is the widespread use of green lighting in sheet steel inspection, despite direct evaluations showing that it gives performance no different from white light of the same intensity. Recent work, however, shows that sheet metal inspection can be improved by careful lighting design (Lloyd 1998).

5. CONCLUSIONS

Human factors has a long history of application to the inspection process and certain solid findings emerge. All inspection tasks appear to have the same generic list of functions, a finding which can be used to bring detailed ergonomic knowledge (e.g. of visual search) to bear on inspection systems design. In the design process, such knowledge can be used both to point the way towards intelligent use of automation, and to design the human-allocated tasks to fit the inspector's capabilities.

Kansei Engineering and Kansei Evaluation

M. Nagamachi

Kure National Institute of Technology, 2-2-11 Agaminami Kure Hiroshima 737-8506 Japan

1. INTRODUCTION

Kansei Engineering was founded at Hiroshima University ~30 years ago and it aims at an introduction of consumers' thoughts on product design as well as function. When purchasing a product the consumer has a psychological image and feeling about the product, and if the product does not fit their expectations, then they do not want to buy it. The psychological image and feeling with regard to a product are called "*kansei*" in Japanese, and nowadays *kansei* is one of the most important design points for the development of a new product. Today consumers are more technology smart and they have a variety of goods at home. However, they will buy new goods if the new products have the characteristics coincident with the their feeling and demand.

Kansei Engineering is an ergonomic technology aimed at consumer-oriented product development which has the following roles: (1) identifying the consumer's *kansei* for a coming new product using ergonomic and marketing survey tools, (2) transferring the consumer's *kansei* to design field and (3) constructing an ergonomic system using computer science technology for a product development by designers or for selection of products by consumers' feeling. Figure 1 shows a diagram of the flow of Kansei Engineering in which the consumers' *kansei* is translated into the design domain through Kansei Engineering

2. KANSEI EVALUATION

2.1. Methods of Kansei Evaluation

The first point about Kansei Engineering is how one can evaluate the consumers' *kansei* accurately. The *kansei*, namely the consumers' feeling, will be expressed on their face and behavior as well as in their opinion. Therefore, the consumer's face and behavior is observed in a variety of situations. To develop a new type of home electric refrigerator, we videotaped a housewife's behavior when using it to prepare a meal, and we found a scene representing her workload when she bent her back. A Japanese home appliance maker, Sharp, developed a new type of home electric refrigerator that has a freezer at the bottom and vegetable room on top of the freezer. This change of position enabled the customers to pick up vegetables more easily than the old style freezer.

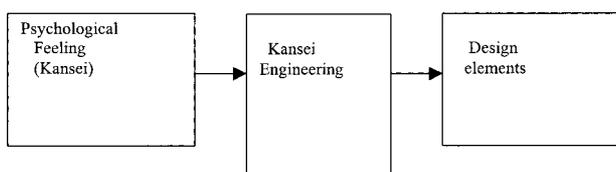
The estimation of physiological phenomena is also useful


Figure 1. Diagram of Kansei Engineering.

index for product development concerning Kansei Engineering. We measured electroencephalograms (EEG) to estimate "Comfort," while heart rate and an electromyogram (EMG) improved movement and operation. All measurement tools used for ergonomic research are applicable to *kansei* with regard to Kansei Engineering. Face feature, face temperature, eye-open width, eye fixation, etc. are all used to estimate the consumer's emotion. Nose temperature was an accurate estimate of body temperature in room air-conditioning control.

Concerning the psychological survey, we often used the semantic differential method (SD). We collected a variety of word of nouns or adjectives which were regarded to *kansei* product features and constructed a five-point scale with those *kansei* words. The *kansei* words of "graceful–not graceful," "beautiful–not beautiful," etc. were used in the SD scale. The subjects of designers or customers were asked to represent their feeling on the SD scale with *kansei* words for a number of the products, and the obtained data on the scale are analyzed by statistical methods. When a sports type vehicle is a target as a new product, many sports cars are collected from the different makers and the subjects are asked to express their feeling about each car on the SD scale for each *kansei* word.

2.2. Statistical Methods of Relations between the Kansei and Design Elements

2.2.1. Factor analysis

First, we used factorial analysis to find the meaning structure of *kansei* to a specific design domain. For sports car exterior design, we evaluated a number of sports cars collected from the different makers on the *kansei* SD scales and these evaluated data are calculated by factor analysis that provides reduced factors with factor loads. This shows the meaning structure of sports car exterior domain and the obtained factors illustrate the design components essential to sports car exterior designing.

2.2.2. Quantification Theory

Second, we applied the statistical method by C. Hayashi "Quantification Theory Type I" to find the relation between *kansei* words and design elements. This method is a kind of multiple regression analysis applicable to qualitative data like the *kansei* and is a very powerful tool to find the design characteristics fit to the specific *kansei*. If our strategy on the new design might be "high class and compact," we followed the design side data from these *kansei* words and obtained several design elements which will contribute to our strategic mission.

2.2.3. Other methods

Neural Network Model was utilized to find the design element from *kansei* words in multiple layer NNM and the Genetic Algorithm (GA) can derive the decision trees connected to the design elements. Fuzzy Integral and Measure Theory is a useful model to make a relational structure between the *kansei* and design domain.

3. TYPE OF KANSEI ENGINEERING

We have developed so far six technical styles of Kansei Engineering methods: Types I to VI.

3.1. Type I: Category Classification

The category classification is a method by which a *kansei* category at the starting point of a planned product is broken down in a tree structure to determine the physical design details. At the beginning phase of a new product development, the project team in general attempts to decide the product concept. In the case of Kansei Engineering, the team decides "the zero-stage *kansei* concept" using whole surveyed data and this *kansei* concept is broken down to subconcepts at the first stage and to more meaningful details at the second concepts, finally to reach the physical specifications. This is like a brainstorming procedure, but in Kansei Engineering the top concept is the zero-stage concept and several concept layers construct a tree structure consisting of group subconcepts. It is said that this procedure is similar to QFD (Quality Function Development).

The physical specifications follow the ergonomic experiments to decide the design specifications and they are integrated to design a whole sports car at the final stage. The final whole design is in general reflected the zero-stage *kansei* concept in Kansei Engineering. The typical example used this technique for the new product development is "Miata" made by Mazda.

3.2. Type II: Kansei Engineering Computer System

Type II is a computer-aided system for Kansei Engineering that has the *kanei* database, image database and an inference engine and that supports the transfer of the consumers' feeling to design domain using an expert system.

The Kansei Database consists of statistically analyzed data of factor analysis and cluster analysis about *kansei* evaluation. The image database is constructed by the relational data between the *kansei* words and the design elements. The inference engine can estimate the design features including a product function through the rules of the expert system.

3.3. Hybrid Kansei Engineering System

Type II of Kansei Engineering means the flow to derive the design elements from the *kansei* words, which is called the "Forward Kansei Engineering System." This has the supportive roles for a designer to get a new idea of product and for a customer to select a good product fit to his/her *kansei*. While the designers want to create a new product based on the candidate that the computer system proposes, in some cases they want to check their new idea in reference to the *kansei* engineering system if it is best fit to the *kansei* database. For this purpose, the backward flow system was combined with Forward Kansei Engineering System, which is named "Backward Kansei Engineering System. Hybrid Kansei

Figure 2. Diagram of Hybrid Kansei Engineering.

Engineering System is an integrated computer system of Forward and Backward Kansei Engineering System (Figure 2).

In Hybrid Kansei Engineering System, a designer inputs his/her *kansei* in the Forward Kansei Engineering System to get the candidates proposed by the system, and the designer inputs the sketch into the system which he/she drew based on the candidate. The computer presents the result of the Backward Kansei Engineering System, which means a diagnosis about the inputted sketch. This technique was used to make the most recently developed steering wheel at Nissan.

3.4. Kansei Engineering Modeling

Kansei Engineering Type III implies a mathematical modeling constructed in a *kansei* system using a mathematical model. In this system, the mathematical model works as if it is a kind of logic like the rule-base. Sanyo Electric Co. attempted to implement Kansei Fuzzy Logic as a machine intelligence in a new color printer and it was successful in a sophisticated color printer which can produce more beautiful color print than the original picture. Nagamachi has developed a computerized naming system for a new product based on Kansei Fuzzy Integral and Measure Logic.

3.5. Virtual Kansei Engineering System

Virtual Reality Technology is now very popular technology in which people can walk through virtually a graphic design created by the computer and displayed by means of HMD (head-mounted display) and data gloves. We tried to combine Kansei Engineering System with Virtual Reality Technology regarding kitchen design in which a candidate of kitchen is determined by the Kansei Engineering System with a specific *kansei* and the customer can have a virtual experience by walking through displayed kitchen. Nagamachi extended this system to a whole house design that is called "HousMall."

3.6. Collaborative Kansei Designing System

We have many *kansei* databases. Then, we decided to implement these databases in the Website which has an intelligent 3D computer graphic system. The designers in separate rooms or in separate area collaborate with each other to create a new design of a product using the intelligent Internet with a variety of *kansei* databases. They talk to each other and correct a partner's proposed design through the Website.

4. REMARKS

There are many applied cases of Kansei Engineering. For instance, automotive, home electric appliance, construction machine, costume and house industries have introduced Kansei Engineering in producing the new products. The names of "Miata" made by Mazda, "Good-up bra" produced by Wacaol and "Ellesse" produced by Golwin are very well known products with applied Kansei Engineering. The introduction of Kansei Engineering has been spread out in the world and the researchers of Kansei Engineering are increasing. Kansei Engineering is an ergonomic technology of consumer-oriented product development and it is very powerful technology to be successful in producing very popular products.

1. INTRODUCTION

Cumulative trauma disorders (CTD) have increasing challenged clinicians in the past two decades as escalating numbers of clients present in medical clinics with neuromuscular problems related to prolonged ergonomic exposures in the workplace. While some CTD conditions require surgical intervention, the majority of CTD requires conservative treatment that addresses multi-level problems. Such problems include not only diagnosis-specific tissue damage, but also proximal muscle imbalances that develop from prolonged awkward postures and potential behavioral problems associated with chronic pain.

Failure fully to address these issues may prevent clients from ultimately re-establishing their capacity for functional tasks.

This chapter will discuss the clinical treatment of CTD utilizing a comprehensive approach that emphasizes a thorough physical assessment, client education, ergonomic intervention, communication with the employer and client responsibility for treatment. It will discuss the goals of treatment at acute and chronic stages along with treatment modalities commonly used to treat CTD.

2. DEFINITION OF CUMULATIVE TRAUMA DISORDERS AND APPROACH TO TREATMENT

CTD, as termed in the USA, refers to a group of injuries affecting tendons, nerves, joints and blood vessels that develop insidiously as a result of longstanding ergonomic exposures. Although protocols for treatment of specific CTD diagnoses exist, the treatment of CTD is rarely protocol-based. Intervention must be considered in the full context of medical, workplace, insurance and family systems. Members of each system must actively communicate and share a perspective that appreciates the complexity of the problem. The following assumptions underlie a comprehensive treatment approach.

2.1. Multi-level Treatment

"Multi-level" connotes that CTD conditions must be examined within the context of multiple systems within the body and multiple levels within each system. These levels include multiple anatomic levels, multiple physiologic systems and multiple psychosocial contexts within the client's realm of functioning.

2.1.1. Multiple manatomic levels

The clinician must address not only local, diagnosis specific pathology but also anatomy both *proximal and distal* (above and below) to the identified injury. As prolonged use of the body in awkward or static positions alters the biomechanics of the entire limb, treatment of the discreet, identified area of pathology may provide only short-term relief.

2.1.2. Multiple physiologic systems

More than one body system may be involved in a CTD diagnosis. For example, while the pathology of lateral epicondylitis is generally regarded as inflammation and degeneration of the extensor tendons as they insert into the lateral epicondyle, the health and mobility of the radial nerve may also be compromised by the inflammatory process (Butler 1991). This example relates to a diagnosis of one system (tendon) which also includes multi-system involvement (nerve and tendon).

2.1.3. Multiple psychosocial contexts

Finally, both work organizational (work-related risk factors for job stress) and psychosocial (attributes of both the job and the individual that contribute to job stress) factors are believed to contribute to the development of CTD. Psychosocial factors may include job autonomy, job uncertainty, work pace and complexity, relationships with authority and peer groups, personal workstyle, job satisfaction and negative affectivity. Researchers believe that *psychosocial demands* may influence the perception and development of CTD in the following manner: (1) these demands increase muscle tension and thus exacerbate the biomechanical strains inherent in task performance; (2) psychosocial demands may impact clients' perceptions of the cause, awareness and reporting of musculoskeletal symptoms especially in VDT work; or (3) that in monotonous jobs, stress-related arousal of the central nervous system may sharpen sensitivity to normally subthreshold musculoskeletal stimuli (Moon and Sauter 1996).

2.2. Holistic Approach

Because CTD are multi-level, treatment must look at the whole person in the context of industrial, social, legal and personal situations, also termed a biopsychosocial approach. In the evolution of a CTD, more acute conditions may involve fewer systems. As CTD become chronic, the interplay between systems becomes more complex. Job and/or family stresses interact with workplace stressors to impact attitude, coping mechanisms and successful adaptation to work following an injury.

2.3. Client Empowerment

In medical models of treatment physicians traditionally take responsibility for "patient cure." These problem-oriented models efficiently treat tissue pathology but rarely prepare clients to prevent and manage future problems. The word "empowerment" builds upon the Latin root *passe*, from which one derives the words power and freedom. In empowerment models of treating, clients are responsible for influencing their health through making informed choices that affect the quality of their lives. Empowered clients influence change in their own personal behavior and social situations. They gain skills at empowerment through information exchange and gradually increasing competency at controlling their lives. Clients and therapists participate in the treatment process as equals and co-learners.

Table 1. Comparison of medical model and empowerment models of client-practitioner interaction. Adapted from Berger, *et al.* (1997).

Medical model	Empowerment model
practitioner-centered	client-centered
authoritarian relationship	collaborative relationship
practitioner holds responsibility to "cure"	client takes equal responsibility with practitioner for health
client compliance in treatment	client commitment to treatment
information giving	information exchange
practitioner must motivate the client	client must motivate self toward goals
client resistance to treatment is harmful	client resistance to treatment yields information

Table 1 outlines a comparison between the medical models and client-empowerment models of treating.

3. CLIENT EVALUATION

Clients are referred for therapy both through the worker's compensations and personal health insurance systems. As managed care expands, clients' access to specialists is limited with primary care physicians orchestrating much of the treatment for CTD. Depending on the physician's experience CTD diagnoses may be adequate but often incomplete. Thus, therapists must perform skilled physical examinations for the upper quadrant (neck, shoulder, upper back and upper extremities) truly to define the levels of injury.

3.1. Client Interview/History

Therapists must take a thorough *medical history*, which includes the presence of systemic conditions affecting soft tissue function, a history of respiratory, vascular or cardiac disorders relative to the patient's aerobic potential and previous or current orthopedic or neurological conditions. The consumption of caffeine and nicotine are addressed as both are vasoconstrictors and may affect target tissue nutrition.

The client *interview* frames clients' perceptions of their condition in terms of the etiology, mechanism and severity. Clinicians request information regarding the onset date, tasks associated with the onset, as well as descriptions of the location and intensity of pain. Pain scales are often used to qualify and quantify client's pain levels. Clients attempt to attribute the causal factors to tasks performed at work, home or both. In the more acute cases of CTD, clients commonly relate specific activity to localized pain. As conditions become more chronic, clients describe more diffuse discomfort throughout the upper quarter that is superimposed on a more tender area. The discomfort in such chronic, multi-level CTD, may be due to altered biomechanics and a combination of chronic and acute tissue damage that often coexist (Higgs and MacKinnon 1995).

3.2. Physical Examination

Clinicians are often misled by anatomically specific diagnoses and fail to inspect the entire extremity, scapula and trunk for multiple tissues involved in the kinetic-chain. This kinetic chain refers to a series of joints interconnected by soft tissues, in which altered structure in one region influences the structure and function of distant areas in the chain (Magee 1997).

A physical examination begins with observations of clients as they enter a room focussing on upper extremity use, guarding of an extremity, posture and facial grimaces. Posture assessments provide valuable insight as to the dynamics of the entire kinematic chain. For example, a forward head, elevated and rounded shouldered posture with pronated arms may indicate tightness of the sternocleidomastoid, scalene muscles and internal rotators. This information will key therapists into further analyzing muscle imbalances later in the assessment. Other components of the physical assessment include tenderness, range of motion, strength, sensation, neural dynamics, reflexes and edema in addition to provocative tests that stress specific tissue and reproduce symptoms.

3.3. Functional Assessment

The myriad roles that a patient assumes (homemaker, spouse, parent) must be examined in equal importance with role of a worker. A functional assessment identifies a client's occupational performance in self-care, leisure and homemaking chores. Activities that the client has identified as relevant and meaningful (such as grooming, gardening or cooking) are used as the benchmark for improved functional independence. Generally, clients with acute conditions complain less vehemently about difficulties performing self-care activities; those with more chronic conditions state that majority of self-care activities are unwieldy. While *pain does not necessarily relate to function*, therapists need to understand the extent to which self-care activities are limited due to the overall context of the illness.

3.4. Job Analysis

Therapists assess the vocational status of the injured worker for length of employment, work restrictions, and worker's compensation history. The job analysis identifies the essential job functions and specific ergonomic exposures related to the job such as awkward and static postures, forceful exertion, degree of repetition, mechanical stresses, vibration and work environment. Importantly, the productivity standards and organizational aspect of the job give insight as to the workplace dynamics. Ergonomic tools such as the NIOSH lifting index and strain index are used to quantify findings and prioritize need for intervention. While valuable information may be gathered through structured interviews, whenever possible the therapist should conduct an onsite worksite evaluation in order to verify information and ensure communication regarding treatment goals and work modification needs with the employer.

3.5. Psychosocial Status

The extent to which an injury impacts the client is closely related to pre-morbid psychosocial coping mechanisms and one's ability to adapt to stress. Clinicians interview clients regarding their home and work responsibilities, stress in their lives, and their means for identifying and coping with these stressors. Generally, those with balanced lifestyles and good support systems manage the added stress of an injury better than those without external supports. Certainly any client that appears depressed or highly anxious is referred for psychological counseling.

Table 2. General goals and treatment modalities for acute treatment of a CTD. Adapted from Duff (1997) with experience of the authors.

Goal for acute stage	Treatment modality
Reduce pain and inflammation	Eliminate activities that provoke signs and symptoms Ice Iontophoresis with dexamethosone Pulsed ultrasound Static splinting
Protect and rest affected regions	Eliminate stress-inducing activities Static splints Adapt workstation Encourage frequent breaks
Decrease proximal guarding of affected area	Promote circulation and good motor control with proximal exercises Breathing exercises Relaxation techniques
Educate client	Discuss risk factors Identify with client activities that *do* and *do not* produce symptoms Problem-solve means to modify activities collaborate on treatment goals
Participate in work-related and self-care activities as able	Provide adapted and ergonomic equipment. Modify home and workstation. Provide activity prescription

4. TREATMENT INTERVENTION FOR ACUTE INJURIES

Once the evaluation is complete the client and therapist set goals for treatment intervention. Goals are based on realistic expectations for tissue recovery and therapists/clients' expectations for functional and vocational task resumption. While the goals and corresponding treatment interventions in Table 2 reflect accepted standards for conservative care, interventions may vary according to the client and stage of recovery.

4.1. Goals and Progression Concepts in Acute Injuries

At the *acute stage* of a CTD, the primary consideration in therapy is to reduce the pain and inflammation while protecting the involved area from further injury. This task is accomplished through eliminating the stress-inducing activities at work and at home and by applying appropriate physical agent modalities in therapy. Numerous methods exist for treating CTD at this acute stage, usually driven by the experience of the therapist or physician. For example, in treatment of carpal tunnel syndrome, iontophoresis, ultrasound, splinting, nerve mobilization and tendon gliding exercises may be used in various combinations according to the individual response.

For therapy to be effective, therapists must communicate the need for job modifications to the employer up-front. Workers often attend therapy during scheduled work hours and return to the originating ergonomics stressors after treatment. If the job is not modified, the therapy process becomes a self-defeating cycle that is scrutinized by employers. Finally, clinicians need to reinforce client's participation in life roles with or without adaptation. Continual participation in customary life habits and work lessens the chances of a client transitioning from the worker role toward the patient or sick role.

4.2. Treatment Interventions in Treating Acute CTD

The following four concepts are essential in treating CTD at *both the acute and chronic stages*. These components address the client's role in treatment, the need to modify activity, balance musculature and address the importance of everyday physical activity.

4.2.1. Client education

Clients' level of knowledge, personal experiences, belief system and culture together shape clients' understanding of their conditions. Clients must accurately conceptualize the pathophysiology involved with a CTD and the rationale for the treatment before they can participate in the recovery process. For example, if a client's believes that passive inactivity will cure a condition, compliance with a home exercise program will be minimal at best. Clients must also understand the relationship between pain perception and anxiety, overly negative thinking and maladaptive coping strategies (Moon and Sauter 1996). Time taken to explain the mechanism of injury often improves clients' commitment to the treatment process.

4.2.2. Activity modification

Activity modification is essential during all phases of recovery and work reintroduction. Clients are taught techniques to unload vulnerable structures by using their upper extremities in a neutral position or by substituting stronger muscles groups for smaller groups. Clients may be taught energy conservation techniques at home and at work to simplify tasks and eliminate unnecessary actions. Activity modification also includes workstation adaptation, work schedule changes and the use of ergonomics tools.

Important to activity modification is monitoring the worker for *proper technique*. Some worker's technique probably contributed to the tissue injury; other workers may have altered their work methods to compensate for pain. In functional retraining clients practice proper technique until these movements are integral to their motor behaviors.

4.2.3. Muscle imbalance

Muscle imbalances must be corrected for longstanding soft tissue health prior to functional and postural retraining. Imbalances can be corrected by stretching tight, hypertonic muscles (typically the scalene, upper trapezius and pectoral minor muscles) followed by strengthening weaker groups (middle trapezius, rhomboids and serratus anterior) (Keller *et al.* 1998).

4.2.4. Physical activity

While the benefits of physical activity are well documented for healthy populations, physical activity potentially benefits those with existing CTD or at-risk for CTD. Physical activity is hypothesized to prevent cInjuries and assist recovery due to the improved oxygen delivery to peripheral tissues, increased capillary density, and increased strength of tendons at the myotendinous unit (junction of the tendon and bone)that occur as a result of

exercise (Magee 1997). Those in good physical condition use a smaller percentage of their total strength to overcome work-related forces as strength improves. Many clinicians recommend a walking program in conjunction with therapy to restore circulation and balance biomechanics.

The following interventions are additionally used at the acute phase of an injury to decrease pain and enhance tissue recovery.

4.2.5. Physical agent modalities

Physical agent modalities are effective short term agents that hasten the recovery process by reducing pain (elevating pain threshold), inflammation, and muscle spasm so that a client may return to functional activities in the most expedient manner. A specific modality will not be effective for all clients; therefore, the use of modalities should be monitored judiciously and evaluated for efficacy. *Cryotherapy* (cold packs, ice cubes, ice massage) is traditionally employed for pain relief and edema reduction in acute injuries. The most common use of cold therapy, cold packs, reduces inflammation by decreasing the metabolism and vasoactive agents at the injury site (Michlovitz 1996). While applications of 15–20 min are considered adequate to effect desired changes, prolonged application of ice may decrease muscle strength and impair nerve function over peripheral nerves. Cold packs may be self-applied during the day or used during treatment.

Iontophoresis utilizes electrical current to deliver ionized drugs such as anti-inflammatory medication transdermally to a specific area. This electrical transfer of medication is highly effective in the relief of acute pain for site specific tissue damage such as in lateral epicondylitis, deQuervain's disease and shoulder impingement syndromes. *Ultrasound* is a form of acoustic energy that stimulates protein synthesis for healing, increases lymph drainage and circulation, reduces edema and pain. Pulsed ultrasound (a mode that utilizes 50% power) produces non-thermal effects primarily used at the acute stage.

4.2.6. Splinting

Splinting can be an effective treatment technique during the acute phase of a CTD to protect soft tissue structures from further injury via compressive forces, mechanical stresses or repetitive strains. For example, a wrist stabilization ("cock-up") splint in a neutral position minimizes compressive forces on the median nerve in carpal tunnel syndrome; a radial gutter or thumb spica splint helps to decrease inflammation of tendons in the first dorsal compartment for deQuervain's disease. Custom splints (those fabricated by therapists) may also enhance function by immobilizing a painful joint yet allowing full mobility throughout the rest of the extremity.

Therapists must be cautious about recommending the use of splints during work. Splints may alter the normal joint biomechanics, alter functional prehension patterns and translate forces to another body part. Splinting should be combined with daily active range of motion to prevent joint stiffness. In short, the goals for splinting should be focussed and the implementation monitored conscientiously as prolonged use can be both physically and psychologically damaging.

4.2.7. Taping

Taping the upper extremity provides the therapist with a temporary means to inhibit over firing of certain muscle groups. For example, a client who subconsciously elevates her shoulder while typing may benefit from inhibitory taping to the upper trapezius. Taping has been used to correct joint instabilities, increase kinesthetic awareness of posture, unload weak painful muscle and assist with motor planning for activity modification.

4.2.8. Nerve mobilization

The circulation and excursion of nerves through tissue becomes compromised with limitations in daily movement. Clients with CTD benefit from careful instruction in techniques designed to promote mobility and circulation of neural tissues. Therapists instruct clients to sense the tension point for a specific nerve and then mobilize the nerve to restore its elasticity and circulation.

4.2.9. Breathing exercises

Treatment of the chronic CTD often begins with breathing exercises to promote circulation throughout the upper quarter. When patients are in chronic pain, they breathe shallowly and overuse the muscles in their neck. Nerves and vessels pass through these muscles and become constricted as patients continue this paradoxical breathing pattern. Diaphragmatic breathing is often the first tool that a client learns to relax and decrease pain.

5. TREATMENT INTERVENTION FOR CHRONIC INJURIES

5.1. Goals for Treating Chronic Injuries

At the *chronic stage* of a condition, symptoms may be provoked with activity but are generally not symptomatic at rest. Clients who have developed a chronic condition need intervention to remediate tissue length, circulation and strength as well as to manage chronic pain that potentially resurfaces with a resurgence of biomechanical or psychosocial stressors. Numerous theories exist about the diffuse, non-localized pain some clinicians associate with chronic, multi-level CTD. Biomechanical theories suggest that adaptive shortening of musculature due to prolonged awkward positioning causes pain as tight muscles are stretched and neurovascular structures are compressed (Higgs and Mackinnon 1995). Neural dynamics theories suggest that in CTD, the absence of normal movement causes venous stasis in the extremity and increased pressure within the neural structures. This increased pressure limits the normal mechanical strain (movement) that is necessary for healing; the central nervous system becomes bombarded with abnormal impulses from these tissues. Overtime, the nervous system becomes sensitized to pain that has spread beyond the original site (Butler 1991). In either situation, a pain cycle may begin that effects functioning of the entire kinematic chain.

5.2. Treatment Intervention for Chronic Injuries

Treatment for chronic injuries must include *patient education, activity modification, muscle balance restoration, and physical activity* as discussed above. Treatment may continue certain therapies from the acute stages but will integrate techniques to remodel and strengthen tissues for function. A sports medicine approach that assumes "pain is gain" is vastly different than the approach

Table 3. General goals and treatment modalities for the chronic phase of a CTD. Adapted from Duff (1997) with experience of the authors.

Goals for chronic phase	Treatment modalities
Restore length and mobility of tissue	Superficial heat Continuous ultrasound Soft tissue mobilization Gentle AROM with stretching Manual techniques Nerve mobilization Massage therapy
Restore strength to premorbid level	Graded isotonic strengthening Proximal followed by distal strengthening
Educate as to disease process and body awareness	Identify activities that *do* and *do not* produce symptoms with client Discuss risk factors Problem-solve means to modify activities Journal keeping
Demonstrate proper use of involved muscles	Provide body mechanics education Practice proper technique at worksite Recognize and avoid compensation patterns
Return to work	Perform worksite evaluation Identify physical limitations Modify job as necessary
Return to independent functioning in self-care, home-related and avocational activity	Modify self-care and home maintenance activities as needed Discuss choices in hobbies
Establish sense of control over life	Cognitive behavioral approaches Learn energy conservation Support groups

to progressing a client with a CTD. Gains are measured by slow stable increments so as not to irritate the originating problem or cause any biomechanical impedance in other areas. Therapist should observe the following:

- Indicate to clients that treatment should not elicit pain except normal muscle soreness due to exercise, called delayed onset muscle soreness (DOMS).
- Note changes in vasogenic and neural activity that are provoked with movement.
- Restore soft tissue length (including muscles and joints) before strengthening.
- Strengthen throughout the entire range after soft tissue length is restored.
- Empower clients to listen to their bodies and not exercise when ill or fatigued.

Table 3 provides common treatment interventions utilized as this stage.

5.2.1. Physical agent modalities
Moist heat is classically applied to more chronic injuries to increase tissue extensibility prior to gentle stretching, decrease pain, and to enhance the healing process by increasing tissue metabolism. *Continuous ultrasound* is another form of heat that can be effective for both superficial and deeper tissues (Michlovitz 1996).

5.2.1. Stretching
Stretching is consistently advocated in subacute and chronic CTD to restore the length of injured tissues. Great care must be undertaken when developing a stretching program; stretches must be safe, easily graded and simple to reproduce at home. Meticulous attention must be paid to proper techniques to avoid a painful reaction. While conventional wisdom supports that stretching may prevent injuries to non-damaged tissue by increasing tissues metabolism and facilitating a glide of tissue, studies have yet to indicate that stretching in isolation of other components to an ergonomics program decreases injuries

5.2.2. Strengthening
Strengthening applies a controlled strain to tissue that promotes tissue regeneration. Strengthening may be implemented when pain levels are under control and the client performs stretches and breathing exercises with good technique. Therapists will follow a progression from active range of motion (AROM) to isometrics, to progressive resistive exercises (PRE) at midrange and throughout the entire range (if indicated for that client). The last step, functional retraining, incorporates broad movements through full range of motion with good posture in all planes of movement. Treatment programs focus on building endurance before strength and allowing adequate recovery time between sessions (24–48 h).

While proximal strengthening is integral to CTD strengthening programs, distal strengthening is cautiously reintroduced, since injured tissues may be more vulnerable to stresses of lower intensity. Therapists educate clients in signs of overuse and many rely on gains through functional tasks to indicate increasing tolerance for work-related activities.

5.2.3. Postural retraining
Proximal stabilization of the trunk, shoulder girdle and scapulothoracic muscles is critical to healthy movement patterns and proper technique (Keller *et al.* 1998). A strong hereditary/behavioral component is inherent to posture. However, most clients benefit from learning to correctly position their bodies and maintain good alignment of joints. This is achieved through proprioceptive exercises, mobilization of the scapulothoracic joint, taping techniques, rib mobilization and graded spinal movements with breathing.

5.2.4. Manual therapies
Manual therapy techniques are "one to one" techniques that help restore integrity to soft tissue systems in the body. Manual therapies include trigger point therapy, soft-tissue mobilization, muscle energy, massage therapy, craniosacral therapy, neuromuscular education and more. Each technique requires execution by an experienced therapist who can discern the level of appropriateness for the client.

5.2.5. Cognitive behavioral therapies
Cognitive Behavioral Therapies emerged in the 1960s with heightened interest in behavioral therapies. The central concept is that a person's affect and behavior are largely determined by the way in which the individual construes the world (Turk *et al.* 1996). For example, some clients that are required to learn new skills at work may respond with anxiety, muscle tension and a

heightened awareness of pain; others view new skill acquisition as a welcome challenge, with no accompanying cascade of physical behaviors. Therapists assist clients in recognizing the connections among cognition, affect, and behavior. Clients learn to become aware of the role that negative thoughts and images play in the maintenance of maladaptive behavior. Change is noted when a client commits to replacing old ineffective behaviors with new positive approaches.

6. INDUSTRIAL REHABILITATION

While all therapies facilitate return to functional and vocational tasks, industrial rehabilitation provides treatment specifically focussed on acquiring or re-establishing work-related skills.

6.1. Functional Capacity Evaluations
Functional capacity evaluations (FCE) are standardized assessments that determine a client's safe physical capacities for weighted activities (carrying lifting), tolerances for body motions (standing, reaching, handling), and manual dexterity for the upper extremity. FCE are used to compare clients' capacities to job demands and thus determine the need for further therapeutic intervention or job modification (Isernhagen 1995).

6.2. Work Hardening Programs
Work hardening programs involve workers in functional activities that attempt to simulate the actual job movements and tasks. Work hardening programs include work conditioning, job simulation and body mechanics educational components to condition injured tissue and practice proper workstyle. Work hardening programs are particularly valuable in transitioning clients into work tasks and work roles who have been absent from the workforce for an extended duration.

6.3. Return to Work Programs
The transition to full duty work should occur over a period of weeks or longer. An activity prescription, usually provided by the physician, outlines the guidelines for modified duty. Activity prescriptions should include (1) specified duration of time in tasks, (2) restrictions for weighted activities, (3) the use of short breaks and stretches during the day and (4) modifications to the workstations as needed. The company determines the actual modified duty jobs in accordance with these guidelines.

7. CONCLUSION

Treatment of CTD requires communication and coordination of medical, industrial, insurance and psychosocial providers. While some clients will necessitate treatment intervention to remediate site specific tissues damage and correct muscle imbalances, other clients will require more complex interventions focussed on gradually gaining strength, self-care independence, improved posture and managing chronic pain. All clients will benefit from a thorough educational program that reviews the injury process and examines causal factors in light of both home and work contexts. This collaborative and client empowering approach will facilitate a smooth transition to work and strive to prevent future injuries from reoccurring.

Organizational Change and Supporting Tools

I. Hamburg[†], H. Paul[†] and J. Bahlow[‡]

†Institute for Work and Technology, Gelsenkirchen, Germany

‡GITTA mbH, Berlin, Germany

1. INTRODUCTION

In many European countries organizational, technical and personal development changes take place due to aggressive market conditions and the development of new technologies. The efforts made to implement cooperative work are examples for such changes. Cooperative work structures require not only organizational measures, but also an adequate technical support and a well-trained staff with the corresponding qualifications like social competence, the ability to deal with decentralized responsibility and a workplace comprehensive vision.

An increasing number of production companies with complex business processes have understood that the implementation and use of tools that help to deal more efficiently with workflows and business processes are requirements which ensure the success of an organizational change. Therefore, workflow systems (WFS), respectively workflow management systems (WFMS), have been developed to realize these requirements.

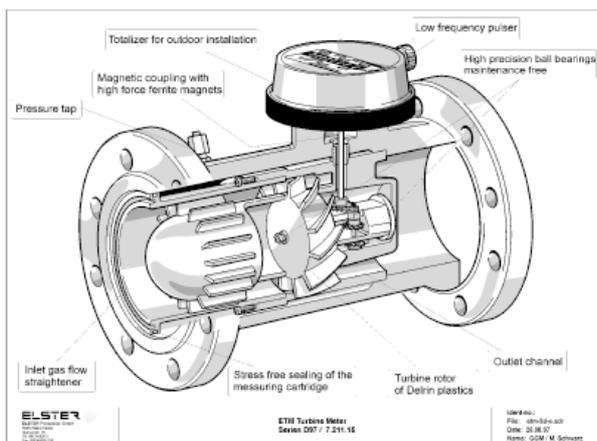
The development of a gas turbine at ELSTER Produktion GmbH is first described as an example for efficient and effective cooperative work, while afterwards a workflow procedure based on Petri-nets (used for an ecologically-friendly modeling of gear manufacturing within a TEMPUS cooperation) is described as an example for new concepts in the design and use of WFMS. Then some reflections on the special needs of WFMS in relation to successful, object-oriented companies – with a special look on the limits of current WFMS – are presented.


Figure 1. Turbine gasmeter developed by ELSTER Produktion GmbH during the RAMONA project.

2. COOPERATIVE PRODUCT DEVELOPMENT UNDER PRESSURE

In March 1996 aggressive market conditions and related factors led to a project on "gas transportation" at ELSTER Produktion GmbH, Mainz-Kastel, Germany. (ELSTER Produktion GmbH and GITTA mbH are partners in the project association RAMONA, "Frame conditions and modelling of new work structures." RAMONA is supported by the Federal Ministry for Education, Science, Research and Technology as a part of "Produktion 2000" and is supervised by the project management agency for manufacturing technologies and quality management at Karlsruhe Research Center. TEMPUS is part of the EU programme for the economic and social restructuring of the countries of Central and Eastern Europe for ELSTER.) It was necessary to develop – within the shortest possible time – a turbine-gasmeter for selected international markets. This especially meant the very fast development of a completely new product under high competitive pressure.

The new turbine-gasmeter was required (Figure 1):
- to enable reduction of costs by one-third compared with the existing products;
- to fulfil the high standards of all ELSTER products on accuracy and reliability; and
- to be available for market introduction within 6–9 months.

It was quickly realized that these highly set goals could only be reached through a team organization that would allow the early participation of all concerned company domains. It was necessary to find and establish an effective project management and a project team organization, being a process supported by the research and consulting company GITTA mbH in Berlin. Thus, a joint concept for organizing the teamwork and for distributing it into subteams was developed:
- Early inclusion of staff from marketing, distribution, buying, controlling as well as production and assembly in the project structure.
- Participation of team members in several teams.
- Restructuring of the teams for production start-up.

In monthly meetings of the whole team, the different backgrounds of experience and varying views on project aims and results were discussed and integrated. These meetings had the function of a bridge between the different subcultures of the company and their corresponding information categories (Schein 1992). The main goals were:
- the fast and uncomplicated cooperation among the team members; and
- the continuous exchange of their individual representations of the project progress.

The FMEA method (Failure Mode and Effects Analysis; Verband der Automobilindustrie 1986) identified possible difficulties and errors in the product concept as soon as possible. FMEA also enabled design engineers at early stages of the project to communicate and elucidate design ideas downstream. The discussion about concrete specifics of the not yet existing product proved highly motivating both for the production and the assembly staff.

Finally, interviews were held with the team members to evaluate the effects of team organization on the success of the project. Not only were the original goals of cost reduction, quality assurance and timely market introduction reached, but also:

- a frictionless production start was achieved;
- possibilities were recognized immediately to improve the customary products; and
- a basis was established for the continued collaboration of the concerned company domains.

The team members had learned a lot about the different problem views in the different company domains. Whenever problems or difficulties concerning product development arise, the team members now know the right persons to address.

The way the product was developed caused an increase in the abilities, qualifications and potential of the company and its staff – a further development that pays more than the success of the product.

3. WORKFLOW MANAGEMENT SYSTEMS BASED ON PETRI–NETS APPROACHES

WFMS are more complex than other information systems (IS) because their modeling objects – workflow processes – are much more complex than the modeling objects of other IS, e.g. data, functions. One of the aspects to be considered in WFMS is which information is used by the processes, from where and when does it come, and to whom and when does it go, as well as its influence on the workflow.

What is required is the capture of major aspects of the processes in a precise and concise manner. Furthermore, it is useful to have a direct relationship between the graphical and analytical representations. This is particularly advantageous in the analysis, simplification and verification of large and complex systems. Finally, the representation should describe abstractions and refinements in the process.

WFMS use optimized organizational structures to automatize workflow. They also influence the ways of individual work, e.g. through the assignment of corresponding work steps (Lehman and Ortner 1998).

Some objectives to aim for in a production company through the implementation and use of WFS (Oberweis 1996) are:

- To increase the productivity, e.g. by taking away some routine tasks from the staff and by decreasing the number of inefficient manual document searching which is needed for the corresponding task.
- To minimize costs, e.g. by minimizing the process running time.
- To improve the quality of products, e.g. by decreasing the error rate of the process' order.
- To increase client satisfaction, e.g. by the correct determination of the state of the current processing task, of the right person dealing with the task and of the task's length as well as by fast and flexible reaction to clients wishes.
- To guarantee openness for organizational changes in the company.

One of the requirements of WFMS in connection with modern cooperative, distributive forms of work is to coordinate the workflow in different company locations. So WFMS have to be developed as distributed systems which run in Internet and support distributed workflow.

From their theoretical basis, WFMS are based on different approaches like Petri-nets (PN), flowcharts or decision trees. Here, extended PN approaches are referred to, to use them for the modeling of business processes taking in consideration different aspects, e.g. also ecological ones.

The basis elements of a classic PN – which is a graph – are two node types called transitions, t, and input and output places, p (containing dots called tokens). The transitions and places are connected via directed arcs.

The generalized PN transition (GPNT) is characterized by a precondition function, functions of selection and functions of token color (for more on GPNT, see Condorovici and Hamburg 1998). To represent the objects (documents, resources, humans) more clearly and readably, some information is attached to the tokens in a PN with GPNT. This information is used, for example, in the analysis of the PN, for producing graphical or alphanumerical reports about the PN's evaluation.

An analyzer of a PN with GPNT has been developed that also facilitates the evaluation of costs and of some ecological aspect of the manufacturing process. In the application it was referred to the electrical energy consumption but, with small modifications, the PN can be used also for other ecological factors.

A workflow procedure was built that is based on the GPNT-concept, using a world-wide web (WWW) browser as a platform-independent user interface which is connected to a HTTP server (Condorovici and Hamburg 1998). The analyzer was developed as a stand-alone application – written in GNU C++ under a Unix operating system – and is automatically run by the server with parameters collected by client application.

The workflow procedure was used for the modeling of gears manufacturing in a Romanian machine tool company, taking in consideration the consumption of electrical energy. These developments are the result of a European cooperation between the Institute for Work and Technology in Gelsenkirchen (Germany) and the University of Iasi (Romania).

4. INSTRUMENTS OF ORGANIZATIONAL CHANGE

Here some findings about organizational change, organizational flexibility – important characteristics of successful companies (Fröhlich and Pekruhl 1996) – and the deriving special needs for supporting computer applications are reflected (Paul 1998).

Organizational change and organizational development should neither be seen as extreme exceptions, nor as nothing but *re*-action to external events. Successful companies can act in an anticipatory and prospective manner. Nevertheless, organizational change can be a risky process – even for an experienced company. Any support and every removed obstacle means an important aid for a changing organization. A workflow management system could be helpful as a supporting instrument of change.

The decisive questions are:

- Who is deciding on the organizational change?
- Who does initiate the organizational change?
- Who is bearing the processes? and
- Who is in control of the processes or who thinks that he is in control of the processes?

Hierarchically organized companies with a centralized way of decision-making differentiate among strategic, tactical and functional tiers: WFMS are tools for defining the functional tier. They are regarded as useful in the support of well-structured tasks with well-defined decision situations. On the superordinate tiers, where decisions about changes in the organizational structure and of its processes are made, WFMS cannot be found. WFMS

are used to bring those decisions to reality – they are not used to support the process of coming to decisions.

The underlying acceptance of the rule that decisions are made "upstairs" and decisions are executed "downstairs" makes this point of view a problematic one. This way of thinking proves counterproductive in organizations with object-oriented units and explicit decentralization of structures of decision-making.

What will happen in one of these autonomous object-oriented units when the unit comes to the conclusion that it has to restructure itself? What will this unit do when it finds out that it has to reshape its *internal* organizational structure and its *internal* processes? How will it handle the possible need to reconfigure the "interface" to its neighboring object-oriented units? How will it deal with tasks that will become unnecessary or that will be swapped out to other units or swapped in into the unit? The most popular way to handle these problems would be simply to do nothing but continue with "business as usual" and to ignore the findings – because one will never succeed with ideas in "higher" places.

There is a clear need for modular, flexible, scalable, tailorable and object-oriented WFMS that are able to deal with frictions. The main characteristic of this "next generation" of WFMS is that it can help the unit to re-structure itself and also to elaborate adequate interactive computer systems to the new structure.

A unit modifying itself needs answers to questions such as: why does the unit has to perform a certain task for who?; what is its function in the general structure of the organization? A WFMS has to provide the answers to these questions, but, therefore, it has to contain more than just data interfaces to applications. For an object-oriented unit, decentralized structures of decision-making and extended scopes of action also mean the treatment of tactical and strategical questions in a decentralized way and also one has to decide about innovation and not just everyday problems on the spot. And it also means change to the local organizational structure and its processes locally when it is needed. WFMS that are real tools of change will support the unit in such a situation – and will not hinder it like most of today's tools do.

It is a special quality of a WFMS as a tool of change that it is a useful aid even before structures and processes are well established and 100% fixed. It is their special task to support the development of the new structures and processes: they will help the organization to re-organize itself.

Organizations need an efficient and effective set of tools to be able to adapt themselves flexibly to changing conditions and the new possibilities. In fact, they need a set of tools that allows them to deal faster and more efficiently with their workflows and business processes, to reach goals more easily and to make more profit out of them. They have to be real WFMS: managing the workflow, and not simply making them flow somehow. They must help the organization to change and to reshape itself, e.g. to set up, run and modify new business branches, to move tasks within the branches, to modify structures of decision-making or to establish new forms of cooperation.

Although important findings were made, especially in the second half of the 1990s, the knowledge about this domain is not complete, e.g. we are still learning about group dynamics and what is triggered off by decentralized structures of decision-making. Little is known about the initialization of organizational change and the possibilities to "control" such processes. There are many more theories and assumptions about hindrances and stimulating factors of organizational change processes than proven facts. Instruments of organizational change are not just around the corner.

5. CONCLUSIONS

Successful organizational change and the use of supporting tools have helped manufacturing companies to survive and prosper in a turbulent market with continuous changes and changing clients' requirements. By being developed from national and international programs, in cooperation with research and industry, new approaches to organizational change have proven that these new concepts are more than just theoretical frameworks. They have increased the competitiveness of SME = Small and Medium (sized) Enterprises and their effectiveness and efficiency. They have helped handicapped companies to find new solutions to their current problems such as controlling, monitoring, optimizing and supporting business processes by using WFMS.

But it has also become clear that the finishing line has not yet been passed. There are many unsolved problems particularly referring to the special needs of object-oriented, decentralized organizations. There are still more questions than answers when it comes to helping companies to change and re-shape themselves.

The answers can be found neither in isolated "think tanks" nor by the companies themselves. Further intensive national and international cooperation among research and industry is required to develop and transfer findings to industrial practice, so that they are verified under realistic conditions.

Organizational Culture and Development

E. Järvenpää and E. Eloranta

Helsinki University of Technology, Department of Industrial Engineering and Management, PO Box 9500, FIN-02015 HUT, Finland

1. INTRODUCTION

Today companies look for competitive advantages in several ways. One of the ways is to develop organizational processes and practices to be as effective and efficient as possible. Development of business processes, organizational structures, demand–supply chains and networking with other companies are approaches companies often use to improve their performance. The aim of development activities is to increase productivity, shorten time-to-market, simplify processes, facilitate information and knowledge sharing and at the same time, increase employee well-being.

In organizational development activities, characteristics of the organization to be developed are not always sufficiently taken into account. Development processes are implemented without a deep understanding about the culture of the organization. This means that the values, norms and behavioral patterns the organization members share are neglected. However, these may have influence on how organization members react, accept and participate in the development activities of their organizations.

People who are responsible for organizational development activities should ask before and during the implementation of organizational development activities the following questions. What kind of organization are we developing? What is its culture like? To what kind of culture are employees socialized? The most important question is how organizational culture and its characteristics support or hinder organizational development. In this chapter, the focus is on the characteristics and effects of organizational culture that should be taken into account when designing and implementing organizational development activities.

2. ORGANIZATIONAL CULTURE

The concept organizational culture is used and studied in several disciplines, such as sociology, management and organizational sciences, work and organizational psychology, and anthropology. Each discipline has its own definitions for the concept and at the same time, different interests in organizational culture. In sociology and cultural anthropology, research deals with characteristics of organizational culture, and how culture is expressed and shared. Work and organizational psychology deals with characteristics of organizational culture and recently organizational learning. Management and organization sciences are interested in connections between organizational culture and other characteristics of organization. One goal is to find out if organizational culture affects business performance and, especially, what these effects are.

The concept organizational culture indicates that organizations have their own culture, i.e. that organizations have their own special features that differentiate them from other organizations. A variety of definitions for culture is proposed by different schools of cultural anthropologists and sociologists. In this chapter, the definition of culture by Hofstede (1997) is adopted. According to Hofstede (1997), culture means the collective programming of the mind that distinguishes one group or category of people from another. Culture can be found on different levels, such as national culture, occupational culture or organizational culture.

Organizational culture indicates how people are used to think, act, make decisions and participate in an organization. In everyday language organizational culture means "the way things are done in an organization." The ways the members of the organization are used to think or act as well as how the values and norms of the organization may affect their acceptance of organizational changes and the willingness of the personnel to participate in planning and implementing changes.

Schein (1985) has defined organizational culture as a set of core values, behavioral norms, artifacts and behavioral patterns, which govern the way people in an organization interact with each other and invest energy in their jobs and in the organization at large. For organizational culture, two levels are usually differentiated (Schein 1985). Culture refers to rather permanent values, norms and basic assumptions about the organization. Climate means procedures, practices and behavioral models according to which things are done in an organization. Organizational climate is also indicated by external signs, such as buildings, decoration, logos or how people dress in the organization. Since organizational culture consists of rather permanent values, norms and basic assumptions about the organization, changes take place only very slowly (De Witte and Van Muijen 1994). Therefore, to change organizational culture, one must first change organizational climate.

Argyris and Schön (1978) differentiate espoused and enacted content themes in studying organizational culture. Exposed content themes mean expressed opinions, i.e. what people think, believe or do themselves. Enacted content themes are abstractions that capture aspects of how people actually behave, rather than how they say they behave. This distinction may be useful in understanding the connections between organizational development and organizational culture.

A great variety of models and dimensions of organizational culture and organizational climate are proposed. Quinn (1989) has developed a model of organizational culture, and DeCock *et al*. (1986) a model of organizational climate. Both models describe culture and climate as follows. First, the organization may be focused on internal or external factors. Internal factors refer to personnel and processes, and the organization itself. External factors are defined as contact to environment, e.g. to customers. Second, organizational culture and climate can be linked to control or to flexibility. Dimensions of organizational culture and organizational climate consist of the combinations of these four elements. They are supportive, rule-oriented, goal-oriented and innovative organizational culture. Harrison (1993) has defined four dimensions of organizational culture: role culture, achievement culture, support culture and power culture.

Ekvall (1996) has differentiated organizational culture from organizational climate, and defines organizational climate as the core concept. It is an attribute of the organization, i.e. a combi-

nation of attitudes, feelings and behaviors that characterize life in the organization. Organizational climate exists independently from the perceptions and understandings of the members of the organization. It means the organizational reality in an "objectivistic" sense. This concept corresponds to the definition by Schein (1985), in which climate is regarded as a manifestation of organizational culture. According to Ekvall (1996), dimensions of the organizational climate that stimulate creativity and innovation are challenge, freedom, idea support, trust/openness, dynamism/liveliness, playfulness/humor, debates, conflicts, risk-taking and idea time. These characteristics of organizational culture can also be expected to support organizational development activities.

The culture within an organization can be considered in terms of consistency or diversity. Martin (1992) differentiates three perspectives in research on organizational culture. They are an integration perspective, a differentiation perspective and a fragmentation perspective. In integration perspective, all cultural manifestations are interpreted as consistently reinforcing the same themes, and all members of an organization are viewed as sharing an organization-wide consensus. An organization is seen to share a common culture. A differentiation perspective describes cultural manifestations as sometimes inconsistent. Consensus occurs only within the boundaries of subcultures; yet, these subcultures may be in conflict with each other. Accordingly, an organization may have several different cultures, e.g. different departments may have different cultures. A fragmentation perspective on ambiguity as the essence of organizational culture. Consensus and dis-sensus are seen as issue-specific and constantly fluctuating. An organization has no organization-wide common culture or subcultures. When designing and implementing organizational development activities for the entire organization, the possible subcultures within the organization should be taken into account. This understanding may help in focusing the development efforts to better fit the employees' "mind-set" and views of their organization, job roles and expectations.

3. ORGANIZATIONAL DEVELOPMENT

In this chapter, organizational development means active, goal-directed development and re-design of work processes and organizational structures regarding, e.g. management processes, business processes and demand–supply chains. The goal of organizational development is to improve different kinds of processes or structures of activities of the organization. The scope of the development varies from development of one work process to the change of the entire organizational structure.

Cultural factors and their effects on organizational development have so far not been extensively studied. Hames (1991) has shown the importance of cultural factors in implementing quality programs. Successful transformation to quality was found to need a fundamental remodeling of organizational and management culture. Siehl and Martin (1990) have discussed the complicated relationships between organizational culture and financial performance of organizations.

Contemporary organizational development seems to be holistic and highly business driven compared with the traditional human resources-oriented efforts or organizational development (OD) approach (French and Bell 1973). In this vein business process re-engineering (BPR) has been among the most popular hypes of the decade. This hype started in the consultancy business and progressed first as a major industrial movement and later also as an area of research interest. One of the first definitions of BPR by Hammer and Champy (1993) reflect this pragmatic drive: "BPR is about fundamental rethinking and radical redesign of business processes to achieve dramatic improvements in critical, contemporary measures of performance, such as cost, service and speed."

The academic interests have been diversified primarily towards hermeneutic research work on one hand – what is this phenomenon about (Davenport 1995) and is it worth the efforts? – and towards constructive research work on the other – how can the practitioners be facilitated by appropriate methods and tools for the successful implementation of re-engineered processes (Laakso 1997, Rajala 1997)? The latter builds on the former. The hermeneutic studies have provided us with evidence that BPR projects tend to be risky and the failure rates of the projects are high. The causality, or at least the related factors behind successes/failures, have been elaborated (Grover *et al*. 1995, Childe *et al*. 1996).

What remains still unanswered is the connection between business process development and organizational development. Is organizational development an enabler for business process development or visa versa? Is one of the underlying enablers for organizational and/or business process development appropriate organizational climate building on appropriate organizational culture? These questions are complex and employ a multitude of complex variables. In spite of this, we have tried to shed some vague light on these relevant issues.

Organizational change processes are usually difficult, time-consuming and expensive processes for companies and their personnel (Hammer and Champy 1993). To manage and facilitate change processes in organizations, different approaches, methods and tools have been developed. They include, for example, participatory methods for design and implementation of organizational changes, and simulation games for teaching and simulating new work processes. Moreover, management involvement and support have been found to be very important in successful organizational changes.

By understanding different dimensions of organizational culture, and their level in a particular organization, the organizational development activities can be focused on those issues in organization that are possible and most important for change. Organizational culture may affect practically any aspect in organizational development.

The approach used in developing organizations should be adapted to the organizational culture. In traditional, rule-oriented cultures, the participatory, bottom-up approach with employee participation in development activities, may not be applicable. More top-down approach with rules and guidelines may be more appropriate. At the same time, the employees should be activated step by step to participate in development efforts.

The time frame of the development activities, i.e. how fast changes and improvement can be expected may depend on organizational culture. In traditional, rule-oriented cultures the time frame may be longer than in dynamic, goal-oriented and innovative organizations.

In multinational organizations organizational culture and climate is highly intertwined with different cultural dimensions. Global business organizations do employ virtual teams that

represent multiple nationalities and social cultures, where, for example, Asians, Americans and Europeans are striving towards customer satisfaction by joint efforts, even without the help of co-location. We do have some inductive evidence in our research material that in such conditions it is extremely hard to isolate the impact of organizational culture from the impact of the culture of the surrounding society and nationality. However, at least inductively it looks apparent that the deeper cultural context (i.e. society and nationality) is extremely hard to be bypassed by any organizational culture. Team members representing a rule-oriented society tend to look after detailed guidelines also in a company with organizational culture emphasizing high employee participation and empowerment. Such behavior is amplified in a business process re-engineering situation where the guidelines are in a state of change by definition and where an individual cannot lean on familiar well-practiced rules.

In designing and implementing organizational development activities in global companies it is important to understand the existence of national culture and organizational culture. Our case study showed that organizational culture at five production sites of a global company differed across countries and production sites (Järvenpää and Eloranta 1996). This means that organizational development activities in each production site should be designed locally, and a centralized, headquarter-directed development program may not be applicable. Moreover, organizational culture within each production site differed according to departments, functions and occupational groups. This indicates the need for more tailored development efforts within organizations.

The results of one of the production sites showed that the organizational culture of the company was in general rather balanced, with the main emphasis on rules orientation. The balanced culture means that none of the organizational dimensions measured was dominating. The culture was rather stable, slow responding and rather slow in decision-making. The goals and focus of the company may be unclear, and the employees may not know if they should concentrate on internal aspects, such as following the rules or external issues, such as customer satisfaction. Rules orientation as the dominating value in the organization may have implications for development activities. The personnel may expect that the development process is a top-down process with rules and guidelines. In general, decision-making in a balanced, somewhat rules-oriented organization may be slow and management-driven. The personnel may expect similar decision-making procedures for development processes. Therefore, the personnel should be activated and encouraged to actively participate in development activities.

In a balanced organizational culture, the resistance to changes may be expected. The implementation of and adjustment to new ways of doing things may need much time. Therefore, the approach and tools used in development activities should motivate and activate the personnel. At the same time, the personnel have to get information on the forthcoming changes and how they affect their job. Active management and leadership are needed, together with personnel participation. The personnel need to know the goals of the development process as well as the importance of their participation in the development project.

At the case company, organizational climate was more innovative than culture. This means that the personnel had new ideas even if the innovativeness was not a prevailing value in the organization. Innovativeness is a good basis for development activities. The personnel may have new ideas and motivation to change their jobs and the organization. However, due to socialization to the rules-oriented organizational culture, they may need empowerment, and even training about how to participate and develop their work and organization.

4. CONCLUSIONS

In organizational development activities, the understanding of the current state of the organization is of crucial importance. This means not only the understanding of the goals, mission and visions of the company, but also how people in the organization behave, and the reasons and rationality behind their organizational behavior. The organizational culture and climate indicate how the employees in organizations act in their daily work. For global, leading-edge companies and other organizations, competent personnel is the most important asset. To enable and guarantee optimal working conditions, and development possibilities to their personnel, organizations should understand the meaning of cultural contexts. This is especially true when organizations are in change, due to organizational developmental activities. National culture, organizational culture and occupational culture with their different characteristics affect how people react, become motivated and are willing to change their behavior and their organizational environment.

1. INTRODUCTION

In this article theory and practice of participatory ergonomics will be discussed. Participatory ergonomics is a way of improving work in an organization by involving employees and other important parties. The knowledge that technological changes are seldom without a change in organizational aspects implies a more active attitude from management towards improving work in organizations to meet the consequences of introducing changes in an organization (Brown and Hendrick 1992). Four forces can be distinguished that change management practices to a more participative character. First, societal forces come from legislation that protects the rights of employees. Employees feel the need and the right to speak for themselves and to demand that the organization is run in a reasonable and fair way. The second force concerns business environment. Increasing competition and the ever-apparent danger for loss of quality or productivity makes a constant awareness necessary. Third, the type of product has changed to service orientation and jobs that require specialized knowledge. Traditional management styles are aimed at industrial production models and are no longer relevant. Instead, human resources and organizational efficiency are major themes. Finally, the workforce generally has a higher educational level and has higher expectations from work and future careers.

These forces argue for alternative management styles. Participatory ergonomics is one of those styles that can be used in certain situations to manage change processes.

2. THEORY OF PARTICIPATORY ERGONOMICS

2.1. Definition

The results of a round table session concerning participatory ergonomics (Vink *et al.* 1992) showed a lack in theory and categorization of the different varieties of the method. However, all parties agreed on the importance of investigating the theory and use of it, since the need for participation constantly occurs in history and modern life.

Some definitions of the methods have been determined in literature. First a definition of the method will be proposed. Noro and Imada (1991: 3) proposed a first definition of the method: "A new technology for disseminating ergonomic information." However, this definition does not specify the amount of influence that an employee has during the process. Also, the definition emphasizes the use of ergonomics, though this is merely a means to achieve a goal, which itself is much more important.

Wilson (1995: 331) recently defined participation within an ergonomics management program: "The involvement of people in planning and controlling a significant amount of their own work activities, with sufficient knowledge and power to influence both processes and outcomes in order to achieve desirable goals." In his definition, Wilson emphasizes the importance of power of the employee. Participation in development can only be successful if the participative parties have a share both in the decision-

making process as in the selection process of the outcome of the project. Furthermore, the amount of participation is mentioned in the word "significant," which sets the boundaries for the participation. Participation is a means, not a goal. The goal of participative ergonomic projects is to improve work activities through joint action and decision-making.

2.2. Approaches

Here some basic approaches of participative ergonomics will be distinguished. Every project initiator will have to decide what type and amount of participation is best suited for a specific project or situation. Employees can be directly involved in a project, or indirectly through representatives. These are two extremes; there is also another alternative, in which employees are directly involved, but not in all stages of the process and decision-making is done by management. The approaches are (Noro and Imada 1991):

- Consultative participation: employees are merely consulted to collect necessary information but they are not present at meetings or decision-making.
- Substantive participation: employees are organized in work teams that delegates a representative for participative problem solving and decision-making.
- Representative participation: employees are part of the management team and are present at meetings and decision-making.

This classification of approaches shows three standard theoretical approaches with varying type and amount of participation. The approaches consist of properties that may vary on absolute or continuous scale. To determine the exact composition of the standard approaches, the following three properties of participation have been defined (Dachler and Wilpert 1978):

- Formal–informal: "a system of rules … imposed on or granted to the organization" as opposed to "nonstatutory consensus emerging among interacting members".
- Direct–indirect: "immediate personal involvement of organization members" as opposed to "some form of employee representation".
- Levels of decision-making; 6 levels were defined ranging from "no information given to employees about a decision" to "decision is completely in the hands of the employees."

If one defines the properties for the standard approaches the following definitions appear:

- Consultative: informal–indirect no decision-making.
- Substantive: formal–indirect decision-making to some extent.
- Representative: formal–direct–full decision-making.

However, participative projects do not have to use a standard participative approach, but may vary the properties to suit the project and situation.

2.3. Benefits and Disadvantages

The method of participatory ergonomics can be used for many reasons. For instance, the involvement of people may increase the acceptance of the results. But participation also implies more efforts of the project organization to execute the project. Therefore, benefits and disadvantages of the project must be carefully weighed before starting a participative project.

Gjessing *et al.* (1994) defined the benefits of participation as follows:

- Enhanced worker motivation/job satisfaction: not only extra salary will improve one's satisfaction over work, but also even more the opportunities to influence your own work.
- Added problem-solving capabilities: the person doing the job has the best knowledge of work methods, resulting in higher quality of the result.
- Greater acceptance of change: a better understanding of the needs for change and opportunities to help structure the change may improve commitment to successful implementation.
- Greater knowledge of work organization: not only knowledge of one's own work, but also the relation to the overall company operation can be improved resulting in improved communication and coordination among members of the organization.

Some case studies have been performed to assess the potential benefits and disadvantages of the method. Although most cases report on good results, other authors start emphasizing the risk of failures (Wilson 1991). These failures can appear at three levels: (1) the results were not achieved for production, (2) working conditions were not actually improved and (3) participants had no benefit from participation.

In spite of these potential failures, the method may still be successfully applied if an approach is chosen which is adjusted to the project characteristics.

2.4. Effectiveness

In literature a broad discussion on the effects of the method of participatory ergonomics can be found. Since innovative projects are depended of many variables, it is difficult to point the results of the projects to participation alone. There are many reasons to explain the positive effect of participatory ergonomics on work. For instance, attention which is paid to employees by management can have positive effects on performance (e.g. Hawthorne experiments). However, other reasons focus on a more cooperative and self-consciousness image of employees. They stress the improvement of quality of result or even more improvement of the implementation process as a result of the commitment of employees.

Furthermore, the effects of the method are difficult to assess since the projects often last a couple of years and changes can only be measured after the first start-up problems.

However, this section will give a resume of the discussion that exists in literature on the effectiveness of the method. Most authors agree on the fact that the way a change process is organized is by far the most important cause of the effectiveness of the project (e.g. Vink *et al.* 1992, Haims and Carayon 1996). Research on the effects of different approaches, as discussed above, of organizing the process showed that indeed some approaches resulted in better effects than others.

Relationships were shown between participation and satisfaction of the user of the result. However, other research proved that these relationships showed only small significant relationships between participation and satisfaction. These small relationships are based though on change processes in general and not exclusively on ergonomic changes. Because of the applied nature of ergonomic changes positive effects on satisfaction are more likely to occur for this type of processes.

More significant relationships might exist between participation and the quality of the results. These relationships should therefore be determined for future participative projects to assess the effectiveness of the method.

3. PARTICIPATORY ERGONOMICS IN PRACTICE

This section gives an inventory of a number of participatory ergonomic methods that are used in practice. The methods in the following overview differ in their set-up and whether the change is of a continuous kind or not. They will be mentioned hereafter alphabetically without further classification. Only publications that define the method used to sufficient extent will be taken into account in this overview. For the specifics of each method the reader is pointed to the references given in each section.

3.1. Ergonomics Coordinator Program (Haims and Carayon 1996)

This is a permanent, internal participatory program that involves increased levels of control, acquisition of knowledge and skill, and developmental growth for individuals involved on a continuos and cumulative basis. This makes outside experts gradually abundant in time as the involved individuals are capable of continuing to program themselves. This transfer of control can be related to higher levels of instrumental, conceptual and organizational job control.

3.2. Health Trak (Moir et al. 1997)

Health Trak combines rapid appraisal (popular education and participative techniques) and participatory ergonomics to perform interventions in the construction industry. This method is developed around 8-week cycles, which utilize three major components. The first components is divided in four steps: (1) problem identification and definition (weeks 1–2), (2) analysis of hazards and strategies for intervention (weeks 3–5), (3) implementation of proposed interventions (weeks 6–7) and (4) evaluation by participants (week 8).

3.3. Participatieve Ergonomie (Vink et al. 1997)

The essentials of the approach are a strong commitment of the management and a direct worker participation as well as continuous feedback to participants and summary feedback after each step. The method has been used in a number of projects to reduce the physical strain of workers in a variety of trades. All projects use six main steps: (1) preparation: initiation and strategy of the project, (2) analysis of work and health: definition of user requirements, (3) selection of improvements: development and selection of solutions, (4) pilot study: testing and adjusting solutions, (5) implementation: applying solutions to work situations and (6) evaluation: evaluating results and process.

3.4. Participatory Ergonomics (Noro and Imada 1991)

This method is the first as such defined for participatory ergonomics, which is a technology for disseminating ergonomic information. The method is designed to be applied by non-experts, using approaches and methods which differ from ergonomics intended for experts. A number of steps have been

determined to be used by small groups: (1) select theme, (2) set goal, (3) grasp present situation and analyze factors, (4) identify problem, (5) develop and improve measures to solve problem and (6) confirm effect of measure taken.

3.5. Problem Solving Group (Wilson 1995)

This program is based upon the Design Decision Group (reported by Wilson) and has seven stages that should finally result in continual improvement after change. The seven stages are: (1) familiarization with tasks, jobs, workplace and team, (2) field visits to similar sites, (3) Design Decision Group (A); drawing, discussion and idea generation, (4) Design Decision Group (B); layout building, discussion and idea testing; (5) lighting and visibility simulation at the site, (6) sourcing and costing of solutions by participants and (7) continual improvement after the change.

3.6. System Group Development Technique (Andersson 1990)

A systems approach, based on the product development process, adjusted to the marketing system and the "initial stages" of the product development process. Participants are drawn from the entire marketing system representing all major functions, such as manufacturing and distribution. The stages are: (1) need session; from ergonomic problem to defined need, (2) idea session; from defined need to alternative solutions, (3) screening session; from alternative solutions to selected concept, (4) concept session; from selected concept to defined concept, (5) design session; from defined concept to design options.

3.7. Tuttava (Laitinen et al. 1997)

This method was designed to support the creation of a participatory ergonomics process intended for continuous use in an organization. First an ergonomic knowledge package was presented to participants including a method manual with among others the description of a dialogue model. This model can be used to structure the dialogue between operators, manufacturing engineers and suppliers, which should result in a proposal for change.

Literature reports on several methods of participatory ergonomics on the basis of case studies. Most methods are basically the same and distinguish themselves only in the number of phases or the goal to be achieved. It seems that in a national context, every country has developed its own way of applying participatory ergonomics and no international standard exists.

In conclusion, can be said that there are a number of aspects in which the methods show some similarity. These are:

- A systematic (stepwise) approach.
- Some form of participation.
- Ergonomic analytic elements.

The selection of a method for a project will be based on the availability on information of the specifics of a method and the suitability of a project for participation. Furthermore, positive experiences of the project initiator will increase the chances of the application of a participative method.

4. CONCLUSIONS

In short, theory on participatory ergonomics has been reviewed to show the experiences with the method from literature. Participatory ergonomics is one of many methods to successfully implement ergonomic changes in organizations to improve work by involving employees. The method is merely a means to achieve a goal and not a goal in itself.

Major advantages of the method are better quality of the innovation and more satisfied employees and major disadvantages are chance of failures and more efforts of management and project organizers needed. The advantages have to be greater than the disadvantages the justify the use of the method. The effectiveness of the method has not yet been proven in literature, but experiences show that especially in the ergonomic context the method will show good results. A number of participatory ergonomics methods are available internationally, which have a number of similar aspects. Namely, a systematic (stepwise) approach, some form of participation and the use of ergonomic analytic elements. The selection of a method depends on the project characteristics and the availability of information on the specifics of the method.

Nowadays, organizations have to innovate to keep up with expectations of their environment. Participatory ergonomics is a way to optimize these innovation process in order to improve the chances of success of the innovation projects.

Participation and Collaboration in Workplace Design

M. Launis

Finnish Institute of Occupational Health, Unit of Ergonomics, Topeliuksenk. 41 a A, FIN-00250 Helsinki, Finland

1. INTRODUCTION

1.1. Reasons for User Participation in Designing

Involvement of the operators and users in design and development activities has become increasingly important in organizations, in order to improve the quality of production and services, to increase the flexibility of their functions, and to prevent disturbances in systems performance. The enhancement of participation is not only a means for achieving direct gains in the efficiency of major activities, but also a means to improve production technology, the work environment, work content and the employees' well-being.

The idea of the users participating in the designing is not new, but only during the past two decades have the overall preconditions in organizations evolved sufficiently to apply it on a wider scale. Participation in designing is not only a question of design methodology, but also it is always an organizational and psychological issue, and strongly affected by the work culture. The present trends in organizations, such as a flattening of hierarchies, the establishment of work teams and the expansion of work tasks and responsibilities, support greater participation, as does the general rise in the educational level of the employees. In addition, the production technology and processes have become more complex, requiring the utilization of all available knowledge and experience within the organization.

1.2. Participative Design Approaches

At present there are several well-established design approaches in which participation is an integrated element. Some of them are aimed to develop production activities, such as quality circles and continuous improvement, some to advance products or systems, e.g. user-centered design and usability testing, and, more emphatically to improve jobs and working conditions, the participatory ergonomics approach. In addition to these, the concept of participative design can be mentioned as a comprehensive term for the basic idea of users' participation in designing. In principle, all these approaches are parallel in aiming at the improvement of activities, equipment and conditions of use by involving operators and users in the development processes.

For more information on participatory ergonomics, see Noro and Imada (1991), and Wilson and Haines (1997).

1.3. Towards a Broader Collaboration in Designing

Development tasks, as a part of the operators' daily activities, such as improving the work tasks in a production team, or as an operator of a complex machine, seem natural expansions of these activities. Workplace design is, however, to a great extent part of an isolated and fragmented process of designing production technology, led by technically oriented designers, and participation in this hasty process does not seems obvious. In the technical design process, the work tasks and working conditions are largely determined, but likely to stem from different starting points and values than those of the people acting in the production. The designers are responsible, first of all, for the technical functioning of the systems at the lowest costs. Thus, in the rigor of the design process the consideration of work activities remains secondary.

The integration of ergonomic impact throughout this design process requires, in addition to user participation, the contribution of many other personnel groups and interest groups in the organization, e.g. that of supervision, of maintenance department, of safety and health specialists, of the human resource management department, etc. Seen from a common viewpoint, it is rather a question of collaboration in the design process instead of participation, which, as a concept, refers to unequal roles of the different actors in the process.

1.4. Aim

The aim of this chapter is to give an overview of the arguments for and against participation in workplace design, of its application, of criteria for the methods and tools, and of preconditions for carrying it out.

2. ARGUMENTS FOR AND AGAINST GREATER USER PARTICIPATION IN WORKPLACE DESIGN

2.1. General

From the ergonomic and human factors point of view there are several arguments in favor of the users' participation in workplace design. Some of them are associated with the results of designing, some with the expected gains in the users' qualification and motivation, and some with the functioning of the entire work organization. When interacting with each other, these effects, if successful, likely cumulate the total advantages of participation.

However, participation is not always beneficial, neither for the outcome nor for the participants themselves. Nor can it be applied in all circumstances. An overall negative aspect of participation can be an obscuring, or even rejection of the role of expert knowledge in the process. The participants' views may be limited to the visible and immediate everyday experience, and seeing the future demands, or the entirety of the design (e.g. in designing entirely new objects or in the development of large systems), may additionally require other forms of expertise.

2.2. Utilization of the Users' Knowledge and Experience

Utilization of the users' experience and knowledge in the activities at the workplace is obviously the first argument for participation. Presently, in complex work processes, it is ever more likely that the user knows best the problems in task execution or the disturbances in the performance of the system. In particular, the user knows his/her own work activity in detail, i.e. the operations and functioning of technical solutions which are potential objects of ergonomic improvements. Furthermore, the load, and difficulty or ease of the work performance experienced by the participants constitute the human criteria for these improvements.

2.3. Accommodation of the Design to the Individual

In the participative design process, the work activity and the design can be accommodated to fit the characteristics of individuals or of a specific user group. In tests and evaluations, the demands of the actual tasks are proportioned to the actual users' capabilities, the result of which is beneficial for individuals who are in some respect physically less capable compared with the average, e.g. for women and aging users. Similarly, the users' task-related expert competence is taken into account.

On the other hand, designing for individuals or small groups can lead to generally inappropriate solutions as regards essential variations within the user population, e.g. in respect to the variation in qualifications, anthropometric dimensions or muscle strength. Also over-motivated participants may tend to demonstrate their capabilities in the design sessions, and this may lead to solutions which are not suitable for the others or inappropriate in the long run.

2.4. Expansive Learning of all Concerned

In participative and collaborative design sessions a lot of essential information is naturally being transmitted between the users and designers, and other groups concerned. The users bring their experience and feedback regarding usage to the designers, and the designers provide understanding of the system's way of operation. This ever-growing general understanding helps the designers to design more operable systems, and the operators to operate the systems more efficiently and reliably.

2.5. Fulfillment of Individual Needs

Well-trained people want to utilize their skills and capabilities and to experience self-realization in their work; participation offers a channel to achieve these. People also generally want to have more control over their work tasks, and to take part in molding their work environment. Apart from the functional aspects, there may also be aesthetic or self-determining needs concerning the environment, and they become evident, for example, when making the work site home-like or to reflect the personality of the user.

2.6. Achieving Commitment and Acceptance

One of the greatest benefits of users' participation is the feeling of ownership regarding the solutions, and the resulting increase in motivation and commitment to the usage. This basically positive consequence involves ethical questions of participation, too, especially if the outcome of the design is not expected to be beneficial for the user, or if it does not entail any positive change compared with the earlier design. If the only purpose of participation is the manipulation of users, it is evidently questionable, and forms an obstacle for later initiatives to involve people in these activities.

2.7. Effects on Organizational Behavior

Increasing the skills of collaboration, added to improved comprehension of the goals and development processes very likely contributes to the functioning of the entire organization. On the other hand, the participation of selected persons or groups may cause envy among those who cannot participate. The participative process may also be unsuccessful, with no useful results, or results

that may be unfavorable to some individuals. All such reasons can potentially cause frustration among the employees.

2.8. Integration of Different Aims

Generally participation serves many purposes at the same time. All in all, the participants assess their workplaces as functional entities, and it may be even difficult to separate e.g. productional and health-related aspects from each other. As a strategic notion, it may be easier to motivate the management to support participation with all-inclusive gains as compared with purely health-oriented or humanistic ergonomic interventions. This situation may lead to the misuse of participation, however, if the designers or management utilize the multiple outcome of participation at the expense of the users' well-being.

3. LEVELS AND MODES OF PARTICIPATION

3.1. General

When participation is applied in designing, it should be made clear to all the parties involved what is the object of design, the structure of the design process and design organization, and the goals and limits of participation. Participative actions can be organized by different groups, e.g. designers, the management, occupational health and safety personnel, or the participants themselves. Participation can take place as a separate project, a part of an ergonomics program, incorporated in continuous improvement activities, or, as part of design projects.

Important issues of participation in these respects are the questions of who should participate, and what are the participants' areas of influence, decision-making power, and responsibility concerning the results. It is also important to find useful and feasible ways of action for different design settings and purposes. These questions need to be solved locally, by mutual consultations of the parties in question, and preferably preceded by the assessment of the overall situation in the organization (e.g. workplace atmosphere, cultural environment, relations between the management and unions, threats of downsizing, etc.).

3.2. Representative versus Direct Participation

In indirect, representative participation only authorized representatives (e.g. shop steward, safety delegate of the union, team leader) of the users participate, in direct participation the actual user of the workplace being improved participates. In some countries it is customary for the union representatives to participate in the meetings of larger workplace design projects. They are not necessarily acquainted with the object of design, however, and their concern is, to a great extent, limited to the general and legally determined aspects of design. As regards the basic principles of participation described earlier, only the direct mode could be considered "genuine" participation. However, this mode is more vulnerable to misuse as there is less control from the union representatives.

3.3. Influence, Power and Responsibilities of the Participants

How determining or influential the participants' role in designing is, varies between two extremes in the different modes of participation. The participants may act merely as sources of information or test subjects, having less power to make decisions concerning the outcome. They may be members of the design

team, sharing the decision-making on some level or, form a separate participative team making analyses and generating solutions or suggestions for the designers, normally within prescribed limits, however. At the other end, the users are designers themselves, which is often true in the designing of personal office environments in ready-made components.

Regardless of their decision-making power, the participants have an opportunity to influence the outcome greatly, whenever they can freely express themselves. When they are given power and responsibility, the question of compensation will arise, which is still a largely unsolved issue of participative design.

3.4. Participation Varies According to Object of Design

The appropriate ways to participate or collaborate depend greatly on what is being designed. The object of design may be a large entity or only a small part of it, or, an entirely new design or merely a correction to an existing design. Also the complexity of the work place (geometric, structural, functional) and its relation to the entire work system dictates the design approach and the associated design methodology, and sets requirements or limitations for involving users in the process. For example, the design objects of work places vary from simple furniture and work equipment, allowing easy or even improvised participation, to complex systems requiring the application of special methods with careful guidance.

3.5. Modes of Participation in Different Stages of Design

The contribution of the users and other groups concerned is needed in all those stages of the design process in which the characteristics of the work tasks and workplaces are determined. Such stages are e.g. gathering and transmitting knowledge and information, setting objectives, making analyses and evaluations, preliminary sketching of the design, assessing drawings, building models and prototypes, assessing them, trying out and testing the designs or completed workplaces, or gathering feedback from ready workplaces and transmitting it to the designers.

There are several ways to participate and collaborate in these stages of the design projects, e.g. in design sessions, formal meetings, reviews and audits. Participation in the project requires open flow of information regarding the schedules of the projects, and the object of design at each time, so that the participants (or collaborators) know when and how to contribute. Also it must be made clear to the designers at the beginning of the projects, who can potentially contribute usefully to each design task. The designers can also develop their practices and methods so as to facilitate and encourage greater participation and collaboration (Launis *et al.* 1996).

In the design projects, new work systems are usually constructed, but still large parts of them will be mere modifications of earlier designs. The human activity will not change entirely, either, and therefore it is possible to convey earlier experiences to new designs through participation and collaboration. In addition to careful analyses of the earlier designs and associated work activities, also "reference work sites" similar in some important aspects, can be visited and analyzed fully to utilize the existing experience in the new designs (Daniellou and Garrigou. 1992).

4. THE NATURE OF USER KNOWLEDGE

The conception of the users' knowledge is the essence of participative design. This knowledge is based mainly on experience, and often can not be expressed as concepts, not even verbally. This tacit knowledge can not always be recalled, either, and therefore, e.g., actual walk-throughs of the work processes at the workplace are needed for processing and voicing it. Also the users' mental models of the functioning of the technical systems arise from experience, and therefore they differ considerably from those of the designers.

5. REQUIREMENTS FOR THE METHODS OF PARTICIPATION

5.1. General

The diversity of the above-mentioned conditions of participation makes it difficult to establish common procedures or even methodology for participative designing. As a matter of fact, in participative design, many well-known design methods are applied in a way that takes into account the nature of the participants and the requirements for the participative design situations. From this point of view, some criteria on the procedures and methods of participation will be presented in the following sections.

5.2. Clarification of the Basic Concepts

The methods used must help to clarify the concepts concerning the work process and functions of the work system. This is a prerequisite for ensuring understanding and fruitful discussion between the designers and the participants. The designing of more complex systems requires also common conceptual models of all functions and their relationships, linked to the associated human activity. This can be done in joint discussions by describing verbally the work processes, the purpose of each task and technical element, and the activities performed by the operators. The use of the wallboard technique can be appropriate for generating such a representation of a larger work system.

5.3. Making Invisible Visible

Work systems and work processes have to be illustrated clearly, especially if they are not obvious or visible, e.g. chemical processes or information systems. Schemes and diagrams may well serve this purpose. Walk-throughs and task simulations are effective in persuading the users to bring out their hidden knowledge. Sketches of the workplace and simulation of layout with cardboard models are well known illustrative means. Computer-aided design with human models, as well as virtual reality technology, can offer means of illustrating designs of the physical environment for purposes of participation, but this requires additional effort from the designers, which is not always feasible in single-occasion workplace design.

5.4. Focus on Interaction between Work Activity and Technology

The emphasis in participative design is on work activity, which is the expertise area of the participants, but the focus must be shifted also to the assessment of the associated technical solutions in their use. Methods of ergonomics for analyzing and restructuring work tasks are useful, but they need to be complemented with user trials and tests of the models, mock-

ups and prototypes. In respect to this main consideration, purely technical aspects, as well as such human aspects for which clear criteria and data have been established, e.g. environmental hygiene, anthropometric variability, or maximum recommended weight limits, may be beyond the scope of participative designing.

5.5. Aim at Consensus Decisions

The users' views and values vary from those of the technical personnel, and in order to achieve appropriate compromises, methods of dealing with different suggestions are needed. Again, the wallboard technique can be applied for gathering ideas, for discussing them, for combining ideas, and for rating alternatives. The resulting group decisions are beneficial for overall acceptance of the design, but they involve the risk of neglecting important factors (e.g. concerning safety) which are not known or only poorly understood in the group. A common understanding of the design goals and the importance of various factors is one prerequisite for a successful group decision process.

5.6. Ease and Efficiency

The limited time provided for participation and inexperience of the participants in designing requires that the methods must be exceptionally easy and the threshold of starting the work must be low. Methods requiring much documentation and verbal formulation are less suitable for participative designing. Specific methods intended for participative inquiries, such as mind-mapping and round robin questionnaire, are examples of cost-effective means. Also ready-made tools supporting designing, such as agendas for meetings, forms for gathering information, checklists and other clear tools can be efficient in participative designing.

6. PRECONDITIONS OF PARTICIPATION

6.1. General

In addition to favorable overall preconditions of participative designing (support from parallel activities, higher level of education of the workforce, democratization of work life, etc.), some specific requirements are apparent. User participation is a voluntary extension of people's daily activities, and thus it is sensitive to both positive (support, motivation) and negative influences (resistance, territorial behavior) prevailing in the organization.

6.2. Commitment of those Concerned

Participation cannot be successful unless all the groups involved in the events accept it. Understandably, however, for several reasons, it is not possible to motivate everybody in these activities. Extra effort, unsuitable timing, or threat of losing power are potential reasons for a negative attitude towards participation. The management and the unions have a decisive role in supporting the basic idea of applying participation in workplace design.

6.3. Consideration of Cultural Differences

In organizations, different groups have adopted different values and principles guiding their action; these may severely hamper the development of workplace design. Designers aim at neat technology with the least use of human work, which makes it difficult for them to consider work activity throughout the design process. The top management is involved with financial survival and marketing processes, and they may experience the development of production activities as remote (Schein 1996). Workplace design, and collaborative activities in particular, must therefore prove their beneficially to the decision makers. A practical strategy that has proven useful is to start from a limited area or project and to spread out to other areas after trying out the methods and obtaining good results.

6.4. Provision of Resources

Participation cannot be put into practice without allocating sufficient time for it. This is important especially when involving persons from production duties in the participation. In most cases participation means costs; this stresses the importance of efficient methods. Also extra effort may be needed on the part of the designers and supervisors to take care of additional actions.

6.5. Guidance

Participative design actions need careful planning, organizing, guidance and many other forms of support. The haste inherent in design activities obviously prevents the designers from concentrating on these time-consuming activities. Participation requires the purposeful contribution of a designated person, a "facilitator" or "internal consultant." The qualifications of such a person are crucially important for the success of participative designing.

7. CONCLUDING REMARKS

Participation in designing has been considered an "easy way" of applying ergonomics in work organizations, because it seems, at least to some extent, to replace the need to employ ergonomics or human factors expertise in the designing. Experience shows, however, that participation can be a fairly laborious way to proceed, but it nevertheless has many positive effects that go beyond the design output itself. So far this way of promoting conventional technologically oriented designing may have been afflicted by start-up problems, but growing demands and the integration of similar trends are creating pressure to make also designing a more collaborative attempt. The evident goal is a design practice and culture, which incorporates participation and collaboration in continuous activities naturally and unnoticeably.

Participation of Users in Architectural Design

J. Å. Granath

Department of Architectural Design, Chalmers University of Technology,
SE-412 96 Gothenburg, Sweden

1. INTRODUCTION

1.1. The Scandinavian Experience

Participatory design in architecture has been practiced in the Scandinavian countries for three decades. Such design has different stages for user participation, and each stage is treated here separately. In real life one does not find clear distinctions between these stages of participation since they often overlap. Nevertheless, one can discern a sort of evolution of the notion of participation in Scandinavia from what the present author calls "power-oriented" to more "knowledge-oriented" processes. In terms of the outcome, one can discern a shift from an "object-oriented" to a more "process-oriented" view. Simultaneously, one can discern a global movement from "producer orientation" towards "customer orientation" that has put participatory design on the agenda today.

1.2. Users

The term *users* denotes those who actually use the building in their everyday activities. In this sense all people working in a building including staff, management and service personnel are users. A kind of user not included in the *user category* here is those who are some sort of visitors or use the building as a part of a service provided in the building. Such groups are students, patients and visitors. Groups also excluded here, if they are not users in the above sense, are owners, politicians, union representatives and public officials. As representatives for important groups their participation is important and their roles are, therefore, discussed in relation to user participation.

1.3. Inherent Tension in the Architect's Profession

The attitude to user participation is ambiguous among architects. Architecture and the profession of architecture embody both an artistic dimension and a social dimension. The artistic dimension can sometimes inhibit users from involvement in the design process of architecture. This is a result of the conception that art is a private and not a collective activity. On the other hand, the social dimension of architecture and the social visions of the profession of architecture encourage architects constantly to try new methods to involve users in the design activity so that the resultant architectural artifacts might attain a more appropriate and effective design.

2. PARTICIPATION IN DESIGN AND PARTICIPATION THROUGH DESIGN

Participation of users in the design process can be interpreted in two different ways:

- To design architecture in such a way that it supports partici-

pation in the use of architecture – participation through design.
- Participation of users in the actual design process – participation in design.

2.1. Participation through Design

Architecture in itself can, however, prevent or support participation from users. This has to do with accessibility, understanding, appropriation and ownership. It is important to understand that the built environment is designed both by expert designers and by us. We use it and live in it and it is by doing so that we design the environment.

2.2. Participation in Design

Participation of users in the design process could be discussed from different points of departure. In architectural practices and research in Scandinavia there have been three stages of development in the participation process motivated by democracy (Figure 1), quality (Figure 2) of the product and improvement (Figure 3) of the client groups through learning.

Participation of users in the design process has developed over the past three decades. In the late 1960s Professor Johannes Olivegren was one of the pioneers in the field of housing design. His involvement in user participation had mainly democratic motives but he was also searching for more appropriate housing design. The process of user participation has not been linear but there is, at least in Scandinavia, a major line from participation as driven by democratic reasons, through quality-driven, towards participation for organizational improvement. If one looks at single design projects, however, one can find early, single instances of all three kinds, and at the moment one sees participation of users as a way of achieving quality in terms of all three aspects.

2.2.1. Benefits of participation

Democratic involvement is in itself an important factor in society. The main reason for setting up legislative procedures in the

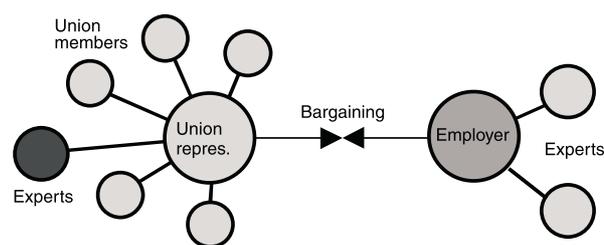

**Figure 1. Bargaining model of communication.**

**Figure 2. Data collection model of communication.**

Figure 3. Collective learning model of communication.

1970s was to ensure that the basic work environment quality was met in the design of work places. This was an improvement in terms of original goals as early 1970s participation praxis had attempted to turn participation into a matter of power instead of an activity that added value to the outcome of the design. The last step in the development of the notion of participation is to improve the performance of the user groups. One can find explanations for endeavor in the fact that information society has today come to see the employee as a company's most valuable resource; this in contrast to the view of the employees in the 1960s and 1970s. In the information society context, the participatory design perceives the employees as a more dedicated, more knowledgeable group. Employees are seen as capable of designing, re-designing and managing production recourses such as the built space they occupy. Participatory design has become a step on the way to a learning organization. A participatory process has developed where the user through *participation in design* can achieve a design solution that supports *participation through design*; on the way they construct knowledge that makes them able to take active part in the re-design and management of the designed environment as demands change.

3. PARTICIPATION AND DEMOCRACY

3.1. Importance of the Context

Two contexts that somehow overlap will now be studied: direct participation and participation through representatives. Typical for the first context is that the stakeholders are well defined. In the second context, a number of stakeholders is involved, with different possibilities to act. The first context is represented by the workplace design in relatively small or local private companies. The design of municipal buildings and workplaces of large companies, where the decision-making process is centralized, represents the other. The reason for distinguishing between these two contexts is the democratic systems that work within them. In private workplace design, one is mainly concerned with two parties: the employer and the employee.

In municipal building design projects it is often more complicated. Here there are politicians who represent the people in society but they might also be the owners and financiers. There

is also the manager of the activity that takes place in the building and the employee. These two last groups are the actual users of the building. In most cases, such as for hospitals, schools and other public buildings, there is a third group, namely the patients, students or visitors, who is also users in a different meaning. In many cases the actual users are not yet employed when the design takes place and those who will visit the building when it is finished is not a well-defined group. Therefore, the participation mostly becomes a matter of formalized democracy involving politicians and municipal officials in public building or representatives for managers and employee from the corporate headquarter in private companies.

In practice it has proven difficult to deal with participation by the actual users in this second context. There are, however, cases both in municipal building design projects and private industrial workplace design where the actual users have taken active part in briefing and designing the buildings. In many such cases there exists an ambiguity for the designing architects concerning the input from the actual users and that from the representatives of different groups.

3.1.1. Shortcoming of a formal participation process

In formal participatory workplace design, participation takes place through union representatives, the counterpart being the employer. (*Formal* here means a participation process that fulfils the procedures in the legislation.) The crucial point in this setting is the overall relationship between the two parties. In many cases where there is a fruitful the relation, the design process has also been rewarding to both parties. In other cases the participation in the design process has been a matter of power (Figure 1).

In municipal building design projects a formal participation process might be sufficient from a political point of view. Direct user participation in this context is more difficult than it is in private companies if one is talking about participation as a way to real influence on the outcome. To accommodate direct user participation, an adaptive design process has been developed. This means that the architects base design proposals on information from elected representatives. These proposals are then presented to the users, if there are any, or to people in the community on specific occasions throughout the design process so that they may have the opportunity to comment on the presented proposal. The architects can then adapt the design to accommodate these comments – if these do not have a major impact on cost and time or other policy decisions made.

One of the shortcomings of this participatory process is that the users seldom get involved in the project early enough to have a chance to influence the conceptual design phase. They may only suggest detail changes for a more or less fixed design. This entails that the more important conceptual input from the users is seen as negative from the point of view of architects and elected representatives since it affects the costs, delays the project and may even be perceived as ignorant or at least out of place. From the architects' point of view, the users' comments often affect the architectural quality of the project as it forces them to make changes to their conceptual design. These changes could easily have been accommodated within the design if they had been part of the brief or taken into account during the conceptual phase.

4. PARTICIPATION AND QUALITY OF THE OUTCOME

Another argument in favor of user participation is that it improves the quality of the outcome. The democratic ambitions to involve users in the design process resulted in the production of design handbooks, pedagogical tools and education programs. These enabled users to take part in design processes. Many practicing architects realized what a tremendous source of information and knowledge the users represented. New methods of retrieving this information from the users into the design projects were therefore developed (Figure 2).

Most commonly architects had extensive interviews with users to understand the essence of the organization they were designing for. They soon realized that the group of involved users was not restricted to union representatives, and the focus of the participation process was shifted from the democracy motivation and the rights to influence the design effort to achieve an appropriate high quality building.

When one uses participation as a tool of achieving better quality, the architect's ambition as an artist might also be an obstacle that needs to be overcome. Artistic values might positively influence the architect's interpretation of the information communicated from the users, but it may also create conflicts between the architect's artistic values and the user's perception of the design.

The strength of focusing participation of the user on quality of the outcome is that both employees and employer can get something out of it. The employers can communicate with the architect directly and, therefore, may have an impact on the outcome. To influence the quality of the building is in the interest of employers wherever they own or rent the building. The problem is, however, that the focus of participation is restricted to the quality of the building. It will be discussed how participation of users can enhance the quality of the outcome of the design process in more ways than getting a better building.

5. PARTICIPATION AND LEARNING

5.1. Participation – An Adaptive or a Generative Process

The experience of user participation in architecture design has been mixed. Many writers on the subject argue that the outcome of participatory processes have not always been received better by users than outcomes of a more "artistic" design process where the architect has played the most dominant role. To understand this we have to elaborate two issues:

- What qualities represent a positive outcome of a participatory design activity?
- What are the significant qualities of interaction between different actors in participatory design processes.

5.1.1. Value of the Outcome

First one has to realize that the above-described stages of participation in architectural design all have their own standards for value of the outcome. From a democratic point of view the procedure of contacts between the parties and a result in terms of a having an impact on the result might be enough. A satisfying result in terms of quality of the product might be better working conditions, e.g. lower noise levels, ergonomical equipment. From the point of view of the employer it might be important that these improvements are advantageous for the production and for the overall social atmosphere of the company. If one, however, looks at the outcome of participation from a learning point of view, both parties will value individual growth, creativity and better overall performance. The focus has shifted from the building to the design process and the development of the organization that uses the building (Figures 1, 2 and 3).

5.1.2. Interaction between actors

User participation based on formal democratic procedure often lacks direct contact between users and architects in the early conceptual phases of the process. Politicians, local officials or union officers may represent the users in the dialogue with the architect. In this case the discrepancy between the users' needs and what they get is mainly a matter of how well the representatives represent the organization they are meant to represent.

Often, however, the participation activity is set up mainly to gain knowledge from the users. In most cases the architects collect information though interviews with personnel and through studies of the previous situations, if there are any. They then *interpret* this information into design solutions that goes back to the users for their comments. Even in these cases there may be problems.

Users are often badly prepared for participation in changing processes. The point of departure for their conceptions of the future is often limited to the existing situation with its restrictions and possibilities. Being asked about what they want, they may have problems *conceptualizing* their wishes, *articulating* them even to themselves and, even more, *communicating* them to colleagues. To communicate something in an interview with architects is more difficult. Architects, on the other hand, often have very early preconceptions of the design solution or they will formulate them after a few interviews. This is not only one of architects' strongest professional abilities, but also one of the obstacles in participation. They will have these preconceptions in their minds and they will, together with architects' professional and cultural values, function as *interpreters* to what the users try to communicate.

Architects' tacit understanding of the situation will be imbedded in the designs that they feed back to the users. These designs are mostly beautifully packaged as rendered perspective drawings, elaborated layout drawings produced in CAD or by hand. Maybe even a three-dimensional real model or a virtual computer model accompany the architect's interpretation. Mostly it is very hard for the users, given their problems of conceptualizing, articulating and communicating their needs, to determine whether the suggested design will really facilitate their future activities

From research and practice in Scandinavia one knows that the users often do not understand the suggested designs until they have moved in and started to use them. Disappointments at this stage not only discourages the users from further participation in architectural design, but also discourages the architect, who may have had strong intentions to listen to the users in order to design a well-functioning building for them.

5.2. The User as Designer

Another kind of user participation is to recognize the user as a co-designer. This process is sometimes called *the collective design process*. The idea is to form cross-disciplinary groups within a company. This group, which includes architects and other external experts as resource persons, drives the design process. In this design setting the focus is taken away from the building. The focus becomes the performance of the organization and how to design a building that supports better performance. The integration between the design of built space, technical systems and organization of work becomes natural in such a setting (Figure 3).

However, such a settings calls for the development of new behavior and new methods. The creation of a mutual language within the design group and mutual understanding of the situation might be the single most crucial factor. The roles of the participants in a collective design process are dual. All participants are experts in their own professional field. Whether they be nurses, teachers, assembly workers or maintenance workers, they can contribute hard facts and experience to the design process. The in-house participants are also users in the traditional sense and as such they have demands on the future design. Experience has shown that the group views the participants *as users* and allows opinions on almost anything concerning the design, based on the fact that their situation will be directly affected by the outcome of the design. If the group participants, on the other hand, see each other only as experts they tend to be more polite and respectful of each other's expertise. They

are, however, both experts and laymen. This makes it easy to everybody's good ideas into account, even if it is not based on expert knowledge. The usual interdisciplinary tacit understanding that often stands in the way of creative solutions can be overcome by the intervention of the kind of "disrespect" only laymen can show towards state-of-the-art solutions. In their role of field experts, can the participants directly influence details in the outcome without the interpretation by architects or other external experts?

There are, however, problems involved in this kind of participatory design. One of these problems is related to the fact that the design group becomes very skilled to the disadvantage of those not participating. They develop group knowledge with its own repertoire of experiences and sometimes its own internal language. The pedagogical problem is then to ensure that everybody knows what is going on and has the opportunity to contribute to the process. It must not become a closed process. The design activities should preferably take place on the premises of the user organization or close to the user organization. It is especially important that management, unions or other groups that are policy makers or have power to manipulate the process or the end result can participate in the manner they feel is appropriate. These groups might otherwise be alienated from the design process as well as the design solutions with all the negative effects that might have.

Another problem is to set up the actual design process. Professional language barriers, professional roles and the preconception of knowledge and design behavior are obstacles to these kind of participatory processes.

Participatory Ergonomics

J. R. Wilson and H. M. Haines

Institute for Occupational Ergonomics, University of Nottingham, Nottingham, NG7 2RD, UK

1. INTRODUCTION

Organizations increasingly appreciate the benefits associated with applying ergonomics to the design of workplaces and jobs, but there is a recognition that ergonomics experts alone cannot achieve widespread and successful implementation of ergonomics at work. Practically, there are simply not enough ergonomics experts to meet the needs of industry, and their employment may anyway not be cost effective for many smaller organizations. Outside experts may also be too isolated to be the core of an ergonomics and safety culture within a company. The alternative is an internally managed participatory ergonomics program.

There has been a significant growth of interest in participatory ergonomics during the past 15 years. Many of the rapidly expanding number of "participatory" initiatives reported worldwide attempt to use this kind of approach with the aim of improving the health and safety of their employees, or else to enhance the chances of success for any implementation of change. Consequently, there are many different types of participatory ergonomics initiative (see Haines and Wilson 1998 for a framework of these; much of the content of this entry is drawn from this source).

2. DEFINITIONS OF PARTICIPATORY ERGONOMICS

There is no general agreement about what the term participatory ergonomics actually means. It can be seen as variously a philosophy, an approach or strategy, a program or even a set of tools and techniques. (Neither is this lack of agreement limited to participatory ergonomics; similar views have been expressed in the participative management field.) A range of views of participatory ergonomics as a mixture of content and process can be seen in its definitions. In fact, participatory ergonomics should not be thought of as a unitary concept; Batt and Appelbaum (1995), for example, make a distinction between "off-line" and "on-line" participation where off-line refers to "off the job" problem-solving processes; "on-line" refers to where decision-making about work is part of the job (e.g. through work teams). Similarly, Zink (1996) draws a distinction between "selective participation" and the attempt to achieve continuous improvement.

Participatory ergonomics is a complex concept involving a number of different dimensions. At its most basic it consists of "stakeholders" contributing to an ergonomics initiative or sharing ergonomics knowledge and methods. Reflecting the broad range of potential ergonomics initiatives across workplaces, jobs and work organizations, a working definition is: "The involvement of people in planning and controlling a significant amount of their own work activities, with sufficient knowledge and power to influence both processes and outcomes in order to achieve desirable goals" (Haines and Wilson 1998). It is clear that employee participation in general, and participation in ergonomics initiatives in particular, can vary widely. Which kind of participation is appropriate in any given context? Cohen (1996) suggests a form of contingency approach, and that a number of so-called "shaping factors" should be considered in making such decisions namely:

- the nature of the issues requiring consideration;
- whether the matters are broad-based or specific to a local operation or group;
- whether the needs for response or action are time-limited or necessitate continuing efforts;
- the abilities of the group most affected; and
- the organization's prevailing practices for joint labor-management or participative approaches in resolving workplace issues.

3. THE CONTEXT FOR PARTICIPATORY ERGONOMICS

Why has there been such a significant rise in interest in participatory ergonomics in recent years? In general, the developed world has become more participative over the past 40–50 years; the public and the workforce in many countries will not accept government or management practices, which were widespread half a century ago. Disappointment with technical investments and recognition that motivation and performance are complex issues has bred human-centered manufacturing initiatives with emphasis upon an educated, involved and responsible workforce; there is a greater emphasis on attributes of quality, flexibility and customer service, rather than merely quantity of output, which in turn supports the need for greater workforce participation. High-performing companies are said to have employee empowerment as one of the enablers to be successful, and this has often been in tandem with teamwork; "people involvement" programs have grown out of quality circles and action groups as a part of Total Quality Management (TQM), although TQM and its derivatives can be viewed as subtle forms of management control, and empowerment and participation can be interpreted as insidious means by which worker power is eroded in the context of industrial disputes and attempts to downsize. Further drive for participatory ergonomics comes from health and safety and workplace regulations across the world.

4. THE PROS AND CONS OF PARTICIPATORY ERGONOMICS

Of all the advantages of participatory ergonomics, there are two direct benefits that are commonly referred to. First, employees have unique knowledge and experience of work and their involvement should, therefore, provide a clearer understanding of both the types of problems being encountered and the solutions that will be appropriate. Second, involving people in analysis, development and implementation of a change should generate greater feelings of solution ownership and may generate a greater commitment to the changes being implemented.

Participation may often be a learning experience for those involved. For workers, knowledge of their own work and organization may be increased, and involvement in a development or implementation process can mean faster and deeper learning of a new system and, hence, decreased training costs and improved performance. Participatory ergonomics may also be a

learning experience for designers or other technical specialists, and a departure from conventional thinking can improve design effectiveness.

At a wider level, by spreading understanding and expertise in ergonomics among those involved, and by attracting interest among work colleagues, solutions can be generalized and ergonomics transferred throughout an organization. If people are involved in making ergonomics changes at work, they are more likely able to adapt when circumstances change or to use the ideas elsewhere, increasing the in-house knowledge base of ergonomics.

The process of participation itself may provide benefits, with participants developing more self-confidence, competence, independence, personal development, social contact, feedback, influence, challenge and variability, the very characteristics that have been identified as contributing towards "good" work and reducing stress at work (Karasek and Theorell 1990).

The effects of worker participation on satisfaction and productivity have been the subject of debate, with some agreement about gains for both and that the greatest benefits come from the more extensive forms of participation. Also, basic workplace ergonomics and health and safety interventions can be carried out very efficiently and effectively through work teams participating together to identify problems and implement improvements. Involvement in such initiatives can help give the work teams a specific focus and strengthen the team basis and functioning. The socio-technical principle of compatibility dictates that it is desirable for the groups that develop ideas for new workplaces, work tasks and work structures to subsequently form into work teams themselves and vice versa.

Despite the considerable potential benefits of participatory ergonomics, it may also bring with it some difficulties. It is not always easy to instigate or support; management and workers might both be reluctant or resistant, because of suspicion, fear or the feeling they lack knowledge, motivation, time and energy. There are potential problems associated with the *process* of participation. Group decision-making can often be fairly unreliable or limited. Planning and developing new systems participatively may be slower, more complex and require greater effort. The process may encourage employees to develop unrealistic expectations about the timescale for management approval, implementation and benefits from their recommendations, or else the extent to which jobs or equipment will be changed. Sometimes the process or content of participation impacts on other parts of the organization in unhelpful ways: increasing the roles of one group may reduce job content for others; a participative process that improves the workplace for some may make those in other departments envious or dissatisfied; also, other groups may wish to be similarly involved and this may be neither possible nor even desirable.

Some projects referred to as participatory ergonomics may be so in name only, being little more than exercises in information provision or even manipulative programs with a covert agenda (Reuter 1987). Cynical use of participative methods may yield some limited dividends in the short-term but will not provide any of the potential greater long-term benefits. This sort of use may partially explain participation's ambiguous tradition within industrial relations, and particularly the suspicions of trade unions.

Finally, there may be problems in providing proof of results; it may be hard to show that participation has truly brought about a better system or system change, or that more autocratic methods would have been less effective. This lack of evidence may contribute to a lack of face validity in the eyes of management.

Clearly a participatory approach to ergonomics problems at work is not a panacea. Some organizations are simply not ready for participative practices. However, while participatory ergonomics will certainly not be universally appropriate, if careful consideration is given to the time, place and the individuals involved, as well as to the structure and methods being used, then its potential benefits may be realized.

5. PARTICIPATORY TOOLS AND METHODS

A variety of different tools and methods have been reported as useful within participatory ergonomics initiatives. Some have been borrowed, adapted or developed with participatory ergonomics specifically in mind, whereas others have been taken from more "traditional" ergonomics initiatives and then applied within a participative exercise. The variety of ways in which participatory ergonomics may be applied means that certain techniques will be much better suited to certain situations. For example, if we are looking to instigate and support participatory ergonomics as a macro-ergonomic strategy, we are likely to be interested in tools to sell a participative approach to stakeholders or to facilitate group-working and improve interpersonal skills. Tools and methods will be employed in various stages of a participatory ergonomics exercise, for instance organization, support, problem analysis, idea generation and concept evaluation.

A major issue in the selection and use of appropriate tools and techniques concerns participants' "expertise." Depending on the structure chosen for the participatory initiative, experts may play a number of different roles. They may restrict their intervention to largely supporting or guiding the participatory process, they may be involved with a variety of other workers as members of a multifunction group, or they may undertake much of the analysis themselves. Generally it is better to avoid using overly complex or technical analytical tools; if one of the aims of participatory ergonomics is to free institutions from reliance on the outside expert then the use of highly complex tools may prove self-defeating. This may restrict the use of some computer-based modeling and simulation tools for the time being (the sophistication here lying not so much in their use as in the interpretation of the results they produce).

Many techniques such as word maps, round-robin questionnaires, layout modeling and mock-ups form part of Design Decision Groups (DDG) (Wilson 1991), themselves derived from the work of O'Brien (1981), who adapted theories and techniques from market research and the literature on creativity and innovation. DDG have been used in a large number of applications in manufacturing, transport, service and process industries, and as part of much wider systematic approaches to engineering and design throughout an organization. An extension of a DDG approach includes reference visits by participants to other, similar, sites and their sourcing and costing of solutions within a budget set by management. This initiative can be extended into a process of continual improvement (Wilson 1995). Role-playing techniques and simulation games are of potential value and there is increasing interest in the place of simulation

games within organizational development, particularly from the perspective of developing work processes or group interaction and teamwork.

6. EVALUATION OF PARTICIPATORY PROGRAMS

Although there are difficulties involved in proving the effectiveness of participatory projects, there are a number of ways in which a participatory program may be evaluated. The most obvious is to measure the extent to which the original, anticipated outcomes have been achieved; is the incidence of musculoskeletal disorders falling, are employees more satisfied with their work, has productivity increased? There are, however, potential difficulties with using such outcome measures: it may take some time for any effects to show, or else effects might be significant but small, or else effects may be confounded by changes in company environment, market, structure, processes or people during the life of the implementation and evaluation.

Alternative approaches to evaluation may use "process measures," such as the number of changes implemented, participants' satisfaction with their involvement or the spread of the program throughout an organization.

For many managers the success of a participatory ergonomics program will be measured in terms of cost savings. However, cost–benefit analyses of ergonomics projects are not always easy to calculate. Accurate economic estimates for all factors are often very difficult to produce and some positive outcomes may not have direct economic consequences. Few cases in the participatory ergonomics literature evaluate their success in financial terms, although a special issue of the *American Industrial Hygiene Association Journal* (vol. 58, 1997) features company-wide ergonomics programs incorporating some degree of worker participation where the primary aim is to reduce musculoskeletal disorders, and attempts have been made to calculate the resulting benefits. One of the cases looks at some of the costs associated with setting up an ergonomics program suggesting that, over 2 years, almost $108 000 was spent on training and consultation and significantly more ($510 000) was spent on ergonomics interventions; during the same period over three times that amount was spent on worker compensation costs (Mansfield and Armstrong 1997). Another case comes from a collection of examples reported by Hendrick (1996). Structured almost like a controlled experiment, it featured seven companies that received training on how to set up a participatory program, and where all but one went on to implement them. Eighteen months later the six companies could report a total saving of over $1.25 million due to reductions in "strain-type injuries" whereas the seventh company reported an increase in injury levels.

7. A FRAMEWORK FOR PARTICIPATORY ERGONOMICS

Participatory ergonomics is not a unitary concept, and participatory ergonomics initiatives can take a wide variety of forms, from a single re-design exercise to development of a full culture of employee involvement. Table 1 identifies some of the dimensions across which participatory ergonomics initiatives might vary.

The first dimension of participatory ergonomics is its *extent or level*, whether participatory ergonomics is applied across an organization, a work system or a single workstation or product. The second dimension concerns *purpose*. Is it being used to implement a particular change or to be *the* method of work organization? Participatory techniques within a design exercise are often part of implementing a change, but may also be used as part of a product design process. A further dimension is provided by the *continuity* of use of participation. Has the process got a continuous or discrete timeline: is participation to be used as an everyday part of an organization's activities or is it applied from time to time as a one-off exercise?

The next dimension of participatory ergonomics — *involvement* — concerns who will actually take part in the process. Full direct participation is when all stakeholders directly affected become participants (however, restrictions on resources may dictate representation by a subgroup of those affected — partial direct participation). Representative participation generally occurs in two situations, where worker representatives are involved in product or equipment or job design, but may not necessarily be the eventual users, or where trade union personnel represent the interests of their members at work. The fifth dimension acknowledges that the *formality* of worker participation in ergonomics may vary, from mechanisms such as teams or committees with attendant procedures, to informal, almost casual use. The sixth dimension is the *requirement* for participation — is it voluntary or compulsory? Voluntary participation is the most usual form, in the sense that participation works best where the workforce volunteers its contributions and is involved in setting up the process. Compulsory participation is seen, for instance, in companies with compulsory quality circles or production groups, where involvement in troubleshooting and continuous improvement is an obligatory part of job specification and roles; it is arguable whether such compulsory participation is truly participative.

The seventh dimension considers *decision-making* structures. At one end of the scale, workers are consulted, although decisions rest with management. At the other end of the scale, workers make decisions. A third category concerns the situation where

Table 1. Dimensions of participatory ergonomics (adapted from Haines and Wilson, 1998).

Extent/level	Organization ——— Worksystem —————— Workplace ——— Product
Purpose	Work organization ————————Design———————— Implementation
Continuity	Continuous ———————————————————— Discrete
Involvement	Direct (full/partial) ———————————————— Representative
Formality	Formal ———————————————————————— Informal
Requirement	Voluntary ———————————————————— Compulsory
Decision-making	Workers decide ——————— Consensus ——————— Consultation
Coupling	Direct ———————————————————————— Remote

input is obtained from a range of those affected and decisions are made by consensus. Finally, how directly participative methods are applied (a concept referred to as *coupling*) may vary. Participative methods may be directly coupled (work groups re-designing their own workplace, for example). Remote coupling involves some filtering of participants' views, for example through the use of company-wide questionnaires.

Figure 1 shows a framework to illustrate the bases on which an organization might initiate and structure participatory ergonomics initiatives. It starts at the point where an organization makes the decision to employ participatory ergonomics and identifies some of the main factors which may motivate this decision. Some form of initiative will then be implemented, the structure of which may be defined across the eight dimensions of participatory ergonomics. Criteria influencing both the structure of the initiative and the selection of participatory methods have been identified. An evaluation of the initiative will contribute to any further motivation to employ participatory ergonomics. The whole process will take place within an organizational and environmental context, which will influence all its elements.

The participatory ergonomics literature shows some agreement about the requirements for a successful ergonomics

initiative. Because participatory ergonomics can operate at many levels, from a single design exercise up to the basis of a shop-floor culture, some requirements will be more relevant than others depending on the type of initiative being undertaken. The requirements can be summarized as:

- Establishing a climate and support for participation.
- Structuring a participatory initiative.
- Enabling participatory processes and methods.
- Evaluating participatory ergonomics initiatives.

8. CONCLUSIONS

Enthusiasm for participatory ergonomics belies the fact that the concept is less than straight forward and people call initiatives "participatory" that, in reality, are not. Participatory ergonomics is complex and diverse, an umbrella used to cover a fairly broad range of ideas and practices. This means that there is a range of models and ways of doing participatory ergonomics, and a multiplicity of tools and methods employed within participatory ergonomics initiatives.

Yet despite these variations, it would appear that most commentators see participatory ergonomics as offering a common set of advantages (Figure 2). First, it is seen as exploiting the detailed knowledge and experience of those who inhabit the very

Factors which may motivate an organisation to implement participatory ergonomics

- availability of expert advice
- legislation
- external recommendation
- workforce / union negotiation
- management philosophy
- awareness of importance of (workplace) ergonomics problems
- worker complaints or compensation claims
- product / market advantage

Decision to implement participatory ergonomics

Structure of initiative

- extent /level
- purpose
- continuity
- involvement
- formality
- requirement
- decision-making
- coupling

Criteria influencing structure of initiative

- size of organisation
- organisational culture
- nature of (workplace) problems
- timeframe available
- stakeholders (who is affected)
- resources available (expertise, time, finance)
- workforce education and training

Implementation process

Criteria influencing selection of methods

- type of problem
- resources available (expertise, time, finance)
- knowledge or experience of methods
- number of participants

Evaluation

Wider social, economic, legal and technical factors

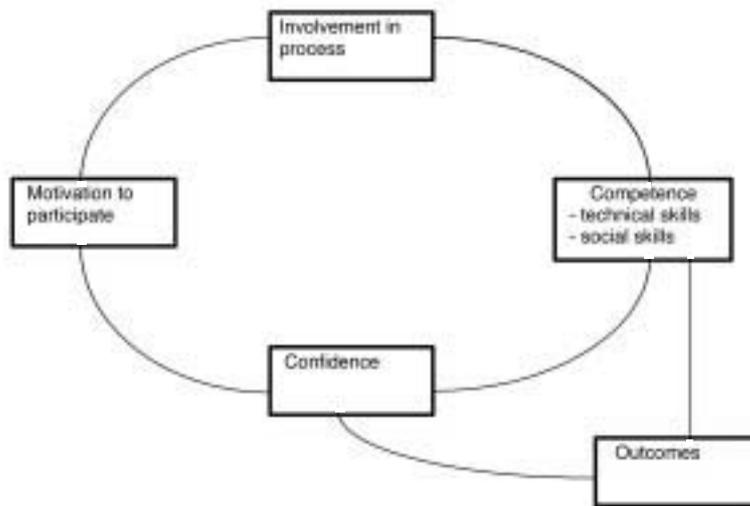

Figure 2. The participatory ergonomics cycle (Haines and Wilson, 1998).

workplace under investigation — getting most from those who, in a sense, should know best. Second, it is felt to encourage a sense of ownership among the participants, such that it helps to secure at least some degree of commitment both to the process itself and to any changes that may result. A third and related advantage of participatory ergonomics is thought to center upon psychosocial factors. Irrespective of the specific details of how these effects operate, it is not surprising that a workforce whose views are sought and taken seriously might feel more positively about both themselves and their workplace. Against such benefits, there may be some concerns about the time, cost and ease of implementing participatory programs, and about inappropriate or poor quality implementations. The potential benefits, though, can far outweigh any possible costs and problems.

Participatory Ergonomics – A Scandinavian Approach

P. L. Jensen

Department of Technology and Social Sciences, Technical University of Denmark, Denmark

1. INTRODUCTION

Participatory ergonomics is a new concept within ergonomics that refers to a practice well known in Scandinavian countries. For years the general, espoused theory on improving working conditions has emphasized participatory approaches. Many studies on change processes based on workers' participation has been conducted resulting in recommendations for tools and procedures. But studies have shown that in practice participation in change processes is not guaranteed and that many difficulties have to be overcome while implementing these approaches. This article will present the status of participatory ergonomics in Scandinavia emphasizing central issues to be developed and researched.

2. DEFINING CENTRAL CONCEPTS

In Anglo-American literature the two concepts "ergonomics" and "human factors" are used to denote activities concerned with "fitting the task to the man." Scandinavians tend to associate ergonomics with applied physiology of work whereas the concept of "working environment" covers analytical, descriptive approaches to working conditions as well as approaches to establish normative recommendations for fitting tasks, workplace and working conditions to man. In this text all three concepts are seen as synonyms

The concept of "participatory ergonomics" was launched in the 1980s (Noro and Imada 1991). Within ergonomics it can be seen as a dissociation from the traditional, expert-based approach to analyses and change of workplaces. Based on an examination of more definitions Haines and Wilson (1998) define participatory ergonomics as "the involvement of people in planning and controlling a significant amount of their own work activities, with sufficient knowledge and power to influence both processes and outcomes in order to achieve desirable goals."

While the promotion of participatory approaches might be a new issue within ergonomics, it has been a recommended practice in the Scandinavian countries at least since World War II. This approach is based on a combination of direct and indirect participation. Indirect participation is based on participation of elected or appointed representatives of workers while direct participation is based on the participation of the workers, having to live with the changes.

There are different degrees of participation. The following typology makes it possible to differentiate between them:

- Information from management to workers on plans for action.
- Gathering of information and experience from workers on present working conditions.
- Consultation allowing workers to make suggestions and present points of view on new work sites.
- Negotiations to define problems and find solutions.
- Joint decision-making in agreement between involved parties on problems and solutions.

On the basis of these concepts the development of the Scandinavian approach can be described.

3. PARTICIPATION IN REBUILDING SOCIETY AFTER WORLD WAR II

After World War II the main issue for most European countries was to rebuild an effective production sector. Several strategies were followed of which one was based on local cooperation between workers and first-line managers to improve production. The existence of a generally highly qualified work force was an important precondition for this strategy. Under the heading "work smarter not harder" simple tools were presented. The aim was to use workers' and first-line managers' detailed experience of every-day activities to improve the production process and the work activities. Simultaneously changes were accepted. This direct participation approach was embedded in a representative, participatory system-based on national, collective agreements. The employees were represented by their shop stewards, which were protected against dismissal through a general agreement. This design was made to guarantee the general legitimacy of the process and the results of the direct participation procedures. In the representative system agreements were made on conditions of participatory schemes and for the allocations of the economic results between workers and employers.

In the 1950s and 1960s the main issue of these arrangements was to achieve increased productivity and higher wages. But simultaneously disputes on working conditions in these rationalized productions appeared. First, the central labor market organizations recommended a more efficient use of the representative bodies before and during organizational and technological change processes. They stressed the importance of joint decision-making or at least efficient consultancy of workers and not only information of their representatives. But in a response to a general discussion of working conditions particularly in industry resulting in wild strikes during the economic boom at the end of the 1960s and the beginning of the 1970s, a new act on working environment was passed in all Scandinavian countries.

4. THE 1970s WORKING ENVIRONMENT ACTS

The acts on working environment legalized employees' participation in issues concerning working environment. The general principle in the acts in accordance with the general prerogatives of management is to make the employers and top-management responsible for establishing safe and sound working conditions. With reference to the Danish act this implies that in planing and implementing chemical substances, technical aids, the design of the workplace, the excursion of work and the scheduling of working time management should prevent risk of accidents, work-related diseases, the observance of ergonomic principles and reduction of psychological stress.

Additionally the act states that employer's responsibility should be fulfilled in cooperation with the employees. To support this cooperation and to ensure a continuous monitoring of the working environment the act orders enterprises of more than 10 employees to form safety groups comprising the local super-

visor and a safety representative elected among the employees in the department. In enterprises of > 20 employees (and more safety groups) a safety committee has to be established including two supervisors elected by the supervisors of the safety groups, two safety representatives elected by the safety representatives of the safety groups and one person appointed from top management. The tasks of management, supervisors, employees, safety groups and safety committees are specified in general terms. The departmental orders under the act presents the aims to follow and a series of duties for all parties is enumerated.

From the beginning of the 1990s additional demands on the management process of working environment has been requested. In Norway and Sweden an "internal control system," i.e. a formalized system for managing working environment is demanded, whereas in Denmark a procedure for workplace assessment implying action plans is requested. In both cases the importance of a participatory approach is emphasized.

The intention of the legislators can be described as, first, to insist on the claim on employers to ensure safe and sound working conditions. Second, to legitimate that a room for a discourse on working environment between top-management, first-line managers and workers represented by safety representatives is set up in enterprises. Judged by the text of pamphlets the recommended approach was based on joint decision-making, but from a legal point of view consultations were demanded.

The majority of the legislators expected this to entail preventive actions in firms.

5. PRESENT STATUS

Many tools for participatory approaches to work place design have been developed and tested in the Scandinavian countries. There is no single textbook neither in one of the Scandinavian languages nor in English, but Haines and Wilson (1998) gives an overview of many of the tools also used in Scandinavia. Recommendations on tools and processes have been widely disseminated by public authorities, labor marked organizations, occupational health services and other agencies. Many stories and studies of success and how difficulties have been overcome have been spread for inspiration. Nevertheless professional in working environment generally find that the achievement of the enterprises do not fulfill the intentions of the act.

There are different interpretations of the problems of establishing effective participatory schemes. It is not perceived as a problem of having adequate tools but rather of the problem of integrating participatory processes into the existing decision-making structure of the enterprise and of qualifying the employees to participate in the process. The safety organization as a platform for a working environment discourse has generally been accepted. It is, however, often segregated form the central actors responsible of the operation and development of the enterprise and from the organizational units involved in the design of changes in productions processes (Jensen 1997).

Second, many cases prove that most of the important decisions are made before the plans are presented to workers and their representatives. The participatory arrangements primarily offers management a possibility to inform the employees' representatives of plans for action and maybe as a final possibility to get information on potential risks for malfunctioning. Seen from the employees' point of view they or their representatives mainly

have the role as a rubber stamp. If they are involved in change processes the representatives often regard themselves as taken hostage by the technical staff and management. When employees are involved in the early phases of a change project they often find it difficult to present their interests in accordance with the present level of conceptualization within the adequate conceptual frame.

6. ORGANIZATIONS AS POLITICAL SYSTEMS

It necessitates a more profound analysis to be developed to remedy this situation. Here the paradigm of organizations as political systems is considered a fruitful approach. This paradigm understands organizations as political systems, i.e. systems of actors and groups of actors, each of them more or less explicit trying to take care of their own more or less explicitly formulated interests. This implies that organizations are regarded as coalitions of stakeholders in different positions of power.

In such a system participation is not power equalization. First, because the different stakeholders have different possibilities to influence the design of and phases in the decision-making processes and the structure in the organization. Second, because the stakeholders have different mental model of the life in the organization. These mental models define the frame in which problems, causes, possible actions and legitimate strategies are identified.

7. IMPLICATIONS FOR ACTION

Persons involved in activities to improve the working environment by participatory approaches often suggest structural elements (like committees and task forces), processes and tools. But the analytical approach presented points to some central elements of the basic understanding of their activities.

First, it is a problem for workers to be formally involved in organizational change processes. It is important that they co-operate with strong stakeholders (among others top management and actors responsible of change programs and processes) in formulating participatory approaches not only as an espoused theory but as a theory in action. Second, it is difficult to keep up with management's initiatives to adapt to the new market conditions, rationalization initiatives and other initiatives entailing organizational and technological changes. Therefore, in implementing structural elements, procedures and tools for participation it is crucial to pay attention to the mental models of the stakeholders involved. This applies, of course, to the employees who should have a basic understanding of the general context of the change processes, the character of the planing processes, and how to make working environment an issue in the different phases of a planning process and how legitimately to present attitudes and make suggestions. But it concerns also the technical staff involved in conceptualizing and planning the changes. They often find it difficult to comprehend the relation between their projects and working conditions. Second, they should be capable of establishing a dialogue on equal terms with other stakeholders.

Owing to legal demands on mandatory courses for elected safety representatives and first-line managers the development of suitable mental models for employees has for years been an issue. Whereas strategies to increase the understanding of the technical design staff have in recent years been subject to research

and development processes with no final recommendations reached yet (Broberg 1997).

Third, it may be difficult for the appointed representatives to prove that they are representing the workers' interest. A combination of representative and direct participation might be a solution to this problem. Direct participation allows ideas for and views on problems, on their position in a causal web and on possible solutions to be presented. It offers a possibility for the representatives to insist on an indebt analysis of ideas and point of views and their implementation.

Fourth, studies of change processes based on participation show that firms may lose motivation if change processes implying a high degree of participation is entailed by normal operation implying a low degree of workers' participation. So participatory ergonomics should be comprehended as an issue both in the design of change processes and as well as in work design for normal operation, which the definition given by Haines and Wilson also reflects.

8. STATUS OF THE SCANDINAVIAN SITUATIONS

The Scandinavian countries have provided platforms for representative participation on a legal basis to legitimate participation and give some protection for the representatives. But the possibilities within the legal frame for this platform remain to be fully utilized.

Legal demands for internal control (i.e. demands for formal procedures for working environment) are presently under implementation in Norway and Sweden, as well as a demand for formalized workplace assessment procedures in Denmark. This may promote the development of participatory ergonomics. The first Danish studies give rise to some optimism (Jensen 1998), but more experience has to be gathered.

Also, the central organization of unions has as a central policy to promote what has been labeled "developmental work" that emphasizes the importance of qualifications and control in work in some of the new concepts for rationalization. Participatory ergonomics is incorporated in this approach.

Present experience show that to benefit from available possibilities an analytical approach stressing the political elements of the process and the importance of reaching compromises between interests seem to be a promising path and in this connection the development of the mental models play an important role not only for the weak parties (the workers) but for all parties involved.

In the Scandinavian countries (and according to Walters 1995 in the European Communities too) participatory ergonomics is a central element of the "espoused theory" on workplace design and change. But it is still not a warranted element of "theories in action" on workplace design and changes. Recommendations for tools and procedures are available in accessible forms, and agencies to promote participation such as occupational health services and the labor inspectorate do exist. It is, therefore, essential to make programs for participatory ergonomics and to analyze both successes and failures to improve our understanding of the conditions of this approach. So a continuation of the cooperation between firms, research agencies and working environment professionals including ergonomists is crucial.

Participatory Ergonomics at the Shop Floor Level

I. Kuorinka

Lieu dit Sénil, F-46160 Gréalou, France

1. PARTICIPATORY PROJECT VERSUS AN ORDINARY PROJECT

Participatory ergonomics at the shop floor level usually takes the form of a project, an ergonomic intervention, which is limited both in time and by its scope. It is, therefore, interesting to have a closer look at how participatory ergonomics projects differ from other projects in the workplace.

The specificity of a participatory project would be easy to outline if there were a typical industrial project, which is not the case. Handbooks of organizational practice usually describe a project as a chain of events that converge towards an endpoint. The links in the chain usually include elements such as entry, diagnosis, action planning, implementation and termination. Although many theorists and probably all consultants admit that in reality any project is full of unexpected events, the process is nevertheless theoretically supposed to move linearly from phase to phase in a coordinated manner.

A participatory project has specific characteristics (either planned or spontaneous) that are iterative and based on experience and learning. It is not specialist-centered but relies as much as possible on available local competence (both formal and experience-based). Even the goal of a participatory project may be loosely formulated at the start, and may change during the project. In fact, the main emphasis is on the process itself: a successful participatory project creates, to a large extent, both goals and methods as result of the process itself. The nature of a participatory project may look odd to someone trained to follow project management step-by-step. It must be emphasized, however, that the aim of a participatory project is the same as that of a traditional project: creating coherence in the design process, reducing uncertainty, and producing a worthwhile end result. It just does it differently. A participatory project is not a social gathering for fun.

A participatory project has subsidiary benefits that go beyond the goal of the project itself: it is largely a learning experience, as will be explained later. It is also an effective means of dealing with and controlling uncertainty in a rapidly changing production environment. This issue has been discussed (e.g. Shipley 1990).

It should be noted that participatory ergonomics projects are usually limited in scope. They usually deal with problems close to the everyday production tasks, involving individuals and small groups. If a participatory project becomes large, it will be closer to participatory management types of issues, which are beyond the scope here.

2. PARTICIPATION, PARTICIPANTS, AND HOW IT WORKS

Participation is not a well-defined issue; it even seems to defy any definition. We may, however, add some qualifications that help us to grasp the concept better. Participation in this context means direct participation, where those concerned try to solve the problems they encounter. Participation combined with ergonomics deals with practical everyday problems in the workplace, not major societal issues. It is down-to-earth problem-solving where learning is an important element.

Many other terms to describe participation in workplaces have been coined: empowerment has been used as a term to describe the employee's right to have more say about his/her own working conditions. Promoting creativity through group work has been explored, especially in white-collar environments.

In this context, participatory ergonomics (project) is defined as an ergonomic intervention that relies on the participation of those who have firsthand experience with the problem to be solved. This contrasts with formal, representative participation, as will be discussed later.

In most cases, participatory activity involves a group. Thus, the methods available and often employed are not necessarily much different from those used in any group activity. Groups whose activity involves some notion of participation have been called, for example, a "design decision group" (Wilson 1991), "quality circles" (e.g. Nagamachi 1991), "focus groups" (Caplan 1990), "participatory design groups," "problem-solving groups." Group techniques have been used in the context of "problem based learning," "value analysis," "quality management," "value analysis and engineering", etc. The list is endless. Depending on personal preferences and the nature of the participatory group, an ergonomist may choose whatever seems to be appropriate in the case in question. Participatory ergonomics has some characteristics, however, that require special attention. This is discussed in the chapter on "ethics."

Members of a participatory ergonomics group do not form a natural group, although they usually come from one production unit, department, etc. They must be selected by taking into account the needs of the intended project. Participant selection is not without problems: the aim is to recruit those and only those who have actual knowledge about the problem to be solved in the project. Formal representatives of management, labor and other social groups may not have the necessary firsthand experience about the problem at hand, which is the requirement of a participatory ergonomics project. It has in fact been shown that participation through representation is less efficient than direct representation (Cotton *et al.* 1988). However, the social actors have a legitimate right to be integrated in some way into the project. Bringing together experienced group members requires diplomatic negotiation. In some cases, separating the "decisional/representative" level and the "operational" level has been a solution, with the latter level reporting to the former.

A participatory ergonomics project may be run in very different ways. It is helpful to think of a project as a learning experience. The ergonomist-facilitator should understand at least the core issues in andragogy (adult learning, e.g. Knowles 1987). Observing modern methods of training at work which rely on (cognitive) psychological principles (e.g. Vartiainen 1987) is not only useful but necessary in designing a participatory ergonomics project.

Learning involves both the participatory process itself and the subject-matter related to the problem at hand. In fact, formal training at the beginning and during the project is desirable. If the group members have no experience with a participatory

process, significant time must be devoted in preparing the group to work together. The principles and general rules to be followed during sessions must be explained. Concepts like consensus, right of veto, dealing with divergent views, responsibilities, etc., must be made clear.

Issues related to the problem's subject-matter must also be taught. At the beginning, it seems useful to present a general picture of the problem. A knowledgeable person, preferably from the company itself, should explain the context of the problem. A description of the technological, organizational and social issues as well as experiences from other companies will help group members understand the problem in a larger context.

The participatory process also aims to elicit knowledge in order to uncover hidden, tacit knowledge. The participatory group is the core actor in seeking such information but should have help from external specialists and the ergonomist himself. Methods such as auto-confrontation are available for discovering important tacit information.

How should a participatory project be run? There is no commonly accepted standard procedure; there is a lot of variation. An approach that is successful in a small company may be inappropriate in a large company with a formal organization. Different professional groups require different approaches. Sen (1987) has presented approaches to be used in a technical professional environment. Wilson (1991) presents practical approaches for designing workplaces.

Some elements are specific to a participatory project, however. It is down-to-earth and deals with everyday problems. The process aims at stimulating participants and their reference groups as well as other organizational groups directly linked to the project. Before the project can even start, there must be a commitment from management and labor as well as from those directly involved. Information and communication are an important part of the project. The aim is to widen the basis of participation and spread knowledge among those not directly concerned by the project.

3. PARTICIPATORY ERGONOMICS, CONCEPT AND DEFINITIONS

The concept of participatory ergonomics is fairly recent. Noro and Kogi (1985) proposed the notion, which in fact seems to have been anchored in the Japanese experience in small group activities and "suggestion" schemes. Several ILO projects under the direction of Kazutaka Kogi have developed the notion further. The 1985 IEA congress in Bournemouth, UK, brought together other persons interested in the theme. The same ideas were undoubtedly discussed and tested well before 1985 but the concept and name of "participatory ergonomics" seem to have been established by that time.

Participation has been promoted as an important element in industrial democracy. We can trace some elements of workplace participation back to the debate on "industrial democracy" (e.g. ILO 1981) and other sociologically colored issues which were largely debated in the 1960s and 1970s. Questions like participation systems, labor unions and their representative role, participation in decision-making, participation in the company's capital, etc., were some of the issues.

Some institutions seem to have had more influence on the debate on participation than others (e.g. the Tavistock Institute in UK).

Also, trends in industrial organization have advanced some forms of participation. Quality management programs and concurrent engineering (Zhang and Zhang 1995) are among these trends (Daniellou and Garrigou 1992).

As explained earlier, progressive trends in society have created interest in participatory approaches. The field has, however, proven to be complex and contradictory. In many cases, participation has been ostensibly promoted, but has in practice met tough resistance from those who fear loss of power and control over individuals.

Participation as a basic principle for organizing work is not unknown but is probably not too extensively practiced, either. In some cultures, collective planning and problem-solving have been natural ways of organizing work. In others, social conflict has been seen as prime mover for solving problems. Some industrial cultures underline a leader's role. Participatory ergonomics proposes participation as a natural way of organizing work while focusing on common goals.

Participatory ergonomics has not been defined authoritatively and may defy any attempt to do so in the future. Cultural differences between countries and organizations are such that even a modest level of employee participation, which under other conditions may look trivial, may be seen as counterproductive and unacceptable.

Martin and Baradat (1998) have analyzed in interesting way the paradoxes of a participatory project.

4. THE ROLE OF AN ERGONOMIST IN A PARTICIPATORY PROJECT

In any project, an ergonomist may serve as a project leader, a specialized resource person or a consultant. If the project is organized in a participatory framework, an additional role is necessary: the ergonomist must become a facilitator. A facilitator's task is to help control the participatory process itself.

Any person, regardless of his profession, may serve as a facilitator if he has the necessary skills to work with a group and has sufficient knowledge about the problem's subject-matter. A well-trained ergonomist has the advantage of being able to deal with work-related matters across professional boundaries. It is thus possible to take into account and balance the organizational, physiological and psychological, working-condition-related, subjective and objective issues in a participatory project.

The requirements of an ergonomist/facilitator are not trivial, as can be deduced from the list above. The task is demanding and requires both theoretical knowledge (about participation itself and the problem's subject-matter) and practical experience dealing with workplace problems.

5. ETHICAL ISSUES OF PARTICIPATION

Participation in the workplace is a complex process where each participant is supposed to contribute constructively to solving the problem in question. It contrasts with the process where participants come together only to defend their interests. In practice, these two modes often exist simultaneously, although constructive contribution dominates the participatory process as defined above. It means that a participatory process is safe from

manipulation and organizational intrigues. It would be helpful to understand participation as an intellectual exchange: the participants bring something valuable and original to the negotiating table but assume that they will receive something equivalent in exchange.

A participatory process can in some cases be a profound subjective experience. Thus all attempts to manipulate, exploit or otherwise take advantage of the situation may provoke a violent reaction among the participants. As a result, the participatory process stops and may be difficult to revive. In one case known to the author, a serious labor dispute was the consequence of such a situation.

Respect for ethical principles is a precondition for a successful participatory process. Some of the conditions are:

- The goals of a participatory project must be transparent and honest. Differences in opinion must be dealt with openly.
- Rules on how to deal with disagreements must be established and agreed to.
- The formal position of the participatory project in relation to other organizational functions, collective agreement, etc., must be defined and agreed to.
- The "ownership" of the results must be defined at the start.
- Rules for dealing with possible unexpected results must be defined.

Prevention and Compensation of Shiftwork Effects

G. Costa

Department of Public Health, University of Verona, I-37134 Verona, Italy

1. INTRODUCTION

Shiftwork, in particular that including nightwork, is a well-known risk factor for health and well-being, as it interferes with biological rhythms and social relations, with consequent negative influence on work performance, family and social life, and health (see the chapter on "Shiftwork Health Consequences").

To prevent such negative consequences it is important to adopt some preventive and protective measures aimed, on one hand, at creating more favorable working conditions and, on the other hand, at preserving workers' health.

Many kinds of interventions aimed at compensating for shift and nightwork inconveniences have been introduced in recent years, in most cases very empirically according to different work conditions and specific problems arising in different companies, work sectors and countries.

According to Thierry's model, such interventions can be defined in two different ways in relation to the domain they deal with:

1. The "counter-weights," that is, the interventions adopted to compensate only the inconveniences. Monetary compensation is the main counter-weight worldwide adopted as basic reward for shift- and nightwork. It is a simple translation of the multidimensional aspects of the problem into money, and its value may vary according to different factors, some of which may not be strictly connected to the severity of the inconveniences (e.g. Unions' power, economic conditions, productive needs). Other counter-weights may be represented by measures aimed at improving other aspects of the work organization, such as work environment and/or job enlargement/enrichment, and fringe benefits.

2. The "counter-values," that is the interventions adopted to reduce or eliminate the inconveniences by dealing with the themes in which the complaints occur; they can be directed:

   - towards the causes of inconveniences, such as: reduction of the amount of night- or shiftwork, planning more ergonomic shift schedules; transfer from nightwork to daywork; reduced work load at night;
   - towards the consequences of inconveniences, such as: canteen and sleep facilities, coping strategies, medical control and re-habilitation, early retirement, extra days off, longer holidays, more breaks at work, better social services (transportations, housing, children care); and
   - towards the psychological meaning of the problems, such as: education, physical and psychological training and social support.

2. ORGANIZATIONAL INTERVENTIONS

Particular attention has to be given to the organization of the shift schedules, taking into account not only economic reasons, but giving priority also to the workers' needs, in particular as concerns the human physiology, the psychological and social problems, and the possible negative health consequences.

The main guidelines for designing shift systems according to ergonomic criteria are:

- Quickly rotating shift systems are better than slowly rotating ones, since they interfere less with circadian rhythms and minimize the extent of any cumulative sleep deficit.
- Clockwise rotation (morning–afternoon–night) is preferable to the counterclockwise (afternoon–morning–night), since it parallels the endogenous circadian rhythms, which show a periodicity slightly longer than 24 h in "free-running" experiments; it also avoids quick changeovers (e.g. morning and nightshift on the same day) and allows longer rest periods for the immediate recovery from fatigue and sleep deficit.
- Early starts of the morning shift should be avoided to reduce the truncation of the sleep (REM phase in particular) and the consequent fatigue and sleepiness.
- Prolonged work shifts (9–12 h) should only be considered when the workload is suitable, there are adequate pauses, and the shift system is designed to minimize the accumulation of fatigue and the exposure to toxic substances.
- Shift systems should be as regular as possible and able to guarantee as many free weekends as possible, to allow people to plan and enjoy their leisure time more conveniently.
- Permanent nightwork can be acceptable only for particular working situations that require a complete adjustment to nightwork to guarantee the highest levels of safety.
- Rest days should come preferably after the night duty period to consent a prompt recovery from the sleep deficit and an easier return to the normal sleep–wake cycle.
- Some flexibility in working times is desirable to give the workers the possibility to combine better work duties with family and social life.
- Supplement crews should be provided to reduce the amount of nightwork of the individual worker.

However, it is worth stressing that there is no "best" shift system to be recommended in general, but each shift schedule should be planned and adapted according to the different job demands, and the specific characteristics, social habits and cultural background of the workers involved. This implies a careful strategy for the arrangement of the shift schedules, which requires the workers' participation in the analysis, design, implementation and assessing of the shift rota chosen. This is of paramount importance, not only for taking into account the suggestions of those who have direct experience of the problem, but also for promoting the right motivation for accepting the changes and, consequently, improving the psychophysical tolerance.

3. COUNSELING

It is very important for shiftworkers to be aware of the possible negative consequences and to receive useful suggestions and guidelines on how to cope best with shift and nightwork.

Therefore, counseling and training has to be done both at individual level and among groups of shiftworkers through educational programs. These should deal with improving self-care strategies for coping, in particular with sleep, diet, stress

management, physical fitness, off-job activities and exposure to bright light.

Basic information should be given on body rhythms and the necessity to maintain as much as possible their normal pattern.

Good sleep strategies and relaxation techniques should be adopted to minimize de-synchronosis and fatigue. Shiftworkers should try to keep tight sleeping schedules and avoid disturbances (e.g. by arranging silent and dark bedrooms, using earplugs, making arrangements with family members and neighbors). The timing of diurnal sleep after a night duty should be scheduled taking into consideration that sleep onset latency and length are strongly influenced by the phase of the temperature rhythm, so that sleep starting in the early morning, during the rising phase of the temperature rhythm, shows longer latency and shorter duration than that starting in the early afternoon.

In addition, a proper use of naps can be very effective in compensating sleep loss and enhance alertness. Useful naps can be taken before nightshift or extended duty periods, during night-work to alleviate fatigue and sleepiness, or after early morning and nightshifts to integrate normal sleep. A proper combination of nap and sleep times makes it possible to avoid the abuse of hypnotics, which can have a negative effect on the process of re-synchronization and cause a transient impairment on vigilance and performance.

People should also try to maintain stable meal times, which can act as co-synchronizers of body functions and social activities.

A proper timing and composition of meals can help the adaptation. During nightwork in particular, assuming that meals with high carbohydrates content facilitate sleep by stimulating serotonin synthesis, whereas meals at high proteins content favor wakefulness and work activity by stimulating catecholamine secretion, it would be preferable that shiftworkers have a pro-tein meal in the early part of the nightshift and then take light snacks with carbohydrates and soft drinks. They should also try to minimize the intake of stimulating substances (coffee, tea, cola drinks) for fighting drowsiness, as they may disrupt the subsequent sleep pattern and have negative effects on the digestive system. To favor a good digestion it is convenient to take a sufficiently long break and have a hot meal by arranging proper canteen facilities.

Keeping physically fit has been proved to be helpful in improving shiftwork tolerance by positive effects on synchroni-zation of circadian rhythms, performance efficiency and restora-tive properties of sleep, thus reducing fatigue and health problems. This can be achieved both by favoring individual regular exercise and sport activity, and by promoting positive fitness programs at work, both as prevention and rehabilitation. Also relaxation tech-niques (e.g. massage, yoga, autogenous training) are becoming more and more popular among people who feel under stress and who need help to control restlessness, anxiety, muscular tension, insomnia and other symptoms of stress.

On the other hand, people should avoid ineffective ways of coping (i.e. smoking, alcohol, drug consumption), which can have an apparent short-term positive effect, but in the long run can add further problems for health and well-being.

The consumption of drugs (e.g. stimulants, tranquilizers, anti-depressants), in particular, can have a positive effect only if they are used (under medical supervision and paying attention to their negative effects on vigilance and performance!) as auxiliary and temporary support for the organization of effective strategies aimed at removing the causes of stress.

A proper exposure to bright light, both through outdoor physical activities and increasing indoor artificial lighting (> 1000 Lux), has certainly a beneficial effect on psychophysical condi-tions. Bright light suppresses the secretion of melatonin by the pineal gland, which plays an important role in the entrainment of the circadian system. Therefore, when necessary, a proper tim-ing of light exposure can influence the direction and the magni-tude of the entrainment of circadian rhythms (e.g. light exposure in the morning causes a phase advance, whereas light exposure in the evening causes a phase delay). Moreover, bright light has a direct stimulating effect on mental activity and has been proved to reduce the symptoms of seasonal affective disorders: and some of the negative effects of nightwork can be likened to a mild form of endogenous depression.

It is also desirable to take into consideration and try to com-bine some psychophysiological characteristics and working con-ditions that may be expected to favor adaptation and tolerance to shiftwork. For example, "morning" types and aged people cope better with morning shifts and worse with nightshifts; on the contrary, "evening" types have fewer problems on nightshift, but more difficulties in the early morning shifts.

4. MEDICAL SURVEILLANCE

Workers' fitness for shift- and nightwork should be evaluated by occupational health physicians before their assignment, at regular intervals, and in case of health problems.

It appears reasonable to consider exemption from nightwork for people suffering from severe disorders that can be either directly related to shift- and nightwork, or can be worsened by irregular working hours because of their interference with sleep, diet or drug treatment, Such conditions are: clinical sleep disor-ders (i.e. insomnia, sleep apnoea, narcolepsy); severe gastroin-testinal diseases (i.e. chronic gastritis, peptic ulcer, chronic active hepatitis, cirrhosis, chronic pancreatitis); ischemic heart disease, hyperkinetic syndromes and severe hypertension; insulin-dependent diabetes; severe thyroid and suprarenal pathologies; severe nervous disorders (i.e. brain injuries with sequelae, epilepsy requiring medication, chronic anxiety and/or depression); chronic renal impairment; malignant tumors; women in pregnancy.

Moreover, particular attention should also be paid to particular workers for which shift and nightwork may represent a possible risk factor under certain circumstances, in particular those exposed to toxic substances; aged people; women with menstrual disorders or small children; people suffering from mild digestive disorders, asthma and chronic obstructive bronchitis, or afflicted by marked hemeralopia or visual impairment; persons taking drugs affecting the central nervous system (e.g. benzo-diazepines, high intake of alcoholics); people with unsatisfactory housing conditions and with long commuting times; persons with high levels of neuroticism or prone to internal de-synchronization of circadian rhythms.

Many of these conditions may represent, in principle, abso-lute or relative contra-indications to night- and shiftwork, thus requiring a temporary or permanent assignment or transfer to daywork. However, it can not be directly assumed that the sole removal of such risk factor can be certainly or totally beneficial to the worker's health. In fact, it has to be considered that most

of the complaints of shiftworkers pertain to the psychosomatic domain and recognize a multifactorial origin, related to family heritage, life styles, social conditions, other occupational risks and intervening illnesses. Consequently, maladaptation and intolerance to shift and nightwork are the result of complex interactions among the above cited risk factors, and can manifest differently in each shiftworker during his/her working life both in terms of severity and time of manifestation.

Moreover, advances in clinical diagnosis, pharmacology and rehabilitation now offer better possibilities for treatment of some diseases (e.g. peptic ulcer, hypertension, myocardial infarction) and, therefore, may consent the permanence on shiftwork of some workers, for whom the transfer to daywork can be problematic, due to either other risk factors or personal resistance to change job.

The complexity of the problem requires a careful attention to the occupational health physicians to avoid a risky attitude towards an a-critical selection of many workers, thus reducing their possibility to find a job (that could be more dangerous for their health and well-being!). It is also to be taken into account that sometimes shiftworkers do not report completely their health troubles, as considered "part of the job," or even mask them because they are more afraid of losing the economic benefits connected to shift- and nightwork.

Periodical checks should be scheduled for detecting early signs of difficulty in adjustment or intolerance to shift and nightwork (e.g. sleep troubles, digestive problems, psychosomatic complaints, accidents, perturbed menstrual cycle, drug consumption), which may require prompt interventions both at the organizational and individual level. Standardized questionnaires, checklists, diaries of the daily activities and recordings of some physiological parameters (e.g. body temperature, cortisol, melatonin, performance) can be helpfully used in evaluating the level of adaptation of the persons. In case of exposure to toxic substances, the biological monitoring should also take into account both timing of exposure and time-qualified reference values.

The periodicity of the health checks should not to be set *a priori*, but in relation to several factors concerning both working conditions (e.g. shifts rotas, combined risk factors) and individual characteristics (e.g. age, health). As a general guideline it appears advisable to plan a second health check not later than 1 year after starting nightwork (as the first year is crucial for adaptation and coping), and successive health checks every 3–5 years for those < 45 years of age, and every 2–3 years for those > 45 years of age.

Principles and Strategies for Team Training

E. Salas, J. A. Cannon-Bowers and K. A. Smith-Jentsch

Department of the Navy, Naval Air Warfare Center Training Systems Division, 12350 Research Parkway, Orlando, FL 32826-3275, USA

1. INTRODUCTION

Teams have become a way of life in organizations. In fact, a recent survey conducted on US industries reported that 82% of businesses with 100 or more employees used teams in one way or another to accomplish their objectives. Teams are more popular than ever and organizations are investing considerable resources in strengthening the communication and coordination mechanisms of their employees. Furthermore, many organizations are now designed around teams so that their very survival depends on effective teamwork.

This interest in teams by organizations has led to an explosion of team training research and practice. The aim of this research has been to address the question: what turns a team of experts into an expert team? That is, what developmental activities can enhance effective team functioning among highly interdependent members that have distributed expertise? To report the state-of-the-art in team training, what has been learned in answering this question will be outlined. Specifically, team training principles and strategies that have been generated in recent years will be focussed on.

To begin the discussion, a team is defined as "a distinguishable set of two or more people who interact, dynamically, interdependently, and adaptively toward a common and valued goal/objective/mission, who have been assigned specific roles or functions to perform, and who have a limited life-span of membership" (Salas *et al*. 1992: 4). There are key concepts in this definition that bound the generalizability of this discussion. The focus is particularly on teams that have distributed expertise, have high task interdependency and are organized hierarchically (i.e. there is a leader). Examples of this type of team include military command-and-control teams, medical emergency teams, some police and fire-fighting teams, cockpit crews, some sports teams and some management teams.

2. WHAT IS TEAM TRAINING?

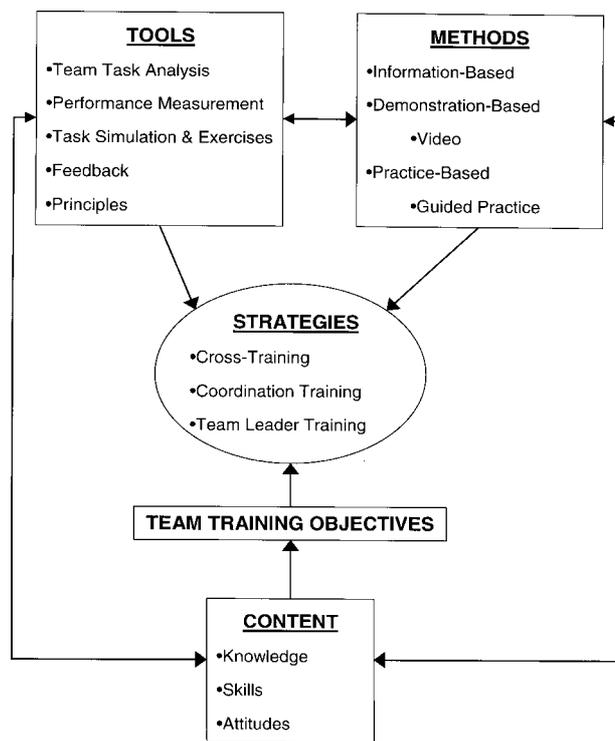
Team training is a set of tools, methods and content that together create an instructional strategy that focuses on enhancing teamwork. Figure 1 outlines the basic elements of team training. As seen, team training is not a program or a place, as it has been popularly characterized. Team training interventions are theoretically based, built around sound instructional principles, based on carefully crafted and designed instructional strategies and focused on promoting the ease of coordination, communication and synchronization among team members. Team training is more than just team building (i.e. where team members learn about each other) and individual training (i.e. where team members learn about their task). Team training is about designing and developing instructional strategies — through tools, methods, team objectives, and competencies — for influencing team processes.


Figure 1. Structure of team training (from Salas and Cannon-Bowers 1997).

2.1. Tools

There useful tools available for designing effective team training strategies. For example, research has shown that an analysis of the coordination demands required for successful task performance can serve to focus the nature of practice and feedback. This coordination analysis requires that subject matter experts (SME) specify the criticality, frequency and difficulty of performing certain team-related tasks. This is usually done via surveys or questionnaires. Team task analysis is also an available procedure. Although much work remains here to demonstrate its utility, this tool allows the uncovering of the knowledge, skills and attitudes (KSA) necessary for effective teamwork given specific task requirements.

Performance measurement is the key to learning. Performance measurement tools embedded into training allow for learning to occur. Measurement tools for teams must consider a number of principles, which are readily adaptable/applicable to any team training environment. First, it is essential that any system of performance measurement have a strong theoretical foundation on which to draw. There are many frameworks now available that can help guide the development process (Brannick *et al*. 1997). Second, a clear purpose for designing such a measurement system must be established up-front. This can be accomplished by first performing team/cognitive task analyses to tease out the criterion (i.e. KSA) upon which the system should be based. Next, opportunities for measurement during the training must be specified. This approach allows for specific and controlled learning opportunities and a manageable context to measure complex team performance. Any measurement system should also be aimed at not only determining "what" transpired but also should explain "why" it happened to facilitate learning. Therefore, process measures (i.e. to capture moment-to-moment actions and

behaviors) must be designed and used. Usually, these measures take the form of observation protocols or scales.

Additionally, team performance measurement systems should be capable of supporting the diagnosis of performance deficiencies so as to provide relevant re-mediation to team members. Another principle that should underlie the development of a team performance measurement tool is that it must not be cumbersome to use. Users should be able rapidly to collect, evaluate and synthesize performance data so that immediate feedback can be provided to trainees. This can be realized by automating the system and by preparing instruction for the assessors.

A key element to the success or failure of any performance measurement system lies with the involvement of the user. Involving SME, of course, in the development process will help to ensure the end product is accepted, useful and effective. Finally, the tools and training necessary for instructors consistently to use the performance measurement system should be provided by way of instructor training packages as well as supporting materials (i.e. guide sheets, definitions, scenario events). Adherence to these principles will ensure that a strong team performance measurement tool to support team training is developed.

Other tools to support team training include feedback and learning principles, which are used to guide and focus the design process. These are available in the literature from not only the human factors perspective but also the education and cognitive disciplines. Finally, task simulation and exercises are also tools for team training. These provide the environment or context that allows team members to practice the requisite KSA.

2.2. Methods

Many methods are available to deliver instruction. These apply to both individual as well as team training. There are information-based methods such as lectures, handbooks, slide-presentations and the like. These are widely used and effective when combined with other methods. There are also demonstration-based methods. These are more dynamic and stimulating. These methods include video demonstrations of effective and ineffective teamwork behaviors as well as multimedia systems that illustrate key principles and performance requirements in teams. Finally, there are practice-based methods. These are more sophisticated, costly and interactive. These methods include simple-to-advanced exercises such as role-play exercises to high fidelity simulation environments (i.e. simulators) for teams to practice. These systems are visually rich and very interactive and engaging to the trainees. Moreover, it is known that simulators are effective training devices when appropriate instructional tools and features (e.g. performance measurement) are embedded in them (Salas *et al.* 1998).

2.2.1. Principles for enhancing the design of team training

Principles exist that can be used to guide the design and delivery of team training. Some representative examples are provided (Cannon-Bowers and Salas 1998, Salas and Cannon-Bowers 1997. For example, team training must foster the development of team skills such as team leadership, adaptability and compensatory behavior; link cue patterns to response strategies not only with regards to the task but also with other team members as well;

provide team members with guided practice under realistic conditions; provide team members with motivational guidance and outline factors that hinder their motivation; make team members aware of the importance of effective communication; develop simulations that allow team members to experience different courses of action; facilitate team members ability to learn about each others' roles and build realistic expectations about tasks requirements; diagnose team members teamwork deficiencies with a combination of process measures and outcome measures; provide the necessary information to team members about effective teamwork, demonstrate those behaviors and actions and allow for the practice with feedback on the requisite KSA; and exercise team members with a variety of novel situations to build adaptive mechanisms.

2.3. Team Competencies

Team competencies are the heart of team training. The task context provides the required KSA needed successfully to complete a team's tasks. KSA in teams are quite different from those found for individuals.

Team competencies describe what team members need to know (i.e. knowledge), how they need to behave (i.e. skills) and what task related attitudes (i.e. attitudes) they need to hold. Using the tools described earlier (i.e. team task analysis) team KSA must be derived as a precursor to developing team training. In fact, the KSA established for a team should provide the training objectives to be targeted in developing instruction.

Recently, researchers have focused attention on developing taxonomies of KSA for different types of teams. In general, this work has highlighted the fact that team cognition — that is, the knowledge component has been overlooked in past research. In addition, results indicate that some teamwork skills are consistent across tasks, while others may be more generic. Likewise some team competencies may be specific to the particular team at hand, while others may hold regardless of team membership (for more detail about KSA, see Cannon-Bowers *et al.* 1995, Cannon-Bowers and Salas 1999).

2.4. Examples of Team Strategies

As stated, the methods, tools and content (with the appropriate team training objectives) create a team training strategy. These take many forms and shapes depending on needs, resources and objectives of the training. Most team training strategies these days combine information, demonstration and practice-based methods.

2.4.1. Team coordination training

Team coordination training is probably the most widely used in organizations. This strategy has been used to train teams in a variety of settings including aviation, medical and military teams, to name just a few. This strategy is also referred to as crew resource management or aircrew coordination training. While the course content differs for each of these settings, there are certain commonalities inherent in all of these training programs. To begin with, this strategy concentrates on teaching team members the general components of teamwork in an effort to encourage it. Next, most of these programs use the general team performance or group dynamics literature as a framework. In addition, the

training is usually delivered through a combination of information, demonstration (e.g. video examples) and practice-based (e.g. role-plays) methods over 2–5 days.

2.4.2. Cross-training

Cross training is a strategy in which team members are exposed to the basic tasks, duties and responsibilities of the positions held by other members of the team. The intent of this strategy is to alleviate the decline in performance following personnel changes as well as to increase implicit coordination (that is, being able to coordinate without the need explicitly to communicate). This is accomplished by the subsequent increase in the interpositional knowledge held by each team member following training (i.e. a strengthening of the teams shared mental models). The training is composed of cross-role information sharing (team-mates, task, equipment, situation), enhanced understanding of interdependencies, roles and responsibilities, and cross-role practice and feedback. The training is usually delivered via lecture, multimedia systems and/or role-plays. Research has shown that cross training can be an effective means of enhancing team performance. Among other things, cross-trained teams are better able to anticipate the information needs of their team-mates, commit fewer errors and display better team process quality (for a review of this and other team training strategies, see Cannon-Bowers and Salas 1998).

2.4.3. Team self-correction

Team self correction, as defined by Blickensderfer *et al.* (1997), is a naturally occurring tendency for effective teams, following a performance episode, to review events, correct errors, discuss strategies and plan for the future (e.g. debrief themselves). This team training strategy attempts to capture this tendency and train other teams how to engage in this process. The end result is a team able to correct their knowledge-, skill- and attitude-based deficiencies without the aid of a formal instructor. This training is delivered through a combination of lecture, demonstration, practice and feedback. The target of training is the team leader (if there is one) and team members. Specifically, team members are taught how to observe their performance, how to categorize their effective and ineffective behavior into a structured format, and how to use this information to each other feedback (Cannon-Bowers and Salas 1998). When an instructor is present, he/she is taught how to probe the team members to come up with examples of effective and ineffective performance. This method of guided team self-correction has been demonstrated to improve team performance.

2.4.4. Event Based Approach to Training (EBAT)

EBAT is a general approach to the design of simulation-based exercises where training opportunities are systematically identified and introduced as "trigger" events in a training exercise. The purpose of doing this is to provide opportunities for students to exhibit specific team behaviors that are based on the team training objectives established through team task analysis. These behaviors are in turn captured, rated and than used later for debriefing and feedback. This strategy has been successfully used in multiservice distributed military training environments as well as in aviation settings.

2.4.5. Assertiveness Training

In complex team environments it is important that teams make use of all available information and resources. This means that the unique knowledge, skills, ideas, opinions and observations of each team member must be exploited to arrive at the optimal decision. In fact, it is often the willingness of team members to voice concerns assertively that can help to avoid potentially life-threatening decisions (e.g. in law enforcement teams or aircrews). Hence, efforts have been directed toward training team members to display effective task-related assertiveness. For example, team members may need to act assertively when providing feedback to other members, when stating opinions, when stating potential solutions or when offering or providing assistance. Training to improve assertiveness should involve practice and feedback to ensure that assertiveness skills will be demonstrated (Smith-Jentsch *et al.* 1996).

Psychosocial and Work Organization Risk Factors for Work-Related Musculoskeletal Disorders

N. Warren

Division of Occupational and Environmental Medicine, Ergonomic Technology Center, University of Connecticut Health Center, MC 6210, Farmington, CT 06030-6210, USA

1. INTRODUCTION

Ergonomic research has made significant progress in identification of biomechanical (physical) risk factors for work-related musculoskeletal disorders (WRMSDs) and in development of intervention strategies to reduce these exposures. This research may have contributed to the observed reduction in WRMSD rates in the second half of the 1990s. However, despite broad agreement on biomechanical risk factors and control strategies, the reduction has been disappointingly small. This suggests the presence of other causal factors not susceptible to intervention techniques focused solely on biomechanical risks. Particularly over the past decade, the ergonomics research community has thus devoted increasing attention to psychosocial risk factors associated with the organization of work. This article addresses these factors. It has four aims:

- Clarify the confusing terminology that has evolved in this field.
- Present the current state of knowledge concerning the contribution of psychosocial, work organization, and higher-level organizational risk factors to WRMSD etiology.
- Explore possible mechanisms for these contributions
- Summarize research directions necessary to expand knowledge in this field.

2. DEFINITIONS
2.1. Psychosocial Stressors

The definition of "psychosocial stressors" varies widely, depending on the researcher and the particular intellectual discipline. Several disciplines use the term to include personal characteristics of the worker — demographic (social class, culture, age), genetic (gender, intelligence), and psychological (personality, attitudes). Although these factors are important contributors to how the individual experiences and reacts to the work environment, this article views psychosocial stressors as nonphysical aspects of the work environment that have a psychological and physiological impact on the worker. Since the psychosocial work environment is usually assessed through self-report of the worker, these psychosocial stressors are thus measures of worker experience — integrated assessments of a wide and subtle range of work environment (and nonwork) characteristics, filtered through the respondent's response templates. Thus, psychosocial risk factors represent the intersection of the psychology of the individual with the sociological characteristics of the organization. It can be forcefully argued that it is this integrated percep-

tion of psychosocial stressor levels that is most closely related to stress and health outcomes.

The physical or biomechanical stressors associated with WRMSD are well defined elsewhere in this encyclopedia. Note, however, that the separation between psychosocial stressors and biomechanical stressors is to some extent artificial; often they are two sides of the same coin. For instance, rapid, machine-paced work is generally associated with constrained job autonomy (a psychosocial stressor) as well as with higher levels of biomechanical stressors (e.g., repetition and force). It is this close link between many psychosocial and biomechanical stressors that makes it difficult to estimate their separate associations with health outcomes.

2.2. Work Organization Stressors

Work organization refers to the way production and the work process is designed — characteristics of the work environment that give rise to the employee's perceptions of psychosocial stressor levels. These characteristics are the visible expression of the company characteristics listed below as well as the company's economic, cultural, and political environment.

2.3. Organizational Stressors

Organizational stressors are aspects of the organization's demographics, structure, technology, and culture that create and/or exacerbate levels of risk experienced by employees. The intersection of the organizational development literature with occupational health intervention literature has focused attention on the crucial role played by organizational culture in the creation or prevention of disease. A complete assessment of factors contributing to WRMSD etiology should also include macro factors that affect the company, its work organization, and the worker — cultural factors, economic pressures, regulatory pressures, etc. These factors are not addressed here.

2.4. Ergonomics

To fully incorporate psychosocial stressors into a full-spectrum definition of risk, it is useful to broaden the meaning of the term "ergonomics" itself. In too much of the literature, ergonomics is treated as the science of identifying and reducing biomechanical risk factors for WRMSD alone. But the Greek root of "ergonomics" is "the natural laws of work." For most practitioners, ergonomics translates into "fitting the work to the worker." Ergonomic practice addresses a complicated mixture of (1) biomechanical risk factors, (2) psychosocial/work organization risk factors, and (3) organization-level risk factors that affect levels of these stressors and the potential success or failure of interventions. Although the term "ergonomic" risk factor is often used synonymously with "biomechanical" risk factor in the literature, this article terms all three types of risk factor "ergonomic risk factors" and suggests that researchers more precisely define the type of ergonomic risk factor they are addressing

3. TYPES OF STRESSORS
3.1. Psychosocial Stressors

What are the psychosocial factors that research suggests are related to stress and health outcomes? The many models of job-related stress identify somewhat different sets of psychosocial stressors. But there seems to be rather broad agreement on their general

nature. A basic reference for the interested reader is the book *Healthy Work* (Karasek and Theorell 1990), which presents a detailed background for the widely used demand-control model (Karasek *et al.* 1985) as well as the expanded demand control–social support model for job stress (e.g., Johnson and Hall 1988). These models relate stress and health outcomes to the interaction between psychological job demands, the amount of decision latitude (conceptualized as a combination of autonomy and ability to learn and use skills) available to the worker, and the amount and quality of workplace social support. The extensive social support literature identifies many axes of this concept; much recent occupational health research has focused on the relative importance of coworker and supervisor support and has distinguished between so-called instrumental support (provision of information, help in completing work, etc.) and emotional support.

Johannes Siegrist (1996) more recently has proposed an effort-reward model, linking job stress to an imbalance between effort expended and rewards received in work. Finally, many researchers would add perceived job security to this brief overview of psychosocial stressors. The reference list demonstrates that each of the broad psychosocial stressor concepts listed here can be further broken down into many components.

3.2. Work Organization Stressors

There are many characteristics of the work organization that are associated with these psychosocial stressors. Kasl (1992), summarizing concepts from a wide range of research, presents a broad taxonomy of work environment factors that affect levels of psychosocial stressors:

- *Physical aspects of work*: environmental factors, biomechanical demands, etc.
- *Temporal aspects of job design*: hours, shift work, work-rest schedules, pace, etc.
- *Job content*: variety, repetitiveness, skill use, mental workload, participation in decision making, clarity of demands, etc.
- *Interpersonal relations*: group cohesion, support from co-workers and supervisors, availability of feedback, etc.
- *Organizational aspects*: structure of the organization, bureaucratic characteristics, etc.
- *Financial and economic aspects*: pay structure, benefits, etc.
- *Community and societal aspects*: status, prestige of job, etc.

Note that the job content and interpersonal relations aspects contain the same labels as some of the psychosocial stressors noted above. In this list they are included as externally measurable characteristics of the work organization. Organization-level risk factors will be explored below.

4. PSYCHOSOCIAL AND WORK ORGANIZATION FACTORS ASSOCIATED WITH DISEASE

The most extensive research connecting psychosocial stressors with disease has been in the area of heart disease. Prospective epidemiological studies, many with very large databases, have demonstrated that the combined effect of high psychological job demands with low decision latitude is predictive of increased blood pressure and cardiovascular morbidity and mortality. Reduced levels of social support increase these predictive asso-

ciations. This literature has motivated investigators to extend the model to WRMSD etiology.

5. PSYCHOSOCIAL AND WORK ORGANIZATION FACTORS ASSOCIATED WITH WRMSD

Although researchers have made great strides in detailing associations between risk factor exposure and the development of WRMSD, the natural history of these disorders is still imperfectly understood. There is controversy over whether the increase (until recently) in WRMSD is attributable to an actual increase in underlying risks, better recognition and reporting, changes in workers' compensation structure, and/or other variables such as cultural and social factors. It seems reasonable to hypothesize that at least some of the increase is related to risk increases, with risk being defined more broadly than biomechanical stressors alone. In its documents on national strategies for prevention of WRMSD, NIOSH has explicitly included the assessment of psychosocial risk and the multilevel examination of organizational characteristics. The same changes in production that have led to increased biomechanical stressors have also driven an increase in psychosocial and work organization stressors, among them increased competition, downsizing and mergers, increased division of labor, and technological changes in tools and processes. This article can only sample the many studies of psychosocial stressors for WRMSD that have appeared over the last decade. For more detailed treatments, refer to Kourinka and Forcier (1995), Bernard (1997), Moon and Sauter (1996). Bongers *et al.* (1993) have also prepared a review of the epidemiological literature. This looks at 29 studies which directly addressed work characteristics and it suggests that monotonous work, high perceived workload, time pressure, low control, and lack of social support are related to musculoskeletal outcomes. Several European projects have found task flexibility and peer contacts to be associated with a number of upper extremity diagnoses.

A 10-year prospective study in Finland demonstrated that social support and work content measures (monotony, autonomy, skill use, etc.) predict changes in upper extremity, lower back, and lower limb disorders. Analyses of the large Monitor database from the Netherlands have demonstrated that psychosocial and biomechanical exposure variables have individual associations and mild interactive associations with outcomes of musculoskeletal strain, pain, long-term sick leave, and partial disability. This research also suggests that the interactive demand-control model can explain a portion of WRMSD symptomatology. A cross-sectional analysis of the Nurses' Health Study cohort demonstrated a relationship between physical function and pain reports and psychological demands, decision latitude, and social support.

Office work has been the site of many suggestive studies (Moon and Sauter 1996), although the research is controversial. The much vaunted Second Industrial Revolution, with promised increases in worker control, innovation, and creativity, has not materialized in most offices. To the contrary, in many workplaces, highly routinized and externally controlled computer work has replaced industrial production as the machine-paced assembly line of the twentieth century. Three NIOSH studies of visual display (VDT) workers have found a relationship between psychosocial stressors and the presence of musculoskeletal symptoms. A number of workplace and laboratory studies have found that

musculoskeletal symptoms in VDT workers were related to a complex mix of biomechanical stressors, psychological demands, decision latitude, and employee relationships with the supervisor (and sometimes coworkers). Computer monitoring of employee performance and productivity has been associated with increased levels of perceived stress and increased musculoskeletal symptoms.

6. ORGANIZATION-LEVEL STRESSORS AND WRMSD

Building on a large body of research linking organizational demographics, structure, technology, and culture to work attitudes, research is just beginning on characterizing the importance of organization-level risk factors for WRMSD. Suggestively, the Canadian Institute of Work and Health found management safety commitment to be a strong negative predictor of accident rates. A number of researchers are examining aspects of "organizational response" that have impacts on the prevention and management of WRMSD. The Monitor analyses, from the Netherlands, have shown that employer and employee perceptions of risks in the company are poorly correlated.

I have done some further analysis of this database and found that the difference between employee and employer risk reports is associated with employee reports of WRMSD symptoms. A growing body of research suggests that employee perceptions of organizational support are important predictors of stress levels (hence WRMSD etiology). A recent randomized survey of the Connecticut workforce found that the employees' perceptions of organizational support showed more consistent negative associations with WRMSD symptom status than increased control, supervisor support, or coworker support. Finally, threat of job loss appears to be associated with a wide array of poor health indicators and stress measures, including musculoskeletal disorders.

7. POSSIBLE MECHANISMS FOR THE ASSOCIATION BETWEEN PSYCHOSOCIAL FACTORS AND WRMSD

At present, the mechanisms by which psychosocial stressors might cause musculoskeletal disorders are not well understood. The recent NIOSH review of the epidemiology of these disorders (Bernard 1997) presents a conservative list:

- Psychosocial factors may increase awareness of musculoskeletal symptoms. The effect of increased awareness is unclear, since increased awareness in the context of a well-organized ergonomic program results in earlier reporting and a lower rate of debilitating WRMSD.
- Psychosocial factors may affect reporting behavior. This is almost certainly true, but these factors, particularly in the arena of social support, present the worker with a complicated mixture of incentives and disincentives to report.
- Psychosocial stressors vary as the result of variation in biomechanical stressors. This article has noted the close connection between these types of stressors, but multivariate analysis of several large and diverse databases shows that the two stressor types also have independent associations with WRMSD outcomes.
- Initial pain symptoms due to biomechanical stressors may result in chronic nervous system disorders, both physiological and psychological, that may perpetuate chronic pain.

- Psychosocial stressors may produce chronically elevated muscle tension, thus predisposing soft tissues to the effects of biomechanical stressors.

The first four possibilities undoubtedly contribute to the association between psychosocial stressors and WRMSD outcomes; note that the first three are also tied to work organization and organizational culture. But this section concentrates on the last suggestion and other potential physiological pathways between psychosocial stressors and WRMSD outcomes. Although it is generally assumed that the psychosocial factors moderate the effect of biomechanical stressors on body tissues, rather than causing WRMSD directly, even in the absence of biomechanical stress, this is not yet clear.

The potential mechanism most studied is increased muscle tension related to levels of psychosocial stressors. The largest body of research has focused on monitoring electromyogram (EMG) signals from the trapezius muscles during laboratory and work-site activities. This research has consistently demonstrated that both biomechanical and psychosocial stressors can independently increase muscle tension and that the combined effect of both stressor types results in the highest tension levels. Individuals exposed to higher levels of psychosocial stressors at work also take longer to unwind after work, thus exacerbating the possible effects of sustained muscle tension. EMG research also demonstrates that psychosocial stress is associated with a reduced frequency of EMG gaps — brief (0.2–2.0 s) unconscious interruptions in the EMG signal that may represent automatic rest breaks for muscle fibers. Reduced frequency of EMG gaps is associated prospectively with trapezius myalgia.

Psychosocial stressors might actually result in an overall disorganization of muscular activity, ineffective muscle fiber recruitment, and prolonged activation of muscle fibers with low activation thresholds (whimsically termed Cinderella fibers). Disorganization of other body regulatory mechanisms may also play a part in the association between WRMSD and psychosocial stressors. Attention to a broader range of regulatory mechanisms affected by psychosocial stressors suggests other possible mechanisms for WRMSD genesis:

- Interference with blood flow to muscles
- Interference with energy metabolism and blood sugar regulation
- Impeded muscle coordination, increasing cocontraction and muscle force output

Chronic exposure to psychosocial stressors is associated with characteristic patterns of increased stress hormones, in particular, the catecholamines (adrenaline and noradrenaline) from the adrenal medulla, and cortisol from the adrenal cortex. These are the hormones responsible for the body's adaptive flight or fight responses to acute stressor exposure. At present, the effects on body tissues of chronic exposure to elevated levels of these hormones are unclear. But the ability of these hormones to break down proteins and other complex organic molecules (to mobilize available energy resources) and to affect immune responses might, over time, predispose soft tissues to injury. As in the EMG research, individuals with higher levels of psychosocial stressors at work appear to maintain elevated blood levels of these hormones long after the workday ends.

Recent research has paid attention to the tendency of individuals under stress to hyperventilate, thus removing CO_2 from

the blood. One theory (Schleifer *et al.* 1999) suggests that the resulting increase in pH of body tissues may cause heightened neuronal and muscle activity (producing increased muscle tension), paresthesias, and a shift in autonomic nervous system balance towards sympathetic dominance. Increased sympathetic activity increases responsiveness to catecholamines — secreted at higher levels under conditions of chronic exposure to adverse psychosocial factors. These proposed mechanisms require much more research. The state of the research at present suggests that these mechanisms would not operate in isolation; rather they represent a complicated and linked set of physiological responses that might combine in several ways to affect WRMSD etiology.

FUTURE DIRECTIONS

- Continued exploration of the physiological pathways through which psychosocial stressors either exacerbate the effects of biomechanical stressors or cause certain types of WRMSD directly.
- Research directed towards gender and age differences in the relationship between psychosocial stressors and WRMSD. Many existing studies suggest that males and females experience and react to different psychosocial stressors in different ways.
- Improved longitudinal studies. Although difficult to carry out, longitudinal studies are the best way to firmly establish causal direction.
- Multidisciplinary and multilevel studies examining the contribution to disease and interaction of a wider range of risk factors.
- Intervention studies to determine the protective effect of reducing psychosocial stressors and to provide organizations with practical work organization change strategies.

SUMMARY

The field of psychosocial epidemiology, especially in relationship to WRMSD outcomes, is relatively young. But an emerging body of research, combining laboratory, epidemiological, and intervention studies, suggests that psychosocial, work organization and organization-level risk factors are implicated in WRMSD etiology. Thus, to devise truly effective strategies for the reduction of musculoskeletal disease in the workplace, practitioners and organizations must address a broad spectrum of "shop-floor" risk factors (including both biomechanical and psychosocial stressors). Interventions must also take a multilevel approach, altering aspects of organizational culture, structure, and technology that create the work organization, which in turn creates this spectrum of risk.

The implications of this integrated prevention strategy are highly political. The experience of major companies indicates that employee involvement is a crucial basis for all safety programs, including ergonomic programs. This is not surprising, given what the research suggests about the importance of autonomy, skill use and learning, and social support in WRMSD etiology. But work organization and levels of psychosocial and biomechanical risk are largely the result of the extremely lopsided distribution of power and information within organizations. There are incentives to increase the employee share of these quantities, on medical, productivity, and innovation grounds. But the social, historical, and economic climate also provides strong disincentives to employers. The choice is becoming increasingly clear; it is unlikely that the high rates of WRMSD experienced by the workforce will be dramatically reduced unless these political questions are resolved and employees have greater power and influence within their organizations.

Quality and Ergonomics in Concert

J.R.C. Axelsson[†‡] and J.A.E. Eklund[†‡]

†Centre for Studies of Humans, Technology and Organisation and
‡Division of Industrial Ergonomics, Linköping University, Sweden

1. INTRODUCTION

Recently there have been many research initiatives attempting to integrate quality and ergonomics issues. However, currently there are few examples of applications in industry and public sector that are based on an integrative approach. This chapter gives a broad overview of ergonomics preconditions for quality and presents a framework for an integrative approach to the development of quality and ergonomics in concert. To illustrate the possibilities and to visualize some of the methods and tools that can be used in this context, some examples will be presented briefly.

1.1. Definitions

There are many definitions of both quality and ergonomics. The Nordic Ergonomics Society uses the following definition of ergonomics: "Interdisciplinary field of science and application *considering integrated knowledge of human requirements and needs* in the interaction human–technology–environment in the design of technical components and work systems." The aims of ergonomics have furthermore been expressed in various contexts ranging from the well-being of employees, customers, clients, users and organizations to communities and society in whole. Promoting health, safety, comfort and satisfaction are seen as relevant for all parties and the crossovers are believed to reduce costs and to increase motivation, commitment, efficiency, productivity and quality. Quality, on the other hand, has been defined as: "The quality of a product or service is its *ability to satisfy the needs and expectations of the customers.*" As modern quality concepts emphasizes both internal customers (i.e. every employee) and external customers the overlap of the two definitions are quite obvious. This is further reflected in definitions of total quality management (TQM) such as: "A constantly developing system consisting of values, tools and methods for *increased customer satisfaction*. It builds on continuous improvement work in all the organization's processes, in which all the *employees are permitted and encouraged to become involved*" (Axelsson and Bergman 1999).

Even though the two disciplines developed separately there have been mutual influences. There are similarities and common features as well as differences. Recognizing these is important for the understanding of the basis for an integrated approach.

2. CORE CONCEPTS OF AN INTEGRATED DEVELOPMENT

An integrated development, incorporating quality and ergonomics may take place at different levels. In this respect, there are opportunities to address a number of core issues. Roughly these can be divided in to four main perspectives:

- organizational values;
- strategic management;
- operational methodology; and
- integrated applications.

As all perspectives are closely interconnected, a holistic standpoint will support and secure an integrated approach. The organizational values provide management control and gives direction regarding the way in which an organization achieves its objectives. A lack of clear values can lead to ethical problems for the organization and motivational problems. The establishment of organizational values and beliefs is part of establishing the culture of the organization, and is, therefore, a part of strategic planning and policy deployment. The strategic issues, when accurately cared for, can be seen as the foundation of a well-organized, properly established and potentially effective management system. An organization with clear objectives without explicit values is, however, in danger of encouraging the employees to use any methods they choose to achieve goals. Hence, to achieve an effective system, the organizational values must support the strategies and be reflected in the operational methodology used. Tools and methods applied must comply with this view, and with the needs and characteristics of the given context.

2.1. Organizational Values

Corporate philosophies, values, beliefs and socio-structural systems influence the specific culture of an organization. The general assumption is that managers can control the culture with policies, visions, tools and techniques, thereby obtaining a strong organizational culture believed to lead to better performance. Implementing an integrated system will depend upon existing structures and values, as will it influence the same (Axelsson 1999).

The quality movement as well as the ergonomics movement inherits their own philosophies, ideologies and values; however, in essence they do have many similarities. As the two disciplines arouse about the time we find a dynamic development of quality and work life issues (Axelsson and Bergman 1999). The interactive maturation of quality philosophies and work life doctrines has made the two concepts share several basic beliefs.

The basic assumptions of the quality movement and the ergonomics movement reflect the basic values these movements build on.

As can be seen in Table 1, the values of the two disciplines are partly in concert and partly complementary. TQM embraces certain humanistic approaches regarding the improvement of

Table 1. Basic assumptions and values of the quality and ergonomics movements.

The quality movement	The ergonomics movement
1. Good quality is profitable	1. Good ergonomics improves performance
2. Everything can be improved	2. Fit tasks and equipment to the human
3. Employees try to perform good quality	3. Employees try to perform a good job
4. Organisations are open systems	4. Organisations are open systems
5. Quality is top-management responsibility but everyone's concern	5. Ergonomics is interwoven with participation
6. Learning is essential	6. Developing work is essential

quality as well as the development of people and work life. It is commonly believed that to achieve high external quality the requirements and needs of the employees (internal customers) must first be meet. People in the organization are the source of continuous improvement and provide the driving force for it. Their knowledge, experience and involvement are needed to achieve long-term success. The socio-technical philosophy emphasizes the necessity of being able to influence the quality output in the job, and has also as a basic assumption that people strive to try to do a good quality job.

Achieving cultural change is central to a human-centered quality system. In this way, the integration of quality and ergonomics becomes an approach or a philosophy, a way of taking account of all customers in the long-term, internal as well as external. As a concept, quality management as well as ergonomics concerns realizing the potential of people — getting people involved, motivated and open to change. According to Kondo (1993), "a company is its people" and however excellent an organization is, it will be useless or even counterproductive if the people in it lack motivation.

2.2. Strategic Management

The rationale for and purpose of strategic planning has been discussed for many years and it represents a broad continuum of perspectives. In the past decade, many of the principles of quality management have emerged into principles of strategic management. For example, popular concepts of customer satisfaction, continuous improvement, process orientation, employee involvement and learning are today closely related to strategic concepts such as mission, objectives, motivation and corporate culture. The concept of worker empowerment has clearly emerged as central to the effective implementation of these changes, and the anticipated performance benefits are regarded as primarily a consequence of a more satisfied and committed workforce. In this context an introduction of ergonomics can play a major role, improving job satisfaction, performance and quality of working life. Macro-ergonomics has even been suggested as a TQM strategy and participatory ergonomics as an approach, highly applicable in the context of quality improvement (Noro and Imada 1991).

Yet, in reality we find that the quality of products or services is often considered an issue of strategic management whereas ergonomics is not to the same extent treated as an integrated part of business. There are, however, those who strongly argue that to achieve long-term success, the strategic goals must be balanced — taking the financial, customer and human perspective into consideration. If the system as a whole lacks the adequate focus on the integrational aspects of quality and human issues including ergonomics, the consequences can contradict the purpose. The main issue is, therefore, how to design effective integrated strategic systems that realizes the potential of synergies between the two disciplines.

To realize such a participatory system integrating ergonomic issues at all levels, a balanced strategic management concept based on Policy Deployment and Balanced Scorecard has been proposed (Axelsson 1999). This system provides a set of indicators that stress the need to include a wide range of performance indicators. Thus, the door is opened for ergonomic-based performance indicators and an integrative improvement approach is supported.

The holistic systems view recognizes employee satisfaction and capabilities as strong driving elements in the profit chain — linking ergonomic factors to excellent internal processes and satisfied customers, ultimately resulting in higher financial performance. Furthermore, to support a participatory planning process a "catchball" strategy is applied — taking strategic issues to the grassroots level, asking employees at each level of management to "add value" to the plan based on data analysis and experience of their functional areas or processes. An additional purpose is to ensure that strategies, objectives and measures are well communicated, understood, balanced, realistic and sufficient to achieve the objectives.

The proposed integrated management system represents a highly effective strategy for participation and enhanced motivation as well as fulfilling its obvious purpose of company alignment and customer control and improvement. By focusing on problems and possibilities in the working environment this connection can be made clear, but there is still a need for participatory problem-solving arenas supported by appropriate methodology.

2.3. Operational Methodology

As discussed above, designing and improving a system in accordance with ergonomic principles can be seen as a quality issue in which the internal customer (employees) requests of ergonomics are given a high priority. In addition, performing good quality at work can be seen as an important prerequisite of job satisfaction and job motivation. However, without a clear understanding, active commitment, involvement and support from all employees, quality performance cannot become a reality. In this context the development of people and their participation in improvement activities is recognized as a key feature — today a highly important element of TQM as well as a current concern of ergonomics.

The issue of participative problem-solving has many dimensions. First, there are various techniques for employee involvement, for instance suggestion schemes, quality circles, cross-functional teams, task forces, business councils and self-managing work-groups. Second, these techniques can be assigned to different levels of participation, being more or less user-controlled, active or passive, organization wide or group oriented, etc. Third, there is a variety of tools used to support improvements, each depending on the technique adopted, and the problems and possibilities encountered. From a quality point of view the Seven QC (Quality Control) tools are seen as the most important tools for use in participatory problem-solving — investigating the causes of why things are not working as expected, so that root causes may be identified and eliminated. Definition of the seven tools varies slightly with different writers, but Professor Kaoru Ishikawa as defines it:

1. Pareto chart;
2. Cause and effect diagram;
3. Stratification;
4. Check sheet;
5. Histogram;
6. Scatter diagram; and
7. Graph and control chart.

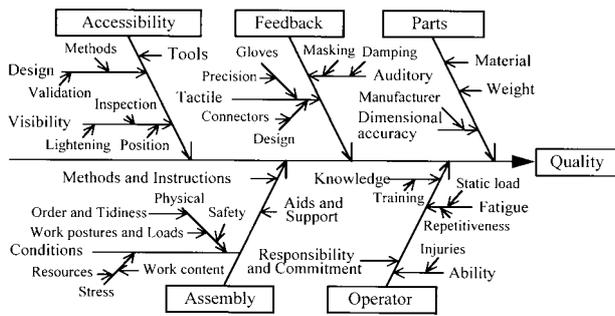
All these tools can be used in quality as well as ergonomics improvements activities, in conjunction often to the advantage of both areas (Axelsson 1999). The following example illustrates


Figure 1. Cause and effect diagram illustrating problems in the subassembly of a microwave oven.

Figure 2. Scatterplot showing the relationship between physical loading and quality.

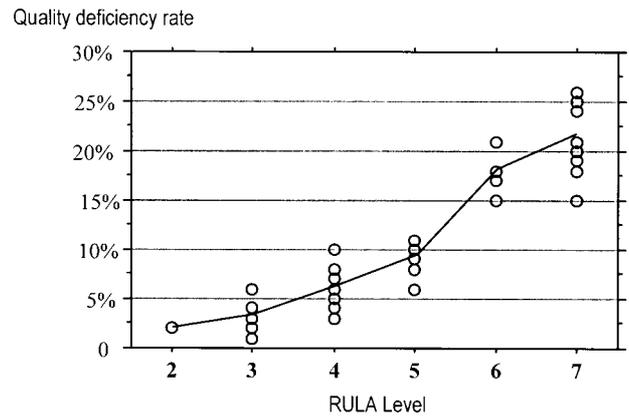
a cause-and-effect diagram used to find the root causes of quality problems in a subassembly task of a microwave oven (Figure 1).

The cause-and-effect diagram provides an excellent basis for participatory problem-solving and can in addition give a clear indication as to whether more data is required and how it is to be collected. The mapping of possible causes, in the example above, clearly indicates that quality problems in large relates to ergonomic difficulties and show that it is not enough just to rely on quality methods to carry out improvements. Many of the problems call for ergonomics methods and techniques. Noro and Imada (1991) suggest a blend of tools for participatory ergonomics initiatives in continuous improvements — containing the 7QC tools as well as ergonomics methods such as link and time analysis, layout modeling and mock-ups, check-lists, man–machine charts and five ergonomics viewpoints.

The Deming PDCA cycle (Plan–Do–Check–Act) for structured problem-solving is another example of a participative method for quality as well as ergonomics improvements. Originally, this was applied so that managers planned, blue collar workers did the job and white collar workers checked it. This was found inappropriate, since it is not until each person (on his/her level) is involved in the whole cycle that the full potential effects on learning, motivation and improvement takes place.

2.4. Integrated Applications
In Axelsson (1999), a participatory problem-solving effort performed by members of a problem-solving group is described. The improvement activity includes a variety of methods, such as SPC charts, 7QC tools, surveys, the RULA method (Rapid method for Upper Limb Assessment), video recordings, walk- and talk-throughs, and brainstorming. To illustrate the successful combination of ergonomics and quality methods the scatterplot in Figure 2 may serve as an example.

The scatterplot examines the hypothesis of a relationship between quality and physical loading on the operator, and as shown in Figure 2 the mean quality deficiency rate was found to be almost 10 times higher for the worst posture compared with the best posture.

Ergonomic tools are well suited in the quality improvement process, and participatory ergonomics can be used not only as an effective tool eliminating ergonomics problems, but also progressively to improve working conditions and performance — stimulating a positive development of quality. To identify such possibilities there is a need to take a holistic viewpoint on production. Generally speaking, most of the work environment


factors influencing human performance will in fact also have an effect on quality. The integrated applications are many and will of cause depend on the context. Some relations can, however, be generalized, as pointed out below.

3. QUALITY SHAPING FACTORS OF THE WORK ENVIRONMENT
There are many studies in the ergonomics literature reporting influences of work environment on performance. In particular, inspection tasks have been subjected to such investigations. Effects on product quality due to ergonomics conditions would, therefore, be expected. Also, ergonomics requirement may also be seen as a part of quality in the context of product design. Eklund (1997) and Drury (1997) have reviewed these relationships, some of which are presented below.

3.1. Noise and Vibrations
There is intentional information in many kinds of sounds, for example human speech and warning signals. Some sounds also include unintended information from work processes, such as the cooling fan of a hand tool, revealing the rotation speed of the tool. There is also pure noise, which by definition is unwanted. Being able to distinguish the sound cues that are needed to diagnose the work process is crucial to perform a good quality job. Noise will have a masking effect and can also impair verbal communication. Arousal will be increased by noise but decreased by infra-sound, a factor which is strongly related to performance. Noise has also been shown to impose stress reactions, disturb concentration, and cause distraction and lapses of attention. Of course, hearing loss and the use of noise protectors create increasing difficulties when trying to hear important information. Vibrations can impair the finger sensitivity in the short-term, and also can cause vibration white fingers and other occupational disorders in the long-term. Difficulties in both hearing and perceiving sensations with the fingers consequently cause performance decrements and increase the risk of errors. If the eyes or the viewed object vibrate, the ability to see small objects deteriorates. One such effect of vibration is that the error frequency in reading tasks may increase. In manual control tasks, vibrations can cause errors due to unwanted movement of the controls. Vibrations at frequencies > 20 Hz can interfere with the neuromuscular processes and thereby cause errors.

One example is assembly work with snap-on fasteners. Increased noise levels as well as the use of gloves increased error rate in production (see the example in Figure 1). Another example is an experienced machine operator who immediately will hear if there is a defect ball bearing, and thus be able to stop the machine for repair before a serious break down occurs. A third example is surface treatment in carpentries. The same persons that frequently use hand-held oscillating grinding machines also have the task to control the smoothness of the surface by touching it with their hands and fingers.

3.2. Climate

Several studies have identified loss of speed and precision of finger movements as a result of a relatively small lowering of finger temperature. This can occur in ordinary offices where low physical activity in combination with light office clothing may result in finger temperatures ~25°C. Outdoor work in too low temperatures might result in deteriorated coordination and difficulties also with upper limb movements. Frost bite in a finger causes deterioration of touch sensitivity in the finger years after the event, a factor the individual is not always aware of. In mental tasks, the error rate has also been shown to be higher already for small deviations from peoples preferred temperature. Further, the accuracy of learning decreases with both high and low temperatures. High temperatures cause sweating, which not only distracts the attention and affects concentration, but also might result in a slippery hand grip. In an unsuitable climate, there has also been an increased rate of accidents recorded, a factor which indicates decreased human reliability.

3.3. Chemical Health Hazards

Some chemical compounds may impair the function of the nervous system. Several other systems might also be affected, including the immune, digestive and respiratory systems, etc. Some effects might be acute and temporary, while others might be chronic and permanent. Solvents and lead are two examples of chemicals with a potential of causing a wide range of symptoms from affecting the nervous system, including nausea, dizziness, head ache, concentration difficulties, memory losses, balance disturbances, longer reaction time, impaired dexterity and even personality changes such as sudden aggressiveness. All kinds of symptoms and impaired physical well-being constitute a risk of distraction from the task and a quicker onset of fatigue. In particular, physical performance deteriorates in terms of loss of speed and precision of motor tasks.

The use of protective equipment is a secondary effect due to deficiencies in working conditions. In general, such equipment may have many adverse effects such as being heavy or uncomfortable to use, making natural movements or activities more difficult, and impairing perception, communication and information retrieval. All these aspects influence human performance and accuracy. In many cases, gloves are worn for protection against health hazards such as chemicals, low temperatures or cutting injuries. As a consequence, precision decreases and the tactile feedback, sometimes necessary to perform a good job, disappears.

3.4. Light

Many studies have identified increased rates of misjudgments and inspection errors due to insufficient light. There may be many contributing factors to this, such as too low light levels, insufficient color rendering, non-optimal luminances and disturbing reflections. Similar problems have been observed in tasks such as proof-reading of texts with poor visibility. In general, jobs including visual work that put high stress on the eye functions may lead to a lower quality of the work result. There are many documented cases from production industries where increased illumination levels have resulted in substantial reductions in rejection rates or wastage. Reductions of ~40% have been reported. In a similar way, substantial increases in the number of defects found in inspection tasks have been seen after improvements of the light. For example, surface irregularities, such as dents, wave shapes or defects in planeness, can be detected more easily with a special light source, giving light at a low angle to the surface. Judgement of the smoothness of painted surfaces improves if light is directed so that the inspector can view the reflex. Judgements of color deviations are aided by light sources with a high-color rendering index in combination with daylight properties. Scratch marks can easier be judged in a diffuse light from light sources with large light emitting areas or from indirect light.

Complaints on light conditions are rare, but an important determinator of the accuracy of quality judgements. Acute symptoms such as headache and eye strain may arise in visually demanding tasks. Further, the effects of insufficient light on melatonin levels could lead to disruption of the circadian cycle, which can cause tiredness and depression symptoms.

3.5. Physical Work Load

The precision and strength capability of body movements varies between different directions of movements and between different muscles in the body. Heavy and strenuous tasks and awkward postures often result in increasing discomfort during the working day, in addition to increasing the risks of musculoskeletal disorders. In such situations, performance of the work and extending it with additional corrections and improvements imposes even more discomfort. Thus, the willingness to improve borderline quality diminishes and quality deficiencies increase with increasing discomfort level. The quality deficiency rate increases substantially for adverse work postures compared with good postures. Several studies have identified a relationship between quality deficiencies and ergonomically problematic work tasks to the extent that ~30–50% of all quality remarks are related to or directly due to ergonomic problems (Eklund 1997, Axelsson 1999). The component design influences assembly ability and the ergonomics work situation which in turn will influence the quality outcome. Some aspects of this, which have been identified in assembly work, are given in Table 2.

Table 2. Examples of component design aspects for improved quality in assembly.

Design–features				
Visibility	Sequence	Weight	Friction	Hardness
Position	Size	Colour	Fragility	Fittings
Layout	Shape	Texture	Heat conductivity	Force

3.5. Physical Ergonomics Influences on Quality

The above results point to that there are several different ways through which ergonomics conditions influence quality. In particular, adverse environmental and physical conditions cause quality deficiencies through several mechanisms. These include the following mechanisms:

- impaired ability to perceive;
- masking of information/cues/signals;
- impaired ability to interpret and decide;
- impaired ability to perform and exert the task;
- reduced feedback; and
- distraction from the main task.

When humans feel discomfort, especially if it is caused by the task, this seems to impair performance and to increase the probability of quality errors or deficiencies. One explanation may be that discomfort may cause distraction and lapses in attention, or lead to changed activity or compensatory activities that compete with the main task.

3.6. Psychosocial and Organizational Aspects

Short work cycles in paced jobs lead to increased rates of quality deficiencies. One reason is the variability in time needed for each operation, leading to unfinished or deficient operations when slight problems occur. Repetitive and monotonous jobs give rise to symptoms of boredom or fatigue, followed by a decrease in performance in terms of longer reaction time and an increased error rate progressively during the work periods. There are also indications that increased work content in simple jobs seem to improve product quality. Status differences and tensions between categories of workers in a hierarchical work organization have been related to quality deficiencies.

Several studies have documented that production philosophy, work organization and personnel policy, as well as wage form may influence quality. It has been reported many times that motivation and job satisfaction leads to improved product quality. Among important factors for this are a continuous interest in the work, challenge, recognized achievement, ownership and communication. Further, companies known for quality are also often characterized by a concern for their personnel.

4. SUMMARY AND CONCLUSIONS

There is no short cut for how an organization is to succeed with integrating quality and ergonomics, but there are studies that describe important characteristics in the work environment as well as the development of integrated systems and processes. Integrative approaches incorporate company values, strategic management, operative methodology and applications. A top-down strategy including management support is seen as a prerequisite for successful results, but the bottom-up participative strategy is also an important prerequisite. Commitment and motivation are important factors in this development, but at the same time they make demands on how the work should be structured. The integrated approach consequently assumes the combination of a top-down and a bottom-up strategy. Thus, all employees must be given the necessary conditions for doing a good job. This also points to the necessity to integrate values and management strategies with simple tools for improving work conditions, i.e. a joint effort of quality and work development. But such a process does not run by itself. It will though be supported by a view that problematizes and develops the interactive and synergistic area that exists between concentration on quality and ergonomics, both operative and strategic.

1. INTRODUCTION

The development of numerically controlled machines, group technology, cellular manufacturing and just-in-time (JIT) production systems have revolutionized the way products are designed and manufactured. These technological and strategic advances have changed the role of human operators in the manufacturing environment. The highly specialized work force of the low-tech manufacturing system has evolved into the multi-skilled work force of the high-tech manufacturing system. Among the multiple tasks that an operator is expected to perform in advance manufacturing systems (AMS) are job scheduling, inventory planning, machine set-up, problem-solving and quality inspection.

Throughout this evolution, human sensory detection capabilities have been a vital but often ignored component of the quality inspection task. Although automation is often employed to construct and assemble products within AMS, most inspections and quality checks are still done by human operators due to the inherent problems in machine vision and decision-making. While humans remain responsible for inspection, it has been widely accepted that the quality inspection task performed by humans is prone to error. Some studies indicate human inspectors typically find only ~80% of the defects. Despite the contributions of human factors research to the understanding of human performance in the quality inspection task, the manufacturing trend has been to design quality schemes that compensate for poor inspector performance instead of trying to improve it (Drury 1992).

2. A VISUAL QUALITY INSPECTION TAXONOMY

Quality is usually defined as fitness for use, or the extent to which a product meets the consumer requirements. Inspection is the act of measuring or examining carefully the quality of a product. Sensory inspections (performed by means of the human senses to assess a product's qualitative characteristics) and physical inspections (performed by means of measuring devices to assess a product's quantitative characteristics) are the main types of quality inspections. The visual quality inspection task has been described as consisting of the following subtasks (Wang and Drury 1989): (1) orient the item, (2) search the item, (3) detect any defect, (4) recognize/classify the defect, (5) decide the status of the item, (6) dispatch the item, and (7) record the information about the item. These subtasks can be combined into two main components: search and decision-making. Thus, the simplest description of the visual quality inspection task is to: search, recognize a defect and make a decision on the part's acceptability within the quality limits.

2.1. The Visual Search Component

Visual search is a sequential process that proceeds as a series of fixations linked by eye movements and which terminates upon successful detection of a defect or the complete inspection of the unit. It has been shown that almost all of the information in a visual search is obtained during the fixations, which account for > 90% of the search time. In the inspector's field of view, a defect is only visible within a limited area referred to as the visual lobe. During a fixation the visual lobe is located around the central fixation point. The visual lobe size will be affected by the luminance of the object inspected, the contrast between the object and the defect on the object, the defect size and the distance of the defect from the inspector's eyes. Megaw and Richardson (1979) conducted eye movement studies of inspectors and concluded that inspectors do not follow a simple pattern or strategy in searching an object. They observed that while a very random appearing search pattern was used for the inspection of complex units (e.g. circuit boards), a more systematic search pattern was used for the inspection of simpler ones (e.g. knitwear).

In addition to the lobe size and the search strategy, the time available for the inspection will affect human performance in the visual search component of the inspection. The more time the inspector has to search, the better the chances are of finding the defect. For the visual search subtask, the best inspectors are those who use fewer, longer fixations, as compared with those with a larger number of shorter duration fixations.

2.2. Decision-making Component

Given its strict relevance to decision-making, signal detection theory (SDT) has been used to explain the decision-making component of the quality control inspection task. In a quality inspection context, SDT proposes that the human, functioning as a defect detection device, builds up in the neural system two distributions of activity: one relating to the probability of accepting a unit, the other to the probability of rejecting it. The degree of separation of these two distributions' means is a measure of the inspector's discriminability of the defects (d¢). The criterion level (b), which is the ratio of the two ordinates of the curves at a given level X_c, delineates the boundary between accepting and rejecting a unit, and in doing so takes in some good units to be rejected and some faulty units to be accepted. Inspectors make a correct decision either by accepting a good unit (correct rejection) or by rejecting an unacceptable unit (hit). They fail either by not detecting a rejectable defect (miss) or by falsely reporting the presence of a rejectable defect (false alarm).

Both decision-making performance measures (d¢ and ß) are derived from the hit rate and the false alarm rate. The pure decision-making component of the quality inspection task can be measured by concentrating on tasks that require no search. The general conclusion of quality inspection studies reviewed by Drury and Fox (1975) is that "the decision-making component is among those rare tasks where a human being behaves like a rational economic decision maker, balancing the costs and payoffs involved to arrive at an optimum performance." As a normative model, SDT defines the optimal criterion ($ß_{opt}$) used by the ideal observer to optimize economic gains. Based on the values of a hit and a correct rejection, and the costs of a miss and a false alarm, $ß_{obs}$ of a rational observer can be calculated and compared with that of the theoretical ideal observer ($ß_{opt}$). After comparing

ß$_{obs}$ with ß$_{opt}$, it has been generally found that rational observers do fairly well at optimizing their winnings. However, they tend not to set extremely low or high criterion, even in situations where these strategies would lead to optimal performance.

3. SIGNAL DETECTION THEORY MODELS OF INSPECTION

SDT was first used to model the decision-making performance of the quality inspection task by Wallack and Adams in 1969. After using SDT to study the performance of industrial electronics inspectors in a visual, subject-paced task, they concluded that SDT performance measures (d¢, ß) were more useful than the other available measures. Wallack and Adams concluded that SDT is useful because in addition to relating performance to payoff, it also indicates the magnitude and the direction of improvement required. Although not all of the research using SDT to study the decision-making performance has been conducted in an industrial inspection context, its findings have been beneficial in understanding human quality inspector performance.

More recently another measure of criterion level or decision-making response bias called index *c* has been developed. The main difference between ß and index *c* is in the way these bias indices locate the criterion (X$_c$). The likelihood ratio measure, ß, locates X$_c$ by the ratio of the heights of the SDT distributions (N, SN), while index *c* locates X$_c$ by its distance from the intersection of the two distributions. The range of *c* is, therefore, the same as that of d¢, although zero is at the center rather than an endpoint. This parametric index is considered to be more effective than ß over a full range of sensitivity in recognition memory experiments and in vigilance. Unlike index *c*, ß has a tendency to produce extremely high values for conservative observers resulting in a scale that does not produce equal intervals. Index *c* is generally more sensitive than ß to the non-perceptual manipulations of signal probability, payoff and probability shifts. Also, ß is less effective than *c* at differentiating variations in response bias tendencies when sensitivity approached chance.

In most if not all of the research using SDT, the quality inspection task has been characterized as a vigilance situation in which the inspector's sole task is to examine a stream of products to detect and remove the defective ones. This characterization is no longer consistent with the reality of the operator's responsibilities in modern manufacturing, also known as advanced manufacturing systems (AMS). The quality inspection task in AMS is no longer a specialized task; instead, it is one of multiple dissimilar tasks conducted by a highly skilled operator. Recent research indicated that the performance of the operator in the quality inspection task while multitasking in an AMS will be determined by the interaction between the number of different types of defects that can be presented at the same time in the inspected parts and multitasking (Pesante-Santana 1997).

3.1. Changes Over Time in the SDT Parameters

Based on the review of 12 studies conducted between 1969 and 1975, Swets (1977) indicated that all 12 experiments showed an increasingly strict criterion (ß) over time when the signal-to-noise ratio was low; eight of the experiments showed a constant sensitivity (d¢) over time. In the four studies in which d¢ did not remain constant, it was found to decrease by 20%. An increase in ß (conservative criterion) represents a decrease in signals detected as well as a decrease in false alarm errors. In general, the performance changes over time have been characterized by a shift in the subject's response criterion (ß).

3.2. Determinants of Decision-making Performance

It is often reported that the decision-making performance is affected by the payoff matrix, knowledge of results (KR) and signal ratios (fraction of defective). Conservative or stringent decision-making should be expected if the operator knows that the cost of an incorrect decision may be a disciplinary action, a monetary penalty or job termination. A similar conservative decision should be expected if the process defective fraction is low (signal ratios), or if the operator receives information (knowledge of results) about specific defects or process conditions that needs to be detected for the benefit of the production area. When none of the conditions previously mentioned are not present a lax decision-making performance should be expected from the operator. However, it is important to recognize that a key element in the decision-making performance is the training. The operator's decision-making performance will not be consistent with the scenarios described in this section if s/he does not have the appropriate training on quality inspection.

4. QUALITY INSPECTION TRAINING

Training is essential to improving the decision-making performance of human operators. Many authors have reported that deficiency in knowledge (education or training) and or feedback (knowledge of results) is a cause of errors consistently made by inspectors. Drury (1992) listed five techniques that have proven effective in training for inspection: (1) cueing, (2) feedback, (3) active training, (4) progressive parts and (5) develop schema.

5. HYBRID INSPECTION SYSTEMS

Zero-defect products and shorter lead-time production are vital for the survival and success of modern manufacturing businesses in the current highly competitive world class manufacturing environment. According to Drury and Sinclair (1983), "this can often be achieved only by 100% inspection, which is known to be unreliable when performed by humans." This dilemma prompted an industry movement towards automated inspection systems. The advent of microprocessor-based automated inspection devices, at prices competitive with human inspection, called for a human factors reassessment of the human–machine function allocation possibilities in quality control (Drury and Sinclair 1983). Gramopadhye *et al.* (1992) proposed a framework for function allocation in inspection. They recommended accuracy, speed, flexibility and reliability as the performance criterion for the inspection system.

One of the first efforts to reassess the human–machine function allocation possibilities in quality control was conducted by Drury and Sinclair (1983). They compared the performance of experienced inspectors and a prototype optical/microprocessor inspection device. The main findings were: (1) neither the human nor the automated systems achieved an outstanding performance and (2) the automated system was better at locating the defects (search) but could not classify them as acceptable or rejectable (decision-making) as well as the human inspectors.

Using the accuracy and speed performance criterion measures combined with the false alarm rate and the hit rate, Hou *et al.* (1993) calculated a cost-based evaluation function. This cost-based evaluation function coupled with the Drury and Sinclair (1983) findings led to the conclusion that allocating the search function to machines and the decision-making function to humans results in better performance than pure human or pure machine inspection. This computer–search/human–decision-making system is known as a hybrid inspection system (HIS). The idea behind HIS is to capitalize on the machine speed and precision to scan the inspection unit, and on the decision-making ability exhibited by humans.

6. QUALITY INSPECTION TASK LOAD

Quality inspection tasks that impose a sustained load on working memory (to recall what the quality acceptability criterion looks like) will demand the continuous supply of processing resources. Parasuraman (1979) conducted an experiment using a successive-discrimination task (which imposed a memory load) in which the signal was specified as the decrease in the intensity of a flashing light. The signals were presented irregularly at a mean rate of two signals min^{-1}, and the event rate was 30 events min^{-1}. The duration of the task was 45 min. He concluded that the performance in such areas of vigilance application as radar monitoring and industrial quality inspection could be adversely affected when the operator has to discriminate a signal from a standard represented in memory and when the event rate is high. This performance decrement may result either from signal-data limits (weak signal in noise), or memory-data limits (quality of stored representation of the standard in delayed comparison memory tasks).

Like many other tasks, quality inspection has been identified as having an inverted-U-shaped relationship between task demand and performance level. The inverted-U theory states that for a given task there is an optimal level of workload or demand that yields the highest level of performance. A departure in either direction from the optimal level of work will result in a performance decrement. While most of the results of vigilance research support the right-hand side of the inverted-U theory (overload) there is a lack of support for the left-hand branch (assertion that the task performance level can be improved by increasing the load). McGrath (1965) conducted one of the first experiments that supported the left-hand side in a vigilance task. After comparing easy and hard visual monitoring tasks conducted concurrently he concluded that the presence of the hard task facilitated performance on the easy one. Wiener *et al.* (1984) conducted an experiment in which a control group performed a vigilance task (the signal was the decrease in distance between two dots presented on a computer screen), and a second group performed a one-dimensional compensatory tracking task in addition to the vigilance task. They found that the performance of the second group (vigilance and tracking tasks) in terms of signal detection exceeded the performance of the control group (vigilance task only). They concluded that these research results provided support for the facilitating effect of increasing the task load (left side of the inverted-U).

Some researchers describe the quality inspection task as being intrinsically boring. According to them, this explains why it is often the case that mild stress will increase the performance in

terms of detection and response time. However, Wickens (1992) has indicated that vigilance tasks with working memory loads are susceptible to interference from concurrent tasks. The results of a recent study on the effects of multitasking on the decision-making component of the quality inspection task were consistent with the information presented herein (Pesante-Santana 1997). The performance of the operator in the quality inspection task while multitasking in an AMS will be determined not only by the number of different types of defects that can be presented at a time in the inspected parts, but also by the mental processing resources required to meet the demand imposed by the multiple independent tasks and the memorized quality criterion. The best performance will be obtained when the additional tasks' load minimizes the monotony of the quality inspection task without interfering with the processing resources needed for the memorized quality criterion.

7. RECOMMENDATIONS

Whenever human operators perform the quality inspection a certain degree of error should be expected. However, some ideas oriented to minimize the quality inspection errors are:

- Identify the inspector with the best performance and understand his/her inspection strategy.
- Provide off-line training/practice on the actual task to be conducted using the strategy of the best inspector.
- Provide continuous feedback to the operators on their performance.
- Assure an appropriate task allocation to avoid unwanted task loading.
- Use the appropriate payoff matrix to improve the operator's performance.
- Let the proper process information (KR) flow among the operators.

Quality Management, Continuous Improvement and Total Quality Management

K. Zink

Universität of Kaiserslautern, PO Box 3049, D-67653 Kaiserslautern, Germany

1. BASIC PRINCIPLES AND DEFINITIONS

When talking about quality management, continuous improvement, and total quality management, it is necessary to define these terms and to show where they originate. But first we have to clarify what we mean when using the term "quality".

1.1 Quality

The word "quality" is derived from the Latin "qualitas", meaning "of what kind or sort". As quality is a word in every day use there are many meanings. Related to quality assurance activities, quality was often described as the quality of a result (e.g. a product). So the dimensions of quality could be described by features like performance, reliability, maintainability, and safety. During recent decades this more technical and objective understanding of quality has had to be completed by a subjectively perceived quality, and so other dimensions like features of the product, aesthetics or perceived quality have had to be added. Apart from the quality of a product, the quality of services is gaining more and more importance, adding dimensions such as responsiveness, courtesy or communication. This development is reflected in the latest version of ISO 8402 from 1995 defining quality as "the totality of characteristics of an entity that bear on its ability to satisfy related and implied needs".

The term "entity" includes not only products but also processes, organizations or persons. Products in the context of ISO 8402 (DIN 1995, pp. 3, 4) are described as "the result of activities or processes and can be tangible or intangible, or a combination thereof".

At this point it is already obvious that there is also a broader scope in the ISO (e.g. including processes and services), but does fulfilling stated and implied requirements contribute to long-term customer satisfaction? Many authors in this field do not believe so. They support the idea of an "attractive quality" that pleases the customer, because it is unexpected. Exceeding requirements only makes sense if customers are offered more or better solutions for their problems than they actually expect — and this leads to additional benefits for them.

In the context of total quality management an even broader understanding of quality arises.

Associating quality with normative aspects, working conditions must be addressed as a further element of a comprehensive quality understanding. This includes participation, technical, methodical or social training on the job, cooperation within and across departments, and providing adequate operating resources. Such task orientation of quality has been known for a long time as "quality of working life".

A comprehensive quality understanding also involves an organization's attitude towards the environment. Therefore, a quality of external relationships can be defined that relates to social responsibilities — for example, environmental protection

or an active role in the community. Environmental protection has an impact on products (waste management), processes (emissions and consumption of resources) and working conditions (work-related diseases).

Obviously, the elements presented here are not independent of each other. While the links between product (or service) and process quality are generally accepted, some still find it difficult to integrate the quality of working life or of external relationships into this concept.

The development of quality understanding described above can also be seen in the criteria for national or international quality awards. They started with a broader understanding of quality which in the meantime has been redefined as "business or organizational excellence".

1.2 Quality management

It is obvious that the definition of quality management is closely related to the definition of quality. Thinking of quality as a result of a process leads to a specific quality assurance which is mainly achieved by testing. Going back into history, the start of this approach is very much connected with the beginning of industrialization, especially Taylor's concept of scientific management which led to a separation of "thinking" and "doing" and brought quality assurance tasks to superiors or special departments. This development was enhanced by introducing Statistical Process Control (SPC) which was a consequence of mass production — and required relevant qualifications. In Japan during the 1960s and in the US during the 1970s, employee-oriented approaches arose. In Japan, the quality (control) circle as a means to include employees in (quality) problem solving was invented; in the US "Zero Defect Programs" tried to motivate people to do things right the first time. In the following years and up to the present time, quality has been seen as a management task too — and consequently quality assurance has developed into quality management. Coming back again to ISO definitions (ISO 8402), quality management is understood as including both quality control (as "operational means to fulfil the quality requirements") and quality assurance (as aiming at "providing confidence in this fulfillment both within the organization and externally to customers and authorities"), as well as the additional concepts of quality policy, quality planning, and quality improvement. quality management operates throughout the quality system. These concepts can be extended to all parts of an organization. "The quality system consists of the 'organizational structure, procedures, processes, and resources needed to implement quality management" (ISO 8402, 1995, p. 17). Quality management and quality assurance standards are described in the ISO 9000 series, for example. The following figure gives a general overview:

As mentioned before, the descriptions of quality management depend on the definition of quality.

1.3 Total quality management

Searching for the origin of total quality management (TQM), one has to refer to several sources. On the one hand, there is the Japanese way of "company-wide quality control" (Ishihawa 1985) or the US approaches of "total quality control" (Feigenbaum 1956). Whereas the content of TQM was already being developed and described in these early approaches, the term "total quality

management" appeared later — especially in the context of quality awards. In the meantime, even ISO has defined TQM as a "global management strategy" with "the participation of all members of the organization for the benefit of the organization itself, its members, its customers and society as a whole" (ISO 8402, 1995, p. 4). In practice TQM is mostly understood and evaluated on the basis of international quality awards. These awards have been created to promote the idea of a holistic quality understanding, which in the meantime (as mentioned above) was redefined as "business excellence" and also applied for example to non-profit organizations (NPOs) around the globe (Asia, America, Australia, and Europe) where such awards can be found. One of the latest developments is shown in the Figure 2.

As can be seen in figure 3, the European Quality Award (and also, for some years, the US Award) gives the same weighting to "enablers" and "results":

1.4 Continuous improvement

The idea of continuous improvement is not new at all, so that all the approaches that have been adopted for many years by both internal and external consultants driving the continuous

improvement process will have to be included here. However, this process was, on the one hand, driven by experts (e.g. coming from industrial engineering) and, on the other hand, caused by the occurrence of specific weak points. After the World War II, instead of this externally driven improvement process, which was only partially "continuous", there were different routes of development in Japan and the Western countries. In the early 1950s and '60s, the Japanese discovered that employees are the real experts concerning problems connected to their work(place). They therefore introduced the so-called quality control circles (QCCs), which have been a huge success. Ishikawa especially saw QCC as one of the most important parts of company-wide quality control. Seeing this success, Western countries (i.e. Western Europe and the US) tried to introduce the idea of employee participation. However, although a success at first, the quality circles suffered after some time because, unlike in Japan, they were not part of a broader approach; thus many of the "quality circles" (as they were named in the West) were abandoned after two or three years, and "lean production" or "lean management" teamwork and continuous improvement became again topics for discussion. At this time the Japanese idea of "KAIZEN" was promoted, especially by Imai, who proposed the advantages of innovation in small steps using different concepts of continuous improvement (KAIZEN). As a result, many of the former quality circles have been revitalized by this concept. Imai gave the idea of continuous improvement a broader base by proposing three different target groups: individuals, teams, and management, and this is illustrated in figure 4 (Imai 1984).

2. THE COMMON DENOMINATOR AND INTERDEPENDENCIES

In comparing the three concepts, we find one common denominator — namely, the improvement of quality — but, as explained before, the definition of quality differs. While the former quality circles and (especially) "total quality management" refer

to a broad definition of quality management or quality assurance, the quality of products or services was, for many years, a central point. But here, too, the foreseeable developments show a more extended approach.

Based on this understanding, although total quality management may deliver the frame, quality management and continuous improvement are also part of TQM. In addition, quality management itself includes the idea of "quality improvement" (ISO 8402, 1995, p. 18), and in Imais's book KAIZEN, the term "total quality control" is the most used one. Therefore, there is no doubt that all three concepts are interdependent. Nevertheless a hierarchical approach, using TQM as the frame, is the most structured one.

As mentioned in defining total quality management , business excellence models play a predominant role as a basis for quality awards in (industrial) practice (even in NPOs). Using these models normally includes the tasks of self-assessment and benchmarking. The aim of these approaches is to find "strengths" and "areas for improvement". Carrying out a yearly self-assessment therefore leads to a structured identification of topics for improvement. Using this tool as (another) base for strategy and operative planning ensures that improvement becomes continuous (in contradiction to past methods). Since all the international award schemes include "process" as a central element, quality management systems are also covered.

Comparing the US Malcolm Baldrige National Quality Award Categories, for instance, or items of 1989 with those of 1999, it becomes obvious that the understanding of quality is now "business or organizational excellence" or, as termed in the Baldrige National Quality Program 1988, performance excellence.

3. TOPIC RELEVANCE FOR ERGONOMICS AND HUMAN FACTORS

As shown before, the field of quality has undergone a transition

	Management-Oriented KAIZEN	Team-Oriented KAIZEN	Individual Oriented KAIZEN
Tools	Seven statistical tools Seven new tools Professional skills	Seven statistical tools Seven new tools	Common sense Seven statistical tools
Involves	Managers and professionals	QC-circle (group) members	Everybody
Target	Focus on systems and procedures	Within the same workshop	Within one's own work area
Cycle (Period)	Lasts for the duration of the project	Requires four or five months to complete	Any time
Achievements	As many as management chooses	Two or three per year	Many
Supporting system	Line and staff project team	Small-group activities QC circles Suggestion system	Suggestion system
Implementation cost	Mostly small investments	Mostly inexpensive	Inexpensive
Result	New system and facility improvement	Improved work procedure Revision of standard	On-the-spot improvement
Booster	Improvement in managerial performance	Morale improvement Participation Learning experience	Morale improvement KAIZEN awareness Self-development
Direction	Gradual and visible improvement Marked upgrading of current status	Gradual and visible improvement	Gradual and visible improvement

Figure 4: The three segments of KAIZEN

from inspection of quality assurance to quality management and continuous improvement. The latest development may be characterized by total quality approaches. Generalizing this process we see more and more holistic concepts instead of fragmented ones, and this includes a change in attitudes. While, previously, quality was a primary task of (inspection) specialists, nowadays, top managers are dealing with the topic. Looking at ergonomics and human factors one can also note substantial changes in scope and issues of interest.

Although, in the past, micro-ergonomic approaches have been accompanied predominantly by the belief that ergonomic interventions only cause costs, we now have a broader conception of ergonomics. For some years organizational design and management or macro-ergonomics have been accepted, including participatory ergonomics, and outside industry new concepts such as "community ergonomics" have been defined. Thus, it can be said that not only is there a development in the (total) quality field to include more and more "new" human factors issues such as the "quality of working life" based on broad stakeholder

concepts, but also a "rediscovery" of the relationship between working conditions and manufacturing quality.

The extension of the types of issues in ergonomics/human factors include areas such as (cross-functional) processes, participation (also in continuous improvements) or quality of life in communities, which are very much related to quality topics like process management, continuous improvement or excellence councils as an approach to regional development.

The inclusion of "people management" issues in all quality awards — for example, participation, working conditions, care for people and people satisfaction — are promoting these topics to top management level. In this context, studies such as the one carried out at Harvard University entitled "The human equation: building profits by putting people first" (Pfeffer 1998) are very helpful.

Returning to the basics of quality management and ergonomics, these have several factors in common. For instance, both approaches are based on:
- prevention
- measurement

1315

● continuous improvement

The best results can be gained by participatory approaches — and both topics are only successful if they are management driven.

Quality of Life and Usability Engineering

E. A. Averboukh

Interdisciplinary Centre for Quality Life and Usability Studies (LUSI-Centre), University of Kassel, Germany

1. INTRODUCTION

Growing and rapidly changing demands towards higher quality of life along with unprecedented rapid technological evolution require to redefine and/or revisit and bridge diverse engineering approaches to manage these changes in a human- and environment-friendly way.

Quality of life can be defined as an extent to which humans achieve their social, economic and ecological goals, and satisfy their needs using technological resources for performing certain functions and tasks in diverse environments and contexts.

Humans and technological resources that they use form an interactive *system* where the behavior of each interacting component affects the behavior and efficiency of interaction of the whole "set."

Hence *quality of life engineering* can be defined as an interdisciplinary process of interactive human–machine–environment *system engineering* within cost and time constraints. It covers design, production and maintenance of trustworthy systems that are *compatible* with humans and with environment and *support user's goals and behavior*. This process ensures that *human's needs are satisfied* and individual *human's resources are enhanced* throughout a system's entire *life cycle*.

Humans interact with technologies or technical systems via so-called *user interface*. This interaction is constrained by their individual sensory, cognitive and biomechanical capabilities. As technologies become more and more intelligent and computer-aided, user interfaces are often called human–computer interfaces (HCI) and provide visual, audio, tactile, etc. communication modalities for presenting information to the human users and for accepting user's requests/inputs. So-called *usability* of technologies and of their HCI, i.e. of their front-end to the users depends on interface suitability to human users, to their capabilities and task performance in specific environments and contexts. Hence usability is one of the most critical quality of life factors and is defined as effectiveness and efficiency of interaction and subjective satisfaction of human users (ISO 1995).

By analogy, *usability engineering* can be regarded as user- and task-centered design, evaluation, production and maintenance of user- or human–computer interfaces within the entire system's life cycle and within cost and time constraints.

Main engineering efforts shift to the early design and evaluation activities and especially to the so-called architecting phase in order to model and to test mutual performance of human users and technical systems and to avoid and/or eliminate usability problems and mistakes before starting detailed design and product development.

2. CRITERIA AND METRICS FOR EVALUATING USABILITY AND QUALITY OF LIFE

Following *usability criteria* drive the design, development and evaluation of interactive systems and their interfaces:

1. *Effectiveness* of user's task performance or so-called *usefulness* of the system, i.e. the possibility for target end-users to achieve their task goal and to perform desired function(s) with the help of technical system in target environments and contexts within given time constraint.

2. *Efficiency* in terms of how easy (or how sophisticated) it is for target users to identify or to recognize systems' role and functionalities, to learn and to use them, to remember over time, etc. in typical task-situations.

   For example, following relative time-estimates may be applied as a metrics for evaluating efficiency:
   - time for error-free task-performance under the given context (t_1/t_0);
   - time for coping with problems or errors (t_2/t_0); and
   - time for recovering from errors (t_3/t_0),

   where $(t_1/t_0) + (t_2/t_0) + (t_3/t_0) = 1$, t_0 is the time to solve the task or to learn task-interaction.

   Efficiency can be also estimated in terms of so-called task-complexity, e.g. as number of task-performance errors, etc. Only rough estimates can be achieved although, as it is difficult to define unambiguously the boundaries of task-situation, as well as to simulate real-life task-scenarios in laboratory's environment, etc. When measurements of the metrics are performed manually or semi-automatically, as it is usually made in industrial usability labs, only qualitative evaluation of efficiency is feasible.

3. Subjective user's *satisfaction* and/or enjoyment, i.e. *user's sensations* when using the product or system.

   Usability criteria apparently transform into the superior quality of life criteria if analyzed in the broader then just ease-of-use and ease-of-learn contexts, i.e. for a brighter range of human activities covering producing, buying, owning, using, presenting, selling, decomposing, recycling the product, etc.

   Human sensations like, for example, feeling of comfort or discomfort can be considered as integrated quality of life criteria. They have to be evaluated in general, i.e. regarding the product or interactive system as a whole, as well as in relation to the specific human user's functions and activities from user's and from the third party's points of view. For example, sensations of driving the motorcycle have to be evaluated from the driver's point of view, i.e. when accelerating, braking, handling, etc., and from the third parties point of view, e.g., humans who are driving cars or walking along the same road, etc.

   Activity-related comfort subcriteria have to be further decomposed regarding human sensory systems (vision, audio, tactile, etc.) involved in these activities, relevant thermal, posture and movement comfort, etc.

   Following metrics are used for evaluating subjective satisfaction or sensations on-line, i.e. during the activity performance and/or off-line, i.e. before and/or after performing certain activities:
   - direct physiological measurements, such as blood pressure, urine composition, heart frequency, etc.;

- indirect measurements of cognitive load, stress, fatigue, etc., such as eye movement characteristics, sweating, temperature distribution over the target points or areas on the human body, etc.; and
- indirect measurements of sensations by monitoring and pattern-recognition of face mimics or expressions, wording, so-called "body language," etc.

All mentioned above quality of life and usability characteristics are subjective. They depend on culture of human users and on their environment in general, as well as on the user's gender, their individual physical, psychological, physiological profiles, cognitive level and professional background, as well as on their linguistical level, i.e. ability to express their wishes and preferences as well as ability to read, etc. These characteristics are not static, but have their own dynamics and evolution. Transformations reflect users learning and mutual adaptation processes when applying target technology, on the one side, and permanent and quite natural human desires to "want more and better," i.e. to intensify positive sensations and to prevent boredom, on the other side.

Availability of non-contact and preferably on-line measurement methods, task-integration and evaluation of the information acquired, its further processing and interpretation into the product's design features and forecast of their future transformations become critical for the success of the discussed engineering processes. Advanced error-tolerant data-modeling, -reduction and -management approaches and relevant computer-aided engineering platforms are, hence, of high demand and determine overall efficiency of quality of life engineering.

3. FLEXIBLE SYSTEM ARCHITECTURES FOR QUALITY OF LIFE AND USABILITY

3.1. Model-based Adaptive User Interfaces

Quality of life and usability engineering activities start from the very early design phases, particularly from analysis and architecting of products, systems and their user interfaces.

Architecting driven by human goals, needs and wishes is a top-down iterative approach and is one of the central system engineering/design activities.

Architectures of systems and user interfaces have to be flexible enough to support easy and time- and cost-effective adaptation to the evolution of the interactive system as a whole, i.e. to the changing requirements of human users, of their functions,

Figure 1. Advanced model-based adaptive User Interface.

activities and organizational structures, of the environmental conditions and enabling technologies, as well as of individual capabilities and preferences of human users.

The functional structure of advanced adaptive user interfaces is illustrated in figure 1.

Three following models are imbedded to control traditional user interface functions which manage dialogue and information presentation and exchange in a user-friendly way:

1. The Human User model (HM) which comprises and tracks information on human goals and objectives, functions and activities, human user behavior and interaction with the technical system via user interface in different situations and contexts, human resources or capabilities available, i.e.

- "long-term" user characteristics such as, e.g., demographic, linguistic, psychological, physical disabilities, certain aspects of professional level and skills which do not change within system life-cycle or change rather slowly, and
- "short-term" user characteristics such as, e.g., physical, physiological and cognitive characteristics which depend on human activities and tasks, their duration and workload, environment and situation, etc.

and generic and task-specific metrics for evaluating quality of life and usability of system for end-users.

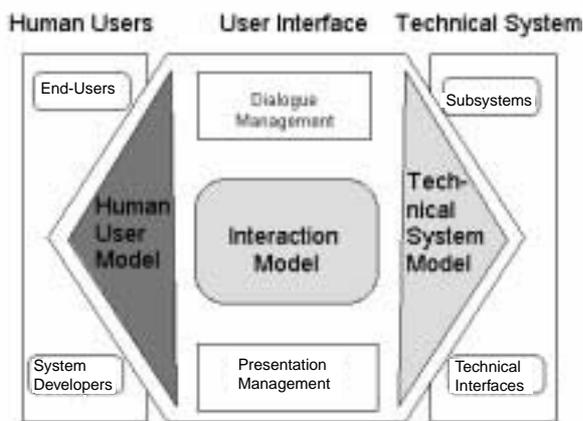
2. The Technical System model (TM) which tracks information on technical goals like production, safety, etc., technical functions and system performance, system status in specific environments and situations, technical status and resources available, generic and task-specific metrics for evaluating system performance (e.g. time, costs, safety, etc.) and extent to which the mentioned above goals can be achieved.

3. The User Interaction model (UIM) which monitors interaction, bridges User- and Technical System Models at different levels of abstraction and from diverse view points, interpret them into relevant interactive modalities for information presentation and managing dialogue between human users and technical systems.

3.2. Evolutionary User-centered System Architecting

Top-down evolutionary and iterative modeling and architecting processes are schematically shown in Figure 2. Models embedded into the user interface reflect different views on system's architecture, i.e. so-called

- operational view (objectives, functions, organization, activities, and information-exchange requirements);
- system view (human capabilities- and enabling technology-dependent requirements and constraints); and
- technical view (requirements of multiplatform- and network interconnections among all subsystems and set of interface standards) (Levis 1998).

Diverse views on architecture of interactive systems have different dynamic of evolution. Enabling technologies, for example, are developing very rapidly. They determine and constraint currently achievable efficiency of supporting user's behavior, as well as it's future transformation when technology is upgraded. Hence, early design activities phase, i.e. function analysis, requirements definition and particularly architecting have to be performed differently, i.e. incrementally. Design, development and evaluation of the limited number of most critical functions using currently available enabling technologies, i.e.


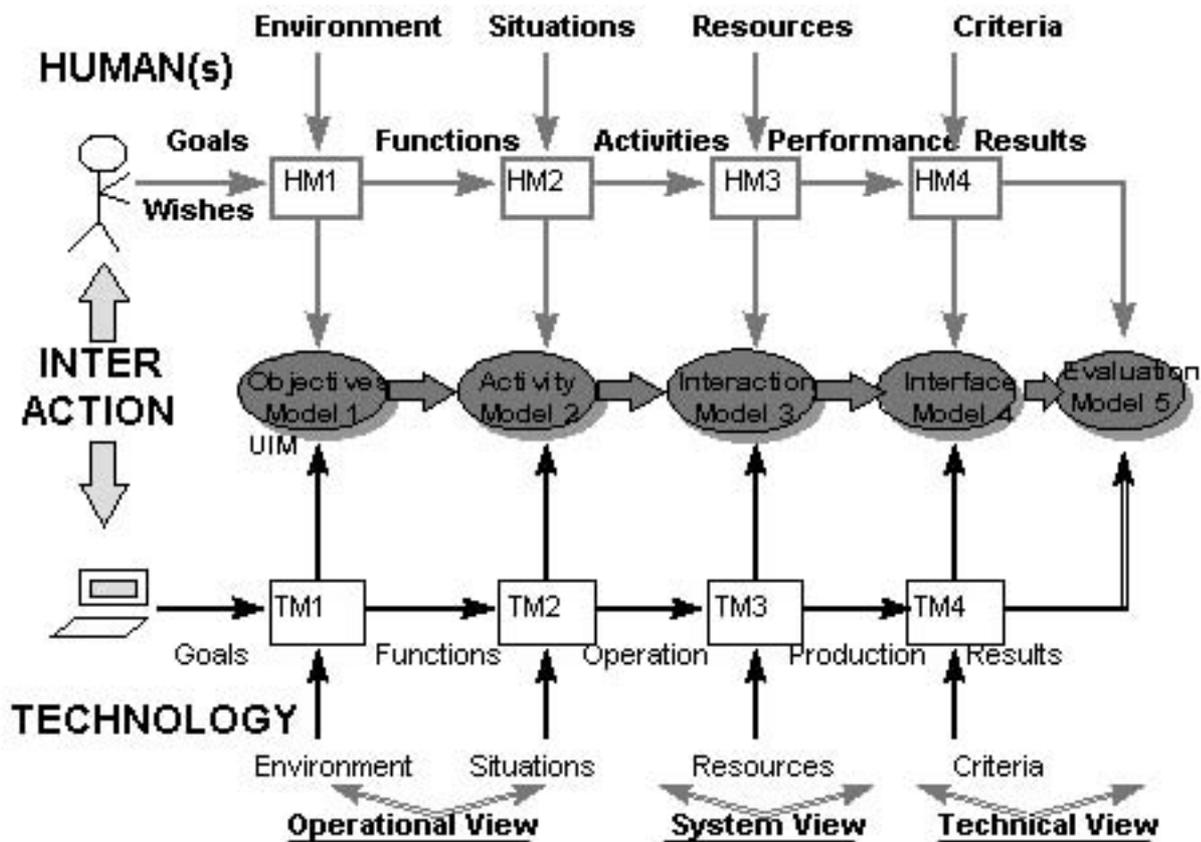


Figure 2. Evolutionary top-down multi-view system architecting and modelling.

"develop a little, test a little" from different architectural views becomes the only feasible way of user-centered engineering of interactive systems. That is why decomposed hierarchical structures of the human behavior models, technical and interaction models have to be considered in adaptive system architectures (Figure 2).

Such decomposition enhances flexibility, minimizes redesign and optimizes adaptation efforts and costs. Joint executable or so-called evaluation-model provides possibility to evaluate mutual compatibility and joint dynamic performance according to diverse quality of life and usability criteria (Venda and Venda 1995, Levis 1998).

Such modular hierarchical structures of the models provide also a basis and an efficient frame for system's life-long information- and usability-knowledge management.

4. ADVANCED USABILITY ENGINEERING LIFE–CYCLE

Usability engineering life cycle is an iterative process that comprises user- and task-driven design and development activities, as well as evaluation or so-called usability testing activities. They are focused on incremental architecting, modeling, prototyping and testing of the mentioned above submodels TM_i, HM_i and IUM_i, $i = 1,5$ (Figure 2) for different categories of target system's users from diverse architectural views. End-user participation from the very early design stages becomes crucial for system's usability.

Relevant usability testing methods have to be applied at different phases of the engineering life-cycle particularly

depending on system's overall goals and time- and cost constraints (Figure 3).

One of the first design activities which determine system's usability is devising it's purpose, selecting specific view point, analyzing human user's and supporting technical functions and building relevant functional hierarchy according to the following principles (Venda and Venda 1995):

- functions at the same level of hierarchy have to be exhaustive and not overlapping;
- they have to be formulated as a "verb–noun" phrase using the words familiar to end-users; and
- repetition of subfunctions at different level of the hierarchical tree is not allowed.

It is especially important to follow these rules when designing human computer interfaces using object-oriented programming languages.

Such top-down functional analysis and selecting of significant system's and interface functionalities via the usability test "Value of Functionality" is indispensable for focusing design and development priorities in a user-centered way. Incremental and hierarchical engineering approach is schematically presented in the Figure 3 as a L-approach to emphasize the above mentioned philosophy "develop a little, test a little." It differs from the traditional V- or waterfall system engineering approaches, where first all possible functions and relevant requirements are specified, designed, developed and only then evaluated.

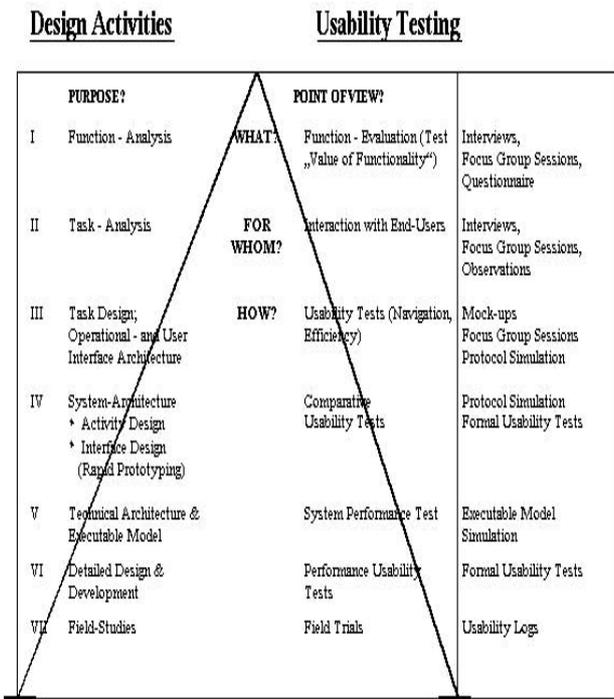
The reliability and effectiveness of the results of usability testing for discovering usability problems depend on the number of test persons and evaluators involved, representativeness of test


Figure 3. Λ-approach to usability engineering of interactive systems.

persons regarding expected user's population, number and representativeness of test-situations and scenarios, and fidelity of the prototypes, etc.

"Ideal" test with a representative sample of at least 20 test persons and three independent evaluators can reveal majority of main usability problems with probability > 70–75% when testing rather low fidelity prototypes (Nielsen 1993). Such exhaustive usability testing is rarely feasible in industrial practice and is often substituted by so-called low-cost or discount usability engineering methods, such as, for example, heuristic evaluation by single experts.

The following set of usability heuristics is typically used for evaluation (Nielsen 1993, Gerhardt-Powals 1996):

1. Minimize workload
   - locate displays and controls in easily reachable and visible zones;
   - elect locations depending on user's tasks, activities and expected motions;
   - provide enough free space for task performance;
   - automate unwanted workload (free cognitive resources for high-priority tasks; and
   - eliminate mental calculations, comparisons, etc.).
2. Improve visibility
   - locate most important and frequently used information in so-called primary areas or windows; and
   - minimize parallax, reflections, etc.
3. Support recognition
   - group data in consistently meaningful ways;
   - reduce uncertainty: display data in a manner that is clear and obvious;
   - use names and/or symbols that are conceptually related to function (context-dependent) and can be recognized without additional help or information;

- use the same names and/or symbols and their groups in the same locations for the same functions.
4. Support interpretation
   - present status and changing of status of interface elements or groups of elements;
   - use coding (form, color, size, length of lines, location, distance, graphical images, etc.);
   - provide multiple coding where appropriate;
   - fuse data: reduce cognitive load by bringing together lower level data into a higher summation;
   - allow user to detect and to interpret seldom situations and/or slight changes which may be crucial for system behavior by presenting critical values;
   - present not only data but also system processes which are important; and
   - provide meaningful aids to interpretation, i.e. use a familiar framework, everyday words, metaphors, etc.
5. Improve navigation
   - display data according to the task flow and to the eye movement or reading stereotypes (e.g. from top to bottom and from left to right); and
   - provide shortcuts that suit to specific task-flows, use-scenario, behavioral stereotypes or which support rapid access to the task-critical information.
6. Limit recall memory
7. Reduce information
   - reduce presented information only to the needed by the user at a given time;
   - allow users to remain focused on critical data; and
   - exclude extraneous information that is not relevant to the current tasks.
8. Optimize user control
   - limit data-driven tasks; reduce time spent assimilating raw data;
   - user controls the dialogue; and
   - provide feedback.
9. Prevent errors
   - reduce uncertainty;
   - consistency and standards; and
   - help users recognize, diagnose and recover from errors.

5. COMPUTER–AIDED PLATFORMS AND FUTURE TRENDS

5.1. Current Practice

Current industrial usability engineering practices show their rather low efficiency. The main reasons are usually following:

- significant underestimating and often lack-of-competence in performing user- and task-oriented system and user interface design activities;
- miscommunication between so-called usability testers or human factors professionals and system designers or developers, e.g. software engineers; and
- lack of integrated cross-disciplinary computer-aided platforms for consistent, mutually balanced and systematic multi-view performing of the above mentioned L-usability engineering activities (Figure 3), etc.

All this consequently devaluate the efforts of human factors

professionals and related investments in corporate usability engineering programs.

First, using expensive usability labs, performing formal usability tests or heuristic evaluations, etc. without being able under the given time and cost constraints systematically to consider obtained test results in system's redesign, does not contribute to better usability and quality of life.

Second, low cost usability testing methods often do not provide reliable enough basis for making right user-centered design decisions.

Third, many companies especially who are working in the same area perform similar low-cost usability tests instead of cooperative performing explicit and informative tests for typical interaction tasks.

Hence main research efforts have to be focused on turning quality of life and usability *studies* into relevant *engineering* approaches and *computer-aided engineering platforms.*

5.2. Future Trends

Systematic approach and notations for multi-view task-oriented architecting of flexible information systems are proposed by Levis (1999). Further enhancement of this technology with user-interface design and testing activities and with related knowledge-management tools is in progress.

Currently available Kansei Engineering methods and software tools allow to model human user's wishes and preferences and link them with static design images of relevant products. Further evolution of these technologies particularly towards dynamic or interaction modeling (Figure 2) has to be considered.

Internet technologies win recognition as a virtual platform especially for intercultural quality of life and usability engineering activities. Hence developing Internet-based databanks for different application areas, where explicitly tested (modular) models of human behavior and interaction with target technologies, i.e. HM_i, TM_i, UIM_i, $i = 1,5$ for different application areas, diverse target user groups, environments, etc. are available as a main data-patterns, will apparently challenge and drive further research and development in the field. Further standardization in this area will help to save time, efforts and costs and speed up developing human-friendly technologies and improving quality of life.

Rapid Macroergonomic Redesign

A. Majchrzak

Marshall School of Business, University of Southern California, Los Angeles, CA 90089-1421, USA

1. THE CASE AND REQUIREMENTS FOR INFORMATION TECHNOLOGY

Critical to the success of many organizations today is an ability to rapidly redesign as their market and customer needs change (e.g. Goldman *et al.* 1995). Not only must the specific human factors of a particular workstation be redesigned rapidly, but the macroergonomics of an organization needs to be rapidly redesigned as well. Macroergonomics is the study and design of jobs, organizational strategy, organizational structure, incentive systems, and training programs, in conjunction with the technology (Hendrick 1987). Evolving from sociotechnical systems (STS) theory (Cherns 1976, 1987, Trist and Murray 1993, Taylor and Felten 1993), macroergonomics is focused on designing these features of the organization so that human skills and abilities are effectively used to achieve personal and organizational goals.

Both macroergonomic and STS design have been traditionally implemented largely as a manual process whereby a design team, composed of a cross-functional mix of members of the organization, become engaged in their own effort at identifying alternative macroergonomic designs. This manual process involves interviewing all members of the organization, collecting objective data about problems in the business process, discussing implications of the data and interview results for technical and organizational redesign, and then persuading each other and management about alternative redesign options. Information technology has not generally played a large role in this process, but see Butera and Schael (1997) for an exception.

As organizations find that they need to speed up the process of macroergonomic redesign, however, the need for information technology becomes more apparent and pressing. In particular, information technology can be useful to an STS-oriented redesign process in a variety of ways. Information technology can hep in a number of ways, outlined under the following headings. Thes headings can be used as requirements of a decision support system for organizational designers. Section 2 onwards looks at TOP Modeler, a tool that meets these requirements.

1.1. Levelling the Knowledge Field

Any redesign should involve a range of stakeholders from shop-floor workers to managers, from line to staff. However, each stakeholder in the design process represents a different level of expertise and different abilities to argue confidently in front of others. For example, it is not unusual to find workers with less than a high school graduate degree unable to convince qualified engineers about problems of a particular technical approach. Information technology can provide decision support capabilities to all stakeholders to help them analyze solutions in a way that overcomes their differences in status, language, experience, and articulation.

1.2. Encouraging rapid Knowledge-based What-if

In considering an option for redesign, the implications of that option for all aspects of the organization should be identified and analyzed. This often takes time and information. Computer-based tools can speed up this process and provide instantaneous feedback, encouraging the consideration of more options and a genuine what-if approach to options not previously considered. Visualization of alternatives can be made much simpler and more realistic with computerized tools.

1.3. Conducting a Comprehensive Assessment of the Organization

The open-systems nature of STS designs means that all aspects of the organization should be considered during any design effort. Invariably, something "falls through the cracks" such as when the culture or incentive structures are overlooked until later in the design. Waiting to consider these factors until later, however, creates the risk that too many other factors will have become constrained, thus limiting the alternatives which can be considered. A knowledge-based tool can ensure that the comprehensive range of factors are always kept in front of the STS design team to avoid overlooking important issues.

1.4. Comparing the Current Organization to Known Best Practices

To encourage the integration of "best practices" into organizational analysis and redesign, design consultants often encourage design teams to visit best-practice sites or otherwise obtain an early understanding of best practices. It is difficult to keep these best practices in front of the designers as the design process unfolds and design decisions are made. A computer-based tool with a knowledge base of best practices can perform this function by allowing users to compare their design options against best practices and immediately receive feedback about gaps.

1.5. Seducing people into a Sociotechnical Systems Orientation

People who are in the greatest need of practising and benefiting from an STS orientation to redesign are often the ones least likely to attend an STS seminar or consciously decide to adopt an STS-oriented approach to organizational redesign. A computer-based tool can help with this learning by making the process of organizational analysis so engaging that users may not be aware they are even learning a new approach to redesign. That is, just as young students are not necessarily aware they are learning valuable reading skills when playing with certain computer games, organizational designers do not have to know they are learning valuable STS skills when performing an organizational analysis on the computer.

2. TOP MODELER

TOP Modeler is a computer-based tool to help designers *align* the strategic, organizational design, technological, and human resource features of an organization (TOP stands for technology, organization, and people). The theory behind TOP Modeler is that an organization will be able to achieve its desired business strategies only when the organizational design, technology, and human resources are aligned with each other and with that strategy. Often people improve one aspect of their organization (such

as a reengineered workflow or technology or organizational chart) without paying adequate attention to other aspects of their organization. The best-intentioned changes will fail to achieve successful improvements unless all necessary changes are made. However, some changes are more important than others, and it can be hard to find out which changes are most critical to achieve a systemic change in the organization.

TOP Modeler contains a knowledge base of systemic relationships among a variety of different features of a manufacturing organization. The knowledge base was developed with a $10 million, five-year investment of the US Air Force ManTech program by an industry-based consortium of the National Center for Manufacturing Sciences, Digital Equipment Corporation, Texas Instruments, Hewlett-Packard, Hughes, General Motors, and the University of Southern California. After development, the knowledge base was validated on one hundred companies. Users of the software include anyone involved in improving their organization: engineers designing a new technology, managers restructuring their organizations, business process re-engineers, and direct labor workers responsible for the continuous improvement of their manufacturing operations.

2.1. Defining a Business Strategy

To begin the analysis process, the design team must agree on a unit of analysis: What is the "organization" being redesigned? Sometimes design teams are confused and believe they are designing an entire factory when they have actually only been asked to redesign a particular department. It is important to obtain agreement on the scope of the organization being designed. For the knowledge base, the scope is immaterial; it has been structured for organizations as small as workgroups and as large as factories (with less than 200 workers).

Having defined a unit of analysis, users select a set of business strategies for their organization. There are three components of an organization's business strategy that must be established: business objectives, process variance control strategies, and organizational values. Sometimes these strategies are determined by management levels above the organization being redesigned. And sometimes the organization under redesign is given some flexibility in establishing its own strategies.

2.1.1. Business objectives

Business objectives are defined as measurable goals that the organization would like to achieve in the near future. The objectives are phrased as continuous improvement objectives rather than objectives which reach a static state; this is because competitors will drive any organization to improve continuously. Two types of business objectives have been identified: (a) those intended to reduce cost while simultaneously improving customer satisfaction — minimizing throughput time, maximizing quality, and maximizing changeover flexibility (reduced setup time); and (b) those intended to enhance the organization's future adaptability — achieving employee teaming, maximizing design for manufacturability, maximizing production process flexibility, and maximizing product development flexibility. Definitions for each of these objectives were developed by the industry consortium and are available at the click of a mouse www.topintegration.com.

2.1.2. Process variance control strategies

Process variance control strategies are the second component of an organization's business strategy. Process variances are technical variations (planned or unplanned) in the production workflow that create uncertainty in the processing of materials. In TOP Modeler there are 18 variances (e.g., quality of incoming material and employee turnover), selected by asking hundreds of production managers to list the process variances that most directly impact their ability to meet production goals. For any of the variances relevant to an organization, the organization must define a control strategy: Will the organization work to proactively eliminate the variance? Will the organization work to effectively cope with the effects of the variance on production? Or will the organization simply do nothing and let the effects of the variance propagate unfettered (the default strategy)?

2.1.3. Organizational values

Organizational values describe the preferences or underlying beliefs the managers have about how employees (management included) should behave. Such values describe the degree of collaboration, risk-taking, and continuous improvement expected of employees. After selecting the three different components of the business strategy, the tool helps users determine whether the strategic components are aligned with each other. For example, an organizational value of no risk-taking is inherently in conflict with a business objective of product development flexibility.

2.2. Describing the As-is Organization

With the business strategy described and aligned, the next step in a TOP Modeler alignment process is to determine the extent to which the current as-is organization is designed to achieve that business strategy. This is done by first describing the as-is organization and then comparing the as-is organization to the ideal organization needed to achieve the business strategy. To describe the current as-is organization, the knowledge base contains a comprehensive list of 11 feature sets for an organization. The 11 feature sets can be viewed as questions about what the current organization looks like:

1. What information resources do the workers in the organization have access to?
2. What do the production process characteristics of the organization look like?
3. For which decisions, if any, are workers empowered?
4. What are the employee values being demonstrated?
5. To what degree is customer involvement encouraged?
6. Which skills do employees have?
7. What does the reporting structure look like?
8. What norms does management actively encourage?
9. What tasks and activities do employees perform in their jobs?
10. What do the general technology characteristics look like in the organization?
11. What are the performance measures and rewards for employees?

For each feature set there are specific features for describing the organization. In total there are over 300 specific features that have been identified for describing the current as-is organization.

2.3. Comparing the As-is Organization to an Ideal

When a user selects a business strategy, this has the effect of defining an "ideal" organizational profile, which the organization should adhere to if the business strategy is to be achieved. Ideal profiles in TOP Modeler are specific to the different business strategies and were developed based on a variety of sources (including an extensive review of empirical academic studies, company best practices, the practical experience of the industry consortium involved in developing the knowledge base, a scientific validation survey of 80 companies, and 20 cases of closely observed use of the knowledge base).

When a user has described both the business strategy for the organization and the current as-is state of the organization, this as-is state can be compared against the ideal. The results will indicate gaps between the two; with gaps interpreted as opportunities for improvement. For example, if the business strategy required a particular empowerment feature and the current as-is organization did not provide that degree of empowerment, then a gap in empowerment would be identified. TOP Modeler helps to quickly identify each gap, either interactively or as lists of improvement opportunities. The emphasis in TOP Modeler is to provide a comprehensive list of improvement opportunities, not just selected opportunities, to ensure the design team does not allow anything to "fall through the cracks."

Once a comprehensive set of improvement opportunities is identified, STS tenets suggest that priorities must be set by the user in order to ensure user commitment to the final implementation plan. Users may set priorities based on management dictate or detailed cost-benefit analyses. Although the tool does not set the priorities, it can provide support by informing the user about which business strategies are affected by each gap, as well as allowing designers to quickly model the proposed new organization to determine whether gaps would be closed, given a proposed prioritization.

3. LESSONS LEARNED FROM DESIGNERS USING TOP MODELER

Thus far, TOP Modeler (and its precursors Action, TOP Integrator, and Hitop) has been used in over 50 cases of organizational and/or technological change. The companies that have used it have ranged from very small companies to very large companies, located in the US, Brazil, and Switzerland. Here are some of the lessons learned.

3.1. IT Can Have Unforeseen Uses in Macroergonomic Design

3.1.1. Strategic plans for small companies

Used by government-sponsored manufacturing consultants (e.g., Switzerland's CCSO), it helped small companies to develop strategic plans for restructuring. In one case TOP helped the consultant to understand that the company's initial strategic plan was unlikely to succeed until management agreed to reduce the amount of variation it allowed in its process.

3.1.2. Persuading clients not to relocate

Used by the large software vendor EDS, it helped a client manufacturing company decide not to relocate its plant from one foreign country to another, because it looked too expensive to close the gaps created by the move.

3.1.3. Joint ventures between large companies

Used by the large manufacturer General Motors (GM), it helped decide whether a joint venture plant was ready to be opened. GM decided on delaying the opening because TOP helped to reveal differences of opinion in how to manage the workforce.

3.1.4. Better good practice for a small manufacturer

Used by the small manufacturer Scantron, it showed whether their good practices needed improving. TOP helped them to discover that while they did indeed have many best practices, they needed to involve the workforce more closely with the suppliers and customers, so that's what they did.

3.1.5. Changing technology in a large manufacturer

Used by the large manufacturer Hewlett-Packard, it helped identify the workforce and organizational changes needed for their new production technology to operate correctly. The result was a substantial improvement in ramp-up time when the new product and production process were introduced.

3.1.6. Improving teamwork in a maintenance crew

Used to redesign a maintenance crew at Texas Instruments, it revealed how the envisioned team approach needed several important improvements before startup.

3.1.7. Pinpointing inconsistencies in manufacturing objectives

Used by a strategic planning committee at a large manufacturing company, it identified areas of misalignment among elements of a new strategic plan (in this case between quality and throughput time).

3.1.8. Revealing the implications of manager-to-manager agreements

Used by a divisional manager at a manufacturing plant, it enabled him to verify the business strategy given him by his group manager. TOP showed he had agreed to deliver on new product development without having authority over the necessary people, skills, and other resources. He went back to his group manager to renegotiate these resources.

3.1.9. Unforeseen uses: some conclusions

These examples suggest a diversity of applications for computer-based STS design tools. Some users find its versatility frustrating since they are more familiar with simulation packages that provide a finite and well-defined set of functionalities. Others recognize that opportunities for injecting a knowledge-based approach into macroergonomic design can seldom be known or specified in advance; they place a high value on versatility. Valuing the versatility seems to be important to the ultimate successful use of information technology in macroergonomic design. Those who tend to value the versatility appear to have the following characteristics:

- Deep understanding of their own organization (including its strategy and operation).
- Basic understanding of the principles of organizational design and human behavior.
- Successful at translating externally derived information about possible process improvements (from books, consultants, and site visits) into the organization.

- Responsibility and authority to suggest process improvements.
- Good group process and presentation skills.

I have also found that successful users engage others in the organization in discussions about alternative ways to use and diffuse the tool. These discussions are often quite value-laden. For example, one manager refused to allow workers unsupervised access to TOP Modeler because, in his words, "they might begin to believe that they know more about organizational design than I know and question my authority. I don't want that; that could lead to chaos." This suggests that having discussions early on about the role of information technology in the macroergonomic design process will help to clarify expectations so these latent values do not come up later to kill the pilot experiences.

3.2. Macroergonomic Designers Don't Like to Admit IT Helped Them

I found several examples where discussions among design team members about macroergonomic design issues proved contentious and frustrating without the use of a knowledge base tool. I would then introduce TOP Modeler to help users reformulate their strategy in greater detail, the discussion usually became more productive, leading to a quick consensus and an action plan. Yet, when asked if TOP Modeler helped them, the design team said no.

Upon further examination, I found that some users believe the knowledge base of TOP Modeler cannot publicly provide any value to them since it would then suggest that they could not perform their own work adequately without it; and no one who is proud of their ability to redesign organizations wants to believe in any dependence or help from a machine! If left unmanaged, this opinion of not attributing value to the knowledge base is detrimental to its further use, especially if an organization is in the piloting stage to determine whether company-wide use should be considered.

I found two remedies to this situation. First, people who believe that they are expert organizational designers are particularly threatened by the tool and will sabotage it unless they have a particular role to play in its use or deployment. Possible roles include integrating the tool into an existing organizational change process which is controlled by the experts, helping experts understand how the tool can be used to more quickly and widely disseminate their own personal knowledge bases, and more clearly identifying the boundaries between the expert's organizational change efforts and those of the users of the tool.

The second remedy is to agree, at the outset of a pilot effort, on the basis for evaluating the success of the information technology. I have used a variety of different metrics for success. One such metric is, Did the user learn anything? In a systematic study of 30 users, I found that 80% reported learning something about TOP integration or about their own organization from using TOP Modeler. Another such metric is, Did the user learn what they had expected to learn? I found that only 50% reported yes to this. Yet another metric is, Could the user generate action plans from its use? In that same study, I found 100% of the users were able to generate action plans as a result of using the tool. A final metric I used was, Were the action plans implemented? In cases where I was told the outcome, I found that about half reported

implementing the action plans. It is clear that the choice of metric will affect how successful the pilot appears to be.

3.3. Who is Responsible for Making Macroergonomic Decisions?

TOP Modeler was designed as a decision support system which would (a) remind users of the comprehensive array of TOP features when redesigning their organizations and (b) provide them with data about the nature of systemic relationships among features so that decisions about organizational redesigns would not be limited to single functional units, single sociotechnical elements, or single interventions. From this perspective, the ideal user would be a person who interacted with the knowledge base, trying out different ideas about business strategies and alternative future designs of the organization, eventually to draw conclusions about the trade-offs for different design options and to decide on a particular design.

I found this ideal user describes a very limited set of the people who are likely to actually use the tool. Most users are not given the time or authority to consider alternative macroergonomic designs, in part because macroergonomics is an interdisciplinary issue that touches on many different functional responsibilities. Instead, they see their role as one of considering a specific macroergonomic design when there is a specific problem with the current design. As a result, such users are focused on fixing a specific problem in the least costly, most advantageous fashion. With this perspective, they are pressed for time and need quick results; they do not appreciate a knowledge base that reminds them of the comprehensive and systemic nature of the problem. Nor do they appreciate a knowledge base that has no cost figures associated with it (it is impossible to generate cost figures for a generic knowledge base).

This means there is often an immediate mismatch between the user's needs to quickly solve a problem and the tool's functionalities to help users solve systemic problems. I found about half of the users to effectively manage the mismatch by using the tool as a check on their decision-making process (e.g., as they decided on their business objectives, they would use the tool to make sure the objectives were not in conflict). The other half of users, however, found the tool extremely frustrating because, in one user's words, "I want it to tell me what to do. Don't just list my problems. Tell me which one to fix first." This suggests that an additional requirement needs to be added to the requirements for STS-based information technology described at the beginning of this article: when users are unwilling or unable to accept decision-making responsibility for their macroergonomic design process, only an expert system tool may be of value.

In the spirit of STS — based on the assumption that there are many different ways to achieve an effective outcome and that for users to be committed to an action, they must create it themselves — it is questionable whether an expert system would actually prove useful. However, not enough research has been done to find out what happens when expert systems are given to those who want them. Do the users implement the expert system's suggestions or do they find a different excuse?

4. SUMMARY

This article began with several requirements for the use of information technology in macroergonomic design. To indicate that

these requirements were feasible, it went on to describe an IT-based tool that fits most of them. Finally, it described some lessons learned from using the tool in macroergonomic design. These lessons clearly indicate there is a role for information technology.

Risk Management

B. Zimolong and G. Elke

Department of Psychology, Work and Organizational Psychology, Ruhr University Bochum, Germany

1. MANAGEMENT PRINCIPLES

Management as a function comprises all processes and functions resulting from the division of labor in an organization such as planning, organization, leadership and supervision. In most organizations more or less formalized management systems serve to structure, develop and direct business processes. Systems differ with respect to branches, nature of business, company size and Human Factors such as culture and policy. As firms grow in size management systems gain complexity and become difficult to use, thus resulting in domain-specific systems such as management of occupational safety, health, loss control, environmental resources, quality or personnel.

Risks include all aspects of accidental losses that may lead to any wastage of the organization's, society's and environmental resources. These resources cover personnel, materials, machinery, procedures, products, money and natural resources: soil, water, energy, and natural areas. Losses may result from the presence of potential harm to one or more elements of the system, either because of the interactions with other elements inside the system or with the environment outside the system. Risk is the measuring stick for this potential, which may be defined as the probability that harm will become manifest within a certain period.

Risk management can be understood as an approach to reintegrate the domain-specific management systems into an integrative management concept. The essence of risk management is to control risks, i.e. to prepare, protect and preserve the resources of the enterprise, the society and the environment. Risk control strategies may be classified into four main areas: risk avoidance, risk retention, risk transfer and risk reduction.

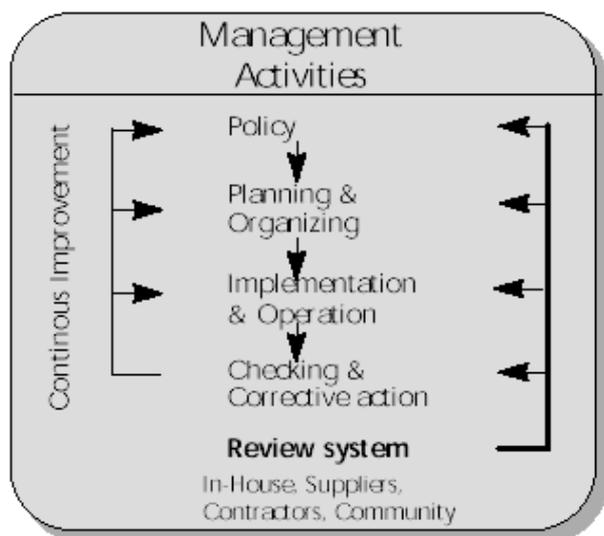
The system elements to be managed include among others:


Figure 1. Management control cycle system based on the environmental management approach in ISO 14001 and BS standard 8800.

- Health and safety of employees, suppliers, contractors, customers and residents of the community (e.g. improvement of public health and safety).
- Reliability and safety of products and services; of materials, equipment, work systems and plants; of transport of hazardous goods.
- Integrated pollution control, radiation protection, waste minimization, recycling and waste disposal.
- Sustainable management of natural resources (soil, water, natural areas and coastal zones), reduction in the consumption of non-renewable energy.

Sustainable development means the improvement in the quality of life that does not impair the ability of the ecosystem to maintain life. Managing for sustainability is predominantly based on the principles of intergenerational and intra-general equity as well as social and ecological balance (Hutchinson and Hutchinson 1997).

Many of the features of risk management are indistinguishable from the sound management practices advocated by proponents of quality and business excellence. Quality and environmental management systems have been introduced as international standards prepared by the International Standards Organization (ISO) in Geneva. The European Community (EC) Eco-Management and Audit Scheme (EMAS) agreed by the EC states in 1992 was set up as a voluntary certification scheme for the assessment of a company's environmental impact. The British Environmental Standard BS 7750 and EMAS contributed to the development of the ISO 14000 series "Environmental Management Systems" standards. Initiatives to launch an international standard on "Occupational Health and Safety" (OH&S) management systems based on the British Standard BS 8800 (1996) have been delayed. BS 8800 shares common management principles with the ISO 9000 "Quality management" series and the ISO 14000 "Environmental Management" standards. In many countries, national guidelines give guidance on OH&S management systems.

The management approach of the ISO standards are based on generic management principles that are derived from different theoretical and organizational perspectives. The elements of the systems are considered to present "best practices" of successful enterprises. They are designed to be used by organizations of all sizes and regardless of the nature of their activities. The key elements of a generic management system are integrated in the management control cycle outlined in Figure 1. The cycle is based on ISO 14000 (environmental management) and on standard BS 8800 designed for an OH&S management system. The key elements from BS 8800 are set out below:

- *Effective OH&S management* stands for developing, coordinating and controlling a continuous improvement process by setting and adjusting OH&S standards. The corporate policy is summarized in a vision, containing perspectives for the future and providing an idea of identification for all members of the organization. Policy and strategy can only become reality if they are translated into a stringent planning process. Both internal and external assessment methods can be used for the evaluation of a strategy's effectivity and efficiency: This needs to be done systematically through regular reviews of performance based on data from monitoring activities and from audits of the OH&S management system.

- *Formulation of an OH&S policy* addresses the preservation and development of physical and human resources and reductions in financial losses and liabilities. The policy provides guidance on the allocation of responsibilities and the organization of people, of resources, communication and documentation. It influences design and operation of working systems, the design and delivery of products and services and the control and disposal of waste. OH&S policy should be aligned with people management policy to secure the commitment, involvement and wellbeing of employees, of suppliers, contractors and customers.

- *OH&S planning* requires a comprehensive organizational approach that emphasizes prevention and involves risk identification, evaluation and control. Hazards are identified and risks assessed and controlled according to a systematic plan before anyone or anything could be adversely affected. Pro-active planning particularly adopts procedures to set OH&S objectives, devise and implement plans to meet them and to monitor both the implementation and effectiveness of these plans. Reactive planning means that measures are only considered after the occurrence of incidents such as loss-damages, accidents or deficient safety performance.

- *Implementation and operation.* Designing OH&S structures concerns the divisions of responsibility and distribution of formal authority, the creation of hierarchical or lean structures, the degree of self-regulation of work groups and units and the formal relations between groups and leaders. Establishing and maintaining control is central to all management functions including OH&S. The allocation of OH&S responsibilities to line managers and work groups serves as an important tool to foster the integration of OH&S into the daily work activities with specialists acting as advisers.

- *Checking and corrective actions* are the final steps in the OH&S management control cycle and part of the feedback loop needed to enable the organization to maintain and develop its ability to control successfully risks. Both qualitative and quantitative measures provide information on the effectiveness of the OH&S system. Learning from experience is supported through performance reviews and independent audits.

- *Management review* is a periodic status review of the OH&S management system and considers the overall performance of the OH&S management system; of individual elements and the findings of audits. The review identifies the actions that need to be taken to adjust any deviations.

2. RISK MANAGEMENT SYSTEM

The above principles seem to suggest that science and industry have reasonable models of how safe and reliable organizations work. This is not the case. The standards only presume that the targets of health, safety, quality and environmental protection are achieved by doing the right things within a reproducible structure, they do not offer guidelines based on scientific research and company's "best practices" which allow to evaluate if the things were done right.

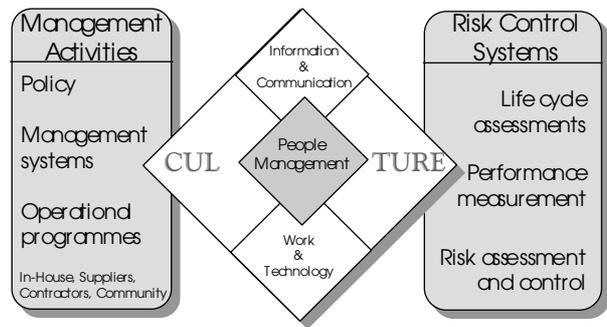
A holistic concept of risk management requires the system to be integrated into the processes of an organization, e.g. integration of health, safety and environmental (HSE) activities


Figure 2. Holistic risk management system.
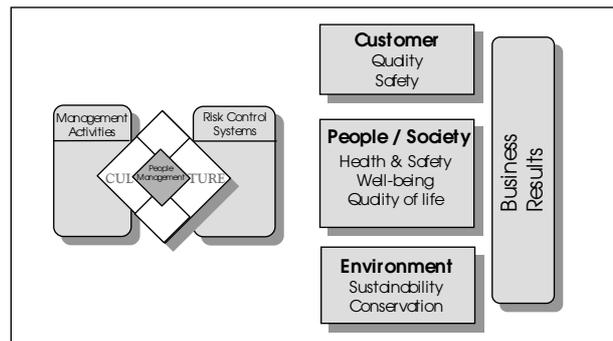

Figure 3. Multidimensional targets of risk management.

into the daily routines of managers, supervisors and employees and of HSE standards and processes into the life cycle of products, services and work systems. Finally human resource management principles have to be applied to foster long-term commitment and involvement of the workforce to HSE, including suppliers, contractors and partner firms.

The Holistic Risk Management System (HRMS) as suggested by Zimolong (1997) has been extended to comply with the management control cycle of the standards of BS 8800 and ISO 14000 (Figure 2). HRMS covers three domains: health, safety and environment. The system addresses the key elements of management as people management, management of information and communication, (re)design of work and technology and creation of an HSE supporting culture. Generic management activities include those of the management control cycle of the standards as described above. The elements of the risk control system to be managed are first of all the risks associated with the life cycle of systems, products and services; second, the process of continuous risk performance measurement as part of the information and communication management; and third, risk assessment and risk control. The outcomes of the risk management process as seen in Figure 3 are assessed with regard to multidimensional targets, which include reliability, quality, safety, health and ecological sustainability. They are given equivalent weight at improving business results. These goals are, however, seldom compatible, often contradictory, may raise internal and external conflicts and have to be solved on company's or society's level, if at all.

3. KEY ELEMENTS OF RISK MANAGEMENT
3.1. People Management and Culture
The implementation of HSE vision and policy into missions and operational programs is a company-wide task and not only the

duty of each individual to comply with standards, regulations and laws. Corporate HSE policy must aim at prevention and integrate the targets of health, safety, reliability and sustainability into business performance, including systems, processes, working conditions, external relationships to business partners and the public. Implementing vision and corporate policy is helped by the creation of a positive culture that secures involvement and participation at all decision levels. Managers take full responsibility for controlling all those factors that could lead to ill health, injury, loss or damage. Corporate HSE culture becomes visible in the way complaints are dealt with, suggestions are treated, errors, mishaps and incidents are blamed for (guilt-free atmosphere) and especially in how problems are solved in daily activities.

Effective management of HSE requires the support and commitment of the employees. The knowledge and experience of the workforce is a valuable resource in the development and operation of the risk management system. Structural arrangements for HSE consultations and representation provide effective means for involving the workforce, for example, HSE committees. Participative risk assessments and controls promote the active involvement of the workforce at the operational level. Implementing an effective HSE people management system requires appropriate structural conditions. Among those to be considered are:

- integrating HSE goals into corporate goals;
- assessing management and employees with regard to multidimensional targets, including HSE objectives; and
- planning and improving people resources, which includes the regular and systematic examination of all processes within personnel management as well as their adaptation to changes in general conditions.

Management of an organization's human resources includes such activities as personnel planning, recruitment, placement, development, performance appraisal, training and competency assessment, counseling and guiding of individuals and groups (leadership), payment concepts, back-to-work programs and rehabilitation at the workplace. Such personnel systems include valid selection procedures for hiring and promotion purposes, performance appraisal and review systems to ensure that the person is measured on the right goals and standards and receives accurate feedback, effective training procedures for the development process and labor relations that are conducive to employee motivation.

Personnel development of people's capabilities means in-company training focused on the company related targets, closing the gap between the actual state of the art and the target state through qualitative personnel planning and supporting and realizing career planning with personnel-related targets. Contractors, suppliers and temporary workers have to be included in the training program according to the level of risk to which they may be exposed or could cause.

With respect to HSE a major purpose of the performance appraisal process is to modify behavior, to feed back information to the employee for counseling and development purposes so that the person will start doing or continue doing the activities critical to effectively performing on the job. The feedback must lead to the setting of and commitment to specific HSE goals. Goal setting affects performance by directing the attention and actions of individuals and/or groups, mobilizing efforts, increasing persistence and by motivating the search for appropriate performance strategies. Setting difficult, yet achievable goals and providing performance feedback, is widely accepted as to be one of the most powerful behavioral modification techniques. Performance feedback is thought to fulfill several functions: as a reinforcer when it conveys success, as a punisher when it conveys failure and as an antecedent when it prompts or cues the conditions under which responses will be reinforced and/or punished. Perhaps it is because it can operate in all these ways at once that feedback has been found to be an especially powerful behavior modification technique (Locke and Latham 1990).

External and internal rewards play a significant role in getting people to accept goals and motivating them to maintain goal-relevant behavior in the long-term. The key reward in organizational settings is probably not feedback but rather the consequences to which feedback leads such as recognition, praise, raises, financial rewards and promotions, privileges, material or monetary rewards, which can be embedded within compensation or performance appraisal systems and preferred activities or assignments. Internal, self administered rewards that can occur following high performance include a sense of achievement based on attaining a certain level of excellence, pride in accomplishment and feelings of success and efficacy.

According to a German study (Zimolong 1999), the most frequently documented as well as practiced personnel systems in OH&S are performance appraisal, leadership, training and reward systems for managers and supervisors. In a successful HSE management system at least two personnel systems are combined with leadership, mostly appraisal and reward systems. Companies striving to get better do not yield typical patterns of personnel systems in their specific transition phase, however, they use the most systems, whereas poor companies use the fewest systems. Which system they prefer depends on the organizational and cultural characteristics of the company. Organizations differ fundamentally in how they control the compliance with the application of personnel systems. Successful companies have deployed monitoring systems. If deviations from standards have been observed, necessary corrective actions are undertaken by the personnel department or by line managers to remedy any deficiencies.

The deployment of corporate targets to the level of teams and individual employees is an essential step towards the achievement of HSE. Management by Objectives (MbO) in a cooperative fashion meets one of the most important requirements of HSE, that of involving all employees. Goal agreement concepts on the individual level cannot be efficient unless there is a functioning system of regular feedback and if consequences are to be expected in the case of goal deviation.

Whereas participatory approaches were pursued in the past mainly under the aspect of the quality of working life, it is the optimum use of human resources nowadays that is emphasized in people empowerment, making it a predominantly an economic target. Teams usually have a higher degree of empowerment. Not only do they accomplish their regular tasks, but also they deal with all processes concerning their unit. This means that they integrate organizational, planning, supervision and improvement tasks, which were traditionally performed by supervisors or special functions/departments. Transient team concepts with

problem-solving involvement include both quality circles and project teams. Forms of permanent teamwork with different scopes of problem-solving and decision-making autonomy have been introduced not only in the manufacturing area, but also in the development, sales and administrative areas.

3.2. Information and Communication

Risk management means coordinating and controlling a continuous improvement process through formulating, setting and adjusting objectives and standards, monitoring and reviewing deviations from standards and providing remedial actions. From this point of view, risk management is a communication concept related to person, group and unit levels. It includes the idea of a complex network of interrelationships at the intragroup, intergroup and even interorganizational levels. In practice, communication and information between people, groups and units is difficult to organize and maintain due to physical, social and psychological barriers. Organizations are open systems and linked in multiple ways with the social and political environment. Successful organizations establish and maintain arrangements for identification and reception of relevant HSE information from outside the organization. This may include new legislation, or at least amendments, information and developments in HSE (best practices) and information necessary for the identification of hazards and control of risks, for example from customers or suppliers.

There is a variety of systems and procedures which ensure the communication of necessary information to all people in the organization who need it. Written statements of HSE policy, documented performance standards, reporting systems and newsletters are quite a few examples. Direct forms are oral presentation, face-to-face discussions at consultative meetings, health and safety tours, team briefings as well as monthly or weekly "tool box talks" on health and safety issues. The new information and communication technologies play an important part to support the processes, for example intra- and Internet communications via e-mail, electronic boards and management information systems.

Organizations need sufficient knowledge, skills and experience to identify and manage HSE risks effectively. Documentation is the process of assembling and retaining HSE knowledge. Accessibility of data is a critical factor to use the knowledge, for example, key documents, such as working procedures, records and instructions should be accessible at the point of use. Other options are:

- Training managers to a sufficient level of competence and keep them up-to-date with developments in HSE.
- Employing appropriate HSE professionals as part of the management team.
- Hiring external specialists support where in-house expertise and/or resources are insufficient to meet the organization's needs.

3.3. Design of Work and Technology

The outcomes of safety, health and well-being depend to a significant degree on the installation and maintenance of safe and reliable technology, as well as on ergonomic and psychosocial aspects of work design. General topics and methods of systems safety engineering are concerned with guarding energy sources,

design and redesign of machinery, equipment and processes, application of environmental standards and establishment of inspection systems, such as statutory engineering inspections of pressure vessels, cranes and lifting machines, or electrical installations (Ridley 1994).

Ergonomic and psychosocial aspects of work are potential contributors to the health and well-being of employees and organizations. Their health effects can also be regarded as contributors to work motivation, or work performance. From an ergonomic perspective, the design of the environment, workstations, tasks, work organizations and the tools or technology should reasonably accommodate the employees' capacities, dimensions, strengths and skills. Particularly, it should accommodate the human sensory capabilities, support the decision-making processes and adapt to the human performance abilities. Error-prone designs place demands on performance that exceed capabilities of the user, violate the user's expectancies based on his or her past experience and make the task unnecessarily difficult, unpleasant and error-likely. One example are back injuries: high physical energy expenditure, no variation in work movements and postures, prolonged standing, sitting or stooping, or repetitive work can contribute to the development of musculoskeletal problems, low-back pain and back disorders.

Critical aspects of the success of ergonomic interventions for providing health and psychosocial benefits are a strong management support for the ergonomic program. Further aspects are: the involvement of managers, supervisors and employees, the willingness to participate in defining problems, proposing solutions and improving work practices; and the application of engineering improvement to reduce biomechanical and physiological loads.

There are various characteristics of working that have generally been shown to have negative physical and/or psychological consequences, for example, machine-paced work, a lack of task control, high job demands, shiftwork, time pressure and poor supervisory relations. A person normally copes with transactional periods of stress by either altering the situation or controlling his or hers reactions. Problems arise when work conditions are in conflict with human capacities and expectations over a long period and when coping fails.

The extent of the negative consequences varies from individual to individual depending on the perceived threat, individual constitution and coping mechanisms. Tension, boredom, worry, anxiety and irritability are inevitably some of the first indicators of strain. Emotional stress reactions are quite normal responses. Short-term stress reactions may include increases in blood pressure, adverse mood states and job dissatisfaction. Depression and apathy are later symptoms. Long-term stress reactions may even accumulate to cardiovascular diseases and upper extremity disorders (Kalimo et al. 1997).

Job control and social support are beneficial factors for well-being and job satisfaction. The person can have control over various job demands, such as the task itself, pacing of the work, work scheduling, the physical environment, decision-making, other people or mobility. When job control is high, the other job demands tend to have less potential adverse effects on health. Social support is thought to exert a protective function during conditions of stress, i.e. to "buffer" a person against the harmful effects of the social environment. Evidence for the beneficial effect

of job control and social support is conclusive enough to promote better job designs and interpersonal interaction at the workplace.

The criteria in job design deal with the physical work environment, compensation systems, institutional rights and decisions, job content, internal and external social relations and career development. According to quality of working life principles the following characteristics of job content are of main interest: variety of tasks and task identity; feedback from the job; perceived contribution to product or service; challenges and opportunities to use one's own skills; and individual autonomy. Depending on the degree of autonomy, the team design approach allows members to regulate their work activities by themselves. People get a better idea of the significance of their work and create greater identification with the finished product or service. If team members rotate among a variety of subtasks and cross-train on different operations, the team can become more flexible. Teams with heterogeneous background also allow for synergistic combinations of ideas and abilities not possible with individuals working alone and such teams have generally shown higher satisfaction, better involvement and superior performance, especially when task requirements are diverse.

In any redesign process there are tradeoffs among specific improvements and achieving the best "overall" job design solution. There is no perfect job design that provides complete psychological satisfaction and health for all employees and maximizes the outcomes of the organization. Making jobs more mentally demanding increases the likelihood of achieving people's goal of satisfaction and motivation, but may decrease the chances of reaching the organization's goals of reduced training, staffing costs, decent wages and error-free products and services. Which tradeoffs will be made, depends on the outcomes the organization prefers to maximize.

4. RISK CONTROL SYSTEMS

4.1. Life Cycle Assessments

Production is cyclical in nature. Raw materials are taken from the earth, processed, used and returned to the earth as waste. Life cycle assessment (LCA) measures the continual process of extraction, use, disposal and extraction. The LCA, commonly referred to as "cradle-to-grave" assessment, examines all aspects of environmental impacts associated with the life of a product or service from the extraction of the raw materials through the pre-production process to the distribution and final disposal. LCA is an integral part of an ecological auditing procedure and provides a systematic framework for impact analysis and the continual updating of procedures. LCA analyses all environmental impacts related to product development and permits the comparative analysis of the environmental impacts of similar products. Assessed is the product rather than the system, as in EMS, but does not include the impacts of the processes involved, such as energy usage. LCA cannot be restrained to just one site or indeed to one company, it requires significant cooperation down the supply chain to produce a product LCA. Since all areas of production have environmental impacts, each stage needs to be traced back to the source to fulfill the requirements of the LCA process. This includes the life cycles of other embedded systems, for example of capital equipment, work systems and goods.

The term system is used to clearly describe defined activities, processes and equipment during the lifetime of the system. The overall lifecycle of a product may comprise the following phases: conception and planning; design and engineering; use/operation; modification and maintenance; demolition and disposal. With regard to OH&S the system is to work the way it was planned and nobody should be harmed by an accident, toxic substance or malfunction. OH&S and ecological management share common objectives. For example, the replacement of hazardous raw materials and the auditing of all substances used in the production process is one measure to improve OH&S as well as one way to minimize waste.

Risk control systems are the basis for ensuring that adequate performance measurement systems and both proactive and reactive control activities are provided and maintained during the operational lifecycle. At the input stage, the aim is to minimize hazards and risks entering the organization. At the process stage, the focus is on containing risks associated with the process. At the output stage, controls minimize the export of risks off-site that may arise from work activities, products and services (HSE 1997). Particularly the system safety concept emphasizes that hazards built into a technology or activity and the preventive measures to eliminate and control them are largely conditioned by the decisions made in the planning and design phase of the activity.

In all stages of the life cycle of a system performance standards are important to control the risks. They cover the physical resources (i.e. workplaces, materials and substances, plants), the human resources (recruitment, selection of personnel and contracting organizations) and the information related to health and safety, risk control and positive health and safety culture. From a systems point of view, unsafe acts and unsafe conditions are substandard practices and substandard conditions, i.e. deviations from an accepted standard or practice. A vast number of substandard conditions involve poor ergonomic design of machine, equipment and the work environment. It is essential to consider these practices and conditions only as symptoms, which point to the latent failures (Wagenaar *et al.* 1994) or basic causes behind the symptoms. The origins of deviations from a standard are deficiencies in management and organization. Detailed lists that cover different factors such as work environment, individuals doing their job and management are provided in Wagenaar *et al.* (1994).

A holistic risk management considers all phases of the life cycle of the plant or facility it exploits and the goods and services it delivers. Each phase is an activity that must be managed according to the formulated policy in its own right and which must feed forward into subsequent phases and have a feedback loop to facilitate organizational learning processes. This approach requires the development and deployment of a performance measurement system, based on a combination of both qualitative and quantitative as well as proactive and reactive monitoring data.

4.2. Performance Measurement

Information needs vary at different levels and in different parts of an organization. For example, senior staff need key performance indicators to confirm that the HSE system is working effectively. At the operational level many other performance indicators may be necessary to monitor implementation and effectiveness of risk controls. Large organizations have developed a system where annual measurement summaries are reported upwards to senior

staff. Both proactive and reactive monitoring data are used as outcome indicators to determine whether objectives are achieved. Proactive monitoring data include:

- number of staff suggestions for HSE improvements;
- staff perceptions of management commitment to HSE (e.g. from an in-house survey);
- frequency of HSE audits;
- quality of health surveillance reports; and
- workplace exposure levels.

Reactive monitoring data include:

- number of unsafe acts observed on a safety tours;
- unsafe conditions examined on a "walk through" basis;
- near misses reported from staff on a monthly basis; and
- lost-time accidents sampled from healthcare station.

Selecting appropriate outcome indicators depends on the chosen objectives. Proactive monitoring is used to check compliance with the organization's HSE activities, for example to confirm by signature that the weekly "tool box" talks have been attended by all members of a unit. Reactive monitoring is used to investigate, analyze and record HSE management system failures — including incidents and accidents. Measuring performance against predetermined standards is based on a proactive examination of both hardware (premises, plant, substances) and software (people, procedures and systems, including individual behavior). Deviations from standard reveal when and where action is needed to improve performance.

In addition to routine monitoring of HSE performance, there is a need for periodic audits that enable a deeper and more critical appraisal of all the elements of the risk management system. Concerning nature and extent of an audit, it may cover the whole risk management system or part of it; technical matters concerning plant, equipment or process; corporate processes or functional units. A validation audit is intended to control the effectiveness of the risk management system, a compliance audit verifies whether the organization or part of it is complying with its own standards and procedures.

4.3. Risk Assessment and Control

Risk assessment and control is part of the proactive HSE planning approach that emphasizes prevention. The main purpose of risk assessment is to determine whether planned or existing controls are adequate.

The following steps are necessary to carry out a risk assessment:

- identify hazards;
- estimate the risk from each hazard, e.g. the likelihood and severity of harm;
- decide if the risk is tolerable; and
- prepare risk control action plan (if necessary).

A hazard is a source of potential harm or damage or a situation with potential for harm or damage. The harmful effects of health hazards, such as hearing loss, cancer, liver damage, silicone are regarded as illnesses. However, back pains may result from improperly designed chairs, headaches from poor ergonomic layout of VDT work place. This exceeds the traditional view on accidents. Consequently, controls are not always identical: the prevention of contact or its reduction to a level where no harm is done is valid only for hazardous or toxic materials, whereas illnesses resulting from poor design require ergonomic standards,

planning and sometimes complete re-installation of the working system.

In the simplest case, hazards can be identified by observation, comparing the circumstances with the legal standards and guidance. In more complex cases, measurements such as air sampling or examining the methods of machine operation may be necessary to identify the presence of hazards presented by chemicals or machinery.

Competent people with practical knowledge of the work activities can carry out risk assessments, preferably with colleagues from another part of the organization who may have greater objectivity. A risk assessment based on a participative approach provides a further opportunity to integrate employees into the activities, use their knowledge, develop a shared perception of hazards and risk, empower responsibility and accountability.

Assessing risks is necessary to identify their relative importance and to obtain information about their extent and nature. This will help to identify where the major efforts in prevention and control should be placed and to make decisions on the adequacy of control measures. It is generally not necessary to make precise numerical calculations of risk. Complex methods for quantified risk assessment are normally only required where the consequences of failure could be catastrophic. Risk assessments in major hazard industries, for example, in the chemical or nuclear industry, may be required by legal standards and guidance. Hazard and operability studies (HAZOPS) and hazard analysis systems such as event or fault tree analysis may be applied when planning a new system or major changes of an existing system.

5. RISK MANAGEMENT CHALLENGES

The past two decades have witnessed a significant transformation in how firms are structured. Tall organizations with many management levels have become flatter, competitors that have adopted a modular organizational structure have gained market shares. Organizational de-layering and the rise of smaller, often entrepreneur-based firms gives self-management new meaning covering personal self-management, self-leading teams and semi-autonomous units. Companies and public services adopt cooperative forms of work at a very fast pace. Teleworks provides flexibility in both working hours and the location of work and allows employees to cultivate tailored life-styles while working a full-time job. These "boundaryless" organizations, e.g. organizations whose membership, departmental identity and job responsibility are flexible create new challenges for risk management particularly for people management.

The traditional approach to managing people focuses on selection, training, performance appraisal and compensation for individuals in specific jobs. It also presumes a hierarchy of control rather than horizontal workflow sequences. When organizations are restructured around teamwork instead of individual performance, different forms of team autonomy and HSE responsibilities are emerging.

Risk management systems in small, medium and modular organizations must rely on the participation of members, on self-management, personal and team responsibility. Selection, performance appraisal and reward policies are the most likely candidates for change. Contingent pay and peer pressure

generated by teams are emerging as substitutes for both managerial influence and internalized member commitment. HSE criteria, rules, procedures and achievements have to be reformulated and integrated into the systems. De-layered organizations also need to develop combined systems, particularly, a recruitment system which includes participatory concepts of job analysis and assessment and a team management system focusing on performance appraisal, compensation, rewards and benefits and personal career development. Systems are based on peer reviews instead of managerial appraisal and on team based output measures instead of individual performance. This requires an intensive qualification process for the employees and new cognitive and social skills to run the systems.

The rewards themselves are changing. Promotions and formal status have become less important and are replaced by lateral moves, presented as career-building assignments Workers often perceive training as a reward, providing self-actualization and the motivation to learn: career development with increased responsibility, autonomy and likelihood of advancement; and psychosocial benefits, including increased confidence, new friendships and better well-being in non-working life.

1. INTRODUCTION

To be an ergonomist in an engineering design environment may be assumed in many ways. Traditionally, ergonomists have been asked for inputs at the final stage of design processes to help designers fix some details to ensure that the final product will fit the human being. More recently, with new methods in engineering new ways of intervention are developing. Moreover, ergonomic interventions now cover many domains in the design field: technical devices, either hardware or software, work organization and training. Ergonomists are now being asked to participate in teams designing whole plants. A model of ergonomic interventions that defines the ergonomist as an effective player in the design process is presented here.

The ergonomist may be an "actor" in the design process, that is, s/he may not only be a resource person called when advice is required but also can actively take part in the design team so as to influence the design output as well as the design process itself. This kind of contribution rests on the consideration that designing is not only a technical process but also a social one (Bucciarelli 1988). Besides being a recognized expert in human characteristics and work activities analysis (de Keyser 1991), the ergonomist can then achieve a complete intervention through structured interactions with project staff and future users. Two conditions seem to be required for such an implication. First, the ergonomist must have a good understanding of the project itself: from what it stems, what are the stakes of the project, what is planned, what is the calendar, what are the methods to be used to reach the results. Second, the ergonomist must analyze the structures in the project: who are the key actors, for example, who is the sponsor (i.e. the payer and often the main decision-maker), who is the project manager, who are the stakeholders. Such knowledge allows the construction of the ergonomic intervention with the different actors. Even if the ergonomist masters a particular field of competence, s/he must have a good understanding of these aspects to provide the right input at the right time. Also, the ergonomist must have some knowledge of the interactions between the different actors to be able to give advice in a form that helps the project manager negotiate the different demands generated by the ergonomic intervention. This may for instance, be the case with suppliers when a fixed budget has been set.

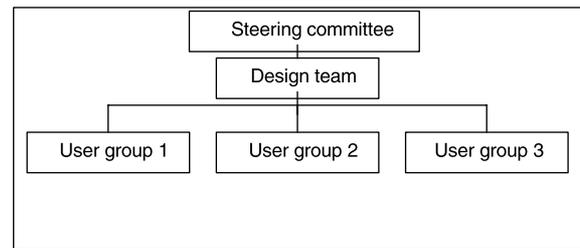
The engineering design environment should include two structures through which the ergonomist will act (see Figure 1). The first is a steering committee composed of the stakeholders, project manager and sponsor. The second is one or more users group (composed of maintenance and production workers, su-


Figure 1. Structures the ergonomist has to interact with in a design project.

pervisors) working on specific topics which the sponsor or one of its representatives will lead from the very beginning until the end of the design process and even after when necessary. The ergonomist will support this group in analyses of the project's ergonomics aspects.

How the ergonomist may contribute to the different steps of the design process will now be examined. Through structures described above and using the concept of "future work activity" developed by Daniellou (1987) the intervention of the ergonomist takes place through the following design process stages: (1) defining the problem, the opportunity; (2) choosing the concept; (3) conducting preliminary studies; (4) conducting detailed studies; (5) construction; and (6) start-up.

One must keep in mind that these stages often overlap extensively in real world projects and that the designing process is an iterative one: many loops backwards in the temporal flow can be observed. For instance, in an overhead crane project that spanned over 1 year, the last month before start-up while the new building structure was being completed, the operator cabin was still at the preliminary studies stage. This example illustrates the short delays an engineering design team is often faced with, particularly when it comes to workstation design.

2. DEFINING THE PROBLEM, THE OPPORTUNITY

Even though the ergonomist might be called at the very beginning of a project, the project's objectives are often already defined. In a longer-term project, however, the objectives may change. Hence, the ergonomist must keep in touch with the stakeholders to be aware of these changes as soon as they occur.

Most of the time, design projects are aimed at solving existing problems. The analysis of the problem will have an impact on its solution. It is important to ensure that the problem is analyzed systematically to identify its true determinants. Often, users will dictate a solution to a problem that has not been subjected to a systematic analysis. The designer may then be locked in a process where the output will not meet users' expectations despite the strong feeling users may have that "this is the solution," Many engineering projects consist in undoing what has been poorly designed because of incomplete analyses. Moreover, as suggested by Schön (1983), "setting" a problem which needs a technical answer is not a technical problem.

Another type of projects arises from an opportunity offered in the company life. For example, an acid unloading station is re-designed in an aluminum plant because of a change in train wagons configuration. This opportunity offers a possibility of

improving working conditions. For example, going back to accident reports of the past years, new objectives stemming from a health and safety point of view may be added (e.g. reduction in manual materials handling work, fewer awkward postures, improved safety). This task of enriching project objectives can be done with the help of a work group composed of production and maintenance workers and proposed to the steering committee as part of the project.

The ergonomist can also assist users in defining their problem from the very beginning of the design process, on the basis of fieldwork done at the installations to be changed. Field observations are very useful when investigating an existing situation. In these observations the ergonomist will try to determine what in the work environment can be harmful to workers and also what in the work activities needs to be improved from a production point of view. The work group can then validate what has been found by the ergonomist and also provides pertinent information about situations that rarely occur but which are critical to installation efficiency. Analysis of a problem will often show that health and safety issues are associated with system dysfunctions and that correcting the latter will improve the former. In particular cases, however, such as with paced production lines, designing for a productivity increase can yield a worsening in working conditions. The role of the ergonomist here is to document the consequences on workers health and safety of the design choices and to ensure that these are thoroughly discussed by the stakeholders. As opposed to the ensuing design process stages where engineers are leading, this first step should be lead by the sponsor and users.

3. CHOOSING THE CONCEPT

Once the problem space is correctly defined, the following step is to determine which concept will provide the most satisfying answer to the objectives set previously. An approach used by most designers is to visit reference sites. The project manager will indeed try to find existing facilities where the setup is close to what is expected in the new design. The ergonomist may add to the technical data obtained by engineers during such visits by completing with work activities data (e.g. kind of problems users have in the existing set up). From his/her knowledge of the situation to be changed, the ergonomist will also try to anticipate future events that could occur in the system under development. One key issue here is for the ergonomist to be aware of the sources of variability in the existing situation such as variability related to operators, to raw materials, to products, to the environment, etc. and to anticipate how these sources of variability will be taken into account in the system under development. Preparing the visit with users, visiting and debriefing with them will usually provide interesting ergonomics input and help in establishing advantages and disadvantages of a concept from the users point of view.

4. CONDUCTING PRELIMINARY STUDIES

Once the concept is chosen, studies are conducted by engineers to determine the feasibility of the project and to quantify the resources needed. At this point, the resources required to ensure the objectives pertaining to the ergonomics aspects must be anticipated. It can take the form of a special budget for conducting simulations on prototypes, or testing workstation concepts

through mock-ups, or having workers participate in meetings and visits. A design alternative can also be evaluated from an ergonomics point of view (e.g. given this particular concept, what will be the activities of the production worker, of the maintenance staff). The role of the ergonomist at this stage is generally underestimated. Since at this stage the structural aspects of the project are decided upon, it will often be difficult to change these later without significantly increasing the project costs (engineering and overall costs). Therefore, if major difficulties from the users point of view have surfaced, these may be attenuated by revising alternatives or design choices. Once this stage is completed the project is ready for budget approval and the main suppliers who will become active players in the next steps can be known.

5. CONDUCTING DETAILED STUDIES

For the project manager, the aim of this fourth stage is to come up with precise plans that will render possible the realization of the installation. In most engineering environments, it is at this stage that the need for an ergonomist is striking: information on conveyor heights, control panel design, seat types, all of these issues need urgent answers. There are, of course, textbooks, reference manuals and software products that can help designers. But most of these data need interpretation and this can only be done by an ergonomist as long as s/he can anticipate what the work activities will be.

This is where it pays to have the ergonomist in the project from the very start: s/he can provide better advice and help the design team in working out the details of the installation with the different suppliers. One way of helping designers in the completion of plans is to simulate with different supports (plans, mock-ups, software products, prototypes) the anticipated workers activities. Scenarios can be constructed from data collected in the existing situations taking into account the future user characteristics, the regular production and maintenance task as well as the related critical tasks. The main goal of simulation is to make forecasts on the future work activities: are the working conditions acceptable for most of the population and from an operations point of view, are the objectives met. Modifications can still be made at this stage without adding undue expenses to the initial cost. This is also the stage where the word "iteration" takes all of its meaning; if the forecast on the workers future activities is poor, designers will modify their proposal which can again be tested and so on until the design is deemed acceptable. Discussions on the acceptability of the proposals will often oppose different professional fields: production, health, safety, maintenance may not necessarily point towards the same solution. The final word always results from compromise. These discussions are important for the remainder of the design process. For example, in a discussion about a joystick, the engineer in charge of the project may suggest to choose one with a high resistance to guarantee that it will not be activated accidentally, while the ergonomist may suggest the force to be as low as possible to prevent musculoskeletal strain. On the other hand, maintenance people will be preoccupied by frequently replacing the joystick's springs. The final decision may reflect all of these considerations; however, every actor involved in the discussion then knows what to expect from the selected design in terms of consequences for the work activities and for the function s/he represents in the plant.

6. CONSTRUCTION

The ergonomist is usually not involved at the construction stage. But from experience, many changes are made on the spot, particularly when building in an existing plant where there are many constraints. Some attention must be paid not to introduce undue risks for future users. One of the rewards related to an early involvement of the ergonomist in the design process is that the work done in the previous stages with the other design actors, including workers from user groups, makes them more attentive to what is being done on the construction site.

7. START–UP

Start-up is a critical period where workers learn to use their new workstations and tools as well as living in a new environment. The training program that has been developed (with a likely contribution of the ergonomist) in the previous stages will be put into practice. As part of the ergonomist's intervention at this stage, an analysis of the work activities and particularly of the problems faced by users during the start-up, can help fine tune the new system and improve the training program. The start-up stage is also a good time for evaluating the ergonomic intervention with the design actors and for modifying accordingly the strategies and methods for a future project.

Whatever type of involvement in a design environment, the ergonomist can enhance the quality of an engineering project. The earlier his or her involvement, the better the results. Even if an early involvement of the ergonomist is not always achievable, one must keep in mind that an engineering project is a re-definition/definition of future work situations. At each stage of the design process, decisions are taken that will affect the way future work will be done. The stakes underlying these decisions require for the ergonomist to act not only in providing information and advice on the end results, but also in keeping alive interactions between stakeholders, sponsors, users and the project manager.

Safety Culture

A. I. Glendon

Department of Applied Psychology, Griffith University Gold Coast, Queensland 9726, Australia

1. INTRODUCTION

The term "safety culture" arose from the Chernobyl nuclear disaster in 1986, in which cause was attributed to a breakdown in the organization's safety culture (IAEA 1986). The concept was heralded as a substantive issue in official inquiry reports into disasters at King's Cross Underground station in London in 1987 and on the North Sea platform *Piper Alpha* in 1988. The term rapidly gained currency within the safety management lexicon. The notion of safety culture arose from the more inclusive concept of organizational culture as well as the related concepts of organizational climate and safety climate. Organizational culture is often held to be critical to an organization's success or failure. Safety culture is frequently identified, for example by disaster inquiries, as being fundamental to an organization's ability to manage safety-related aspects of its operations – successfully or otherwise. The assumed link between safety culture and major disasters was subsequently extended to include accidents of all types.

It is generally agreed that culture operates at different levels and through various mechanisms. Cultural features are complex, shared characteristics of a group dynamic relating to a system (e.g. group, community, nation, religion). They include beliefs, values, attitudes, opinions, motivations, meanings, ideas, expectations, linguistic features, specific actions, rituals, ceremonies, symbols, general behaviors and associated norms. More tangible aspects include buildings, uniforms, documents, liveries, logos, equipment and design features. Within the culture of an organization or other definable system, subcultures may be identified in respect of groups whose characteristics are sufficiently distinct from those of the mainstream culture or from other subcultures.

2. ORGANIZATIONAL CULTURE

Two contrasting perspectives on organizational culture dominate the literature as well as managerial and professional practice within organizations (Waring and Glendon 1998). These have been described as functionalist and interpretive. Functionalist approaches assume that organizational culture exists as an ideal to which organizations should aspire so that it can, and should be, manipulated to serve corporate interests. The notion that organizational culture has as its prime function to support management strategies and systems is premised on the assumption that it can be reduced to relatively simple models of prediction and control. This approach primarily aligns organizational culture as a support for managerial ideology, goals and strategy, in extreme cases involving managerial use of "culture" to coerce and control.

However, many aspects of culture are not reducible to cause–effect quantitative relationships, and ideological use of culture as a weapon in organizational struggles reveals a powerful unitarist bias. Interpretive approaches to organizational culture provide an alternative approach to this concept and assume that organizational culture is an emergent complex phenomenon of social groupings and serves as the prime medium for all members of an organization to interpret their collective identity, beliefs and behaviors. Thus, organizational culture is not owned by any single group but is rather a unique creation of all the organization's members.

From assumptions characterizing interpretive approaches to organizational culture, it follows that managerial attempts to manipulate culture, for example in seeking to drive rapid organizational change, are likely to fail because of the application of an inadequate model of processes that they are attempting to manipulate. An analogous point, in respect of organizations seeking to enhance safety culture as the "philosopher's stone" to improving health and safety, is made by Cox and Flin (1998).

In practice, many organizations display elements of both approaches. For example, through rigorous adoption of formalized risk management practices, an organization might be seen as invoking functionalist aspects of its safety culture. Simultaneously, a more interpretive side may be revealed by individual and group commitment to open-ended learning from past mistakes, such as those leading to accidents. This could be achieved through communication and discovery processes that involve a developing identity for organization members.

3. FROM ORGANIZATIONAL CULTURE TO SAFETY CULTURE

Contrasting perspectives on organizational culture inform directions that organizations take in respect of safety culture. Functionalist assumptions may be appropriate for components of safety culture that can be shown to follow reliable cause–effect type models, for example as represented by readily quantifiable relationships. An interpretive approach may be subsumed within an essentially functionalist framework as a management tactic for maintaining control. For example, the dominant safety paradigm for an organization may be a legislative/standards driven formalized risk assessment system. Within this may be incorporated employee consultation or involvement of various types, which may use various methods to enhance or augment the mainstream system. This differs from a system that is premised by trusting safety to staff at all levels and which is tolerant of diverse and heterogeneous contributions.

To understand the nature of major accidents within organizations and systems, it is essential to invoke the notion of culture (Reason 1997). The notion that diversity and flexibility are essential components of an organizational culture that contributes positively to safety is championed by several researchers in the field (see, for example, contributors to Cox and Flin 1998). This challenges the functionalist assumption that a monolithic culture across an entire organization is desirable, and is premised upon the certainty of an unknown future in which accidents or disasters will differ from those previously experienced and also be difficult to imagine, but which could nevertheless occur. A number of authors caution that seeking to use components of safety culture as a "defence in depth" against major accidents, perhaps through a "total safety culture" ideal, is doomed to long-term failure through organizational complacency as well as lack of diversity and flexibility of response.

4. DEFINING SAFETY CULTURE

A range of meanings has been attached to safety culture, three of which are summarized by the UK Institution of Occupational Safety and Health (1994):

- those aspects of culture that affect safety (Waring and Glendon 1998);
- shared attitudes, values, beliefs and practices concerning safety and the necessity for effective controls;
- the product of individual and group values, attitudes, competencies and patterns of behavior that determine the commitment to, and the style and proficiency of, an organization's safety programs (cf. UK HSC 1993).

The latter two definitions are premised upon a functionalist perspective. This approach implies that safety culture is conflict-free and aligned with the objectives of a controlling function. The first of the three meanings reflects a more interpretive approach, also espoused by Glendon and McKenna (1995), implying a looser definition around a set of principles that is at least pluralist in orientation.

HSC (1993) proposes as a definition of safety culture, "the product of individual and group values, attitudes, perceptions, competencies, and patterns of behavior that determine the commitment to, and the style and proficiency of, an organization's health and safety management." It argues that organizations with a positive safety culture are characterized by communications founded on mutual trust, by shared perceptions of the importance of safety and by confidence in the efficacy of preventive measures. From their review, the HSC concluded that effective health and safety provision depends as much on organizational culture as upon specific attention to health and safety matters.

While definitions of culture and safety culture abound, partly because the theoretical underpinning for safety culture is weak, the concept remains problematic. For example, there is little or no theoretical basis for determining what makes an organization's safety culture "positive," "healthy," "strong," "excellent" or merely "good" – or the antonyms of these frequently used descriptors. Reason (1998) argues that a safe culture is one that is informed and just, being based upon problem solving rather than indiscriminate blame apportionment, and includes reporting as an essential element. Reporting of mistakes and violations is likely to be encouraged when people feel that the organization trusts them and shows evidence of responding in a problem solving manner that rewards their behavior.

5. CULTURE AND CLIMATE

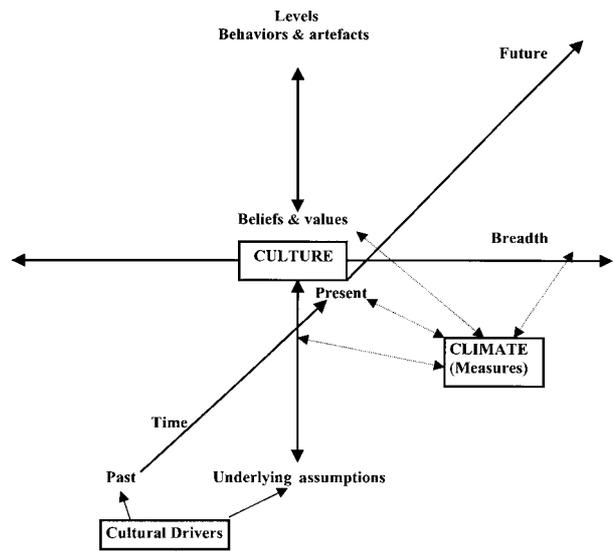
Confusion continues between use of the terms "culture" and "climate" and they are often used interchangeably. While there is a strong relationship between them, organizational climate refers essentially to the perceived quality of an organization's internal environment in which employee attitudes and perceptions feature prominently. Climate is regarded as a more superficial concept than culture, being descriptive of important aspects of the current state of an organization. Culture is often seen as being long-term and strategic, while climate is perceived as short-term and tactical. Scaled dimensional measures are the most popular means of measuring organizational climate and many of these have been devised. Dimensions typically assessed include autonomy, cohesion, trust, pressure, support, recognition, fairness and innovation.


Figure 1. Organizational culture and organizational climate (Glendon and Stanton 1999).

A typical three-level classification of organizational culture embodies relatively accessible, intermediate and deep levels. The most accessible level refers to observable behaviors and associated norms. The intermediate level includes attitudes and perceptions, which are not directly observable, but which may either be inferred from behaviors or assessed through questioning. At the deepest level are core values, which are much less readily assessed. Other key dimensions of organizational culture that have been identified include depth, breadth, progression, strength, pervasiveness, direction and localization (Waring and Glendon 1998).

Some authors consider climate to be one manifestation of culture. Figure 1 represents one view of the relationship between organizational culture and climate. Here organizational culture is represented at three different levels as well as having breadth and time dimensions. Organizational climate measures can access certain components of the dimensions of organizational culture across a limited range. For example, those relating to member attitudes, beliefs and perceptions as well as cultural breadth at the time that the survey is undertaken and perhaps a little in the past as well. However, as organizational culture change is generally taken to occur over a period of years, the time frame for assessing culture must reflect this important time dimension.

6. SAFETY CLIMATE

Contemporaneously with the derivation of safety culture from organizational culture, another important influence was from the associated term "safety climate," which comes from a more empirical tradition. Some researchers distinguish between safety culture and safety climate. The prime research method for investigating safety climate is the questionnaire, completed by sufficient numbers of employees to enable statistical analysis to reduce a large number of items to a small number of dimensions. Typical safety climate dimensions include management attitudes to safety, safety training, worker involvement and employee risk perception.

"Safety culture" is generally taken to be more embracing than

"safety climate," although the two terms have similar meanings. "Culture" implies a notion of residing within an organization. "Climate" has more passive connotations, reflecting attitudes and perceptions of organization members to both internal (e.g. management actions) and external (e.g. economic) influences. Exclusively psychometric (e.g. questionnaire survey) approaches have proliferated as measures of safety climate (cf. Cox and Flin 1998, Hale *et al* 1999), but have restricted range in respect of representing measures of safety culture.

7. MEASURING SAFETY CULTURE

Several empirical studies have sought and found associations between many ascribed individual components of safety culture, safety climate and other measures. However, convincing evidence of causal links between global measures of safety culture or even safety climate and safety performance outcomes has so far proved elusive. This has led to a degree of skepticism among some Occupational Health and Safety (OHS) professionals in respect of whether these terms might obscure more concrete safety performance measures, such as accident outcomes. It remains a possibility that attitudinal and cultural aspects of safety are not particularly strongly related to behavioral and environmental components. However, a definitive answer to this issue must await more fundamental advances in measurement of these concepts.

Ways in which safety culture and safety climate have been measured and explored include case studies, comparative studies and psychometric approaches. Hitherto most empirical studies in this field, mainly using questionnaires, have measured dimensions of safety climate. Studies using triangulated methodologies to investigate broader, deeper and historically derived safety culture features have been undertaken and it is in this area that methodological advances are most required.

Studies that model various aspects of safety climate and safety culture are beginning to appear (see, for example, contributors to Cox and Flin 1998, Hale *et al* 1999), although where questionnaires are the only data gathering instrument, common method variance and restriction of range are generic methodological problems. A few studies seek to validate the safety culture or safety climate measure used by correlating features of it with accident or other outcome measures (e.g. protective clothing or equipment use). However, as behavioral measures these have limited utility. Despite the possibility of discriminating between high and low accident rate organizations on the basis of a range of features that may be broadly ascribed to the culture or climate pool of elements, using safety culture components as a predictor of either large-scale disasters or accident/incident rates remains problematic. The two types of outcomes typically have distinct etiological patterns.

Typically a functionalist perspective views culture as a route to identifying, assessing, controlling and monitoring apparently measurable features of an organization's internal environment. In contrast, an interpretive approach would seek data from multiple sources with a prime aim of advancing learning through increasing understanding. Measuring safety culture is problematic. Ethnographic approaches, for example involving participant observation, action research and grounded theory, while possibly the most valid from an interpretive perspective, are also costly and time consuming. Before determining how safety culture can be measured, there needs to be some agreement as to what it is,

although a grounded theory approach would incorporate this issue within its analytic fabric.

A triangulated methodology is required. One component of this methodology might be some form of audit, which follows from a functionalist risk management perspective. The Human Factors subgroup of the UK Advisory Committee on the Safety of Nuclear Installations (now NUSAC) (HSC 1993) present a framework for measuring safety culture, comprising questions on leadership, management style, communication, policy, planning, risk assessment, risk management, perceptions, stress, training, monitoring and regulation. In 1998 the UK HSE released a tool for measuring safety climate that was partly based on the HSC (1993) report. Cooper (1998) proposes a methodology for changing safety culture that incorporates risk assessments, audits, training, climate surveys and behavior change programs.

Because organizational culture, or some aspect of it such as safety culture, exists at different levels and across several dimensions, complex measures are required to assess it. Questionnaires or similar tools are inadequate for measuring all aspects of organizational culture, including safety culture components. Measurement of safety culture must be based upon an adequate multifaceted model and seek to measure at all levels from individual psychological to executive strategic. Approaches that have been used to assess and analyze organizational culture include soft systems methodology, organizational climate surveys supported by triangulated methods and grid-group analysis. Other methods that have been used include repertory grids, "twenty statements test" and group discussions. In many high reliability organizations, conventional safety audits and accident analyses that are coded for human and organizational factors can be incorporated within a triangulated methodology. A more comprehensive analysis might also require checklists (to capture data on artifacts) and activity analysis (for information on behavior patterns).

From a variety of sources, key dimensions of safety culture for assessment include:
- extent of trust and shared concern for safety among groups within the organization;
- a variety of perceptions and other aspects of culture among subgroups;
- organizational learning, including reflection on practice and feedback systems;
- norms and rules permitting flexibility in dealing with all types of safety issues;
- top management commitment, support and resource allocation;
- soundness of safety policy and applied safety management techniques;
- continuous motivation of all staff;
- safety training provision;
- fostering a problem solving and not a blaming approach to safety issues; and
- persistence of purpose.

At least of equal importance with measurement is the development of theoretical models that adequately express the mechanisms by which safety culture or safety climate might influence individual, group and organizational behaviors that are relevant to safety outcomes. A combination of ethnographic and field experimental approaches could help to identify and

clarify these mechanisms by building adequate theoretical models for empirical testing. This is likely to be a fruitful approach to developing a useful safety culture concept in the future.

8. CONCLUSIONS

Debate on safety culture and safety climate is at an early developmental stage. Within organizational practices, there is some convergence between theoretically distinct functionalist and interpretive approaches. Maintaining a theoretical distinction between the overlapping concepts of safety culture and safety climate is useful, even though in practice they may be treated as partially fused components of a safety management system.

As Pidgeon (1998) and others observe, a major current barrier to improving comprehension of safety culture is an adequate theoretical model that can drive data gathering and analysis to facilitate better understanding. Such a model is likely to include reference to safety culture dimensions, different parties' objectives, un/desired outcomes, processes and procedures, and internal and external contexts, as well as incorporating both functionalist and interpretive perspectives.

Although important, safety culture remains an enigma with several variations. This is due to the complexities of large organizations and the larger overlapping systems within which they reside. A central paradox of safety culture is that by seeking to use it as a rigid functional means to control hazards to health, safety and organizational integrity, more serious outcome scenarios that result from multiple but very rare combinations of events, requiring more flexible organizational responses, may be overlooked.

Safety, Ergonomics and Total Quality Management

A. Leino and M.K. Mattila

Occupational Safety Engineering, Tampere University of Technology, PO Box 541, FIN-33101 Tampere, Finland

1. INTRODUCTION

Ergonomics is a product quality criterion from the viewpoint of total quality management (TQM). An effective quality system should be designed to satisfy stated or implied needs and expectations of customers while serving to protect the organization's interests (EN ISO 9004-1: 1994). Today the manufacturing personnel in an industrial context are considered to be internal customers, and the end-users are considered to be external customers. All customers have needs and expectations, including ergonomics and quality, regarding their interaction with products (Eklund 1997).

Management of quality, occupational safety, health and ergonomics have many overlapping elements. On the one hand the origins of quality, safety or ergonomic problems may derive from the same faults, and on the other hand handling of one specific problem, for example a quality problem, may unintentionally cause problems in other areas, such as occupational safety (Zwetsloot 1994).

Modern safety management emphasizes the pro-active approach in planning, organization and measurement. These emphases are identical to those of modern quality management. Therefore, occupational safety and health (OSH) and ergonomic issues can be effectively and economically integrated in the total quality management system (Mattila 1997).

A quality system based on the ISO 9001 or ISO 9004 standards is a valuable management resource in the control of quality. Also a management system for environmental issues, introduced in the ISO 14000, standard is widely implemented. management systems for occupational health and safety have been produced e.g. in the BS 8800 standard.

Integration of these systems has been recommended (Zwetsloot 1994) where companies implement two or more management systems simultaneously. A well-structured integrated system combines diverse management systems with quality management, improves the company's quality of performance and saves time, work and money.

2. ERGONOMICS IN TQM

The TQM system introduces four assumptions as starting points: improved quality is profitable, people want to do a high-quality job, all the parts of the organization are highly interdependent and quality is the ultimate responsibility of top management (Hackman, Wageman 1995). In addition to these assumptions, the basic principles and foundations of TQM are customer focus, process orientation, employee participation, management involvement and continuous improvement (Eklund 1997).

Table 1. Management of safety and ergonomics as part of the quality system in accordance with the standard ISO 9001 (1994)

ISO 9001 Quality standard	Integrating safety and ergonomic issues
4.1 management responsibility	— occupational safety and ergonomic issues are included in company quality strategy and quality policy — occupational safety and ergonomic objectives are included in business activity objectives (for example job satisfaction)
4.1.2 Organization	— occupational safety and ergonomic issues are included in responsibilities and authorities at each level within the organization — occupational safety and job satisfaction are measured regularly — a management representative has been nominated for occupational safety and ergonomic issues — enough resources have been allocated to maintain and continuously improve safety and ergonomics — management review includes occupational safety and ergonomic issues
4.2 Quality system	— safety and ergonomics management issues are included in a company's quality system — occupational safety and ergonomic issues are considered in working instructions and courses of actions
4.3 Contract review	— contract review includes occupational safety and ergonomic issues — product safety requirements are recognized — technical product documents and instructions correspond to customers' requirements — the working and enviromental conditions of products are examined
4.4 Design control	— safety and ergonomic aspects are considered in product design — customers' special ergonomic demands are considered in the product design process — satisfactory technical documents and instructions for use are delivered with the product to make sure that the product is used in a right, ergonomic and safe manner
4.5 Document and data control	— document and data control covers also occupational safety and ergonomics, courses of action and work instructions
4.6 Purchasing	— purchasing and subcontracts share the same product safety requirements as a company's own design and production — production purchasing takes occupational safety and ergonomic requirements into account — subcontractor audits include occupational safety
4.9 Process control	— risk and ergonomic assessment is included in continuous evaluation and follow-up of working conditions — safety and ergonomic aspects are also included in condition assessment and preventive maintenance of machines and devices — occupational safety and ergonomic aspects are taken into account in working instructions and courses of action — employees participate in developing work ergonomics

ISO 9001 Quality standard	Integrating safety and ergonomic issues
4.14 Corrective and preventive action	– sickness leaves and accidents are analysed – job satisfaction is observed – ergonomics and order of work environments are observed – the efficiency and effectiveness of corrective and preventive occupational safety and ergonomics are observed
4.15 Handling, storage,	– insruments for lifting and their ergonomics are included in regular condition assessment – occupational safety and ergonomic aspects are considered especially when stocking and preserving critical products – occupational safety and ergonomic issues are considered during packaging, loading and unloading a product
4.16 Control of quality records	– occupational safety records are included in quality records
4.17 Internal quality audits	– safety and ergonomic issues are included in qualtiy audits – audits are conducted by persons who are trained to assess quality, safety and ergonomic issues or an expert group conducts the audits
4.18 Training	– occupational safety and ergonomic issues are included in training in working methods – special safety and ergonomic training is arranged and a register is kept of these trained employees – enough employees should be trained for first aid and their preparedness is maintained by training – employees' preparedness to act in cases of urgency and failures is developed by regular training and exercises
4.19 Servicing	– occupational safety and ergonomic issues are taken into account when working in customers' premises during commissioning, mounting and service – safe and ergonomic commissioning, mounting and maintenance are taken into account in the technical product documents and instructions

TQM regards the entire business process from supplier to customer. Therefore, it must consider all elements of a company's processes and dimensions of quality, including ergonomics (Luczak *et al.* 1998). It has been proved that ergonomic work conditions support product quality. There is a clear relationship between poor work conditions, such as insufficient lighting, noise and vibration, and effects on human performance, including error frequency and other unwanted deviations.

Integration of OSH and ergonomics management into the TQM system has proved to be efficient and possible in practice. Connections between safety and ergonomics management and quality management are described in Table 1.

3. MODEL FOR IMPLEMENTING INTEGRATED MANAGEMENT SYSTEM

A model for implementing a safety and ergonomics oriented TQM system for small and medium-sized companies has been developed and tested. The model integrates occupational health and safety and environmental issues in the TQM system. The phases of the model are described in Figure 1.

One of the prerequirements is that it is ensured that the top management has a clear vision of the development when the process is starting, before the development work has progressed. This can be achieved by adopting the basic principles and definitions of TQM, ergonomics and safety. The objectives of the programme have to be unambiguous in order to achieve an enduring commitment from the top management.

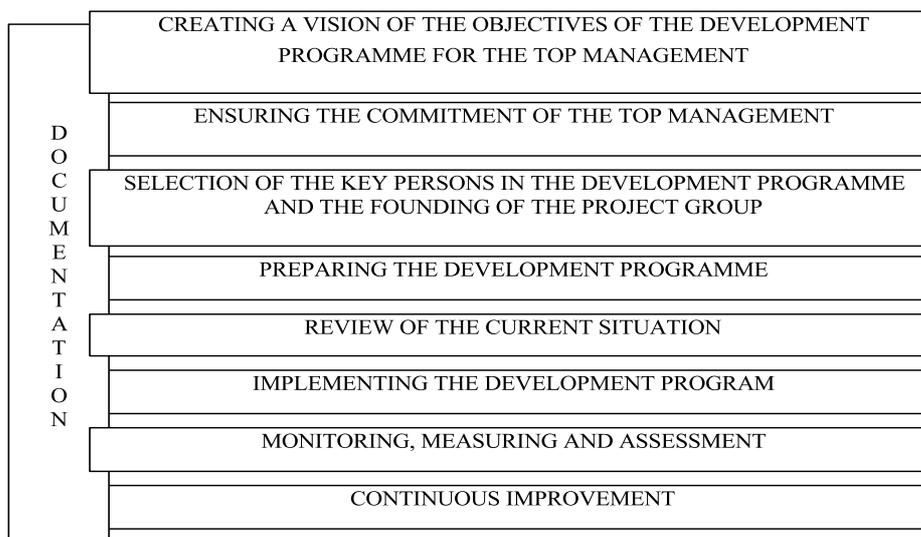
The model significantly emphasizes the importance of the analysis of the current situation, and the implementation of risk analysis and assessment is crucial. The review consists of the following phases:
- survey of customer satisfaction.
- survey of job satisfaction.
- identification of main processes and responsibilities.
- assessment of occupational safety.


Figure 1. Operations model for implementing occupational safety oriented TQM system

- assessment of work environment, including ergonomics.
- assessment of environmental aspects.

Based on the analysis and risk assessment, the areas for improvements are selected. Responsibilities will be allocated, schedules for implementation documented and the structure of monitoring, measuring and assessing defined. The documentation of the integrated management system is completed. Continuous improvement concerns the whole management system, including ergonomics.

4. RECOMMENDATIONS

1. Total quality management, TQM, regards the entire business process from supplier to customer. Therefore, it must consider all elements of a company's processes and dimensions of quality, including ergonomics.

2. The integration of management systems for quality, environment, occupational safety and health and ergonomics has become actual where companies implement two or more management systems simultaneously.

3. The integration of management systems has proved to be beneficial. Both modern safety and quality management emphasize the pro-active approach in planning, organization and measurement. An integrated system combines diverse management systems with quality management, improves the company's performance and saves time, work and money.

4. System integration is a continuous process which needs to be evaluated at regular intervals. The Malcolm Baldridge National Quality Award is an assessment method that can be used for monitoring and reviewing the integrated TQM system. The assessment criteria could be developed to cover also ergonomic issues.

5. It has been proved that ergonomic work conditions support product quality as well as human performance.

Self-managed Work Teams

J. R. Wilson[†] and C. Whittington[‡]

†Institute for Occupational Ergonomics, University of Nottingham, Nottingham, NG7 2RD, UK

‡Holly Bank, Church Lane, Farndon, nr Chester CH3 6QD, UK

1. INTRODUCTION

The notion of teams is implicit and explicit within manufacturing and other industries. There are, for instance, design, development, core or steering teams. Increasingly companies are concerned with teams in a different sense, those that are formed within the organization of production, as an improved way to re-design work. These teams are termed here as self-managed work teams, although the same or very similar concept may be described instead as self-regulating, autonomous, semi-autonomous or self-directing. These distinctions have emerged to help discriminate between teams with varying levels of autonomy and with different types of internal or external leadership and supervision. However, all of the definitions embrace the concept of a work group that has the opportunity for greater independence of decision-making than is traditionally available, although the boundaries of this decision-making, and the degree of mutual cooperation and support that are required, may vary.

2. WHAT ARE SELF-MANAGED TEAMS?

Self-managed teams differ from the more traditional concept of the work group in that the team, rather than the first-line supervisor, controls many of the critical management processes of planning, organizing, prioritizing and staffing. Although the degree of autonomy exercised may vary, the team will normally have responsibility for a complete area of work. Activities within the team are normally interdependent and team members are generally multi-skilled so as to enable interchangeability between different activities. In the view of Rothwell (1993), teams can be classified along scales of formal/informal and permanent/temporary; the self-managed work team (SMT) is formal and permanent.

Teams at work are often not defined in the literature, but where definitions are given there is some agreement. Hackman (1990: 4–5) believes that organizational work groups are those with attributes of being "real" groups (that is, they are intact social systems with boundaries, member interdependence and differentiated member roles), with one or more tasks to perform with collective responsibility, and who operate within an organization or a larger social system. Katzenbach and Smith (1993) define teams as comprising a small number of people possessing complementary skills who are committed to a common purpose, and who are mutually accountable for goals and approach. In terms of manufacturing industry, self-managed teams (or self-regulating work groups) usually have 4–12 members (although as many as 20–30 might be found) with an optimum often specified as about six or eight; personnel specifications will usually include self-organizing or interpersonal skills as well as technical ones, and in the more sophisticated implementations decision-making and problem solving skills also.

SMT vary with respect to two main dimensions: the extent to which managerial authority is delegated (autonomy) and the degree to which roles within the group are interchangeable (multi-skilling). Neither autonomy nor multi-skilling will occur overnight and new teams will need considerable help in making the transition to full self-management. In practice, many teams are likely to move along a continuum, and the role of the supervisor will gradually evolve from controller (stage 1), to team leader (stage 2), then to team coordinator (stage 3) and boundary manager (stage 4), and finally to team resource (stage 5). This progression is mirrored in the development of the team members who move from individuals who are told what to do, to working together as a group, assuming shared responsibility and finally running all the day-to-day operations and being accountable for their own work.

Where a team will sit on this continuum could be determined both by planning (e.g. how much management is willing to give up in terms of control) and also by events (e.g. the speed and enthusiasm with which the team acquires new skills). Therefore, the rate of development of teams, and the extent to which they actually reach the different levels of maturity, will vary considerably.

2. HISTORY AND EARLY DEVELOPMENTS

Interest in the idea of teamworking in manufacturing and other industries, and particularly in what became known as autonomous (later semi-autonomous) work groups, grew out of the work by a number of researchers at the Tavistock Institute in London. Researchers such as Trist, Bamforth and Emery developed a socio-technical systems theory and consequent principles for group work design, from their experiences during World War II and afterwards (e.g. Trist and Bamforth 1951; and see below). The founding group was composed of psychologists, sociologists and anthropologists. The basis behind socio-technical design is the recognition that the social system in any new implementation of work will have as great an influence on its success as the technical and economic systems; by recognizing the interaction of these subsystems and jointly optimizing them, there is an opportunity to improve both work performance and quality of work life for individuals. By extension, a further tenet is that the work organization is a whole open system, influenced by what we would know these days as the complete supply chain.

The first experiments in the UK in group work design took place in the mining industry (the Longwall Mining Study) and afterwards spread into Australia, Canada, Norway, India and Sweden among other countries. The basic principles lying behind these implementations of (semi-)autonomous work groups meant they were:

- Groups of workers with high levels of self-management engaged in cooperative completion of whole identifiable parts of the process.
- Independent of external control for long periods.
- Groups that could formulate goals decide when, where and how to work, distribute tasks internally, decide membership and decide on leadership.
- Given increased responsibilities, often including training, target setting, quality and maintenance.

There was a considerable debate on variations in autonomy at around this time, particularly on the types and degrees of autonomy. For instance, a group could have work method

autonomy (discretion regarding work methods and procedures), work schedule autonomy (the extent to which people can control when they do things) or work criteria autonomy (whether people can choose the criteria to evaluate their own performance). Also the degree of autonomy could vary on a spectrum, from the group examining alternatives and selecting in consultation with management through to the group both developing the alternatives and making a final selection among them on its own.

Some of the most famous cases in group working in the 1960s and 1970s took place in Scandinavia. Along with experiments in a wire drawing and paper mill in the Norwegian Industrial Democracy program, and further experiments in a fertilizer plant, the best-known initiatives were in the Swedish motor industry, and in particular at Saab–Scania (Södertälje) and Volvo (Kalmar and elsewhere). Both these developments involved motor vehicle assembly; the changes involved elements of what we would call today product based manufacture, and also included initiatives to improve the work environment as well. The principal observable outcome was to increase the work cycle time, from ~1 to 30 min (e.g. Valery 1974, Agurén *et al.* 1976).

Although many evaluations of the Saab and Volvo experiments at the time were positive, in terms both of social and technical measures, there have been criticisms ever since. These vary from suggestions at one end of the spectrum that they were one-off developments that could never be repeated because of the scale of effort required, through to suggestions at the other end of the spectrum that really the managers were merely playing with the situation and the changes were not particularly radical. Nonetheless, the developments have had a profound impact on work re-design for a period and have been re-visited more recently as work team design for the 1990s has re-emerged.

3. SOCIO–TECHNICAL SYSTEMS AND THEORY

One important outcome of the work of the 1960s and 1970s has been the socio-technical systems design principles bequeathed to later researchers and investigators. One listing of these appears in Cherns (1987), as follows.

- Principle 1: Compatibility
  The design process must be compatible with its objectives.
- Principle 2: Minimal Critical Specification
  Negatively — "no more should be specified than is absolutely essential." Positively — "state what has to be done but not how to do it."
- Principle 3: Variance Control
  Variances should be controlled as close to their source or origin as possible.
- Principle 4: Boundary Location
  Organization and function boundaries should be drawn with care to allow the sharing of information, knowledge and learning.
- Principle 5: Information Flow
  Information needed to take actions should be provided to those who require it and when they require it.
- Principle 6: Power and Authority
  Groups should exercise the degree of power and authority needed in order to accept responsibility for their performance.
- Principle 7: The Multifunctional Principle

It is beneficial for an organization to have employees with knowledge of a wide range of tasks.
- Principle 8: Support Congruence
  Systems of social support should reinforce required behavior and be consistent with the work design philosophy.
- Principle 9: Transitional Organization
  Planning and design are required for the transition from a traditional to a new organization.
- Principle 10: Incompletion
  Systems design is an interactive and continuous process.

To these 10 principles one must add the basic principles of group and teamwork design, and indeed good job design generally. The objective of organization design should be to provide a high quality of work life for employees and team members as well as providing for the successful performance of the organization. To achieve this the jobs within the teams should:
- be demanding and varied;
- provide the ability to learn on the job;
- provide for an area of decision-making;
- give a degree of social support and recognition;
- relate work life to social life; and
- give a feeling that the job leads to a desirable future.

4. ADVANTAGES AND PROBLEMS FOR SELF-MANAGED TEAMS

During the 1990s, teamwork in manufacturing, as in other businesses, has become the organizational form of choice. This has largely been for business and production reasons rather than being directly aimed at improving the quality of work life. Nonetheless in many industrial and service sectors teamworking is now regarded almost as a panacea and as the only practical way of handling a complex, technical and rapidly changing commercial environment. It is misleading, though, to assume that SMT are applicable to every work situation or that effective teams are easy to establish, and this is reflected in the extent to which potential benefits appear to have (or, in fact, have not!) been actually realized in practice. While many company presentations appear to show significant overall benefits to the organization, the academic literature suggests less impressive results.

Advantages of work organization in teams for companies and individuals are well documented. They help meet many of the principles of socio-technical systems theory, and provide a convenient mechanism for job rotation or enrichment and for increases in job characteristics such as variety, involvement, significance and feedback. They parallel new production methods (e.g. cells) and imperatives (e.g. involvement, responsibility, high competence), and are less vulnerable to the uncertainty possible with individual-based jobs and isolated workstations and processes. Demands at work must be balanced by improved control (over timing, method and boundary), social interaction and responsibility; teamwork can aid all of this and especially can give effective boundary control, timing control, support from colleagues and rational allocation of demands and responsibilities.

There are, though, several problems with a team-based organization of which one must beware. Inter- and intra-group conflict, dislike of groups (just as of participation or increased autonomy generally) shown by significant minorities of workers, harmful effects on supervisory and technical support jobs,

increases in self or group paced stress, and difficulties in establishing equitable and workable performance measurement and payment systems, have all been found in different organizations at different times.

In recent years, the emphasis for manufacturing teams has been on achieving high performance, sometimes to the exclusion of quality of working life considerations. For example, the introduction of teams in many cases is driven by a restructuring, downsizing or process re-engineering exercise. In this context, messages about improving the quality of working life and enhancing motivation and commitment can have rather a rather hollow ring. If badly handled, the resulting tension between employee needs and business needs can mean that the conditions for fully implementing self-managed teams are unlikely to be met. This is reflected in the figures, which are often quoted for the proportion of teamworking initiatives failing to meet expectations. For example, figures quoted in discussions at a recent conference on SMT suggested that two-thirds of programs aimed at the introduction of such teams achieve only moderate success or else fail.

5. DESIGN OF TEAMS

Less prominent in the literature than the generally favorable comments about teams and the "vision" required is detailed advice on *how* to set-up and implement teamworking and *how* to evaluate it. This is a serious hurdle for human-centered systems generally, where various approaches to work re-design, which are not mutually exclusive and are of varying degrees of formality, have been found, including:

- top-down framework of all issues and their interactions, change at a higher level supporting change at a lower one;
- bottom-up, *ad hoc* or sequential change, each decision throwing up the need to make several more;
- skills-based changes, identifying and making explicit the existing and potential shopfloor skills;
- following a job design model at individual or group work level, with the other areas of human-centered systems interfaces, tasks and environment, support systems) dealt with as convenient;
- use of a decision support system to assist engineers, designers and managers at plant level to re-design work;
- contemporary approaches to allocation of function, allowing for under- as well as over-load, in a task-oriented approach; and
- use of a task force, which in change to SMT means that the process and content of the change are fundamentally linked.

Across the literature, conditions and management strategies for changes to teamworking have been defined, propositions laid down for types of team, content for different levels of autonomy specified, suggestions about team leadership, size of teams and payment systems given, and decision aiding tools and decision support systems proposed. Analytical frameworks do exist which may be used in selection and training of team members, for instance Belbin's (1981, 1993) team roles.

However, a detailed program covering all implementation issues likely to be faced by a company introducing group work is hard to find. Published advice is more at the level of desirable concepts (such as shared vision, values and conviction,

management faith, common knowledge base), rather than the direct operational guidance needed for implementing work teams while managing all the other direct and tangential issues involved. One must face the fact that such guidance may not exist because it is impossible to generalize from specific cases, and that content of any change must be set in the light of prevailing circumstances. This would make the mechanisms used to support change to teamwork even more crucial (Wilson and Grey Taylor 1995).

On team evaluation also there is a relatively inadequate literature to give guidance. As well as assessing technical performance, organizational infrastructure (e.g. absenteeism) and work attitude outcomes, we need to evaluate the very group structure and its workings, in terms of how well the team is operating as a group. Measures are beginning to emerge but some of the better initiatives in this area may possibly do well to learn from related work with the armed forces or other such teams (e.g. Brannick *et al.* 1997).

6. CONCLUSIONS

Recommendations for a group or team structure appear so often in ergonomics, occupational psychology, management or health safety literature, that "teams" are in danger of being seen as a panacea for all hitherto intractable problems of work organization. It sometimes seems that "teams" are turned to by companies both as a first (easy) answer and are also clutched at as the last chance when other solutions have not succeeded. They are, in fact, a way of organizing manufacturing activities that require considerable planning, communication, flexibility, insight and luck, but which present a model for work which can satisfy a number of needs of both employers and employees.

Service Quality and Ergonomics

C. G. Drury and A.-C. Chen

Department of Industrial Engineering, University at Buffalo, Buffalo, NY 14260, USA

1. INTRODUCTION

A service industry is one that produces intangible goods for customers, in contrast with manufacturing and agricultural industries whose products are physical objects. The world's nations have developed from largely agricultural economies through manufacturing (following the industrial revolution) to service-based. A developed country will now have service as its largest employment and revenue sector, followed by manufacturing with agriculture a distant third. In addition, our primary industries depend on service companies, for example, to transport our food from producer to consumer, or to raise the capital required to expand manufacturing.

Service industries are becoming global in the same way as are manufacturing industries. An organization seeks to balance the need for local knowledge and direct customer involvement against tactical advantages of different locations around the world. Thus, it is often found that a call to an airline is answered from a rural location, remote from airline activities, where commuting costs for workers are less and possibly so are wage rates for the organization. This globalization is currently limited by the language knowledge needed for direct customer interaction, but it is not limited by communications availability. A service agent can interact as well with data sources from anywhere on the planet, in what appears to the customer to be real-time. There are obvious implications for both organizational and worker well-being in this globalization process.

With these trends in mind, the definitions of some of the unique characteristics of the service sector are given. Examined too is how service quality can be defined and measured, and the ergonomic implications of service quality are presented

2. SERVICE DEFINED

Service can be defined as the production of largely intangible items for the benefit of customers. Items are intangible in the sense that they are only secondarily evidenced by a physical item or commodity. Thus, a visit to a physician may involve paper records, X-rays and medicines but the objective of the visit is to diagnose, give a prognosis and develop a course of treatment for the customer. Service typically represents a change in the status of a customer or their belongings. Thus, a car is washed, a customer is transported to work, funds are moved to or from a customer's bank account or a telephone conversation takes place. Hence, the key commodity in service is information rather than a physical product. Note, however, that a large fraction of manufacturing activities is in fact services, such as buying, information management, personnel, marketing or sales.

Another key to service is that the customer is involved much more directly than is the case for manufacturing or agricultural operations. A customer interacts personally, or via communications media, with an agent (human or machine) of the service company, rather than being at the end of a long chain of operations. Thus, many service employees see customers continually, rather than only occasionally. In the transactions between customer and service employee, the outcome is decided by their joint actions. At the start of a transaction it is quite possible that neither will have a clear idea of either the objective of the transaction or its outcome.

This closeness of customer contact and interaction is a key dimension of service activity. Across the whole spectrum of service organizations it can range from high, for example interacting with an architect for the design of a home extension, to low, as is a customer placing a coin into a vending machine for a beverage. Haywood-Farmer (1988) developed a general classification for service industries based on three dimensions:

1. Degree of customer interaction.
2. Degree of labor intensity.
3. Degree of customization.

Customer interaction is greater in some industries, such as travel agencies, where the customer is an active participant in the service provision. Labor intensity refers to the relative abundance of personnel in some service industries, such as teaching low values imply a more automated service. Customization incorporates the notion of differentiation between the needs of different customers. A fast-food restaurant has few options on its menu compared with a full-service restaurant, allowing customers less freedom to choose according to their different tastes.

With these dimensions go three attributes of the service, each of more or less importance depending on the industry:

1. Physical facilities, procedures.
2. Personal interaction.
3. Professional judgement.

In industries with low customer interaction, low labor intensity and low customization, the physical facilities and highly developed procedural rules are what dominate a customer's judgement of service quality. Personal interaction is important for service transactions with high labor intensity, such as beauty parlors or barbershops. Professional judgement distinguishes services with a high degree of customization and customer interaction, where a highly differentiated outcome is needed.

These classification schemes become useful when the ideas of quality and quality management are applied to service industries. Service quality will now be examined before explaining its impact on ergonomics.

3. SERVICE QUALITY

Quality is fitness for use of either physical or intangible goods. The Quality Movement has been reviewed elsewhere in this encyclopaedia, so service quality will only be concentrated on. Service quality has been defined and measured from three different perspectives: performance observations, customer perceptions and service failures.

Service performance observations are the most straightforward definitions for service quality and, more importantly, they are easily measured. They can be further categorized into either temporal or behavioral measures. Temporal measures, which are widely used in various service settings because of their intrinsic simplicity and measurability, quantify service performance as customer's waiting time (e.g. time waited

for service responses or time spent in processing services) or promptness. On the other hand, behavioral measures are qualitative performance observations. Service personnel's greetings, verbal responses and even non-verbal gestures (e.g. smiling, bowing or handling customer's belongings) are frequently considered as behavioral performance measures. These performance observations have arisen from the direct transfer of the quality experiences from manufacturing settings to service settings. The applicability of statistical process control (SPC) techniques is emphasized. Most importantly, service performance measures are meant to be objective, explicit and able to be monitored on-line and internally. However, the meaningfulness of these measures to service quality improvement or even to service quality is in some doubt.

The second type of service quality measure comes from the customer's perspective, i.e. the quality of service is determined directly by the customer. The well-known Gap model and SERVQUAL (Parasuraman *et al.* 1988) defined service quality as the gap between customer's expectations and customer's perceptions of service. Although this service quality definition has been debated, the emphasis on a user perspective with customers as the final judge of service quality is well accepted. However, the major shortcoming of this definition is that the information from the customers is external and may be difficult to relate directly to service quality planning.

The third approach for defining and measuring service quality focuses on error-free service. That is, service quality is assured as a reduction in service defects or failures and/or the presence of recovery modes for service failures. Service recovery strategies such as unconditional service guarantee are promoted as the corrective approach to ensure service quality. Critical incident techniques (CIT) are widely utilized to assess and collect the information regarding service failures. Fail-safe design (Chase and Stewart 1993) has also been promoted as a preventive approach towards error-free service. One major advantage of using these failure-based approaches is that service quality is described in terms of the tasks and the context of the interactions between service personnel and customers. Therefore, the information collected is more activity- or context-oriented and thus more meaningful to quality assurance or quality improvement. Caution should of course be exercised because of reporter- or context-biases in interpreting service failure data.

4. THE HUMAN ROLE IN SERVICE QUALITY

If quality is seen as the control of errors, then examples of human factors in service quality are relatively plentiful. In the medical profession there have been several studies of error, how errors arise, how they propagate through the system and how they can be controlled. Bogner (1994) provides a number of such examples and more recent work has applied human error analysis techniques to the blood supply. Similarly in transportation, error studies go back to the dawn of human factors in the Second World War, and forward to studies of automation-induced pilot error in modern airlines. Recently, errors in aviation maintenance, another service industry, have had similar attention.

These error studies, although certainly in the service sector, do not address some of the characteristics more typical of the 'higher' ends of the service taxonomy, where human professional judgement during direct customer interaction plays an important

role. In one sense they are closer to our usual examples from manufacturing. Within the service quality community, human factors/ergonomics has often been confined to the measurement of customer attitudes, opinion and satisfaction. There is clearly a role for ergonomics in a set of tasks with these characteristics:

There is direct interaction between the operator and the ultimate customer in many service applications, such as retail or banking. Most interactions between customers and operators are less routine than those between physical processes and operators. Each operator/customer interaction is in a sense unique.

The error measures available, or even possible, may not be as amenable to SPC techniques. For example, it is possible to plot control charts of the number of errors per hundred or thousand or million interactions, but can these errors really be added together? What action does the SPC chart indicate when a significant increase in error rate is discovered? In one sense, if there are enough errors to count, the service system has already failed its customers.

Service may have unique characteristics, but many human factors techniques should be directly applicable. An example is the model of customer/operator interaction in service quality proposed by Chen and Drury (1997). They used examples of service providers who must handle a wide variety of customer requests, for example bank officers or travel agents. Both of these operations are undergoing rapid computer conversion, so that there are often two parallel customer/operator models: with and without a human agent. In both cases, the ultimate aim of the customer is to access data (available through the computer, print media or via networks of contacts) to solve a unique problem, such as obtaining a loan, making an investment or booking a vacation. In both of these the customer's objective is to obtain the service required, but which the customer may be currently unable to articulate. It is the task of the agent in Figure 1 or the computer system in Figure 2 to make the customer's needs explicit enough to access the correct data base and to search it for the solution that best matches the customer's needs.

As an example, a bank customer may wish to invest $1000 for 3 months, but much interaction would be required to determine whether the customer's investment strategy should be characterized as aggressive (e.g. maximum return on investment) or risk-averse (e.g. minimum probability of monetary loss). The customer may not even use such terms. To complicate matters further, the customer may be willing to invest a somewhat

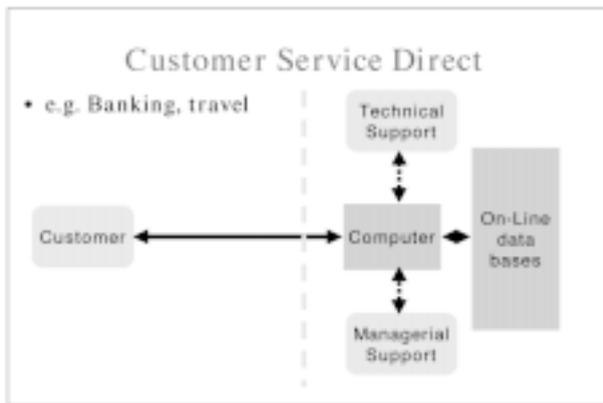
Figure 1. Customer service direct.


Figure 2. Customer service via agent.

different amount (e.g. if a particularly attractive investment had a $1200 threshold) or to change the time scale slightly.

With a human agent (Figure 1) this explanation of alternatives may be an interesting and feasible, if time-consuming, exercise. But where the allocation of function has been changed to an entirely computer-mediated transaction (Figure 2) many differences arise. For example, a computer program may be able to ask pertinent questions but would be unlikely to be useful to a customer who had little concept of elasticity and risk. Thus, changing the function allocation would likely change the type of customer who could be served. This particular service could end up with quite different customers choosing the alternative system designs represented by Figures 1 and 2, with the less informed and less computer literate customers migrating to a service that may have a higher price.

The implications of using models such as Figures 1 and 2 to study service quality is that they remain focussed on the central transaction between customer and system. Thus, human factors/ ergonomics techniques have to be used to understand the essence of the service. In this way it can be understood *why* errors arise rather than just counting and charting them. This allows one to move beyond statistical process control techniques and to develop a true application of ergonomics to service quality.

Shift Work

K. Kogi

The Institute for Science of Labour, 2-8-14, Sugao, Miyamae, Kawasaki, Kanagawa 213, Japan

1. REASONS FOR SHIFT WORK

Shift work is done by two or more groups of workers who alternate their work shifts assigned at different times of a given day. A shift refers to hours of the day in which a worker or a group of workers is scheduled to be in the workplace. This enables the undertaking to operate longer than the usual period of a work day, extending the business to night or early morning hours. The total period of time covered by the shifts can be either continuous for 24 hours, or discontinuous for less than 24 hours a day.

In the modern industrial society, shift work spreads to various sections of industry. While the emphasis may depend on different economic structures, the reasons for employing shift work are similar in different countries:

(a) Shift work is necessitated by technological requirements for continuous plant operation, as in iron and steel mills, metallurgical factories, chemical and other continuous processes.

(b) Shift work is used in many manufacturing, mining, and construction undertakings for economic reasons in order to profitably use costly or automated equipment. This profitability results from the rapid depreciation of expensive equipment, increased competitiveness due to reduced overall costs per unit of production, and increased flexibility in meeting changes in demand.

(c) Shift work is widely used for public services attending people during night and early morning hours. Often, 24-hour operation is needed as in communication services, public transport, power generation, health and welfare services, hotels and security. Though not necessarily for continuous 24 hours, radio and television stations, car service stations, entertainment centers and restaurants also require shift work. Shift work is increasingly used in computerized services and local authorities.

(d) Natural environmental factors or the interaction with natural resources may require shift work as in the case of farming work, livestock raising, plantations, fishing, food processing, and others.

(e) Social factors may be mentioned where business or service operations are extended for social reasons, such as reduced normal hours of work resulting in the adoption of shift work.

Thus the spread of shift work largely depends on the industrialization and urbanization of the national economy. As industrialization proceeds, about 10–20% or even more of the workforce may be engaged in different forms of shift work. A series of international labor standards are relevant to shift work. The Night Work Convention (No. 171) adopted in 1990 by the International Labour Organization (ILO) has broadened the scope and applies to both genders and nearly all occupations, stipulating the provision of safety and health services, maternity protection, resting periods, social services, consultation on work schedules, and others. The European directive 93/104/EC also confirmed the need for regulating measures of shift work for improving safety and health protection.

2. SHIFT WORK SCHEDULES

Shift work schedules may be organized in a large variety of ways. A shift system may include day work plus one or more shifts worked outside these normal day-work hours. Thus the number of shifts per day may be two, three or more. These shifts may be shorter or longer than, or of the same duration as normal day-work hours, sometimes overlapping with them. Major problems of shift systems arise from the extension of business hours that result in a phase-displacement of the sleep period and therefore substantial changes in the daily life of shift workers. These changes create many problems compared with a minor extension of day-duty hours toward the evening that may not necessarily hamper the sleep period.

Most shift systems can be classified according to the four basic features:

(a) whether the crews of different shifts rotate or work permanently on a particular shift;

(b) whether any shift extends into hours that would normally be spent asleep (i.e. night hours);

(c) whether the shifts cover the 24 hours of the day; and

(d) whether the shifts are worked throughout the week or with a free weekend.

As shown in table 1, shift systems are first categorized according to whether they rotate (rotating systems) or not (e.g. permanent night work), and then into two groups, those involving night work and those without night work. The latter is represented by "double dayshift" systems worked by morning and afternoon shifts and normally without weekend work. Those night-working systems are either manned for 24 hours a day (24-hour systems) or for less than 24 hours a day (discontinuous systems). A typical discontinuous system involving night work is one in which day and night shifts are alternated with operations suspended for a few hours between them and during the weekend. Twenty-four-hour systems can be further divided into continuous systems, worked 7 days a week, and semi-continuous systems that do not involve weekend work.

The number of shifts per day may be two or three in typical shift systems. Today, most discontinuous systems have two shifts, either morning and afternoon shifts (as in the case of "double day-shift" systems) or day and night shifts. Twenty-four-hour systems have two, three, or more shifts, the length of the shifts varying much between different systems. Two 12-hour shifts are frequently seen, whereas the two shifts may differ in length, for example, comprising an 8-hour shift and a 16-hour shift. Typical three-shift systems have three 8-hour shifts, but the actual shift length may vary, sometimes overlapping with each other for the reason of work duty changes. There can be four-shift systems consisting of 6-hour shifts or split-shift systems. Permanent shift systems are generally less frequent, although countries such as the United States engage many permanent night workers in addition to rotating shift systems.

There are a large number of irregular shift systems in which shifts of various starting and finishing times are worked by workers to cover the required production or services demands. These irregular systems are common for transportation, telecommunication, and services. Further, it should be noted that

Table 1. Classification of different shift schedules

Systems	(a) Rotated?	(b) Night-involving	(c) 24-hour business	(d) Weekend work	Number of straight shifts
Permanent shifts	no	mostly yes	yes or no	yes or no	various
Double-day shifts	usually yes	no	no	usually no	usually 5
Discontinuous systems involving night work	usually yes	yes	no	usually no	up to 5–6
Semi-continuous systems	usually yes	yes	yes	no	up to 5–6
Continuous systems	usually yes	yes	yes	yes	1–5
Irregular systems	mostly yes	yes or no	yes or no	yes or no	various

mixed or hybrid systems are not uncommon. An increasing tendency of shift work is to have systems comprising different shift schedules; for example, continuous three-shift schedules combined with weekend 12-hour shifts.

Increasing flexibility in organizing shift systems is an emerging feature for many shift systems. This relates to the need for extending business hours despite the general trend for shorter hours of work per worker as well as to the need for accommodating workers' preferences for flexible working time. Flexibility is achieved by varying shift hours or by allowing workers to change their own shift-rotating schedules depending on their preferences as well as by combining different shift schedules. There are many innovative patterns for increasing flexibility. Flexitime allowing individual workers a choice of the day's working hours can also be introduced to shift systems if workers can change their starting and finishing times by making arrangements among those working at the same worksite. Compressed work weeks (e.g. three 12-hour shifts per week) or combinations of different shift systems may be used for increasing flexible manning of various shifts. Part-time work and job-sharing schemes may also be used. Numerous variations of flexible shift schedules are increasingly applied, including reduction in the frequency of unpopular night shifts, more time off in weekends, additional working time reductions or additional holidays, opportunities to exchange shifts as well as preferential treatment of time off or vacations for particular workers. Advantages and problems in adopting flexible work schedules for the enterprise and for the worker are listed in table 2.

Shift schedules with increased flexibility are advantageous for more competitive business operation and for responding to workers' preferences. Economic and manning advantages for the enterprise are significant. This contrasts with often remarkable disadvantages for workers who may have to work longer shifts or suffer from irregular schedules and sometimes increasing strains in social and family life. The need to reorganize job content as a result of increasing flexibility is also obvious. This is because it is often necessary to redistribute job duties among shift workers when more flexible work schedules are introduced, such as reorganizing night work tasks, improving communication, or applying multi-skilled jobs. Thus it is important to redesign work tasks themselves in realizing flexible shift systems.

3. ASSESSMENT OF SHIFT WORKERS' PROBLEMS

The problems of shift workers relate to both the phase-displacement of their work–sleep periods and adverse negative working conditions that may be combined with shift work. The effects of the phase-displacement lead to disruptions in physiological "circadian" rhythms. Human biological rhythms are adapted to daily work–sleep schedules and cannot be easily inverted even if we change the phase of these work–sleep schedules. These internal rhythms are called "circadian rhythms" as the rhythms have an approximate cycle period of 24 hours and manifest day-and-night changes in functional levels of various parameters reflecting the "internal clock". Circadian rhythms are found in many physiological functions, such as body temperature, blood pressure, heart rate, blood concentrations of proteins, electrolytes, hormones, etc., as well as cerebral functions. Some of the internal rhythms can be phase-displaced relatively easily in accordance with the change in work–sleep periods, but many others cannot be so easily phase-displaced. It is well known that, in the case of "jet lag" after travelling by jet planes to a place with a time difference of several hours or more, people suffer from disturbed sleep, feeling unwell, and reduced work capacity. Such jet-lag symptoms disappear within a few days as the internal circadian rhythms are adapted to the new time zone. In the case of shift workers, however, similar "shift-lag" symptoms persist as long as the night-work–day-sleep schedule continues.

As a result of this incomplete reversal of circadian rhythms, the shift workers may be subjected to problems in work, sleep, safety, and health, in addition to other effects associated with shift work and with disrupted social and family life. These problems are best shown by the stress and strain relationships of shift workers as shown in table 3.

Shift work, in particular night work, can have negative

Table 2. Advantages and problems in adopting flexible shift schedules

	Advantages	Problems
For the enterprise	Longer business hours	Higher administrative costs
	Adjusting to fluctuating demands	More difficult supervision
	Improved labour productivity	More welfare services
	Improved recruitment	Increase in training costs
For the worker	Shorter working hours	Fatigue by longer shifts
	More time for personal needs	Strains in family life
	Increase in voluntary options	Separate social life
	More responsible jobs	Temptation to a second job

Table 3. Stress and strain relationship of shiftworkers

Stress --->	Intervening variables --->	Strain --->	Potential effects
- Phase-displacement of work/sleep hours	- individual characteristics - job-related factors	Sleep changes Fatigue	- Inefficiency - Unsafe work
- Unfavourable working, organizational, and social conditions	- environmental conditions - domestic circumstances	Less capacity Complaints	- Impaired health - Reduced well-being

impacts on health and well-being of workers. Deterioration of health can be manifested in disturbances of sleeping and eating habits, and, in the long run, in more severe health disorders. Since reaction time, computation and problem-solving performance are significantly affected, declining during night hours often with sleepiness, one serious consequence of fatigue and sleep deficit by shift work is the increased risk of accidents. Chronic health disorders prevalently deal with gastrointestinal (colitis, gastroduodenitis, peptic ulcer), neuropsychic (chronic fatigue, anxiety, depression) and cardiovascular (hypertension, ischemic heart diseases, cerebrovascular disorders) functions. In addition, reports show that shift and night work may have more specific adverse effects on women's health both in relation to their hormonal and reproductive functions and their family roles. Many shift workers leave shift work after a short time because of serious disturbances, while those remaining in shift work show different levels of adaptation and tolerance. The effects of such stress conditions can vary widely among shift workers in relation to many intervening variables, as well as working life situations.

4. DESIGN OF SHIFT SYSTEMS

The design of shift systems is a complex issue, often requiring special skills. We should note that there are no ideal systems simply computed using given criteria. This is because a variety of organizational and social aspects must be taken into account. Not only the nature of work and manning demands, but also safety and health effects, social needs, workers' preferences, absences and fluctuating business must be considered. Usually, a basic shift pattern is negotiated between managers and workers to agree on modified patterns meeting the local needs. This cautious approach is recommendable.

The design process greatly differs between different categories of shift systems shown in table 1. The shift patterns agreed on may be relatively straightforward in the case of permanent night and evening shifts or weekly rotated systems without weekend work. In the case of continuous or irregular systems, however, the design process is complex and varies considerably on account of local customs and differences in preceding systems. Normally, options for shift design relate to a number of factors: permanent or rotating shifts, direction and rate of rotation, length of work shifts, number of consecutive shifts, number of consecutive days off, shift changing times as well as special provisions and rules for work shift use. One prominent problem arises from the number of consecutive night shifts and that of days off, both varying greatly according to industries and local customs. Longer periods of consecutive night shifts have been common in some countries such as the United States, while rapidly rotating systems with 3–4, or less, consecutive work days in the same shifts are increasingly popular in many other countries. But even in the latter systems, actual shift patterns differ greatly. Some useful suggestions for shift pattern design are given in table 4.

The night shift is the most disturbing because of disruptions in circadian rhythms, sleep difficulties, and well-being problems. Thus, minimizing the use of night shifts should be the primary concern. Reduction in overall working hours and avoidance of excessive overtime work are necessary for shift workers considering their special burdens. Wherever possible, night work should be avoided or minimized. Except for established local lifestyles favoring permanent night workers, the use of permanent night shifts is not recommendable for the majority of shift workers. For rotating shift patterns, the suggestions in the table are generally advisable.

Because there is no "optimal shift systems", managers and workers should find a reasonable compromise between business demands and workers' needs. Many guidelines and manuals are available. There are many innovative shift patterns and the advantages of these new patterns should be referred to. Recent examples include rapidly rotating (two or three consecutive night shifts) five-team three-shift systems, systems with free weekends, systems with

Table 4. Useful suggestions for designing better shift systems

(a) Nature of work	The nature of work and workload suitable for extended hours.
(b) Use of night shifts	The use of night shifts minimized as much as possible.
(c) Overtime	Overtime not added with arrangements for cover of absentees.
(d) Consecutive night shifts	Only 1–3 night shifts in succession wherever possible.
(e) Between-shift intervals	Short intervals between two shifts (e.g. 7,10 hours) avoided.
(f) Free weekends	Some free weekends with at least two consecutive days off.
(g) Length of shift	Depending on physical/mental load, shorter for night shifts.
(h) Shift rotation	Forward rotation (morning to afternoon to night) preferred.
(i) Shift change times	Allowing individuals some flexibility.
(j) Good sleep periods	Good bedroom quality, securing longer sleeps and naps.
(k) Eating/physical fitness	Eating at regular times, keeping fitness with medical checks.
(l) Social and family life	Sharing household work, planning time off positively.

reduced staffing of night shifts as well as continuous systems involving day-work periods taken in turn by different shift teams.

Rapidly rotating schedules have advantages compared with slow or weekly rotation. Faster rotation tends to disrupt the circadian rhythms in a lesser degree because the original day-work–night-sleep style is quickly resumed before fatigue and sleep deficiencies accumulate. Field studies show that the majority of shift workers favor quicker rotation after a trial period. Rapid rotation seems to facilitate more opportunities of participation in family life and more regular social contacts. To confirm the long-term effects of rapid rotation, detailed studies may be necessary. Some basic examples of weekly and rapidly rotating schedules are indicated in table 5.

Other features of shift systems including the length of shifts, between-shift intervals and shift-changing times also influence both physiological adjustment and social life of shift workers. Forward rotation is favored as it can avoid short intervals and easier to adapt. While avoidance of lengthy shifts and too short between-shift intervals is generally favored, they occur in many shift schedules. For example, 12-hour shifts are frequently adopted as they lead to less commuting frequencies and more days off. It is argued that 12-hour shifts, as in the case of four-team two-shift systems in continuous operations, may be applicable if the work is not physically or mentally strenuous. As one of disadvantages of 12-hour shifts is increased fatigue, single night shifts or a maximum of two night shifts seem recommendable. Another argument for 12-hour shifts is that these

Table 6. Examples of support for shift workers

(a) Better work schedules	Consultation about shift schedules, increasing flexibility
(b) Keeping capacity at work	Ergonomic work design, fail-safe operations
(c) Securing restful conditions	Flexible schedules, resting facilities, housing
(d) Support for family care	Child care facilities, child care leave, social services
(e) Facilitating coping measures	Group work, training on coping
(f) Support for health	Health counselling, health check, access to daywork
(g) Support for career planning	Retraining schemes, educational leave, early retirement

shifts can increase flexibility in shift patterns. Examples include combination of 12-hour shifts with three-shift schedules or the use of part-timers for week-end 12-hour shifts. It is necessary to examine the use of flexible working time arrangements in assessing shift schedules.

5. MANAGING SHIFT WORK AND SUPPORT FOR SHIFT WORKERS

Improving shift patterns and providing various support measures for shift workers are both important in managing shift work. Examples of support measures for shift workers are listed in table 6.

Safety and health measures must be given a priority, including safe-work methods, good teamwork, rest periods, better work environment, health checks, counseling, and providing access to day work for workers suffering from ill-health due to shift work. Support for good housing conditions and for family care is important. Maternity protection and support for women shift workers having family and other burdens are very important. Reduction of sleep problems, food intake, physical fitness, and support for taking various coping measures are also important. Further, individual day-work–night-sleep patterns are important in supporting their adjustment to shift schedules, including "morning" and "evening" activity patterns. In general, support for sleep and coping strategies of individual workers in their different daily life situations is essential. While many compensation schemes exist for shift work, comprehensive approaches should be taken to meet varying needs of shift workers.

Shiftwork and Sleep

Professor D. I. Tepas

Industrial Psychology, Connecticut Transportation Institute, University of Connecticut, 179 Middle Turnpike, Box U-202 Storrs, CT 06269-5202, USA

1. INTRODUCTION

With regard to hours of work, the term *shift* is defined as the hours of the day that a worker is required to be in the workplace. Given this definition, most workers are shiftworkers. Work schedules take many forms. A worker may have *permanent* hours, with their shift at the same time of day every workday. Many workers have *rotating* hours, with the time of day they work changing in a scheduled way. Some workers are employed on *irregular* hours, with shift starting times and/or durations varying in an erratic or unpredictable way.

The work schedule categories for individual workers, noted in the previous paragraph, may or may not be combined to form the *work schedule system* for a group of individuals operating within an organization. These operations may be *continuous*, employing workers around the clock, seven days a week. In many cases these are *discontinuous*, not requiring around the clock work and/or weekend operations. Emergency and/or military activities often require *sustained* operations, requiring workers to perform as long as they can. Given these variations in operations and the forms work shifts hours take, an immense variety of work schedule systems are possible.

Work schedule systems requiring night work, unpredictable work hours, long or short workdays, and weekend duty are often perceived as being non-traditional, unusual, infrequent, undesirable, uncommon, and unneeded work. Although some of these adjectives accurately describe many existing work schedule systems, these generalizations are not warranted and many are associated with service requirements. For example, the requirement for night work in the healthcare industry precedes the factory system and the industrial revolution. The humanitarian value of emergency search-and-rescue operations is widely accepted. Weekend work to monitor nuclear operations is mandatory. In fact, it would appear that the majority of US workers are now employed on what some would term non-standard work schedules (Presser 1995). In the contemporary world, the question is not if these alternative work schedule systems are to be used, but rather how and where these systems should be deployed.

2. SLEEP

At first glance, the importance of sleep to the ergonomic study of shiftwork is not obvious. Some of the factors contributing to this impression: many work systems do not require night work; nearly everyone has experienced acute but short-term exposure to sleep deprivation without having a catastrophic problem; for many people, sleep appears to be a behavior they can control within what they perceive of as reasonable limits; and, many human factors people assume that time-of-day effects are the same as time-on-task effects. Research in the last 20 years has demonstrated that: sleep deprivation and/or time-of-day factors can lead to catastrophic events; there are few (if any) successful countermeasures to avoid falling asleep when one is sleepy; and, time-of-day and time-on-task effects interact and sometimes mask

each other. Numerous studies, by many investigators using a variety of methods, have reported that sleep complaints are elevated in shiftworkers. But what does this mean?

People are diurnal beings. since they tend to be active during the day and they do have a physiology driven by an internal biological clock. These variations in physiology and behavior are said to be *circadian*, given their cycle time of about 24 h. Research has shown that it is generally difficult to make quick and large changes in the timing of biological clock circadian variation. Data from jet-lag observations, sustained operations, and individuals in social isolation tend to confirmed this finding. These studies demonstrate that over a short-term period attempts to be active when the internal biological clock says sleep result in degradation of performance, changes in mood, and disturbed sleep. Under these acute conditions, performance is often driven by biological factors.

The impact of long-term chronic exposure may be quite different. Shift workers subject to chronic exposure to night or rotating shiftwork have biological, social and cultural problems (Tepas, Paley and Popkin 1997). With regard to sleep, these problems are manifest as a *reduction* in sleep length (Tepas and Carvalhais 1990), rather than as a sleep disturbance (Mahan, Carvalhais and Queen 1990). Equally important is the conclusion that social factors may outweigh biological ones (Monk 1989). Thus, evaluation of the chronic impact of a bad work schedule must consider not only the impact of sleep deprivation but also the workers perceptions and preferences.

A study of experienced shiftworkers demonstrates the role of chronic sleep deprivation and worker perceptions (Tepas and Mahan 1989). This was a study of 324 hourly workers on permanent discontinuous shifts. These workers were selected from a larger pool of workers to produced three matched groups, with 108 workers in each group. The three groups were matched on the basis of age, shift tenure, gender, and industry. The three groups were: D/D, workers who were employed on the day shift and most preferred to the day shift; N/D, workers who were employed on the night shift and most preferred the day shift; and N/N, workers who were employed on the night shift and most preferred the night shift.

Figure 1 shows the mean sleep length for workers in each of these three matched groups on workdays and non-workdays. For all three groups, non-workday sleep length was significantly longer than workday sleep length, but the differences between the three groups were not significant on non-workdays. On workdays, the D/D group slept significantly longer that the other two groups. These data demonstrate a chronic reduction in the quantity of sleep on workdays, with night shiftworkers showing a significantly greater impact. There was no evidence in this data base to support the notion that workers who like night work sleep longer or fully make-up for lost sleep on their days-off.

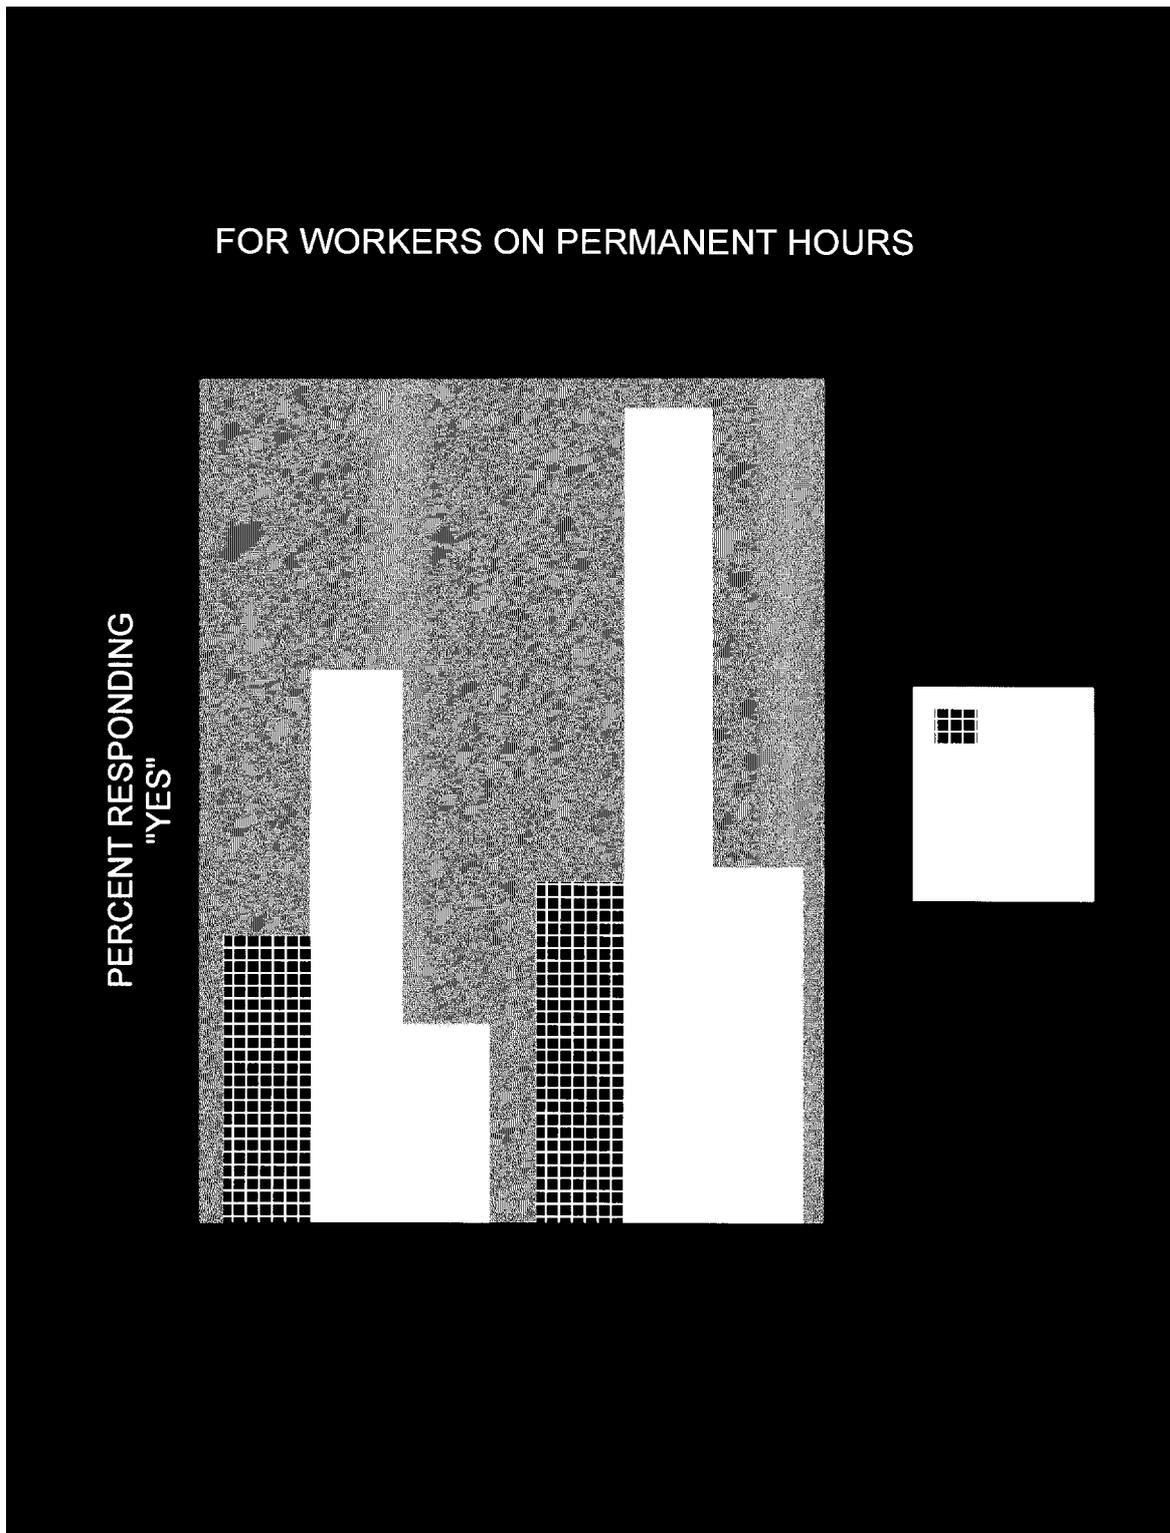
Shift workers often complain about the quality of their sleep, even though their polysomnographic sleep recordings suggest a reduction in sleep length is the major factor, rather than a disturbance of sleep (Tepas, Walsh, Moss and Armstrong 1981). These reductions in sleep length are most often associated with night shiftwork and they do *not* disappear with continued exposure to night shiftwork. It is important to note that the reduction in sleep length associated with night shiftwork is also present in workers who prefer night work and do not report many complaints about the quality of their sleep. Figure 2 shows


FIGURE 1. Mean reported workday and non-workday sleep length in minutes for workers on permanent hours.
[*Note*: **Data from three matched groups, with 108 workers in each group: D/D, workers who were employed on the day shift and most preferred to work the day shift; N/D, workers who were employed on the night shift and most preferred to work the day shift; and, N/N, workers who were employed on the night shift and most preferred to work the night shift. Graphs plotted from data reported by Tepas and Mahan (1989).]**

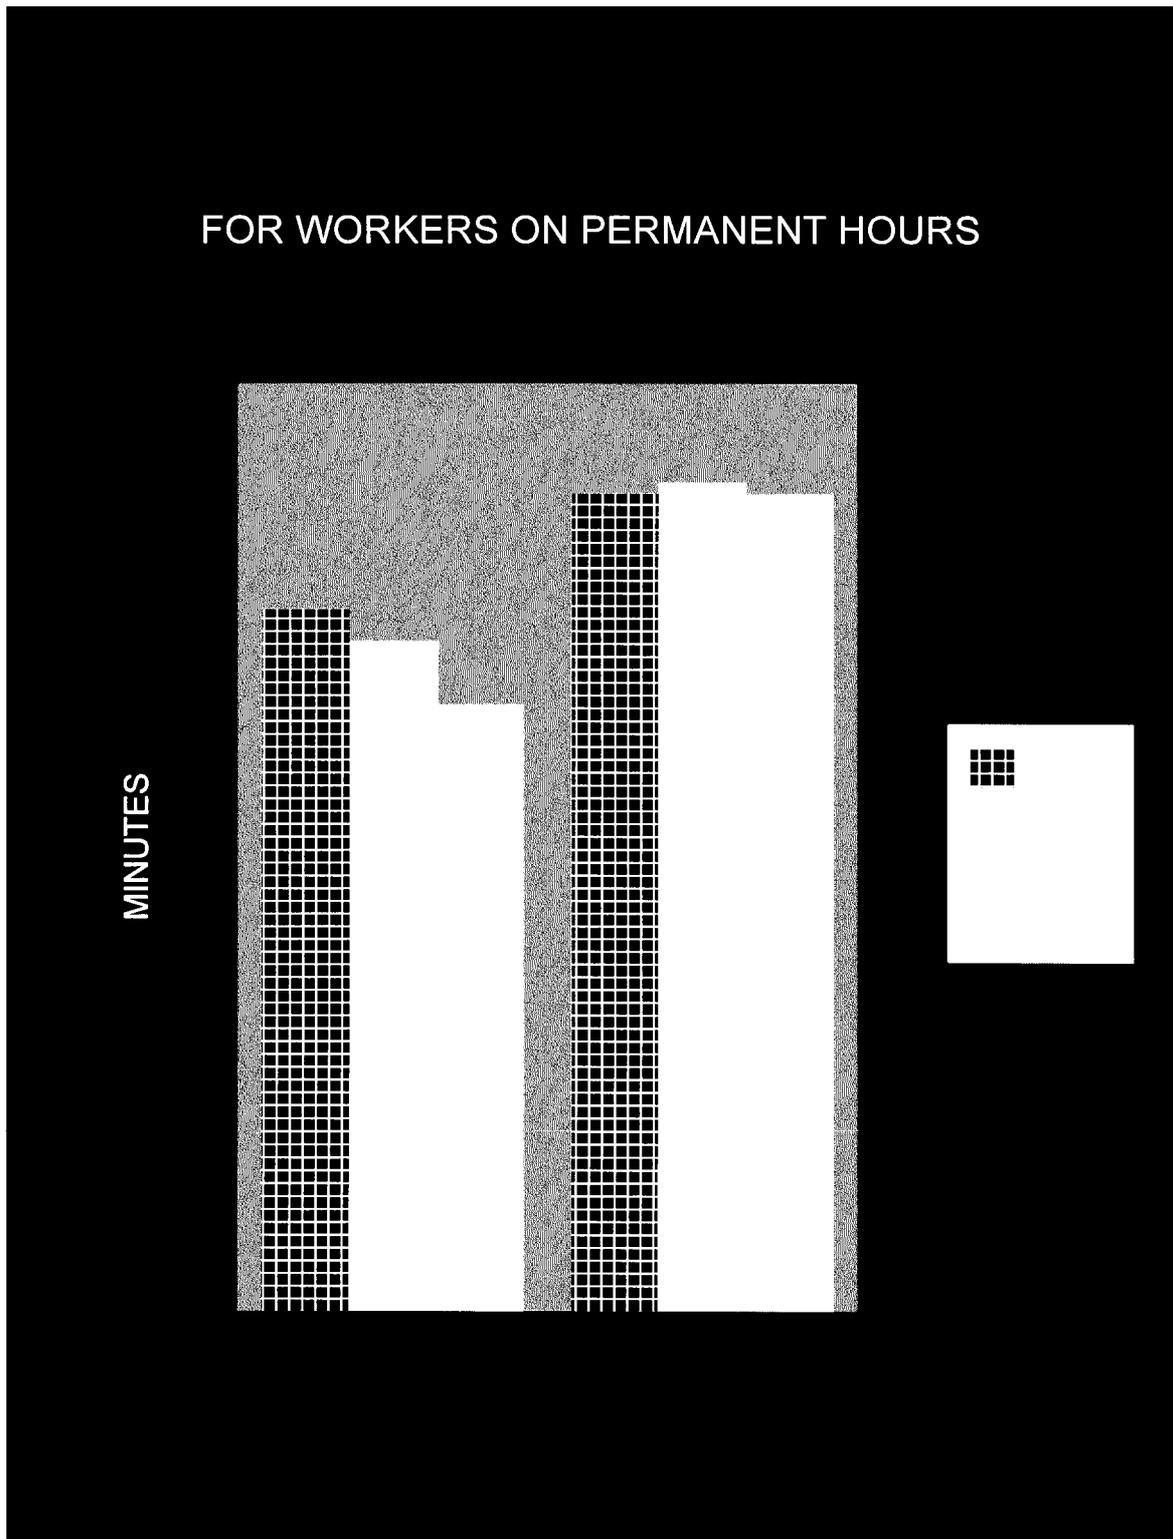
the response of these three groups to two sleep quality questions: "Do you often have difficulty falling asleep?" and "Do you often have difficulty staying asleep?". The results obtained for the two questions are quite similar in each case. Workers in the N/D group most often reported that they had sleep problems. These data suggest that complaints by night shiftworkers about the quality of their sleep are related to their work shift preferences, perhaps more than to working the night shift per se.


FIGURE 2. Percentage of workers responding "Yes" to two sleep quality questions: "Do you often have difficulty falling asleep?" and "Do you often have difficulty staying asleep?".
[*Note*: Data from three matched groups, with 108 workers in each group: D/D, workers who were employed on the day shift and most preferred to work the day shift; N/D, workers who were employed on the night shift and most preferred to work the day shift; and, N/N, workers who were employed on the night shift and most preferred to work the night shift. Graphs plotted from data reported by Tepas and Mahan (1989).]

When chronic exposure to a work schedule system is to be assessed, sleep length data are often a benchmark which can be used to assess the merits of a specific system. *Sleep data provide the ergonomic investigator of work shift systems with a valuable tool.* However, this does *not* mean that ergonomic analysis need only focus on estimates of physiological systems or chronobiology. Chronic reductions in sleep are associated with health and safety hazards, but the usability of a given work schedule system depends on many variables. The state and interaction of multiple physiological, social and cultural variables must be considered. In most cases, if not all, intervention efforts call for a macroergonomic approach to work schedule system design.

3. ERGONOMIC DESIGN CONSIDERATIONS

Given the conclusion that multiple interacting variables determine the impact of a given shift schedule, it should not be surprising that work schedule systems take many forms. In fact, thousands of different work schedule systems are being used. In practice, managers often behave as if they think work schedule systems take only a few forms. They assume that one or two of these forms can be labeled by the expert as the best schedule available. However, the contemporary consensus among work schedule experts is quite different. Research data leads work schedule experts to assume that there are *no* universal work schedule solutions for shiftwork which can be applied to most workplaces or all workers. Some dimensions which should be considered in designing a system are: worker age and gender; job task load; household size and duties; worker preferences and experience; current employment conditions; and, assessments of stress, fatigue, health and safety data.

Just as it is reasonable to conclude that there is no single variable which determines shiftworker maladjustment or adjustment, it is also reasonable to expect that multiple work schedule solutions may all be acceptable for a given workplace. Most ergonomic design efforts consider and evaluate alternative designs, and this is also true when one evaluates work schedules. A good work schedule systems design or evaluation effort includes a consideration and evaluation of alternative work schedule forms. Some of the options which should be considered are: whether the hours of work should be permanent or rotating; the direction of rotation, if there is to be any; the rate of rotation, if there is to be any; the length of workdays; what days of the week are to be non-workdays; the time of day shifts start, and the temporal regularity of shifts.

4. WORK SHIFT USABILITY TESTING

The macroergonomic focus for work shift design places an emphasis on the development of assessment tools, rather than a search for universal solutions. The array of tools used to schedule, design and/or evaluate work is referred to as *workware*, just as the term software refers to an array of tools used to program computer hardware to perform tasks and/or evaluate hardware. *Work shift usability testing* is one form of workware. Just as a computer software program requires software usability testing, a good work schedule systems requires work shift usability testing. Like other forms of usability testing, work shift usability testing makes the assumption that reliable and valid testing with real users is required.

Recommended approaches to work shift usability testing are detailed in Tepas (in press). These are new and evolving technologies whose use will become more common as around-the-clock operations continue to expand. For the present, it is reasonable to assume that many managers are not aware of the range of alternative work schedules available, or the need for a professional systems approach to the selection and evaluation of work schedule systems (Tepas 1994). The definitions and notations used for many shiftwork terms and categories often vary in the literature, in popular use, and from nation to nation (Tepas, Paley and Popkin 1997). Good ergonomic practice should stress the importance of clear definitions, good notation systems, and the quantitative assessment of existing and new installations. Unlike some ergonomic design problems, work shift usability testing does require a macroergonomic approach.

Shiftwork Health Consequences

G. Costa

Department of Public Health, University of Verona, I-37134 Verona, Italy

1. INTRODUCTION

Shiftwork is increasing in modern society as an important tool of flexibility of the work organization. It enables one to cope with round-the-clock activities in relation to technological constraints, productive demands, social services and leisure activities. According to some recent statistics ~20% of workers in industrialized countries are involved in some form of shiftwork including nightwork.

There are several types of shift systems that differ according to their main characteristics such as: permanent or rotating; continuous or discontinuous (interruption on weekend or on Sunday); with or without nightwork; regularity/irregularity and length of the shift cycles, duration of the shifts (e.g. from 6 to 12 h); number of crews; start and finishing times of shifts; speed (fast, slow) and direction (clockwise or counterclockwise) of shift rotation.

Shiftwork, in particular that including nightwork, can have a negative impact on workers' health due to a mismatch between psychophysiological functions and environmental synchronizers, which can cause significant disruptions of biological rhythms, social and family life. This can have adverse effects on performance efficiency, health and social relations, and lead to increased risk of errors and accidents, morbidity and absenteeism, with consequent high economic and social costs both for the individual and the society.

2. INTERFERENCE ON PSYCHOPHYSIOLOGICAL FUNCTIONS

On shiftwork, and particularly on nightwork, workers are compelled to alter their normal sleep–wake cycle according to the changed activity and rest periods. This interferes with the regular oscillation of bodily functions ("circadian rhythms"), which are linked to the normal diurnal pattern of human life showing, in general, higher levels during the day (ergotrophic phase) and lower levels during the night (trophotropic phase). This rhythmicity is controlled by a "body clock," located in the suprachiasmatic nuclei, and influenced by environmental "synchronizers," in particular activity, sleep and light exposure.

The perturbation caused by shiftwork is evidenced by a flattening of the amplitude and a shift of the acrophase (peak of the function) of the biological rhythms, which can be more or less pronounced according to the number of successive nightshifts worked and the forward (i.e. morning–afternoon–night) or backward (i.e. afternoon–morning–night) rotation of the duty periods. Consequently, a de-synchronization among the partial adjustments of the different functions is observed, also due to the "masking" influence of the physical activity, which has more effect on the functions having a prevalent exogenous component (e.g. heart rate) than those with a strong endogenous control (e.g. body temperature, cortisol).

In relation to this perturbation, workers complain to a greater or lesser extent of a syndrome similar to "jet lag," characterized by fatigue, sleepiness, insomnia, dyspepsia, irritability and impaired mental agility.

3. INTERFERENCE ON SLEEP AND MENTAL PERFORMANCE

Shiftworkers have to change sleep times and strategies according to the duty periods; consequently, both sleep length and quality can be affected considerably according to the variable retiring and rising times on the different shifts.

On nightshifts in particular, the subsequent diurnal sleep is perturbed both for physiological reasons, being difficult to fall asleep and sleep for a long period when sleep starts during the rising phase of the body temperature rhythm, and for unfavorable environmental conditions (light and noises in particular) or domestic commitments (mealtimes, child care): sleep is shorter, frequently interrupted and altered in its stage sequencing.

A reduction of hours of sleep is generally recorded also on morning shifts, due to the early start time of the duty period, which causes a cut off of the last part of the sleep, richer of REM phase.

In the long run, sleep perturbations and deprivations, besides having influence on de-synchronization of circadian rhythms and on "shift–lag" syndrome, can yield persistent and severe disturbances of sleep itself, chronic fatigue and psychoneurotic syndromes (such as chronic anxiety or depression), which often require treatment by hypnotic or psychotropic drugs.

Sleep disturbances, chronic fatigue and oscillatory fluctuations of vigilance and performance can be also important contributing factors of the "human error" and consequent accidents. It is worth mentioning that shift and nightwork and sustained operation have been claimed as important causal factors in many work accidents and in some tragic events occurred at night, e.g. the Three Mile Island and Chernobyl nuclear accidents, the Bophal disaster, the Exxon Valdez shipwreck, as well as the Challenger space-shuttle explosion.

Moreover, sleepiness due to a too early starting hour on morning shifts or in case of prolonged duty periods, can favor higher frequencies of errors and accidents also during the dayshifts, as it has been reported in train and bus drivers, and long-haul pilots.

However, the epidemiological studies on accidents in industrial shiftworkers are not all in agreement on this matter; in fact, this has to be evaluated taking into account the complex interactions between the chronobiological and the organizational factors, such as environmental conditions (e.g. lighting), job content, fluctuations in work load, time pressure, long working hours (e.g. 12-h shifts), number of workers and supervision levels.

4. DIGESTIVE AND CARDIOVASCULAR DISORDERS

Shift- and nightwork interfere also with meal times and content, thus favoring digestive disorders. These are due to displacement between meal times and phases of gastrointestinal secretion and motility, as well as to changes in food quality (e.g. cold prepackaged food), too short work pauses for meals, nibbling and, sometimes, increased intake of caffeinated drinks, tobacco smoking and alcohol consumption.

Disturbances of appetite, dyspepsia, heartburn, abdominal pains, constipation, grumbling and flatulence are frequently complained by shiftworkers (20–70 compared with 10–25% of dayworkers), who may also develop more serious illnesses such as chronic gastritis, gastroduodenitis, peptic ulcer and colitis. According to many epidemiological studies peptic ulcer shows an incidence 2–5 times higher, and a shorter latency from starting work and diagnosis, among shiftworkers with nightshifts opposed to dayworkers; on the other hand, there is a significant decrease of complaints and disorders after transfer from shiftwork to daywork.

Shiftwork can also be a risk factor for cardiovascular diseases, in particular coronary heart diseases. As a stressor, it can cause a neurovegetative activation with increased secretion of stress hormones and consequent effects on blood pressure, heart rate, thrombotic processes, lipid and glucose metabolism; these can derive also from interference on compensatory mechanisms connected to more stressful living conditions and more risky life styles (i.e. smoking, diet, sleep disturbances).

In recent years some epidemiological studies have drawn the attention on this topic, showing a prevalence of some risk factors for cardiovascular diseases in groups of apparently healthy shiftworkers, and a higher incidence of complaints related to angina pectoris and hypertension in some groups of shiftworkers. Other studies have reported an increased risk for myocardial infarction in occupations with high proportions of shiftworkers, and a higher morbidity for cardiovascular and ischemic heart diseases with increasing age and shiftwork experience.

5. INTERFERENCE ON WOMEN'S REPRODUCTIVE AND PARENTAL FUNCTION

Women can be more vulnerable to shift- and nightwork in relation both to their more complex circadian and infradian (menstrual cycle) hormonal rhythms and to extra demands related to family life and domestic commitments.

Disorders of the menstrual cycle and reproductive function have been reported in many groups of women shiftworkers, leading to a higher incidence of menstrual pains, abortion and interference on fetal development, such as premature births and low birthweight.

Besides, women shiftworkers (those married with small children, in particular) can have more difficulties in combining their irregular working schedules with the additional domestic duties, thus suffering more for sleep troubles and chronic fatigue than their male colleagues.

This can support the view that women shiftworkers, without being discriminated in terms of parity, should have more protection, i.e. exemption from nightwork when pregnant, and possibility of transfer to daywork during the first 2–3 years of age of their children.

6. TOXICOLOGICAL RISK AND DRUG EFFECTIVENESS

Shiftwork can influence the risk of intoxication due to chemical substances in relation to both the circadian fluctuation of biological susceptibility to xenobiotics, and a de-synchronization of the mechanisms of detoxification. This has been proved by studies of experimental chronotoxicology, which show a circadian rhythmicity of effectiveness of some toxic compounds given at different times of the day, and variations of the susceptibility after changes of the light–dark regimen. A suggestive evidence in humans came from the Bhopal disaster (1984), where surprisingly none of the nightworkers died from the vapors of methyl isociante, while thousands of inhabitants of the near villages died in their sleep; at the same time thousands of cattle died, while small nocturnal active rats were observed to be scurrying around the corpses and carcasses.

Therefore, risk assessment should consider the circadian fluctuations of physiological responses (in terms of absorption, metabolism, excretion) in relation to shift- and nightwork: some studies have already evidenced a circadian pattern of excretion of some toxic substances or metabolites, which can be used for a better strategy of protection of the workers.

On the other hand, these aspects should also be considered in case of regular drug assumption for certain illnesses (e.g. diabetes, epilepsy, hypertension, asthma, hormonal and sleep disorders), as the persistence on shift and nightwork can interfere significantly with the efficacy of the pharmaceutical treatment, which requires a precise timing of administration and a stable life regimen.

7. EFFECTS ON FAMILY AND SOCIAL LIFE

Persons engaged in shift- and nightwork are frequently out of phase with the society and can face greater difficulties in their social lives since most family and social activities are arranged according to the day-oriented rhythms of the general population. Consequently shiftwork can lead to some social marginalization due to the interference between the workers' time budgets (working hours, commuting and leisure times) and the complex organization of social activities (on daily and weekly basis mainly), particularly when these refer to groups of persons and require regular contacts.

Shiftwork may also interfere with the coordination of family timetables according to family composition (i.e. number and age of children, cohabiting persons), personal duties (i.e. school, housework), availability of public services (i.e. shop hours and transportations). "Time pressure" is a constant condition among those who have a high family burden (e.g. women with small children), and this can have a negative influence on marital relationships, parental roles and children's education.

Such family and social difficulties are often the main cause of maladaptation to shiftwork, since they have also a clear influence on the development of the psychosomatic disorders already mentioned.

On the other hand, shiftwork may consent a more flexible use of daytime hours to meet particular needs or preferences (i.e. access to public services, to study, second job, solitary hobbies) or in case of persons who give a higher priority to family and domestic duties than to personal leisure (e.g. women with children).

8. FACTORS INFLUENCING SHIFTWORK EFFECTS ON HEALTH

There is a high interindividual variability on tolerance to shiftwork. According to several studies, ~15–20% of workers are forced to leave shiftwork in a short time because of health disorders, whereas 5–10% do not report any complain during their working life; the majority withstand shiftwork with different levels

of maladaptation, showing different times and severity of manifestation in terms of troubles or diseases.

Many factors concerning individual, social and working conditions can interact and influence both short-term adjustment and long-term adaptation.

As concerns the individual aspects, the more important ones refer to age, gender, physical fitness, behavior and personality traits, For example, aging can be associated with a progressive intolerance due to reduced psychophysical fitness, decreased restorative properties of sleep, and proneness to internal de-synchronization of circadian rhythms. Besides, subjects having the characteristics of "morningness" generally face more difficulties in short-term adjustment to nightwork compared with the "evening" types. Moreover, people who present high levels of neuroticism, or the characteristics of rigidity of sleeping habits and lower ability to overcome drowsiness, have more difficulties in their adaptation to irregular work schedules. On the other hand, good physical fitness and a strong commitment to shiftwork could favor a better coping.

Family situations (e.g. marital status, number and age of children, partner's (shift)work, housing) and social conditions (e.g. socio-economic status, labor market, leisure activities, social services, commuting times) can also play an important role on short- and long-term tolerance.

Moreover, working conditions (e.g. work sector, work environment, work load, job characteristics, income level, qualification, job satisfaction, career opportunities, human relations) and, in particular, the organization of the working hours (e.g. shift schedules, number of crews, rest pauses, night duties, free weekends, etc.) have a crucial influence both on the biological adjustment and on the psychophysical conditions.

All these factors can affect tolerance to shift and nightwork according to the specific circumstances, and their interactions can give rise to not only possible additive or multiplicative, but also to subtractive effects. Consequently, health complaints or disorders can manifest with various degrees of severity and in different periods of worker's life, thus making difficult to compare the effective harmfulness of shiftwork in different groups and individuals.

This is also influenced by the process of self-selection that often occurs among shiftworkers (the "healthy worker effect"); in fact, many epidemiological studies examined groups of workers where a more or less relevant part had left shiftwork because of health troubles or social problems.

Also reports on absenteeism can be sometimes misleading. Although it is a rather indirect indicator of health, it can be affected by the shift scheduling (i.e. amount of nightwork, speed of shift rotation, overtime, shift start and finishing times) in association to other factors connected to work organization, socio-economic conditions and individual characteristics. However, shiftworkers may show a lower absenteeism rate, despite of a higher frequency of troubles and illnesses, both because of a higher solidarity towards colleagues (since an unexpected absence may cause more problems for shift handovers than for normal daywork) and for a higher threshold in the perception, labeling and reporting of complaints, that shiftworkers often accept as "part of the job."

Therefore, proper intervention measures should be undertaken to prevent negative effects on health and well-being. They should deal with work organization, social support, medical control, education and counseling for better coping strategies with shift and nightwork (see the chapter on "Prevention and compensation of shiftwork effects").

Shiftwork Stress

L. Smith

Shiftwork and Safety Research Group, School of Psychology, University of Leeds, Leeds LS2 9JT, UK

1. INTRODUCTION

1.1. Shiftwork

Shiftwork is widespread in all industrialized and developing countries. It is a way of organizing working time that can be very disruptive to the lives of shiftworkers and their employers. Shiftwork often requires people to work regularly at night and this can result in direct disruption to the human biological clock, impairment to sleep and mood, reduced alertness and increased fatigue, and interference to social and family life. There may also be consequences in terms of employee performance, safety, productivity, moonlighting, absence for sickness and turnover (Colquhoun *et al.* 1996). This article highlights the issue of shiftwork as a stress factor. To accomplish this, models of shiftwork stress are presented that indicate different perspectives to the application of this issue to working life and identify practical implications with respect to shiftworker's lives.

1.2. Shiftwork as a Stress Factor

Cooper and Marshall (1976) identified a number of sources of stress at work within a model of organizational and personal disease development. They included: factors intrinsic to the job such as work over-/underload, time pressures, shiftwork, physical working conditions and repetitive work; role-based stress such as work role ambiguity, work role conflict and levels of responsibility; interpersonal relationships with subordinates, colleagues and superiors; career development factors such as lack of job security, under/over promotion thwarted ambition and organizational structure and climate issues, including office politics, communications, participation in decision-making and the organization of work and organizational trust. Job conditions are a major stress factor and a major part of a person's working conditions is, of course, their work schedule. Cooper and Marshall (1976) recognized this fact and included shiftwork as an element of their model. The following section presents a number of shiftwork-related models of stress.

2. MODELS OF SHIFTWORK STRESS

A number of models of shiftwork stress are founded on stimulus-based theories of stress that focus on environmental factors which cause a response in the person, i.e. strain. Shiftwork stress models using this approach describe shiftwork as an environmental factor that causes strain that manifests itself as health problems (e.g. Akerstedt and Froberg 1976, Rutenfranz *et al.* 1981, Knutsson 1989). Transactional models have also been used. These models describe stress as a product of the ongoing interaction between the person and her/his environment. Stress occurs when demands tax or exceed the resources available to a person. It is an approach that emphasizes the role of cognitive appraisal, personality and behavior in the stress process. A number of shiftwork stress models has adopted this perspective (e.g. Haider *et al.* 1982, Monk 1988, Olsson *et al.* 1990).

A number of these models have been proposed, such as a model with three components: objective stress, subjective strain and intervening variables. The stress of shiftwork is seen as the work rota-imposed requirement to alter the timing of activity and sleeping relative to the normal phases of circadian (24-h) rhythms in physiological processes and performance. Being out of phase can lead to strain in terms of increased health and sleep complaints and lowered well-being, but the pathway between stress and strain may be mediated by intervening variables such as family situation, personality, housing/locality and organizational factors.

Another model (Akerstedt and Froberg 1976) proposed two separate causal links between shiftwork and health: first, disruption to circadian rhythms; and second, disruption to social rhythms. Shiftwork hours conflict with physiological, family and social rhythms, and results in the establishment of new circadian and social rhythms. These interact to cause stress and health problems. Severe disturbance to social rhythms is also believed to contribute to psychological stress.

Knutsson (1989) suggested a shiftwork-health model. The model was based on cross-sectional, prospective and longitudinal cohort studies on shiftwork with heart disease as the health measure. The data provided evidence of a dose–response relationship between years of shiftwork experience and heart disease, and increased levels of heart disease risk factors in shiftworkers compared with day workers. Three causal paths to disease are suggested: first, disturbed physiological rhythms; second, behavioral changes; and third, disturbed social rhythms. For this model disruption to body rhythms and social rhythms have separate effects. Disturbed circadian rhythms lead to poor sleep, increased susceptibility to illness and internal desynchronization, all of which lead to disease. Disrupted social rhythms result in the adoption of new behaviors (often palliative, or inappropriate coping behaviors such as increased smoking, alcohol intake or drug abuse) in response to the interference with social life and stress. These, in turn, are a risk to health.

This type of model moves away from a stimulus–response conceptualization with a direct link between shiftwork and poorer health. Instead it considers that the personality, thoughts and behaviors of shiftworkers will moderate the stress experience (Haider *et al.* 1982). The model suggests that the balance between three spheres of activity is central to adaptation to shiftwork schedules, namely: sleep behavior, family life and attitudes to shiftwork.

These domains interact and exist in a dynamic equilibrium that functions in a regulatory capacity. For example, a conflict can exist because more time with the family may be gained at the expense of obtaining less sleep. Difficulties with sleep and family relationships may then lead to negative attitudes towards shiftwork that in turn result in poor sleep. Destabilization to the "dynamic equilibrium" between the three domains is caused by the different activity pattern when working shifts. Resulting conflicts may then affect physiological systems and cause impairment to health. In addition to this, shiftworkers may engage in more "risky" coping behaviors that contribute to impairment to health, e.g. increased smoking, caffeine, alcohol, or drug use and changed eating habits. However, the model recognizes that the destabilization process may be modified by personality factors. Coping efforts form explicit components of other models (e.g. Monk 1988). The ability to cope with shiftwork is determined

by the interaction and direct effects of three factors: the biological clock/body rhythms, sleep, and social and domestic factors. For example, the body clock has to be reset when working shifts. This results in sleep complaints, malaise and digestive problems. Sleep is influenced by both the body clock and external factors such as daytime noise. The shiftworker's routine conflicts with timing of family and community activity. So, all three areas are interdependent. A successful adapter to shiftworking is viewed as someone who applies multifaceted strategies that affect aspects of the three most influential factors.

Shiftwork experience is suggested to moderate the destabilization process. Three phases are suggested: first (0–5 years), there is the adaptation phase where the quality of sleep, family life, social activity and work demands have a strong influence on health; second (5–20 years), there is the sensitization phase in which the primary predictors of health will be job satisfaction, attitudes towards shiftwork and the family situation; and third (20+ years), family and social situations are suggested to remain stable or improve but sleep behavior linked to aging and the development of risky behaviors will have the greatest adverse effect on health.

Olsson *et al.* (1990) offered an approach that viewed shiftwork as only one of many occupational stressors that may lead to poor health outcomes. Shiftworkers are viewed as engaging in a two-way relationship with their environment. Threats to well-being are cognitively appraised. There is also the appraisal of a personal capability to deal with or manage the potential threats. Coping strategies are adopted in response to these judgements. Coping can alter the environment directly and/or it can change the appraisal process to alter the stressfulness of the situation. Problem-focused coping may involve dealing with sleep problems by learning a relaxation technique, or adopting a strategy of napping to promote alertness, or even to changing to permanent daywork. Emotion-focused coping, on the other hand, refers to the shiftworker expressing their feelings about their difficult situation, or using relaxation techniques and mental strategies to help reduce anxiety or unwanted thoughts. Thus, the thoughts and behaviors of the shiftworkers play a central part in determining their stress experiences when working shifts.

More recently Barton *et al.* (1995) recognized that the problems faced by individual shiftworkers are both complex and multifaceted. Their model of shiftwork stress is a representation of the way in which problem areas relate to the features of shift systems and to one another. The model offers a conceptual framework that helps guide research efforts to examine the impact of different shift systems on individuals and organizations. Shift systems and their features such as shift timing and duration are seen to impact on health and safety. This influence may be relatively direct but there can also be indirect effects resulting from the influence on the whole of a person's life. Interrelated disruptions of biological rhythms, sleep, and family and social life may be moderated by individual differences as well as situational differences such as domestic circumstances or commuting time. The acute effects of shiftwork, such as when an individual returns to a block of night shifts, may also be moderated by the more chronic effects on mental health. In the long-term, physical health may be impaired by chronic impact on, for example, psychological well-being while safety may be compromised by the acute negative impact of shiftwork on mood and cognitive performance.

3. CONCLUSIONS AND IMPLICATIONS

Theoretical and research-based models of how shiftwork impacts upon the lives of shiftworkers are useful for a number of reasons. For example, Taylor *et al.* (1997) noted that the models help to identify possible interventions that will minimize the negative impact of shiftwork by (1) providing an understanding of the potential interactions between variables considered to influence the experience of problems when working shifts, (2) helping to understand the development of shiftwork problems and identifying possible strategies to combat shiftwork disruption and (3) helping to identify research questions that may form the basis of future study.

Some models are explicitly based on empirical data. For example, Haider *et al.* (1981) formulated their model from the results of tests on cross-sectional data. Causal relationships were inferred from a complex pattern of associations. The models presented provide an overview of the shiftwork research field by organizing existing knowledge about the development of shiftwork-related problems. They can be considered to be both theory-driven and theory building as they have helped the formulation of general hypotheses that could add to the understanding of shiftwork effects and ways of intervening.

Stress theory has been used to help describe the shiftwork–health relationship through the application of stimulus-based and transactional models of stress. These conceptualizations tend to influence suggestions for strategies aimed at reducing shiftwork problems. In the case of stimulus-based models that assume that the work environment causes ill health, the basic premise is to remove and/or improve detrimental work conditions. That is, work stress simply 'happens' to the shiftworker and removing the source of the stress will result in the prevention of health problems. Transactional models tend to advocate educational and stress management training approaches to improve coping skills. This is because they recognize the role played by the individual's thoughts and behaviors in the experience of work stress. It should be noted, however, that one negative aspect of adopting a transactional rather than a stimulus-based approach is that the responsibility for the employee's health is transferred, at least in part, to the shiftworker. It is possible that in future there will have to be a re-emphasis of the impact of shiftwork as a risk factor and the shiftwork environment. This would result in an increased resort to providing better shift systems and using other interventions at the level of the organization (e.g. installing bright lights) if the problems of shiftwork are to be reduced for the largest numbers of people who regularly work shifts.

Situational Awareness Issues at Work

M. A. Vidulich

Crew System Interface Division, US Air Force Research Laboratory, AFRL/HECP, 2255 H Street, Wright-Patterson Air Force Base, OH 45433-7022, USA

1. INTRODUCTION

Situational awareness is a term that arose out of the fighter pilot community to explain the outcomes of air combat training exercises. In some cases, the more experienced pilot in the more capable aircraft might unexpectedly lose an engagement. In debriefings, these events were often explained by asserting that on this specific occasion the less experienced pilot had achieved better situational awareness and used it to win (Waddell 1979). With a user community already convinced that situational awareness was a valuable concept in human–system performance, it was natural that the human factors research community would follow suit and investigate situational awareness. Throughout the 1980s and 1990s, situational awareness emerged as a very active human factors research area. For example, a bibliography of situational awareness was published in 1994 that listed and reviewed > 230 situational awareness citations available at that time (Vidulich *et al*. 1994).

2. DEFINITIONS OF SITUATIONAL AWARENESS

Not surprisingly, one of the first great issues in situational awareness research was the matter of defining situational awareness. For example, Dominguez (in Vidulich *et al*. 1994) found and analyzed 15 different definitions of situational awareness. He consolidated the different definitions into a proposed consensus definition of situational awareness as (Vidulich *et al*. 1994: 11) "Continuous extraction of environmental information, integration of this information with previous knowledge to form a coherent mental picture, and the use of that picture in directing further perception and anticipating future events". Probably the most popular definition of situational (or "situation") awareness was advanced by Endsley (1995a: 36), "Situation awareness is the perception of the elements in the environment within a volume of time and space, the comprehension of their meaning, and the projection of their status in the near future". Both of these definitions and most others emphasize the operator's perception of the elements of the current situation and their integration with knowledge to form an adaptive understanding of what is going on and to maximize the opportunity to choose an appropriate course of action. The situational awareness concept has demonstrated great vitality in inspiring research into selection of individuals predisposed towards developing good situational awareness, training procedures to maximize operator situational awareness, and interface design to aid situational awareness (for examples, see Vidulich *et al*. 1994). In all of these proposed applications of the situational awareness concept, an underlying theme is the need for situational awareness measurement. After all, the evaluation of any intervention designed to improve situational awareness requires that some means for assessing situational awareness exist.

3. MEASUREMENT OF SITUATIONAL AWARENESS

A recent analysis of the sensitivity of situational awareness metrics in 65 studies of interface manipulations (Vidulich, 2000) found that three major approaches to situational awareness measurement have emerged: performance-based, memory probe and subjective ratings. The results of all three of these measurement approaches are instructive in understanding the importance of the situational awareness concept and the role that it may play in human–system analysis.

4. PERFORMANCE–BASED MEASUREMENT

Measuring operator performance is not usually considered a direct measurement of situational awareness. However, a core assumption behind the interest in situational awareness is that in most circumstances better situational awareness will be associated with better performance. Almost all of the papers in the Vidulich (2000) review included some measure of performance. In about one-half of the studies the performance measure was included in addition to some specified situational awareness metric. However, in the other half of the studies, the performance measure was the basis for inferring any changes in situational awareness. Overall, performance measurement was the most common type of measure used in the database. Regardless of whether the experimenter used performance as a measure of situational awareness, changes in interfaces that were intended to improve situational awareness tended to improve performance. This finding demonstrates the potential practical value of the situational awareness concept applied in system design.

4.2. Memory Probe Measures

If situational awareness is regarded as the information in awareness, then explicit measures are the most direct method of assessing situational awareness. Two main categories of explicit measures can be identified: retrospective event recall and concurrent memory probes. Retrospective event recall occurs after the operator has completed a simulated mission. Concurrent memory probes usually involve randomly stopping the simulation sometime prior to its completion to assess the contents of awareness at that moment. For the most part, retrospective and concurrent approaches share the same general strengths and weaknesses. The greatest strength is face validity. In any complex goal-directed task, conscious decision-making would be expected to be important. Explicit measures assume that such conscious data are reportable. The best known approach for collecting this type of data is the situation awareness global assessment technique (SAGAT; Endsley 1995b). SAGAT, and very similar procedures, have been widely used in system evaluations.

Vidulich (2000) found that the sensitivity of memory probe measures of situational awareness was strongly influenced by the breadth of probe questions used in the evaluation. Evaluations that used a very broad set of memory probe questions were generally sensitive to the interface manipulations. On the other hand, evaluations that used a very small set of focused questions (or even one question) tended to be insensitive to interface manipulations.

4.3. Subjective Ratings

Implementing subjective ratings as a measure of situational awareness is simple; operators are merely asked to rate their experience of situational awareness after completing a task. Early attempts at subjective situational awareness ratings used a straightforward unidimensional situational awareness scale. Although this was simple, this approach also tended to be insensitive. Currently the most popular and validated subjective metric is the situation awareness rating technique (SART) developed by UK researchers at Farnborough. SART has been demonstrated to be sensitive to many manipulations of situational awareness in laboratory and high-fidelity simulator evaluations. In fact, SART was the most reliable measure of situational awareness examined in the Vidulich (in press) review.

4.4. Situational Awareness as a Meta-measure

As described above, manipulations of interface design that were undertaken to improve situation awareness tended to improve task performance. This suggests that situation awareness researchers are justified in believing that the situation awareness construct represents an important phenomenon in human–machine interaction. As Selcon *et al.* (1996) have suggested, it might be worthwhile to consider situation awareness a "meta-measure" in system evaluation. These researchers pointed out that it is seldom possible to evaluate all of the mission relevant uses of a display. Thus, a metric approach is needed that provides a generalized link to likely future performance in a wide variety of settings. In other words, rather than focusing on task-specific performance, it might be preferable to examine meta-measures that encapsulate the cognitive reaction to using a given interface. One proposed meta-measure was mental workload. Presumably, if a task can be performed with one interface while experiencing less mental workload, this should provide for more robust transfer to using that interface in more challenging conditions. Another possible meta-measure is situational awareness. Presumably the interface that provides a better understanding of the situation will provide the better chance of reacting appropriately to that situation. The fact that the Vidulich (2000) database suggested

that manipulations designed to improve situational awareness generally improved performance in a wide variety of tasks and by a wide variety of measures is consistent with the suggestion that situational awareness measurement could provide a useful meta-measure of system interface design.

5. CONCLUSIONS

The main points concerning the concept of situational awareness and its measurement can be summarized as follows:

- As a component of human factors research, situational awareness has displayed considerable vitality since the 1980s.
- Sensitive situational awareness measurement tools have been developed and demonstrated.
- System design changes intended to improve situational awareness also tend to improve system performance.
- In system design evaluations, situational awareness can serve as a meta-measure that will test overall design quality in a fairly generic fashion.

Sociotechnical Systems Analysis

B. M. Kleiner

1. INTRODUCTION

While many valid and potentially useful work process evaluation/ improvement methods exist and are in use, a general framework which has strong theoretical support and which integrates ergonomic interface design and function allocation and other macro-ergonomic tools is described. The following methodology is detailed in Hendrick and Kleiner (1999). It has been developed based on the writings of Emery and Trist (1978), Taylor and Felton (1993), Clegg *et al.* (1989) and the authors' own experience with large-scale organizational evaluation and change in academia, industry and government (Kleiner 1996, Kleiner and Drury 1999) with specific emphasis on integrating socio-technical systems theoretical propositions and prescriptions with micro-ergonomics.

This methodology can be used to conduct both formative and summative evaluation of production, non-production, linear and non-linear work processes. Although the methodology can be used by an inside or outside consultant, it is best used in a participatory ergonomics framework.

2. PHASES OF WORK SYSTEM PROCESS ANALYSIS AND DESIGN

2.1. Phase 1 — Environmental and Organizational Design Subsystems: Initial Scanning

Achieving a valid organization/environment fit may be the most important step to ensure future work system success. Mission, vision and principles (or MVP) provide definition or identity to the work system. Once defined, a gap between what the organization claims are its defining characteristics and its actual organizational behavior is identified. To assess the severity of this gap, the formal company identity statements are documented. Gaps in MVP can be inferred from what the work system actually produces in terms of products, bi-products, services, attitudes and behavior relative to what it formally declares as its outputs.

System scanning is the process of defining the workplace in systems terms including defining relevant boundaries. This step is aided by the construction of an input/output diagram, in which inputs, outputs, suppliers, customers, processes, internal controls and feedback mechanisms are identified for the work system. The system scan also establishes initial "boundaries" or domains of responsibility. As described by Emery and Trist (1978), there are throughput, territorial, social and time boundaries to consider.

In the environmental scan, the organization's subenvironments and the principal stakeholders within these subenvironments are identified. Their expectations for the organization are identified and evaluated. Problems are viewed as opportunities for process or interface improvement. The work system itself can be changed to conform with external expectations or the work system can seek to change the expectations of the environment to be consistent with its own direction. The ergonomist designs or redesigns interfaces among the organizational system and relevant subenvironments to improve communication, information exchange and decision-making. Rather than delay to address organizational design until all subsystems have been analyzed, it is useful develop preliminary organizational design hypotheses at this stage based upon the environmental scan and iterate later. By referring to the empirical models of the external environment, initial optimal levels of complexity (both differentiation and integration), centralization and formalization can be proposed.

2.2. Phase 2 — Technical Subsystem Analysis: Define Production System Type and Performance Expectations

As described above, it is important to identify the work system's production type since the type of production system can help determine optimal levels of complexity, centralization and formalization. The system scan performed in the previous phase should help in this regard and the ergonomist can consult the production models discussed previously.

In this context, the key performance criteria related to the organization's purpose and technical processes are identified. First and foremost, this requires a determination of success factors for products and services, but may also include performance measures at other points in the organization's system, especially if decision-making is important to work process improvement. As described in Kleiner's (1997) framework adapted from Sink and Tuttle (1989), specific standardized performance criteria guide the selection of specific measures which relate to different parts of the work process. Measures can be subjective, as in the case of self-reports, or measures can be objective, observed from performance.

Once the type of production system has been identified and the empirical production models consulted, the organizational design hypotheses generated in the previous phase should be supported or modified until the personnel subsystem can be thoroughly analyzed as well. From the Clegg *et al.* (1989) function allocation methodology, this is also the appropriate time to specify system level objectives. Requirements specifications can be developed, including ergonomic requirements. Also included are system design preferences for complexity, centralization and formalization.

2.3. Phase 3 — Flowchart the Technical Work Process and Identify Unit Operations

Unit operations are groupings of conversion steps that together form a complete piece of work and are bounded from other steps by territorial, technological, or temporal boundaries. They are exemplified by natural breaks in the process (i.e. boundaries determined by state changes (transformation) or actual changes in the raw material's form or location (input) or storage of material). For each unit operation or department the purpose/ objectives, inputs, transformations, and outputs can be defined (see Phase 1).

The current workflow of the transformation process (i.e. conversion of inputs to outputs) should be flow charted, including material flows, workstations and physical as well as informal or imagined boundaries. In linear systems such as most production

systems, the output of one step is the input of the next. In non-linear systems such as many service or knowledge work environments, steps may occur in parallel or may be recursive. Unit operations are identified. Also identified at this stage are the functions and subfunctions (i.e. tasks) of the system (Clegg *et al.* 1989). The purpose of this step is to assess improvement opportunities and coordination problems posed by technical design or the facility. Identifying the workflow before proceeding with detailed task analysis can provide meaningful context in which to analyze tasks. Once the current flow is charted, the ergonomist can proceed with a task analysis for the work process functions and tasks.

2.4. Phase 4 — Collect Variance Data

A variance is an unexpected or unwanted deviation from standard operating conditions or specifications or norms. As Deming and Shewhart suggested, variances can be assigned special or common causes, the former being abnormal causes and the latter expected system variation from normal operations. Special variances need to be tackled first to get the work process in control, at which time common variation can be tackled for overall system improvement. For the ergonomist, identifying variances at the process level as well as the task level can add important contextual information for job and task redesign. By using the flowchart of the current process and the detailed task analysis that corresponds to the flow chart, the ergonomist can identify variances. Deviations in raw material are called *input variances* and deviations related to the process itself during normal operations are called *throughput variances*. These can both be identified at this stage. Differentiating between types of variances helps determine how to control the variances.

2.5. Phase 5 — Construct Variance Matrix

Key variances are those variances that significantly impact performance criteria and/or may interact with other variances thereby having a "multiplying" effect. The purpose of this step is to display the interrelationships among variances in the transformation work process to determine which ones affect which others. The variances should be listed in the order in which they occur down the vertical *y*-axis and across the horizontal *x*-axis. The unit operations (groupings) can be indicated and each column represents a single variance. The ergonomist can read down each column to see if this variance causes other variances. Each cell then represents the relationship between two variances. An empty cell implies two variances are unrelated. The ergonomist can also estimate the severity of variances by using a Likert-type rating scale. Severity would be determined on the basis of whether a variance or combination of variances significantly affect performance.

A variance is considered *key* then if it significantly affects quantity of production, quality of production, operating costs (utilities, raw material, overtime, etc.), social costs (dissatisfaction, health, safety, etc.), or if it has numerous relationships with other variances (matrix). Typically, consistent with the Pareto Principle, only 10–20% of the variances are significant determinants of the quality, quantity or cost of product.

2.6. Phase 6 — Personnel Subsystem Analysis:

Construct Key Variance Control Table and Role Network

The purpose of this step is to discover how existing variances are currently controlled and whether personnel responsible for variance control require additional support. The Key Variance Control Table includes: the unit operation in which variance is controlled or corrected; who is responsible; what control activities are currently undertaken; what interfaces, tools or technologies are needed to support control; and what communication, information, special skills or knowledge are needed to support control.

Role analysis addresses who interacts with whom, about what and how effective these relationships are. This relates to technical production and is important because it determines level of work system flexibility. A *role network* is a map of relationships indicating who communicates with the focal role. First, the role responsible for controlling key variances is identified. Although multiple roles may exist which satisfy this criterion, there is often a single role without which the system could not function. With the focal role identified within a circle, other roles can be identified and placed on the diagram in relation to the focal role. Based upon the frequency and importance of a given relationship or interaction, line length can be varied, where a shorter line represents more or closer interactions. Finally, arrows can be added to indicate the nature of the communication in the interaction. A one-way arrow indicates one-way communication and a two-way arrow suggest two-way interaction. Two one-way arrows in opposite directions indicate asynchronous (different time) communication patterns. To show the content of the interactions between the focal role and other roles and an evaluation of the presence or absence of a set of functional relationships for functional requirements, the following are indicated: the short-term goal of controlling variance; adapting to short-term fluctuations; integrating activities to manage internal conflicts and promote smooth interactions among people and tasks; and ensuring long-term. Also the presence or absence of particular relationships is determined by describing the work process functions in terms of five types of relationships: vertical, equal, cross-boundary, outside or non-social. The effectiveness of the relationships identified in the role network can also be evaluated. At this juncture the organizational design hypotheses can be tested against the detailed analysis of variance and variance control. The role analysis and variance control table may suggest for example, a need to increase or decrease formalization or centralization.

2.7. Phase 7 — Function Allocation and Joint Design

Having previously specified system objectives, requirements and functions it is now appropriate systematically to allocate functions and tasks to human and machine or computer. It is helpful to review the environmental scan data to check for any subenvironment constraints (e.g. political, economic, etc.) before making any mandatory allocations (Clegg *et al.* 1989). Next, provisional allocations can be made to the human(s), machine(s), both or neither. In the latter case, a return to developing requirements specifications previously is called for using four groups of criteria: technical feasibility; health and safety;

operational requirements (i.e. physical, informational, performance); and function characteristics (i.e. criticality, unpredictability, psychological). See Kleiner (1998) for a review of macro-ergonomic directions and issues in function allocation.

Technical changes are made to at best, prevent or at worst, control key variances. Human-centered design of the following may be needed to support operators as they attempt to prevent or control key variances: interfaces, information systems to provide feedback; job aids; process control tools; more flexible technology; redesign work station or handling system; or integrating mechanisms.

After considering human-centered system changes in the previous step, it is time to address supporting the human directly by addressing knowledge and/or skill requirements of key variances and any selection issues that may be apparent. In the variance control table, who controls variances and the tasks performed to control these variances were identified. At this stage, it is suggested that personnel system changes to prevent or control key variances be identified. This may entail specific skill or knowledge sets that can be acquired through technical training, formal courses, workshops or distance learning.

At this point in the process, organizational design hypotheses have been generated and iteratively adjusted as new analyses are performed. Next, take the specifications for organizational design levels of complexity, centralization and formalization and produce specific structures. Depending upon the level of work system process analysis, this may require design/redesign at the organizational level or at the group/team level or at both levels. The former level is exemplified by choices between functional structures, product structures, geographic structures or matrix structures while the latter may specify a functional team, cross-functional team, self-managed or high performance work team.

2.8. Phase 8 — Roles and Responsibilities Perceptions

It is important to identify how human operators perceive the roles documented in the variance control table, especially if the table was initially constructed by those who do not occupy the roles identified. Through interviews, role occupants can participate in an analysis of their perceptions of their roles. Using the previously constructed table, expected roles, perceived roles any gaps can be identified. Gaps can be managed through training and selection as well as technological support. In essence, two role networks are operating, the one needed and the one perceived. Any variation between the two can be reduced through participatory ergonomics, training, communication, interface design or tool design.

2.9. Phase 9 — Design/Redesign Support Subsystems and Interfaces

Now that the work process has been analyzed and jointly designed, other internal organizational support subsystems may require redesign. Of particular interest are the management system, and reward system and maintenance system. In all cases, the goal is to determine the extent to whether a given subsystem impacts the socio-technical production system; to determine the nature of the variance; determine the extent to which the variance is controlled; and determine the extent to which tasks should be taken into account in redesign of operating roles in the supporting subsystem units.

According to the Clegg *et al.* (1989) method of function allocation, individual and cumulative allocations made on a provisional basis can be further evaluated against: requirements specifications (including the scenarios developed earlier); resources available at the time of implementation (including human and financial); and the sum total outcome. In addition to a check of function allocation, interfaces among subsystems should be checked and redesigned at this juncture.

Especially at the team and individual levels of work, the internal physical environment should be ergonomically adjusted if necessary to promote effectiveness. Investigating the technical and personnel variance analyses, an assessment can be made about whether there are physical environmental changes that will promote improvement. These changes might include changes to temperature, lighting, humidity, noise control/hearing protection, etc.

2.10. Phase 10 — Implement and Improve

Finally, it is desired to implement the work system changes prescribed, design interfaces and allocate functions. Since in most cases, the ergonomics team will not carry the direct authority to implement the changes suggested by the analysis, proposals with recommendations for change may be required for presentation within the formal organizational structure. Based on the proposal feedback, modifications and an iteration to an earlier analysis or design stage may be necessitated.

Once the proposal for change is accepted and implementation begins, regular reviews of progress are required. To compliment the weekly formative evaluations performed by the implementation team, semi-annual summative evaluations should be performed by an objective outside party.

Socio-technical Theory

R. J. Badham†, C. W. Clegg‡ and T. Wall‡

‡Institute of Work Psychology, University of Sheffield, Sheffield S10 2TN, UK

1. INTRODUCTION

Socio-technical theory has a long tradition stemming from its explicit theoretical origins in the 1950s. It was initially established in the classical work of the Tavistock Institute in the British coal mining industry, soon to be followed by the work of Rice and colleagues in the textile industry in India, and by Emery Thorsrud and others in the Norwegian Industrial Democracy program. As a general approach to the analysis and design of organizational structures, it has promoted a philosophy of participatory democracy, an open socio-technical systems conceptual framework, and an action research methodology. Its key ideas are now embodied in a wide range of concepts and practices employed in a number of countries by researchers and practitioners working as university academics and researchers as well as external and internal consultants to organizations (van Einjatten 1993, Taylor and Felten 1993).

In the 1950s the Tavistock Institute was involved in a number of projects investigating how "longwall mining" had mechanized and enlarged the scale of coal mining operations, and replaced traditional group-based methods of work by specialized and fragmented manual jobs coordinated and controlled by an external supervisor. The change in work had broken down the previous social structure and led to a catalogue of individual, organizational, social and performance problems. Yet, in a number of sites, the Tavistock researchers discovered that different forms of work organization had been introduced. Increasing mechanization had also been accompanied by the creation of relatively autonomous groups interchanging roles and shifts and regulating their affairs with a minimum of supervision. High levels of personal commitment, low absenteeism, infrequent accidents and high productivity accompanied cooperation between task groups.

The Tavistock researchers, who had a strong background in trade unionism and work psychology, provided a particular interpretation of this experience. They were impressed by the dramatic effects of new technology, concerned about the breakdown of traditional group work, but also excited by the potential of the naturally occurring experiments in new forms of work. The last of these was seen as providing a model for combining higher levels of mechanization with new forms of group cohesion, self-regulation and participation in decisions about work arrangements. For this reason, the book which overviewed the Tavistock mining studies was subtitled "The Loss, Rediscovery and Transformation of a Work Tradition" (Trist 1981).

The commitment of the Tavistock researchers to improving working conditions and enhancing the ability of workers to control their own work organization has remained an enduring part of the socio-technical legacy. This has been reflected in frequent advocacy of autonomous or self-regulating work groups. It has also found expression in recommendations ranging from individual job enrichment to institutionalized co-determination and industrial democracy. The ultimate failure of many of the experiments in the UK coal industry to take hold was seen by some Tavistock researchers as a sign that socio-technical re-design had to address the "extended social field" of forces at a broader societal level. The Norwegian Industrial Democracy program in the 1960s, involving four major socio-technical field experiments in direct worker participation, was given more chance of success as the social setting was seen to be more conducive to successful and enduring outcomes (Trist 1981).

The open socio-technical systems framework that emerged from the Tavistock Institute during the 1950s and 1960s was strongly influenced by von Bertalanffy's (1950) "Open systems in physics and biology." The Tavistock researchers developed the framework in an attempt to reflect on and generalize their ideas about the interdependence of technology and work organization, the existence of choices between different forms of work organization, and their commitment to group self-regulation. The key features of the open socio-technical systems framework were that work or production operations should be seen as:

- *Systems* with interdependent parts.
- *Open* systems adapting to and pursuing goals in external environments.
- Open *socio-technical* systems possessing an internal environment made up of separate but interdependent technical and social subsystems.
- Open socio-technical systems with *equifinality*, i.e. in which system goals can be achieved by different means. This recognized the existence of organizational choice in the type of work organization that could complement any given technology.
- Open socio-technical systems in which performance depends on *jointly optimizing* the technical and social subsystems, i.e. where neither the technical nor social subsystems are optimized at the expense of the other.

The adoption of the open socio-technical systems framework has led to socio-technical theory being characterized as a representative of both *organic* approaches to organizations and *contingency* approaches to organisational design. In contrast to mechanistic models of organizations that underlie formal administrative and Tayloristic approaches, organizations are viewed as *purposeful* systems, with effective organizations possessing a social system aligned to that purpose. In opposition to universalistic theories presenting *one best way* of organisational design, the understanding of organizations as open systems also implies that the optimum socio-technical design is *contingent* on the purposes and environment of the organization.

The open socio-technical systems framework has also provided the basis for more detailed analysis and re-design of systems based on specific characterizations of the technical and social subsystems and the relations between them. At the core of technical analysis and re-design lies a view of technology as more than machines and equipment. The technical subsystem is seen as a conversion process transforming system inputs into outputs. This conversion process proceeds through a number of stages or "unit operations," each of which is subject to unpredictable "variances" (deviations from predicted or required output) which affect completion of the task. These variances, and causes such as machine breakdowns, etc. have to be controlled if system goals are to be achieved. The need to control variances is the central

link point between the technical and the social system, as people within the social system are required to assist in the control of variances. This is summarized in the now classic "variance control chart" (Taylor and Felten 1993).

The social subsystem is regarded as more than a set of technical control tasks that have to be performed by people. These technical tasks are combined into individual jobs and the responsibilities assigned to groups. In any analysis and re-design of the social subsystem, these jobs and, equally importantly, the broader social roles of which they are a part are examined for their implications for the technical subsystem *and* the extent to which they enhance or reduce the quality of working life for the individuals and groups involved in production. It is the commitment to this social analysis and the quality of working life that underlies the celebrated comment in 1975 by one of socio-technical theory's founders, Herbst, "the product of work is people" (Trist 1981, Davis and Taylor (eds) 1979).

These key systems concepts have been differently interpreted by alternative branches of socio-technical theory, and have undergone substantial development since their origin in the 1950s. Among the more recent developments are the integral socio-technical model of de Sitter and The Netherlands school, influenced by the systems theory of Luhmann (van Einjatten 1993, Mathews (ed.) 1997) and the GAIL model employed by a number of US researchers and practitioners (Taylor and Felten 1993). Some socio-technical writers have also sought to broaden the unilinear technical analysis into a broader multidimensional analysis more suitable for knowledge work and services (Barko and Pasmore (eds) 1986).

The socio-technical approach has been described as a *practical paradigm* by van Beinum (van Einjatten 1992). It is well known as a set of re-design principles, partially embedded within the open socio-technical system concepts but also incorporating a set of design heuristics and social values. The classical formulation of socio-technical design principles was articulated by Cherns in 1976, and further refined in 1987 as the following (Cherns 1987):

- *Compatibility* — the process of design should be compatible with the design objectives (i.e., processes should be highly participative).
- *Minimal critical specification* — while objectives should be specified, the means of achieving them should not be.
- *Variance control* — variances should be controlled at source (and should not be exported across boundaries).
- *Boundary control* — boundaries should not be drawn so as to impede sharing of information, knowledge or learning.
- *Information flow* — information should be provided to those who require it when they require it.
- *Power and authority* — those who need equipment, materials, or other resources to carry out their responsibilities should have access to them and authority to command them.
- *The multifunctional principle* — individuals and teams should take on multiple roles to increase their response repertoires.
- *Support congruence* — supporting systems and subsystems need to be congruent. (e.g. planning, payment systems and career systems).
- *Transitional organization* — periods of transition require planning and design, and transitional organizations may be different from the old and the new systems, and are themselves subject to socio-technical design.

- *Incompletion* — re-design is continuous and is the function of self-regulating teams.

Chern's principles provide criteria that can be used to guide the design of individual jobs, group work, technology, work processes, organizational structure and the design process. These principles have been taken up and further developed by socio-technical and other researchers and practitioners. *Individual job design criteria* for promoting worker motivation and performance have been further developed, particularly in Anglo-Saxon and continental European work psychology, and are now a widely accepted component of work re-design (van Einjatten 1993). *Group work principles* have been further extended by work and social psychologists and have been developed in a wide variety of methods for analyzing group work and establishing semi-autonomous, self-regulating or self-managing work teams (Ulich and Weber 1996). Methodologies for *the re-design of work processes* have been further extended in different socio-technical traditions, and have been taken up and developed by both Total Quality Management and Business Process Re-engineering philosophies. (Taylor and Felten 1996). A broader commitment to *organizational re-design* has been emphasized by many branches of socio-technical theory, in particular the Dutch socio-technical school, as a prerequisite for effective and enduring work re-design (Mathews (ed.) 1997). Since Burns and Stalker's classic contrast between "mechanistic" and "organismic" organizational structures in 1961, socio-technical practitioners have promoted different versions of organic structures, finding its most recent expression in advocates of "high performance" and "excellent" organizations (Buchanan and McCalman 1989).

While socio-technical theory has traditionally failed to intervene effectively in or develop adequate design criteria for the *re-design of technology*, understood as machinery and equipment, socio-technical researchers have attempted to remedy this situation by developing criteria for human–machine interface design and the appropriate allocation of functions between technology and people (Grote *et al*. 1995, Clegg *et al*. 1996). Influenced by the rise and diffusion of information technology, socio-technical researchers have collaborated with ergonomists, human–machine interface specialists, and branches of work psychology, to help develop technology design criteria inspired by socio-technical design principles. These have been well represented in the "human centered systems" and "computer-supported cooperative work" movements (Badham (ed.) 1991). Finally, the *process of re-design* has received considerable development. Socio-technical consultants have systematized and refined different stage models for socio-technical re-design, extending Emery's original nine-step method, with substantially different models regularly applied by US socio-technical consultants, and the Dutch and Swiss socio-technical schools (van Eijnatten 1993, Grote *et al*. 1995). There has also been substantial development in attempts to provide more effective methods for participative involvement in design. This has been strongly influenced by Emery's participative design approach, involving such techniques as "deep slice" re-design groups and "search" conferences. These have been developed into systematic re-design packages by socio-technical practitioners in the US and elsewhere (Greenbaum and Kyng (eds) 1991).

As with any influential theoretical tradition, socio-technical theory has a number of in-built ambiguities and tensions, giving rise to different paths of development, and sometimes differences

of opinion between advocates. Socio-technical theorists have differed widely in their degree of commitment to a systems perspective, the systems models that they deploy and, particularly, in the degree to which they have emphasized the contingency and choice implied by the open systems model. While socio-technical theory has been widely associated with a universalistic prescription for highly autonomous and self-regulating group work, a number of socio-technical theorists have emphasized that this prescription contradicts the principles of system openness, organizational choice and equifinality. The nature and level of participation advocated by different socio-technical theorists and practitioners has also varied widely. While some emphasize participation in work re-design, others are far more committed to industrial democracy and broader changes in corporate governance and societal structures. For some practitioners, socio-technical interventions are strongly client driven and expert assisted processes while, for others, it is a far more participatory process driven and "owned" by the direct users or recipients of its results (Greenbaum and Kyng (eds) 1991, van Eijnatten 1993). Finally, alternative views on action research have informed different socio-technical theorists and practitioners. For some, this is a question of the type of action, with answers ranging from more expert driven views of "action science" as a test of knowledge, to more participatory views of research as a tool for promoting the interests of disadvantaged groups in the workforce. For others, the central concern is the degree to which socio-technical theory has managed to combine research excellence with practical effectiveness. Different critics have condemned either an observed decline in in-depth research on the actual nature of work practices or an increasing academicization of the discipline at the cost of effective interventions in organizational change processes.

Socio-technical theory is now in a somewhat anomalous state. On the one hand, it has been subjected to severe criticism on a number of grounds (Barko and Pasmore (eds) 1986, Mathews (ed.) 1997). These include: an excessive focus on shopfloor work re-design and neglect of broader organizational and strategic change; an over-preoccupation with social and technical issues and lack of attention to hard economic issues and realities; a general failure to establish enduring successful exemplars and long term proven results; an inability to effectively address and intervene in technological change despite its proclaimed technical as well as social orientation; a perceived lack of impact on the development, implementation and use of the vast array of new information and communication technologies which are revolutionizing (or have the potential to revolutionize) many organizations; a simplistic identification of autonomous work groups as a universal solution for work re-design; and a general neglect of power and politics in its concepts and practices. It has also failed to develop the kind of cult managerial following and sets of tools characteristic of total quality management and business process re-engineering movements, though some might express relief at this. There is also, arguably, an excessive degree of fragmentation and dispute amongst its supporters, with socio-technical advocates often preferring to classify their work in different terms as, variously, self-managing or self-directed work team philosophies high performance work system design, participative design, self-design or rapid design (US and Australia), integral renewal (The Netherlands) or MTO (Mensch Technik

Organization) (Switzerland). A recent attempt to reinvigorate socio-technical theory as an international STS2, network has so far not succeeded in overcoming this self-admitted fragmentation.

On the other hand, it can be argued that many of socio-technical theory's key ideas and concepts have been widely diffused, so much so that they have become part of the conventional wisdom of many disciplines, consultants and managers. In the face of rapidly changing markets and innovations, there is now a far greater commitment to organizational development and flexibility, teamwork, organizational decentralization, continuous innovation and learning. Arguably, at least in the US, The Netherlands and Switzerland, socio-technical practitioners have been influential in explicitly promoting socio-technical ideas and concepts in industry as well as academia.

It is clear that socio-technical researchers and practitioners have not succeeded in establishing themselves as an intellectual discipline or as a profession and set of institutionalized practices with authority over socio-technical activities in organizations. There would not even be common agreement on whether such a goal would be desirable. Yet, the central ideas of the socio-technical tradition have an enduring relevance, in large part because they continue to be honored in theory and to some extent in practice. The challenge for both academic disciplines and organizations is to work further on overcoming the technology-social divide, increase worker or user participation in change, and take advantage of technical and organizational choices to promote increased productivity and the humanization of work. In addressing these issues, some heed should be given to the recent verbal reflections of Lou Davis at the 1997 HCI Conference on his past work as one of the founders of socio-technical theory in the US, "Our main mistake was that we under-estimated the role of power."

Systems Approach to Training

K. Henriksen, R. C. Glennon and R. E. Jones, Jr

Raytheon Systems Co., 1070 Parkridge Boulevard, Suite 200, Reston, Virginia 20191 USA

1. INTRODUCTION

In terms of its origin, the systems approach to training (SAT) is an adaptation of the systems engineering process, a methodology that rapidly evolved during World War II for the efficient development and deployment of new equipment and weapons systems. SAT is best viewed as a subsystem of a larger operational system. The larger operational system imposes certain requirements on the personnel who are charged with operating, maintaining and managing the system. The training subsystem is responsible for ensuring that assigned personnel can satisfy their job requirements, employing what has become known as SAT. Decisions regarding training development are, thus, based on an analysis of system requirements and subsystem relationships. Since the training subsystem is frequently under development at the same time as the primary operational system, practical considerations regarding schedule, resources and costs have significant influence. With the build-up of the US defense industry during the 1950s and 1960s, the requirement for an efficient and cost-effective way to train large numbers of recruits who became the operators and maintainers of the new systems was apparent.

An early conceptualization of the systems approach to training is generally credited to Miller (1953) who presciently took into account such present-day concerns as training device design for individuals and teams, task allocation, task procedures design, human factors engineering, job aids, behavioral analysis and research, performance evaluations, personnel selection and collective training. A discussion of some of the concurrent educational influences to the systems approach to training – programmed instruction, task analysis, the behavioral objectives movement, self-paced instruction, mastery learning, individualized instruction, criterion-referenced testing – can be found in Risner (1987). By 1976, a five-volume set of prescriptive procedures entitled *Interservice Procedures for Instructional Systems Development*, developed at Florida State University, was introduced for use by the armed forces whereby the outputs of one phase served as inputs to the next phase (Bronson *et al.* 1976). Most practitioners use the terms "systems approach to training" and "instructional systems development" interchangeably (as will be the tendency in the present paper) since both provide an orderly and systematic approach to developing instructional materials by integrating the processes of analysis, design, development, implementation and evaluation. The major distinction between the two models appears to be the point of entry to the analysis phase. Analysis in the SAT model will most likely start at the broader mission and collective task level, while with the Instructional Systems Development (ISD) model, it typically starts at the individual task level.

Rather than signaling a lack of acceptance, the fact that various versions of the SAT process have been adopted by the military services, by private industry and by a broad cross-section of government agencies attests to its versatility and robustness. Although the process has a behavioral flavor with its emphasis on observable outcomes, it is derived from neither educational theory nor pedagogic method (Meister 1985). It is simply a very pragmatic approach for ensuring the job-relevance of training materials in an efficient and cost-effective manner. When first introduced, it represented something akin to a paradigm shift in the way knowledge is presented. Rather than starting with generalized scholarly knowledge which traditionally gets organized into a textbook and is relayed to students by teachers under the assumption that knowledge for its own sake is good, the SAT approach starts with an organizational need, for which training has been identified as a viable solution, and then proceeds to deliver a body of tailored instruction to designated students who have a job requirement for the specified skill or knowledge (Branson and Grow 1987). Once the SAT creators formalized the steps of the process in the form of a set of guidebook procedures, it was assumed that lay personnel who were placed by their services in the role of trainers could develop the training materials at relatively low cost. Although subject-matter experts are utilized for their technical input, they typically do not develop nor deliver the instruction.

Figure 1 shows the earlier SAT model that was adopted by

Figure 1. **Phases and steps of the systems approach to training.**

the US armed forces. It has served as a prototype of the numerous versions spawned during the past 25 years. Each of the five phases of the model is discussed in turn.

2. ANALYSIS

The Analysis phase provides the foundation upon which successful materials are based. To ensure that instructional materials are based on job requirements, a job/task analysis is performed. In brief, a job/task analysis establishes what constitutes adequate on-the-job performance. It answers the questions: what tasks, performed in what manner, under what conditions, in response to what cues, to what standards of performance, make up the job? Not all tasks uncovered during the job analysis are candidates for training. Only those tasks and functions that job holders need to know (and do not already know) for the successful performance of their jobs are earmarked for training. Tasks that are performed infrequently or information that is "nice to know" but not essential is not included. To collect this information, three data collection methods are typically used: review of existing documentation (e.g. job descriptions, operator manuals); structured interviews with job incumbents, supervisors and subject-matter experts; and, where possible, observation of on-the-job performance. Job performance measures that serve as indicators of successful task performance are developed next. Each task selected for training has a job performance measure associated with it. Since the development of training materials is both time-consuming and labor-intensive, careful review of existing training materials and documentation helps the training developer avoid duplication of effort and may provide insight into what has worked well with similar tasks in similar operations. With respect to the instructional setting, ideally training is conducted in a setting that will maximize the student's ability to acquire and retain the instruction; however, logistical or administrative considerations frequently influence the venue for training.

3. DESIGN

The development of training objectives is the first step of the Design phase. Subsequent steps in the SAT process depend heavily on carefully prepared objectives. If the training objectives are poorly defined or couched in terms too vague, the instructional program will lack focus. Foremost, a well-stated objective specifies the desired outcomes in observable and measurable terms. It identifies what the student is to do, the conditions under which the task is performed, and the standard of performance that must be achieved. Such objectives aid the instructional developer by specifying the exact performances and knowledge the training is expected to produce. When desired outcomes are specified in observable and measurable terms, it becomes readily apparent when the instructional methods have succeeded, when they have failed, and when they need further development to increase their effectiveness. Criterion test items provide students with immediate confirmation about whether they are performing the specified terminal behavior called for by the course objectives. These tests are based on job performance measures that represent the best approximations of task performance, given the practical considerations of ease of administration and acceptable fidelity. Test items can be used as pretests for placing students at an appropriate instructional level, as within-course progress tests and for confirmation of mastery of objectives at the end of an instructional unit. To describe entry behavior, an entry-level test is devised and administered to assess initial assumptions about what learning objectives students know and do not know. Where the learning of an objective is dependent upon the prior learning of another objective, careful consideration is given to the way learning objectives are sequenced and organized in groupings.

4. DEVELOPMENT

The Development phase starts with a classification of learning objectives by learning category and subcategory to identify learning guidelines necessary for optimal learning to take place. A media selection process determines how the instruction is to be presented, taking into account learning categories, media characteristics, training setting criteria and costs. Compared with other decisions, the selection of media has a considerable impact on resources, development schedule and costs. Instructional management plans for the appropriate management and allocation of resources are developed. Existing materials are analyzed for appropriateness and new materials are developed for learning objectives not covered by existing materials. Specific development activities, of course, depend upon the media under development. Each medium has its own unique features and trade-offs that need to be considered. For example, multiple paths through lesson modules are one of the features that set interactive computer-based forms of instruction apart from more traditional media. Whenever multiple paths are open to students, the number of sequences that development personnel must undertake to develop increases considerably. It is, thus, necessary to arrive at a reasonable balance between all the possible paths that a developer might advocate for adding interest and individuality to the courseware and what is actually possible given the very real constraints of time, resources and budget. Once the materials have been developed, they undergo validation or formative evaluation where small-group tryouts are conducted with representative users for the sole purpose of improving the quality of the instructional materials.

5. IMPLEMENTATION

The Implementation phase affords the opportunity to observe and evaluate the instructional materials under actual training conditions. An implementation plan is developed which includes all facets of training management and administration, personnel roles and responsibilities, training system description, initialization procedures and schedule, equipment storage and utilization, student grading and evaluation, training materials management, facilities utilization, training of instructors and contingency planning. Sometimes called operational tryouts, the first implementation of the instruction provides an opportunity to evaluate procedures for the combined and integrated functioning of instructional materials, instructors (if required), actual students, equipment and facilities. Feedback from this larger and more representative sample in the job or training setting allows some of the less obvious problems to be uncovered, thus ensuring a more comprehensive quality control process.

6. CONTROL

The last phase, Control, refers to evaluation and revision of the instructional materials. The training materials may have been successfully implemented, but how well do they hold up across

repeated offerings of the program? Internal evaluation addresses the effectiveness of the instructional materials in terms of the extent to which students can master the training objectives. Is it more difficult to reach criterion-level performance on some of the units of instruction compared with others? External evaluation, on the other hand, assesses the extent to which the training program prepares students for on-the-job performance. Despite the care and resources that go into developing instructional materials, it is possible that graduates fall short of satisfying on-the-job requirements. Sometimes on-the-job requirements change in a short period of time. If graduates of the program do not need what they were taught, or need instruction they did not receive, this information needs to be fed back to the maintainers of the training system. Because of the methodological difficulties of experimentally demonstrating transfer of skills and knowledge to the job setting, most external evaluations, when conducted, rely on interview and questionnaire techniques.

7. ISSUES AND CHALLENGES

7.1. Isolation of Critical Steps

Several issues deserve comment. Any practitioner of the SAT process will quickly point out the distinction between the ideal and real. Because the SAT process was originally developed for use by individuals who were not trained neither in the subject-matter nor in the development of instruction, it was highly prescriptive in nature. Since training development is a labor-intensive activity, training developers are quick to bypass unnecessary steps. Organizational needs with respect to training also vary considerably. In short, plenty of adaptation and reinvention occur. When different organizations and federal agencies codify these adaptations and produce their own SAT models, one realizes there is no universal model that is applied unaltered across organizational settings. This gives rise to the question about what steps are of limited value and perhaps better treated as optional and what steps are essential or without which the integrity of the model would suffer to the extent to render its SAT character unidentifiable. Despite the emphasis placed on iterative evaluation in the SAT process, there is little in the way of research that attempts to isolate what the critical variables are and show their relationship to measures of effectiveness.

7.2. Importance of Front–end Analysis

While there might not be empirical support for the necessity of certain processes, training researchers and practitioners alike agree on the importance of the front-end analysis phase. Not everybody understands the importance of a thorough job/task analysis. Sometimes clients do the job/task analysis in-house and hand it off to an external training developer to do the design and development work. The job/task analysis is the foundation upon which training materials are developed. It can require an extensive effort. If it is not done completely and correctly at the outset, a careful following of the remaining steps of the model will be all for naught. An incorrect or incomplete front-end analysis should be redone immediately before design and development activities are undertaken. The penalties for not doing so include significant rework, slippage in the schedule and budget overruns.

7.3. Cognitive Task Analysis Procedures

While the SAT model has been applied successfully to jobs where most of the tasks are procedural and performed in a stable envi-

ronment, the application of the model to more complex tasks and dynamic environments, where the role of the individual is more of a problem solver or decision maker, is less convincing. In addition to performing operations, today's complex automated systems call upon operators to monitor, interpret and intervene in the case of abnormal system states. One of the ironies of automation, as observed by Bainbridge (1987), is that the most successful automated systems with the rarest need for manual intervention require the greatest investment in operator training. The correction of unusual abnormal system states depends on more than simple "how-to-do-it" procedural sequences. Cognitive task analysis procedures have emerged during the past couple of decades which look at skilled performance as a composite of (1) declarative or domain knowledge (knowledge of the system or device), (2) procedural (how-to-do-it) knowledge, and (3) strategic (how-to-decide-what-to-do-and-when) knowledge (Gott 1989). While experts can coordinate these multiple types of knowledge quite efficiently, novice operators are likely to experience gaps in declarative knowledge structures and in knowing when to deploy specific pieces of knowledge. As a way of capturing the tacit knowledge of experts and the cognitive processes involved in the deployment of that knowledge, Hall *et al*. (1990) developed the PARI (Precursor, Action, Result and Interpretation) methodology. PARI is a verbal protocol approach for eliciting knowledge from technical experts working in complex problem-solving domains (e.g. avionics troubleshooting). By focusing on the knowledge structures and cognitive processes that underlie skilled observable performance, the approach is considered an extension of the earlier behavioral procedures. While cognitive task analysis techniques have commanded the attention of a large body of cognitive scientists, they also are intended as practical, analytic tools that can be used by non-scientists for training development (Hall *et al*. 1990). The new century, no doubt, will witness continued progress along these lines.

7.4. Opportunities for Innovation

Training managers and developers sometimes treat the SAT model as a panacea for developing effective instruction. Effective instruction depends on more than simply following the steps of the SAT process. By attending to form over substance, training managers may gain a false sense of security, yet be unaware of innovative techniques that can be employed for enhancing student motivation and involvement with the training materials. There is nothing about the SAT process that says instruction has to be repetitious and tedious, yet much of it is. At the same time, there is not much guidance in the SAT steps on how to develop truly engaging instruction. Sometimes organizations invest heavily in a given instructional technology (e.g. web-based training, video teleconferencing, a new electronic performance support system) and then see every training problem as requiring that particular technology. There is more than an element of truth in the old adage about giving someone a hammer and every problem becomes a nail that requires pounding. Contrary to feeling constrained by the SAT process or any given technology, training developers have the opportunity to give free vent to their imaginations and more fully to exploit the unique instructional qualities that each medium provides. Recent years have seen the development of new instructional technologies, methodologies and tools

for providing expert advice, for interacting with students on a tutorial basis, and for allowing students to explore problem domains where they can constructively enhance their knowledge structures for responding to situations not previously encountered. These developments have the potential to make instruction more responsive to student needs and more manageable. Starting with the SAT process as a useful point of departure, the challenge for training efforts in the new century will be both conceptual and pragmatic: to explore new ways of thinking about enhancing on-the-job performance and to seek new ways of maximizing the instructional effectiveness of the ever increasing array of training technology.

Task Analytic Methodology for Design of an Aircraft Inspection Training Program

G. M. Nickles and A. K. Gramopadhye

Department of Industrial Engineering, Clemson University, Clemson University, Clemson, South Carolina, USA

1. INTRODUCTION

Aircraft inspection and maintenance is a complex system (Drury *et al.* 1990, Drury 1991) with many interrelated human and machine components. The linchpin of this system, however, is the human. Recognizing this, the Federal Aviation Administration (FAA), under the auspices of the National Plan for Aviation Human Factors, has pursued human factors research. In the maintenance area this research had focused on the aircraft maintenance technician (AMT). Since it is difficult to eliminate errors altogether, continuing emphasis must be placed on developing interventions to make inspection and maintenance more reliable and/or more error tolerant. Inspection is affected by a variety of geographically dispersed entities. These entities include large international carriers, regional and commuter airlines, repair and maintenance facilities, as well as the fixed-based operators associated with general aviation. An effective inspection is seen as a necessary prerequisite to public safety, so both inspection and maintenance procedures are regulated by the US federal government via the FAA. Investigators conducting this study found that while adherence to inspection procedures and protocols is relatively easy to monitor, tracking the efficacy of these procedures is not.

2. AIRCRAFT MAINTENANCE PROCESS

2.1 Maintenance Procedures

The maintenance process begins when a team that includes representatives from the FAA, aircraft manufacturers, and start-up operators schedule the maintenance for a particular aircraft. These schedules may be, and often are, later modified by individual carriers to suit their own scheduling requirements. These maintenance schedules are comprised of a variety of checks that must be conducted at various intervals. Such checks or inspections include flight line checks, overnight checks, and four different inspections of increasing thoroughness, A, B, C, and D; D is the most thorough and most time-consuming. In each of these inspections, the inspector checks both the routine and nonroutine maintenance of the aircraft. If a defect is discovered during one of these inspections, the necessary repairs are scheduled. Following these inspections, maintenance is scheduled to (1) repair known problems, (2) replace items because the prescribed amount of air time, number of cycles, or calendar time has elapsed, (3) repair previously documented defects (e.g., reports logged by pilot and crew, line inspection, or items deferred from previous maintenance), and (4) perform the scheduled repairs (those scheduled by the team including the FAA representatives).

2.2 Importance of Aircraft Inspection

In the context of an aging fleet, inspection takes an increasingly vital role. Scheduled repairs to an older fleet account for only 30% of all maintenance compared with the 60-80% in a newer fleet. This difference can be attributed to the increase in the number of age-related defects (Drury 1991). In such an environment the importance of inspection cannot be overemphasized. It is critical to perform these visual inspections effectively, efficiently, and consistently over time. Moreover, 90% of all inspection in aircraft maintenance is visual in nature and is conducted by inspectors, so inspector reliability is fundamental to an effective inspection.

2.3 Ergonomic Improvements in Aircraft Inspection

An analysis of the inspector's role in inspection has pointed to a number of issues, e.g., inspector-oriented issues, environmental design issues, workplace design issues (Drury *et al.* 1990, Lock and Strutt 1985). These issues have been continually addressed by the FAA as part of the National Plan for Human Factors in Aviation. Research conducted under this program has identified several ergonomic changes to the system and the inspector. System changes have included improved work control cards (Patel *et al.* 1994) and crew resource management interventions (Stelly and Taylor 1992). Inspector-oriented interventions are (1) selection and (2) training. Although individual differences in simulated aircraft inspection have been found (Thackray 1992), the correlations are typically too small to use as a basis for personnel selection. This article concentrates on training as an improvement strategy. Although aircraft inspection is used as a domain, some of the issues have broader applicability in training for industrial inspection.

3. OBJECTIVE: TRAINING FOR AIRCRAFT INSPECTION

As in any system that is highly dependent on human performance, efforts made to reduce human errors by identifying human-system mismatches can have an impact on the overall effectiveness and the efficiency of the system. Given the backdrop of the inspection system, the objective of this study was to use training as an intervention strategy to reduce inspection errors.

This article documents a task analytic methodology used in the development of a computer-based inspector training program, the automated system of self-paced instruction for specialized training (ASSIST) for aircraft inspectors. The ASSIST program is described in another article. The development of the inspection training program followed the classic training program development methodology. It began with a thorough analysis of the requirements and needs (goals) of the training program.

The next step was to establish the training group and identify the trainers and participants who would be involved. Following this, a detailed task analysis of the job was conducted to determine knowledge, skills, and abilities necessary for the job in order to specify the behavioral objectives of the training program. These objectives then formed the basis for evaluating the training program. After this, the next step was to define criteria measures against which inspectors will be trained and their performance measured, to meet the quality goals.

The abilities of the incoming trainees were compared to

requirements imposed by the task to determine gaps, and hence define the contents of a training program that will help close this gap and meet the defined criteria. At this stage, the appropriate training delivery system (i.e., the instructional technique), such as tutoring, on-the-job computer-aided instruction, had to be chosen. Once the training system is designed and developed, it goes through an evaluation to determine whether the program has met the ultimate goals.

The designer must choose criteria to be used for evaluation, identify a method and protocol for collecting evaluation data, and analyze the data to form conclusions about the training program's effectiveness. Figure 1 also shows the organizational inputs and objectives or goals at each step of the training program development phase. Up to this point, the steps in describing the training program have been sequential. But in reality many of them are iterative, with the designer fine-tuning the training program based on outputs obtained from later stages (as illustrated in Figure 1).

Thus training program design means translating content into a training program. Besides its content, the program is composed of the training methods, the training delivery systems, and the trainees. In the airline industry there is strict regulatory control over the trainees for inspection, as they are required to be licensed mechanics first. Hence the trainee is a relatively fixed input to the system.

4. DATA COLLECTION

The first stage of the assessment was to collect detailed information about the inspection process. A variety of data collection techniques were used to collect not only the process and procedural information and the idealized way of completing inspection tasks, but also information about the way tasks actually get accomplished. Here are the main information sources for collectiing task-descriptive data:

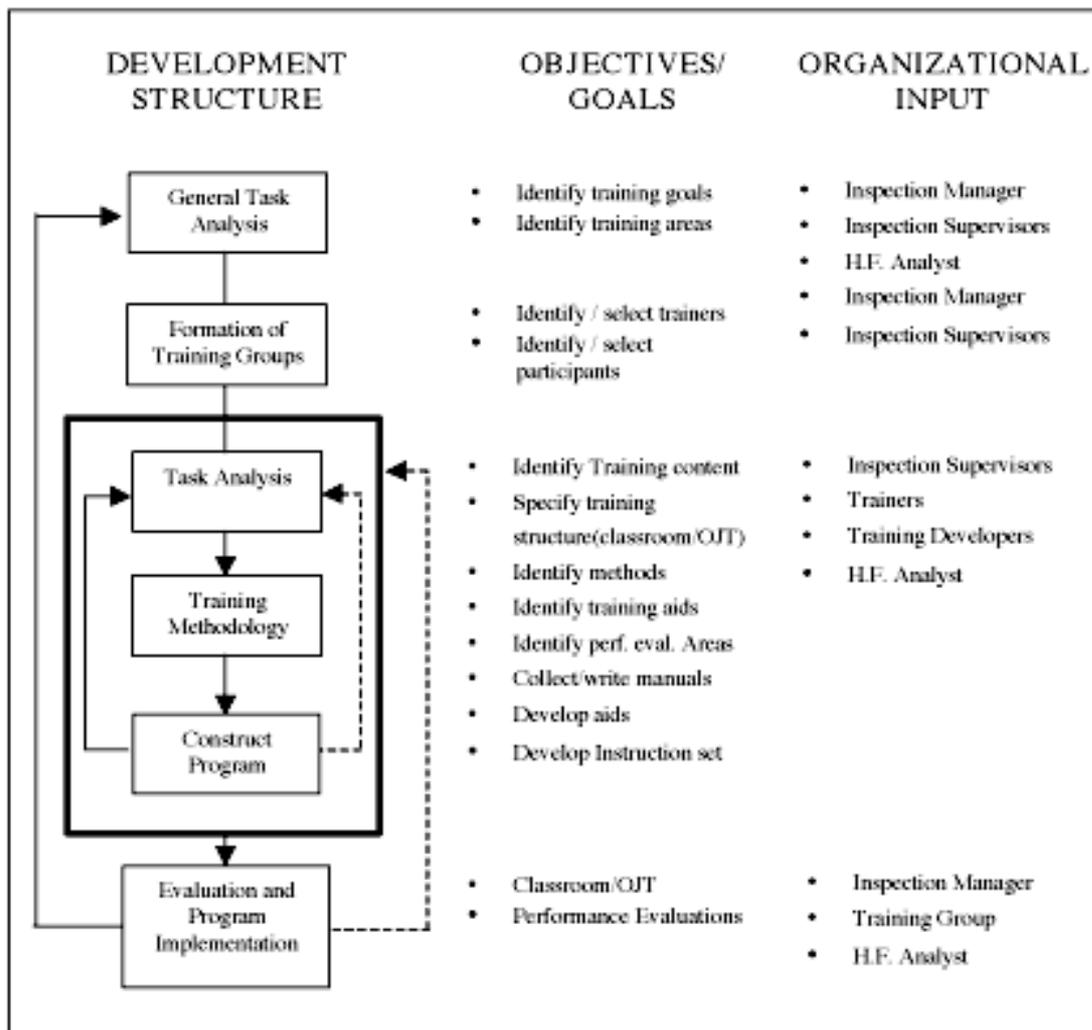
- *Observation and shadowing*: Data was collected by observing aircraft inspection and maintenance operations at various sites ranging from large international carriers to start-up and regional operators of general aviation. This involved watching various inspectors and maintenance technicians accomplishing various tasks over several shifts.
- *Interviewing*: Personal interviews conducted with inspectors, supervisors, aircraft maintenance technicians, lead mechanics, foremen, managers, planners, and other personnel associated with aircraft maintenance, were used


Figure 1. Model for training program development in commercial aviation

to collect data on aircraft maintenance tasks. Interviews with system participants at all levels helped investigators to collect data on the structure and functioning of the system as well as to collect data on the rare events such as system errors. This process was used to identify not only the prescribed way of working on the task but also the "quick and dirty" way that those tasks often get completed in reality.

- *Documentation*: Information on aircraft inspection and maintenance procedures was obtained through company-wide procedures, FAA mandated procedures (Federal Aviation Regulations, FARs), airworthiness directives, aircraft manufacturers' manuals and other documents.

Information from these sources was used to obtain a basic understanding of the tasks involved and to identify problem areas.

5. TASK DESCRIPTION

The information on the inspection process was represented in various formats: (1) an inspection flowchart, (2) a task description based on generic inspection, and (3) a task description form. Here are more detailed descriptions of each of these formats.

5.1 Inspection Flowchart

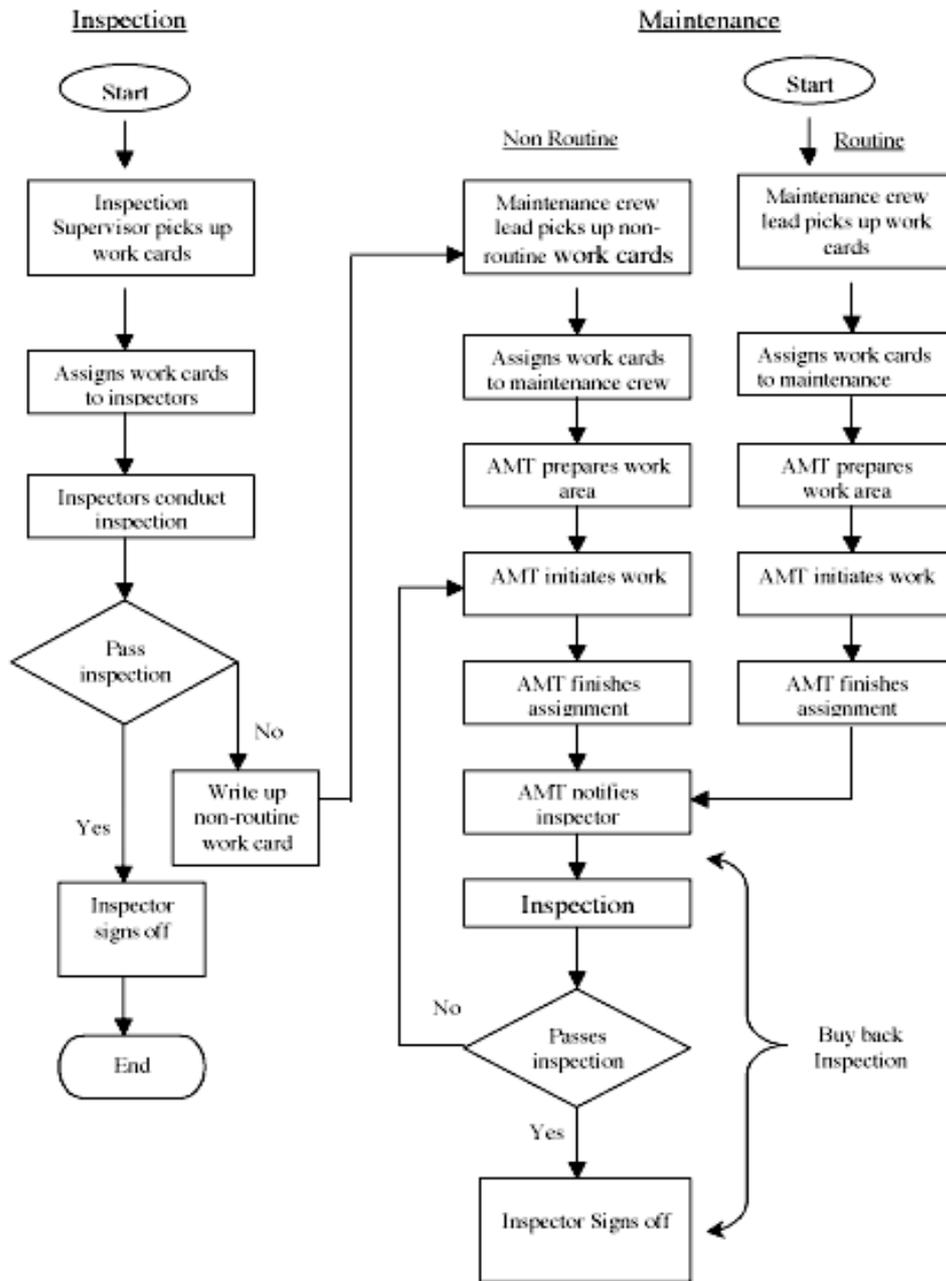
As a first step, a flowchart of inspection and maintenance activities was developed to illustrate the relationship between inspection and maintenance activities and the relationships among the personnel involved (Figure 2).


Figure 2. Aircraft inspection flowchart

5.2 Task description Based on Generic Inspection Activities

Although general task description approaches are widely available (Drury 1983; Kirwan and Ainsworth 1992), investigators in this case decided it would be advantageous to use an approach directly related to inspection. Literature describing human factors in inspections has produced the following generic list of inspection activities (Sinclair 1984): (1) present item to inspector, (2) search for flaws, (3) decide on rejection or acceptance of each flaw, and (4) respond by taking necessary action.

Table 1. Detailed breakdown of aircraft visual inspection by task step (Drury 1991)

Task Description	Visual Example	Task Step
1. Initiate	Get workcard. Read and understand area to be covered	1.1 Correct instructions written 1.2 ….
2. Access	Locate area on aircraft. Get into correct position	2.1 Locate area to 2.2 ….
3. Search	Move eyes across area systematically. Stop if any indication	3.1 Move to next lobe 3.2 …
4. Decision making	Examine indication against remembered standards (e.g. for dishing or corrosion)	4.1 Interpret indication 4.2 Access comparison standard 4.3 Access measuring equipment 4.4 Decide if it is a fault 4.5 Decide on action 4.6 Remember decision/action
5. Respond	Mark defect. Write up repair sheet or if no defect, return to search	5.1 Mark fault on aircraft 5.2 …
6. Repair	Repair area (drill out and repair rivet)	6.1 Repair fault
7. Buyback inspect	Visually inspect marked area	7.1 Initiate 7.2 ….

Note that not all steps may be required for all inspections; for example, some inspections may not necessitate search (e.g., color matching) and some may not necessitate decision making (e.g., absence of a rivet head on a lap splice). The unit of task description was the workcard (instructions outlining the specific inspection activity). A task was seen as continuing until a repair was completed and had passed airworthiness requirements. The workcard was the unit of work assigned to one particular inspector on one physical assignment, but the actual time required to complete work shown on a workcard is not consistent from workcard to workcard. Typically, inspectors were expected to complete work outlined by the workcard within one shift, but work might have to be continued across shifts. The work listed on each workcard could potentially require several inspections. Detailed task descriptions were obtained through site visits to various aircraft maintenance facilities (Table 1)

5.3 Task Description Form

Data collected through interviews and site visits was transcribed using a standard working form (Table 2), with a separate form for each of the five steps (initiate, access, search, decision making, and respond) in the generic task description. During the data collection phase, the human factors analysts remained with the inspectors, asking probing questions while these inspectors were actually at work. Following this step, human factors models of inspection performance and the functioning of individual subsystems were used to identify specific subsystems and potential human-system mismatches under the observations column in Table 2.

6. TASK ANALYSIS

Following this step, a detailed taxonomy of errors was developed from the failure modes of each task in aircraft inspection (table 3). This taxonomy, based on the failure modes and effects analysis (FMEA) approach, was developed due to the realization that a

Table 2. Task description form (Drury 1991)

Task descriptions	A	S	P	D	M	C	F	P	O	Observations
				Subsystems						
Search										
1.0 Inspect slat structure, wiring and installation										
1.1 Check wear on male duct of telescope shaft duct										
1.1.1 Check wear by moving it			X		X					• No prescribed force
1.2 Inspect slat well area for corrosion and cracks							X			• No standards for wear
1.2.1 Hold flashlight such that light falls perpendicular to the surface							X			• Holding flashlight for a long period at odd positions—strenuous
1.2.2 visually look for cracks and corrosion			X	X	X					
1.2.3 The visual indication confirmed by tactile			X	X	X					• Lack of information on type of cracks and figures
1.3 Look for play in slat actuator nut										

Attention: number of time-shared tasks   **Memory:** SSTS, working, long-term   **Senses:** visual, tactile, auditory
Perception: **Feedback:** quality, amount, timing   **Decision:** sensitivity, criterion, timing
Control: continuous, discrete   **Posture:** reading, forces, balances, extreme angles

Table 3. Task and error taxonomy for visual inspection (Drury 1991)

Task	Errors	Outcome
4.1 Interpret indication	Classify as wrong fault type	All indications located are correctly classified
4.2 Access comparison standard	Choose wrong comparison standards Comparison standard not available Comparison standard not correct Comparison incomplete Does not use comparison standard	correctly labeled as fault or no fault, and actions correctly planned for each indication
4.3 Decide if it is a fault	Type I error, false alarm Type II error, missed fault	
4.4 Decide on action	Choose wrong action Second opinion if not needed No second opinion if needed Call for buyback when not required Fail to call for required buyback	
4.5 Remember decision/action	Forget decision/action Fail to record decision/action	

Figure 3. Components of the ASSIST aircraft inspector training program

proactive approach to error control is needed to identify potential errors. Thus, the taxonomy was aimed at the phenotypes of error (Hollnagel 1989), i.e., the observed errors. Using the generic task description of the inspection system, the goal or outcome of each task was postulated as shown in Table 3 (third column). These outcomes then formed the basis for identifying the failure modes of each task and included operational error data gained form the observations of inspectors and from discussions with various aircraft maintenance personnel, which were collected over a period of two years. Later the frequencies of each kind of error were estimated, then the consequences of errors on system performance were deduced. The error taxonomy provided the analysts with a systematic framework to suggest appropriate

content for developing the content of the ASSIST training program.

The ASSIST training program specifically focused on the search and decision-making components of the inspection task. These appear to be determinants of inspection performance (Drury 1978, Sinclair 1984) and the two most critical tasks in aircraft inspection (Drury 1991, FAA 1993).

The overall structure of the ASSIST program is shown in Figure 3. As an example, table 4 shows how errors (column 5), identified from the error taxonomy, for each subtask of the decision-making task (column 1) were addressed by the specific modules of the ASSIST training program (columns 2, 3, and 4). Column 2 specifies the training content, column 3 outlines the method used for training, and column 4 specifies the training module within ASSIST.

Table 4. ASSIST program showing errors addressed for the decision task

Task	Content of assist	Method	Program Module	Error addressed from task analysis
4.1 Interpret indication	Present examples of defects and identify in simulator	Active and feedback	General module simulator	• Classify as wrong fault type
4.2 Access comparison standard	Use simulator to access information on defects, locations, and action	Active and feedback	General module simulator	• Choose wrong comparison standards • Comparison standard not available • Comparison standard not correct • Comparison incomplete • Does not use comparison standard
4.3 Decide if it is a fault	Use simulator with real defects and feedback	Progressive parts, active, and feedback	Simulator	• Type I error, false alarm • Type II error, missed fault
4.4 Decide on action	Complete NR card with feedback in correct way to fill out card	Active and feedback	Simulator	• Choose wrong action
4.5 Remember decision/action	Enter multiple defects and complete NR card with feedback	Active and feedback	Simulator	• Forget decision/action Fail to record decision/action

7. CONCLUSION

This article describes a step-by-step methodology to develop a task analytic training program. The research used existing knowledge of inspection training principles to design the ASSIST training program. Note that the development of ASSIST was driven by the requirements of the inspection environment rather than the ability of the research team to implement a specific ergonomic intervention or apply a specific technological solution.

Team Effectiveness and Competencies

1. INTRODUCTION

The recent rise in use of teams in modern industry can be traced to several sources. First, advances in technology have resulted in more complex systems that often require contributions from physically dispersed team members. Second, it has been recognized that team-based organizations have advantages in terms of employee motivation and involvement. Third, teams can often accomplish more than individuals and provide the redundancy required in high-risk environments. For these reasons, it has been important in recent years to examine the factors that contribute to team effectiveness. The purpose of this paper is to discuss some of these factors, in particular the competencies required for effective teamwork. Other papers in this volume describe additional factors that have been shown to have an impact on team performance (Bowers *et al.* 1999).

First, the knowledge, skill and attitude competencies that seem to be required for effective team performance are delineated. Next, the nature of competencies held by team members is described — whether they are specific or generic to the task and team. In conclusion, several measurement issues associated with assessing team effectiveness are discussed.

2. TEAM COMPETENCIES

As noted, the focus is on identifying and discussing the competencies required for effectiveness in a team. Note that team competencies can be thought to fall into two related categories (as originally outlined by Morgan *et al.* 1986). First, *taskwork* competencies refer to those knowledge, skills and attitudes (KSA) that a team member needs to accomplish his/her portion of the team task. Taskwork competencies are what are typically thought of as individual skills. However, taskwork competencies are a necessary but not sufficient condition for effective team performance. In other words, team members need to be proficient at their individual tasks, but in addition to this they require competencies at the team level. Hence, *teamwork* skills are required above and beyond taskwork skills if a team is to be most effective. Such teamwork competencies encompass not only both the team-level KSA required in teams but also the important teamwork processes that characterize effective teamwork. The following sections expand on the notion of teamwork competencies and how they are thought to affect team performance.

2.1. Types of Team Competencies

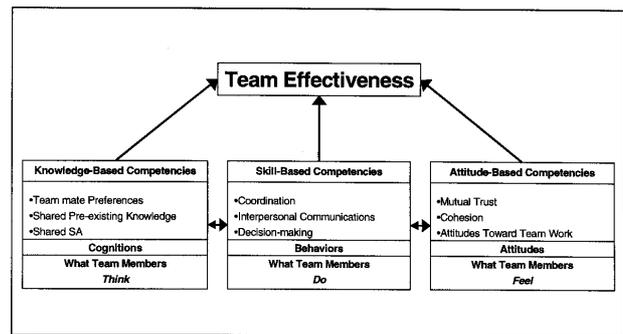
It has been argued that team competencies include all of those KSA that are necessary to perform effectively as a team member. According to Figure 1, this means that effective teams understand the underpinnings of effective teamwork and how these are expressed in the task at hand; are able to execute relevant


Figure 1. Competencies that affect team effectiveness.

teamwork skills when and how they are required; and have appropriate team-related attitudes that support their team performance. Each of these types of competencies will be detailed below.

2.1.1. Knowledge competencies

Knowledge competencies in teams express what team members need to know to be effective. This refers both to pre-existing knowledge that team members must bring to the team task, and also to knowledge that is constructed dynamically during the team's performance. Beginning with the pre-existing knowledge, several researchers have begun recently to study shared mental models or, more simply, shared knowledge in team members (for more detail on the subject, see Cannon-Bowers *et al.* 1995). Briefly, it has been suggested that when team members have a rich understanding of the task and its demands, and of the strengths, weaknesses, preferences, knowledge requirements and tendency of team mates, they are better able to coordinate their actions. This is particularly important in high workload situations where team members may not have much time to communicate or discuss potential task strategies. In such cases, effective teams appear to rely on an "implicit coordination" strategy where team members seem to be utilizing pre-existing knowledge about the task and each other to support performance.

In addition to shared pre-existing knowledge, team members must also be able to build dynamically a compatible picture of the situation to coordinate implicitly. This means that they must understand well how particular task cues are related to specific team strategies. This kind of knowledge in teams has been referred to as shared situational awareness (Salas *et al.* 1999).

Team members must also have knowledge about their mission, norms, roles and responsibilities. In addition, they require knowledge of teamwork skills, task sequencing and the team's relationship to the larger organization (Cannon-Bowers *et al.* 1995).

2.1.2. Skill competencies

Skill competencies reflect what team members must *do* to perform effectively. Recently, Cannon-Bowers *et al.* (1995) summarized the literature regarding teamwork skills. They found that > 130 labels had been given to team-related skills in the literature. They organized these into eight skill dimensions, including adaptability, which enables the teams to use information gathered from the environment and to adjust their strategies accordingly; shared situational awareness, which creates a common understanding of the task and situation; performance monitoring and feedback, which allows team members accurately to monitor each other's

performance and correct errors; leadership, which provides team members with the ability to direct, focus or coordinate activities; interpersonal skills, which enables members effectively to resolve conflicts and motivate each other; coordination skills, which enables team members to organize and use all the resources available; communication skills, which facilitates the exchange of information to be done clearly and accurately; and decision-making skills, which enables team members to gather and integrate information to execute the task.

2.1.3. Attitude competencies

Dick and Carey (1990) define attitudes as an internal state that influences an individual's choices or decisions to act in a certain way under particular circumstances. Team attitudes are important because they influence how team members will perform in the team. Some examples of attitudes relevant to teams include: (1) attitudes toward teamwork, which fosters the need to coordinate and communicate among team members; (2) mutual trust, which allows team mates to communicate their opinions without fear of being ridiculed; (3) collective orientation, which enables the disposition to receive and value inputs from others; and (4) cohesion, which creates the desire of team members to remain in the group. The importance of individual's attitudes to team success or failure has been investigated in a number of studies and has been show to strongly influence performance.

3. NATURE OF TEAM COMPETENCIES

According to Cannon-Bowers *et al.* (1995), team competencies (i.e. KSA) can be thought of as varying on two dimensions. First, they may be specific to a particular task at hand, or may be more general, thereby applying to a host of team tasks. For example, good communication skills might be general enough to have a positive impact on teamwork in many tasks. Hence, they would be considered *task-generic* teamwork competencies. On the other hand, task sequencing (i.e. knowing when to make contributions to the overall team task) is specific to the specific task at hand. This would be considered a *task-specific* teamwork competency.

Cannon-Bowers *et al.* (1995) also distinguish between *team-generic* and *team-specific* competencies. Team-generic competencies are those that remain the same regardless which specific team members are present. Conversely, team-specific competencies only apply to a specific set of team mates. For example, collective efficacy refers to the team's belief that it can accomplish the task at hand. By definition, this competency is team-specific because it will change depending on the team members being considered. On the other hand, collective orientation — an individual's propensity to be comfortable performing as part of a team — is not dependent on the particular team members being considered.

Figure 2 displays how Cannon-Bowers *et al.* (1995) postulate the types of teamwork competencies are related. Inspection of this figure reveals that the team specific/generic and task specific/generic categories can be combined to form four quadrants of competencies. Beginning in the upper right quadrant are *context-driven* competencies. These are specific to both the task and team. Moving to the upper right hand quadrant, the competencies here are labeled *team-contingent*. They are specific to the particular team members being considered, but generalize across tasks. In the lower left quadrant are *task-contingent* competencies that are

Relation To Task

	Specific	Generic
Specific	*Context-driven*	*Team-Contingent*
Generic	*Task Contingent*	*Transportable*

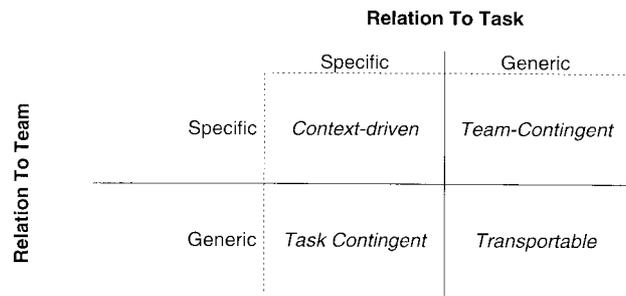
Relation To Team


Figure 2. Types of team competencies.

specific to the task at hand, but applicable to a variety of team mates. Finally, in the lower right quadrant are *transportable* competencies that generally hold for any task or team.

To determine which type of competencies would be appropriate for any given team, Cannon-Bowers *et al.* (1995) offered some notions regarding how task and environmental characteristics drive the nature of team competencies required for effective performance. First, they hypothesized that high interdependency within a team task would require that team members to possess context-driven competencies. The rationale behind this proposition was that interdepency causes team members to be reliant on one another and better able to select team strategies in a smooth, coordinated manner. This means that team members have a rich understanding of the task and its demands, and also of the information needs and tendencies of their team mates. They also suggested that when the team's task environment is fairly stable, task-specific competencies would be required, but not necessarily team-specific competencies. This is because in stable tasks, the behavioral discretion of team members is low — that is, the task is done pretty much the same way by any team member. Hence, it is more important to understand the task in this case than it is to understand the idiosyncrasies of team mates performing it.

Another proposition offered by Cannon-Bowers *et al.* is that rapid turnover in a team also reduces the need for team members to hold team-specific competencies. Obviously, if the team's configuration changes rapidly, investing time in learning about team mates would be wasted. On the other hand, when the same set of team members interact together in a variety of different tasks, the opposite is true. That is, in this case, team-specific competencies should improve performance, while task-specific competencies may not be an option.

Cannon-Bowers *et al.* also argued that transportable team competencies, which are generic to both the task and the team, should be provided to team members who hold membership on multiple teams. Also, when the organization is moving to team-based organization, training transportable teamwork competencies may provide a viable precursor to more specific team training.

4. DELINEATING COMPETENCIES FOR TEAMS

Table 1 shows a fairly comprehensive listing of team competencies categorized in accordance with the scheme offered by Cannon-Bowers *et al.* (1995). It summarizes the results of numerous studies of team performance and should provide an excellent starting point for those interested in determining the KSA required for any particular team. These competencies can be used to

Table 1. Proposed competencies for teams.

Nature of team competency	Description of team competency	Knowledge	Skills	Attitudes
Context-driven	Team-specific; task-specific	Cue-strategy associations Task-specific team mate characteristics Team-specific role responsibilities Shared task models Team mission, objectives norms, resources	Task organization Mutual performance monitoring Shared problem-model development Flexibility Compensatory behavior Information exchange Dynamic reallocation of functions Mission analysis Task structuring Task interaction Motivation of others	Team orientation (morale) Collective efficacy Shared vision
Team-contingent	Team-specific; task-generic	Team mate characteristics Team mission, objectives, norms, resources Relationship to larger organization	Conflict resolution Motivation of others Information exchange Intrateam feedback Compensatory behavior Assertiveness Planning Flexibility Morale building Cooperation	Team cohesion Interpersonal relations Mutual trust
Task-contingent	Team-specific; task-specific	Task-specific role responsibilities Task sequencing Team role-interaction patterns Procedures for task accomplishment Accurate task models Accurate problem solving Boundary-spanning role Cue-strategy associations	Task structuring Mission analysis Mutual performance monitoring Compensatory behavior Information exchange Intrateam feedback Assertiveness Flexibility Planning Task interaction Situation awareness	Task-specific teamwork attitudes
Transportable	Team-generic; task-generic	Teamwork skills	Morale building Conflict resolution Information exchange Task motivation Cooperation Consulting with others Assertiveness	Collective orientation Belief in importance of teamwork

establish the selection requirements for team members, or as an indication of the type of team training that is required.

5. MEASURING TEAM EFFECTIVENESS

The discussion of team effectiveness cannot be complete without considering how team performance is measured. According to Cannon-Bowers and Salas (1997), team performance measures must fulfil three related concerns. First, they must describe the performance of interest. Owing to the dynamic nature of many team tasks, even this simplest level of measurement is complicated. The moment-to-moment changes in team performance — especially those involving communication — are sometimes difficult to capture. The next level of measurement involves comparing observed performance to a standard. This 'evaluative' level of measurement seeks to determine how the team's performance compares to some standard (whether it be absolute or normative). The final level of measurement that is needed to assess team performance, particularly in training, is at

the diagnostic level. Here the concern is to determine the causes of effective and ineffective performance. This is imperative as a basis to provide feedback and/or construct remedial activities.

To diagnose team performance, Cannon-Bowers and Salas (1997) argue that performance measures for teams must assess the processes involved in accomplishing the team task as well as the outcomes of team performance. Outcome measures are what are typically thought of when measuring performance; essentially, they describe whether the team's performance was successful. Outcome measures include task accuracy, timeliness, latency, quality, productivity and so forth. It is essential to assess team outcomes to get a full picture of how the team performed. On the other hand, process measures described *what* happened during the course of the team task. Moreover, they also help to describe *why* certain outcomes were achieved. They are essential if an understanding of why the team was effective is sought, and are a primary mechanism for diagnosing team performance as described above.

Cannon-Bowers and Salas (1997) also distinguish between measures at the team and individual levels. As noted above, team performance consists of competencies that both the individual and team levels. Hence, it is important that team performance is measured at both levels as well. When combined with the outcome versus process and descriptive, evaluative and diagnostic delineations described above, a simple matrix of performance measures for teams is formed. According to Figure 3, four categories of team performance measures — at the descriptive, evaluative and diagnostic levels — are necessary to provide a full picture of team performance.

Figure 3 indicates that within each quadrant a set of performance measures can be developed for any given task. For example, in the team process box, it is recommended that the team's degree of shared task models, understanding of cue/strategy associations and collective efficacy is assessed. In the individual process box (still referring to teamwork processes, but those held at the individual level), it is recommended that assertiveness, mutual performance monitoring and task procedures be measured. Taking this a step further, Cannon-Bowers and Salas (1997) offered suggestions about what type of measurement strategy would be most appropriate for each category. Beginning with the upper left quadrant (team process measures), they recommend that observational scales targeting teamwork processes are an effective means in assessing this aspect of performance. Such scales can be developed using subject matter

experts (SME) to guide delineation of critical behaviors that must occur in team members. SME can also be employed as experts as expert raters when the task is particularly complex. Another technique for assessing team process is content analysis. By reviewing what happened over the course of team performance — what decisions were made and by whom — an assessment of the team's process is (at least partially) possible. Such data can be collected by observers or through automated systems that capture various aspects team performance. Related to this, an analysis of the team's communications (called protocol analysis) is also a useful mechanism to assess team process.

Turning to individual process measurement, several techniques apply. First, policy capturing seeks statistically to determine the relationship between inputs (cues) and outputs (strategies or decisions) in and individual's decisions. Next, decision analyses — which are more qualitative in nature — can help to reveal how decisions were made and how these led to task action. Observational scales and protocol analyses can also be geared toward individual processes (as well as team processes as described above).

At the outcome level, several more traditional methods for assessing task performance may be useful. In addition to expert ratings and observational scales, critical incidents may be used, archival data (i.e. performance trends) and automated performance recording are all viable options (Cannon-Bowers and Salas 1997).

1. INTRODUCTION

The increasing complexity of modern technological systems, such as power plants, manufacturing factories or aircraft cockpits, has made it necessary for teams of workers to coordinate their actions to achieve successful performance. However, several notable failures, incidents and accidents in these systems suggest that even highly competent and trained workers are sometimes poorly suited to perform together as a team. Therefore, there has been a recent interest in assessing the nature of teams and the variables that impact team performance. Issues such as staffing, individual team member characteristics, and the design of workspace and workflow have been among the topics studied in team performance research.

2. DEFINITION OF TEAMS

The initial stages of team performance research were somewhat hampered by a debate concerning the definition of teams. Because the terms "teams" and "groups" were often used interchangeably, an early controversy arose concerning whether the large body of existing research on the performance of groups could be used to predict the performance of teams. The result of this debate has been that there appears to be some value in discriminating between teams and groups in more detail before generalizing from one to the other. Consequently, teams are currently thought to form a specific and identifiable subset of the various multi-person units that are described by the more general term "group".

Teams are differentiated from other collectives by three characteristics (Swezey and Salas 1992):

- To be part of a team, team members must work toward a shared, valued goal. While some groups are formed so that their members work toward a common goal, others are formed by affiliation (e.g. professional organizations), belief (e.g. political parties or religious groups), demographic characteristics (e.g. graduating classes in college), random assignment (e.g. juries in court cases) or purely by coincidence (e.g. audiences in a movie theatre). Thus, individuals may belong to the same group, but have widely differing goals. On the other hand, by definition, all members of a team work to accomplish the same goal.
- Team members work interdependently toward their common goal. That is, no individual member of the team can normally complete the entire team's task. Rather, the performance of team members is interdependent on the performance of other team members. In groups, on the other hand, members routinely have equivalent resources and information, and any individual can often represent the group through their actions. As a result, the size and member responsibilities for teams tend to be much more specifically defined than for groups.
- Team members must coordinate their activities. Given the requirement for interdependence, teams perform their work by sharing resources and sequencing their activities. Often,

the success of a team is determined by the ability of its members to coordinate effectively. Groups, on the other hand, have no such requirement. The content and timing of communication in groups is generally not dictated by the task. Consequently, the quality of their performance tends to be less correlated with coordination behaviors than in teams.

3. FACTORS AFFECTING TEAM PERFORMANCE

3.1. Team Effectiveness Model

Salas *et al*. (1992) have presented a model that describes many of the factors that have been shown to affect team performance. This input–process–outcome model is called the team effectiveness model (TEM). A number of input factors from this model are discussed below. Variables associated with team processes and outcomes are discussed within other entries in this encyclopaedia (for example, Cannon-Bowers *et al*. 1999).

3.2. Individual Team Member Characteristics

3.2.1. Task skills

Not surprisingly, teams whose members are more competent in their performance of individual tasks tend to demonstrate better team performance. It should be noted, however, that the correlation between individual team member skill competence and team performance is lower than one might expect. Further, the performance one would predict on the basis of individual team member skill competence is usually higher than that actually achieved by the team. This phenomenon has been described as 'process loss' (Steiner 1972).

3.2.2. Interpersonal skills

Because interdependence and coordination are required among team members, it seems reasonable that team members must possess interpersonal ("teamwork") skills in addition to their specific task skills. The research on interpersonal skills training for teams, however, is somewhat mixed. Research indicates that training that is specifically targeted at the coordination needs of the team within the context of its assigned task is more successful than general interpersonal skills training. For example, in the case of junior team members who struggle to communicate with senior team members, general social skills training (e.g. social mores, politeness) is less likely to improve team performance than targeted team skills training (e.g. assertiveness).

3.2.3. Attitudes

A relatively large body of research is devoted to individual attitudes toward teamwork and their impact on team performance. This research has shown that attitudes toward teamwork differ among individuals and that there is some relationship between these attitudes and team performance. This relationship has been the impetus for team training that focuses on improving team performance by improving team member attitudes toward working as a team. At the same time, however, the effectiveness of these interventions also hinges on the presence of adequate team member competence in the required task and interpersonal skills.

3.2.4. Personality characteristics

When individuals join teams, they tend to carry their long-term

patterns of behavior with them. Thus, it seems reasonable to predict that these personality styles and characteristics also affect team performance. Interestingly, the literature, in general, seems not to support this prediction. While differences in personality among team members are associated with differences in the processes used by teams to achieve their goals, they do not necessarily impact the outcome or result of the team's actions.

3.3. Team Characteristics

3.3.1. Team size

The size of a team is typically determined by its task demands. That is, the number of team members is a function of the resources demanded by the task. That said, it is tempting to form large teams to maximize the number of available resources. This strategy is especially effective in the domain of problem-solving if the goal is to achieve a very high-quality solution. However, it should be noted that increasing team size is associated with several drawbacks. First, it is more difficult for large teams to communicate and coordinate their actions. Thus, they are not usually effective in highly interdependent tasks. Second, large teams typically perform more slowly and make more errors. They are generally not recommended in critical, high time-pressure tasks. Third, increasing team size is associated with higher communication workload, perhaps leading to greater process loss.

3.3.2. Collective attitudes

Two collective attitudes that have received research attention are collective efficacy and team cohesion. Collective efficacy refers to the shared belief that the team can perform its tasks effectively and achieve its goals. Similar to effects reported with individuals, teams with higher collective efficacy seem to perform better than their low-efficacy counterparts. However, this conclusion is based largely on correlational research and requires additional study. Team cohesion refers to the degree to which team members prefer to remain in a specific team. This team attitude has been associated with several positive team outcomes, including lower absenteeism and reduced turnover. However, the relationship between cohesion and performance is less clear.

3.3.3. Team member homogeneity

It is reasonable to suggest that teams are more effective when their members are "compatible" along some number of traits. In general, research has shown that teams made up of more similar members usually require less time to coordinate and achieve higher performance in routine, proceduralized tasks. However, there might be an advantage for heterogeneous teams performing tasks that require creativity, such as dynamic problem-solving, new product development and the like.

3.4. Task Characteristics

- Task type — teams are employed to perform a variety of tasks, from relatively routine, proceduralized tasks (such as product assembly) to unpredictable problem-solving tasks (such as system diagnosis). While these tasks, in and of themselves, do not fully determine team performance, they are prone to interact with other team performance characteristics (as demonstrated above). For example, the nature of the task can interact with team size to influence team processes.

- Time pressure — as mentioned above, the need to communicate and coordinate among team members is an additional workload factor for teams. When confronted with time pressure, the team's choices are either to increase their speed or reduce their communication. Research has indicated that effective teams often possess the ability to maintain performance while reducing communication. That is, they can share resources in the absence of explicit communication. The mechanism underlying this pattern has been labeled "implicit coordination" (Kleinman and Serfaty 1989). Presumably, team members can coordinate implicitly because they possess a shared understanding of the task and can anticipate one another's needs. It should be noted that while this pattern might be effective for high time-pressure situations, it increases the risk of errors.

3.5. Work Characteristics

3.5.1. Work structure

Researchers have studied the impact of forming structured, hierarchical ("tall") teams versus somewhat less structured ("flat") teams. Generally speaking, the research has indicated that hierarchical teams tend to display performance disadvantages. This is probably due to the inability of members to choose subtasks that fit their personal strengths. It is interesting to note, however, that these performance differences tend to disappear under high time pressure. In fact, hierarchical teams appear to posses a slight advantage in high time-pressure situations.

3.5.2. Communication structure/modality

Team members in modern workplaces are often geographically distributed. This distance often is associated with communication structures that use a variety of modalities, from video to e-mail. There appear to be potential positive and negative effects of mediated (i.e. non-face-to-face) communication. Negative effects include increased time to perform, which might render this type of communication unsatisfactory for high time-pressure tasks. Furthermore, studies have suggested that team members might display more emotional behaviors in mediated communications, leading to reduced cohesion. However, advantages of mediated communication have also been reported. Namely, mediated communication often leads to an increased ability of all members to contribute. This, presumably, is associated with higher qualities of decision-making. Similarly, the opinions of junior members appear to be considered more fully in mediated communications.

3.6. Organizational and Situational Characteristics

3.6.1. Organizational support

One important environmental characteristic that affects the effectiveness of teams is the teamwork support provided by the organization. In many examples from industry, teams that were created to improve worker participation, job satisfaction and organizational performance have failed because on-going organizational support for teamwork was missing. For example, teams fail sometimes because their explicit goals are contrary to the goals of the larger unit in which they are supposed to work. Conversely, positive organizational support for teamwork can manifest itself in the form of organizational commitment towards participative decision-making throughout the organization,

mission statements that explicitly endorse teamwork, training initiatives that emphasize team skills, etc.

3.6.2. Supervision and reward

In addition to the general support provided to teams by the organization, the ways in which organizations supervise and reward teams have important implications for team processes and performance. Most team members have to balance individual task performances with efforts that are required to maintain intra-team communication and coordination. Research has shown that organizational feedback and rewards substantially affect the way in which team members create and maintain this balance. For example, team members who are rewarded on the basis of their individual performances are much more likely to emphasize the individual task aspects of their work and to neglect coordinating and communicating with other team members. Conversely, team members whose rewards are based on their attempts to coordinate with others are more likely to emphasize coordination and to neglect their individual tasks, even if that tends to hurt overall team performance. Therefore, organizational rewards should be structured in a way that mirrors the importance of individual and team tasks for overall organizational success.

4. CONCLUSIONS

Teams are created for a variety of reasons: because the work cannot (or should not) be completed by an individual, because organizations would like to take advantage of the diversity of resources that a number of individuals bring to a team, or because the use of teams increases redundancy and reduces the chance for (catastrophic) errors. In recent years, teams have show great promise for fulfilling these intents within a wide range of academic, industrial and military settings. However, it is erroneous to believe that selecting and training a group of competent individuals will necessarily result in effective team performance. As discussed above, a variety of factors converge to determine the success (or failure) of teams. Only by understanding the way in which these factors interact can organizations reap the full benefits of effective team performance.

Division, 12350 Research Parkway, Orlando, FL 32826-3275, USA

1. INTRODUCTION

Teams have become a way of life in organizations. In fact, a recent survey conducted in US industries reported that 82% of businesses with 100 or more employees used teams in one way or another to accomplish their objectives. Teams are more popular than ever, and organizations are investing considerable resources in strengthening the communication and coordination mechanisms of their employees. Furthermore, many organizations are now designed around teams so that their very survival depends on effective teamwork.

This interest in teams by organizations has led to an explosion of team training research and practice. The aim of this research has been to address the question, What turns a team of experts into an expert team? That is, what developmental activities can enhance effective team functioning among highly interdependent members that have distributed expertise? In order to report the state of the art in team training, we outline what has been learned in answering this question. Specifically, we focus on team training principles and strategies that have been generated in recent years.

To begin our discussion, we define a team as "a distinguishable set of two or more people who interact, dynamically, interdependently, and adaptively toward a common and valued goal/

Figure 1. The structure of team training (Adapted from Salas and Cannon-Bowers 1997)

objective/mission, who have been assigned specific roles or functions to perform, and who have a limited life-span of membership" (Salas *et al.* 1992: 4). There are key concepts in this definition that bound the generalizability of this discussion. We focus particularly on teams that have distributed expertise, have high task interdependency and are organized hierarchically (i.e., there is a leader). Examples of this type of team include military command and control teams, medical emergency teams, some police and firefighting teams, cockpit crews, some sports teams, and some management teams.

2. WHAT IS TEAM TRAINING?

Team training is a set of tools, methods and content that together create an instructional strategy that focuses on enhancing teamwork. Figure 1 outlines the basic elements of team training. It reveals that team training is not a program or a place, as it has been popularly characterized. Team training interventions are theoretically based; built around sound instructional principles; based upon carefully crafted and designed instructional strategies; and focused on promoting the ease of coordination, communication, and synchronization among team members. Team training is more than just team building (i.e., where team members learn about each other) and individual training (i.e., where team members learn about their task). Team training is about designing and developing instructional strategiesæthrough tools, methods, team objectives, and competenciesæfor influencing team processes.

2.1. Tools

There are a number of useful tools available for designing effective team training strategies. For example, research has shown that an analysis of the coordination demands required for successful task performance can serve to focus the nature of practice and feedback. This coordination analysis requires that subject matter experts (SMEs) specify the criticality, frequency, and difficulty of performing certain team-related tasks. This is usually done via surveys or questionnaires. Team task analysis is also an available procedure. Although much work remains here to demonstrate its utility, this tool allows us to uncover the knowledge, skills, and attitudes (KSAs) necessary for effective teamwork given specific task requirements.

Performance measurement is the key to learning. Performance measurement tools embedded into training allow for learning to occur. Measurement tools for teams must consider a number of principles. These principles are readily adaptable/applicable to any team training environment. First, it is essential that any system of performance measurement has a strong theoretical foundation upon which to draw. There are many frameworks now available that can help guide the development process (Brannick *et al.* 1997). Second, a clear purpose for designing such a measurement system must be established upfront. This can be accomplished by first performing team/cognitive task analyses in order to tease out the criteria (i.e., KSAs) upon which the system should be based. Next the opportunities for measurement during training must be specified . This approach allows for specific and controlled learning opportunities and a manageable context to measure complex team performance. Any measurement system should also be aimed at not only determining what transpired but should also explain why it happened, in order to facilitate

learning. Therefore, process measures (i.e., to capture moment-to-moment actions and behaviors) must be designed and used. Usually these measures take the form of observation protocols or scales.

Additionally, team performance measurement systems should be capable of supporting the diagnosis of performance deficiencies so as to provide relevant remediation to team members. Another principle that should underlie the development of a team performance measurement tool is that it must not be cumbersome to use. Users should be able to rapidly collect, evaluate, and synthesize performance data so that immediate feedback can be provided to trainees. This can be realized by automating the system and by preparing instruction for the assessors.

A key element to the success or failure of any performance measurement system lies with the involvement of the user. Involving SMEs in the development process will help to ensure the end-product is accepted, useful, and effective. Finally, the tools and training necessary for instructors to consistently use the performance measurement system should be provided by way of instructor training packages as well as supporting materials (i.e., guide sheets, definitions, scenario events). Adherence to these principles will ensure the development of a strong team performance measurement tool to support team training.

Other tools to support team training include feedback and learning principles, which are used to guide and focus the design process. These are available in the literature from not only the human factors perspective but also the education and cognitive disciplines as well. Finally, task simulation and exercises are also tools for team training. These provide the environment or context that allows team members to practice the requisite KSAs.

2.2 Methods

Many methods are available to deliver instruction. They apply to both individual training and team training. There are information-based methods such as lectures, handbooks, slide presentations. These are widely used and effective when combined with other methods. There are also demonstration-based methods. These are more dynamic and stimulating. They include video demonstrations of effective and ineffective teamwork behaviors as well as multimedia systems that illustrate key principles and performance requirements in teams. Finally, there are practice-based methods. These are more sophisticated, costly, and interactive. They include simple to advanced exercises such as role-play exercises to high fidelity simulation environments (i.e., simulators) for teams to practice. These systems are visually rich and very interactive and engaging to the trainees. Moreover, we know simulators are effective training devices when appropriate instructional tools and features (e.g., performance measurement) are embedded in them (Salas *et al.* 1998).

2.2.1 Principles for enhancing the design of team training

Several principles can be used to guide the design and delivery of team training. We provide some representative examples (Cannon-Bowers and Salas 1998, Salas and Cannon-Bowers 1997, 1999). For example, team training must foster the development of team skills such as team leadership, adaptability, and compensatory behavior; link cue patterns to response strategies not only with regards to the task, but other team members as well;

provide team members with guided practice under realistic conditions; provide team members with motivational guidance and outline factors that hinder their motivation; make team members aware of the importance of effective communication; develop simulations that allow team members to experience different courses of action; facilitate team members' ability to learn about each other's roles and build realistic expectations about task requirements; diagnose team members' teamwork deficiencies with a combination of process measures and outcome measures; provide the necessary information to team members about effective teamwork, demonstrate those behaviors and actions, and allow for the practice with feedback on the requisite KSAs; and exercise team members with a variety of novel situations to build adaptive mechanisms.

2.3. Team Competencies

Team competencies are the heart of team training. The task context provides the required KSAs needed to successfully complete a team's tasks. KSAs in teams are quite different from those found for individuals.

Team competencies describe what team members need to know (i.e., knowledge), how they need to behave (i.e., skills), and what task-related attitudes (i.e., attitudes) they need to hold. Using the tools described earlier (i.e., team task analysis), team KSAs must be derived as a precursor to developing team training. In fact, the KSAs established for a team should provide the training objectives to be targeted in developing instruction.

Recently, researchers have focused attention on developing taxonomies of KSAs for different types of teams. In general, this work has highlighted the fact that team cognitionæthe knowledge componentæhas been overlooked in past research. In addition, results indicate that some teamwork skills are consistent across tasks, while others may be more generic. Likewise some team competencies may be specific to the particular team at hand, while others may hold regardless of team membership (Cannon-Bowers and Salas 1999, Cannon-Bowers *et al.* 1995).

2.4. Team Strategies: Examples

The methods, tools, and content (with the appropriate team training objectives) create a team training strategy. This strategy may take many forms and shapes, depending upon the needs, resources, and objectives of the training. Nowadays most team training strategies combine information, demonstration, and practice-based methods. Here are a few of them.

2.4.1 Team coordination training

Probably the most widely used in organizations, team coordination training is also known as crew resource management or aircrew coordination training. It has been used to train teams in a variety of settings, including aviation, medical, and military. Although the course content differs for each of these settings, there are certain commonalities inherent in all of these training programs. To begin with, this strategy concentrates on teaching team members the general components of teamwork in an effort to encourage it. Next, most of these programs use the general team performance or group dynamics literature as a framework. In addition, the training is usually delivered through a combination of information, demonstration (e.g., video examples), and practice-based methods (e.g., role plays) over a 2-5 day period.

2.4.2 Cross-training

Cross-training is a strategy in which team members are exposed to the basic tasks, duties, and responsibilities of the positions held by other members of the team. The intent of this strategy is to alleviate the decline in performance following personnel changes as well as to increase implicit coordination (i.e., being able to coordinate without the need to explicitly communicate). This is accomplished by the subsequent increase in the interpositional knowledge held by each team member following training (i.e., a strengthening of the team's shared mental models). The training is composed of cross-role information sharing (teammates, task, equipment, situation), enhanced understanding of interdependencies, roles and responsibilities, and cross-role practice and feedback. The training is usually delivered via lecture, multimedia systems, and/or roleplays. Research has shown that cross-training can be an effective means to enhance team performance. Among other things, cross-trained teams are better able to anticipate the information needs of their teammates, commit fewer errors, and display better team process quality; see Cannon-Bowers and Salas (1998) for a review of this and other team training strategies.

2.4.3 Team self-correction

Team self-correction, as defined by Blickensderfer *et al.* (1997), is a naturally occurring tendency for effective teams, following a performance episode, to review events, correct errors, discuss strategies, and plan for the future (e.g., debrief themselves). This team training strategy attempts to capture this tendency and train other teams how to engage in this process. The end result is a team that is able to correct its knowledge-based, skill-based, and attitude-based deficiencies without the aid of a formal instructor. This training is delivered through a combination of lecture, demonstration, practice, and feedback. The target of training is the team leader (if there is one) and team members themselves. Specifically, team members are taught how to observe their own performance, how to categorize their effective and ineffective behavior into a structured format, and how to use this information to give each other feedback (Cannon-Bowers and Salas 1998). When an instructor is present, he or she is taught how to probe the team members to come up with their own examples of effective and ineffective performance. This method of guided team self-correction has been demonstrated to improve team performance.

2.4.4 Event-based approach to training (EBAT)

EBAT is a general approach to the design of simulation-based exercises where training opportunities are systematically identified and introduced as "trigger" events in a training exercise. The purpose of doing this is to provide opportunities for students to exhibit specific team behaviors that are based on the team training objectives established through team task analysis. These behaviors are in turn captured, rated, and then used later for debriefing and feedback. This strategy has been successfully used in multiservice distributed military training environments as well as in aviation settings.

2.4.5 Assertiveness training.

In complex team environments, it is important that teams make use of all available information and resources. This means that the unique knowledge, skills, ideas, opinions, and observations of each team member must be exploited to arrive at the optimal decision. In fact, it is often the willingness of team members to voice concerns assertively that can help to avoid potentially life-threatening decisions (e.g., in law enforcement teams or aircrews). Hence efforts have been directed toward training team members to display effective task-related assertiveness. For example, team members may need to act assertively when providing feedback to other members, when stating opinions, when stating potential solutions, or when offering or providing assistance. Training to improve assertiveness should involve practice and feedback to ensure that assertiveness skills will be demonstrated (Smith-Jentsch *et al.* 1996).

Team Training for Aircraft Maintenance

D.C. Kraus and A.K. Gramopadhye*

Galaxy Scientific Corporation, Tucker, Georgia, USA and *Industrial Engineering Department, Clemson University, Clemson, South Carolina, USA

1. INTRODUCTION

Research and development efforts related to human factors in aviation have often focused on the pilot and the cockpit. However, a recent study conducted in the USA has shown that 18% of the accidents could be attributed to maintenance-related issues (Phillips 1994). In response, the FAA has pursued maintenance-related human factors research. The Federal Aviation Administration (FAA) reports on human factors in aviation maintenance (Shepherd 1991, FAA 1993, 1995) have identified training as a primary intervention strategy to improving performance. However, this training has primarily focused on improving individual skills of the aircraft maintenance technicians (AMTs) This training has ranged from improving diagnostic skills for aircraft maintenance training (Johnson 1990) to acquiring and enhancing visual inspection skills to improve airframe structural inspection (Gramopadhye et al. 1992). A large effort in the past has concentrated on developing individual skills of AMTs; however, very little effort has been placed on developing team skills.

The task analyses of aircraft inspection and maintenance activities (Drury et al. 1990, Taylor 1990, FAA 1991, 1993) have revealed the aircraft inspection and maintenance system to be complex, requiring above average coordination, communication and cooperation between inspectors, maintenance personnel, supervisors and various other subsystems (planning, stores and shop) to be effective and efficient. A large portion of inspector and maintenance technician work is accomplished through teamwork. The challenge is to work autonomously but still be a part of the team. In a typical maintenance environment, first the inspector looks for defects and reports them. The maintenance personnel then repair the reported defects and work with the original inspector or the buyback inspector to ensure the job meets predefined standards. During the entire process, the inspectors and maintenance technicians work with their colleagues from the same shift and the next shift as well as personnel from planning, stores, etc., as part of a larger team to ensure the task gets completed (FAA 1991). Thus, in a typical maintenance environment, the technician has to learn to be a team member, communicating and coordinating the activities with other technicians and inspectors. Though the advantages of teamwork are widely recognized (Hackman 1990) in the airline industry, the work culture assigns responsibility for faulty work on individual AMTs rather than on the teams in which they work. The reasons for this could be the individual licensing process and personal liability, both of which often result in AMTs and their supervisors being less willing to share their knowledge and to work across shifts with less experienced or less skilled colleagues. The problem is further compounded since the more experienced inspectors and mechanics are retiring and being replaced by a much younger and less experienced workforce. Not only do the new AMTs lack knowledge or skills of the far more experienced AMTs they are replacing, but they are also not trained to work as a team member.

The FAA has continually addressed the earlier problem of the development of individual AMT skills. For example, the newly established FAR Part 66 (new AMT's certification requirements) specifically addresses the significantly technological advancements that have taken place in the aviation industry and the advancements in training and instructional methods that have arisen in the past decade. The FAA, through the Office of Aviation Medicine, has also funded efforts for the development of advanced training tools to train the AMTs of the future. These advanced tools include intelligent tutoring systems, embedded training, etc., which will be available to airframe and powerplant (A&P) training schools. It is anticipated that the application of these new training technologies will help reduce the gap between current AMT skills and those needed for the maintenance of advanced systems. However, the AMTs joining today's workforce are lacking in team skills. The current A&P school curriculum often encourages students to compete against one another, and often AMTs are not fully prepared for cooperative work in the future. To prepare student AMTs for the workplace, new ways have to be found to build students' technological, interpersonal and sociotechnical competence by incorporating team training and communication skills into their curriculum. This study explored the potential of advanced technology for team training within the aircraft maintenance environment.

The general objective of this research was to understand the role of team training and specifically that of computers for team training. The team training model (figure 1) for the aircraft maintenance environment, developed by Kraus et al. (1996), was used as a framework to develop a computer-based team training software, the aircraft maintenance team training (AMTT) software (Gramopadhye et al. 1995). The model served as the first step in understanding teamwork in aircraft inspection and maintenance operations, and illustrated the interaction between internal factors, external factors, the team process, training strategies and outcomes measures. Using the model and the AMTT software, a controlled study was designed and conducted to evaluate the effectiveness of computers for team training. The specific objectives of this research were (1) to evaluate the usefulness of computers in assisting AMTs in acquiring knowledge on team skills, (2) to determine whether a computer-based multimedia tool would be easy for AMTs to use, and (3) to determine whether computer-based team training was as effective as traditional instructor-based training.

2. COMPUTER–BASED TEAM TRAINING: AMTT SOFTWARE

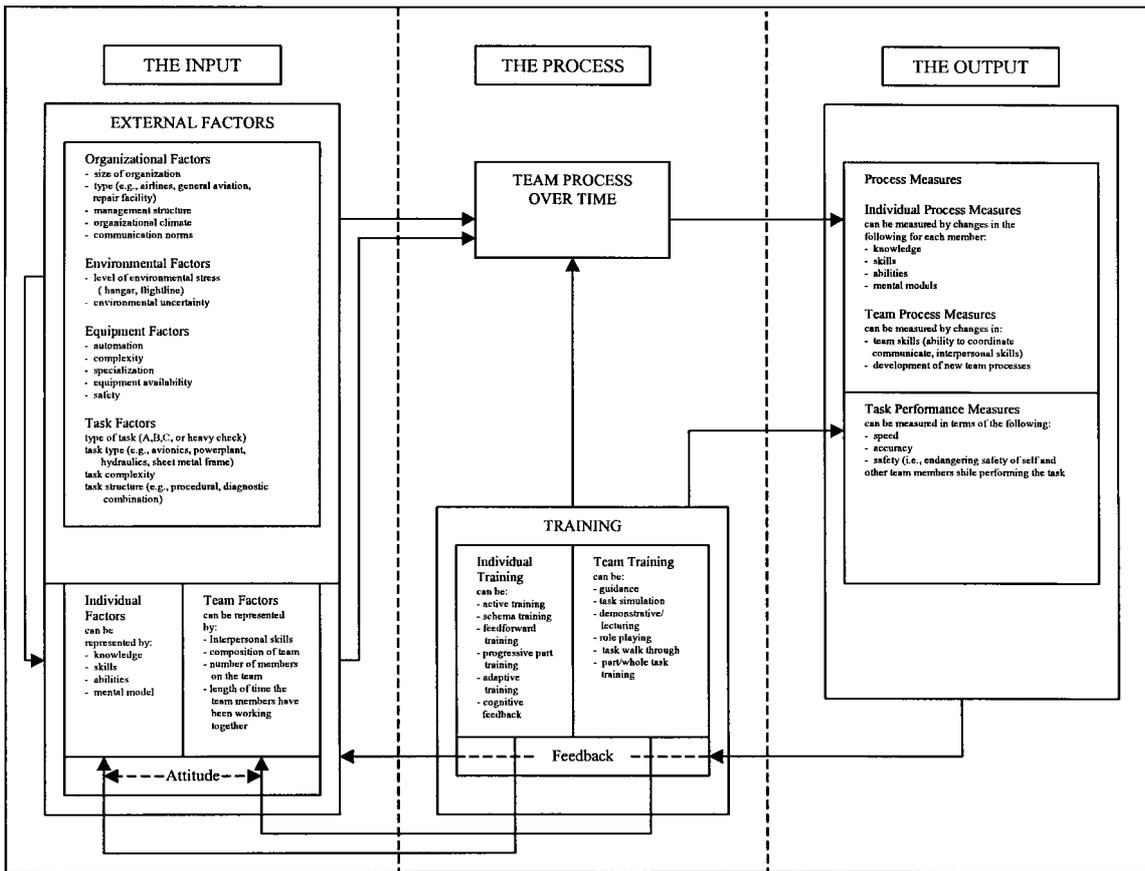
Specifically designed for training aircraft maintenance technicians in basic team skills, AMTT uses a multimedia presentational approach with interaction opportunities between the user and the computer. The multimedia presentation includes full motion video which provide real-life examples of proper and improper team behavior, photographs and animation that illustrate difficult concepts, and voice recordings coupled with visual presentations


Figure 1. Team training model for the aircraft maintenance environment
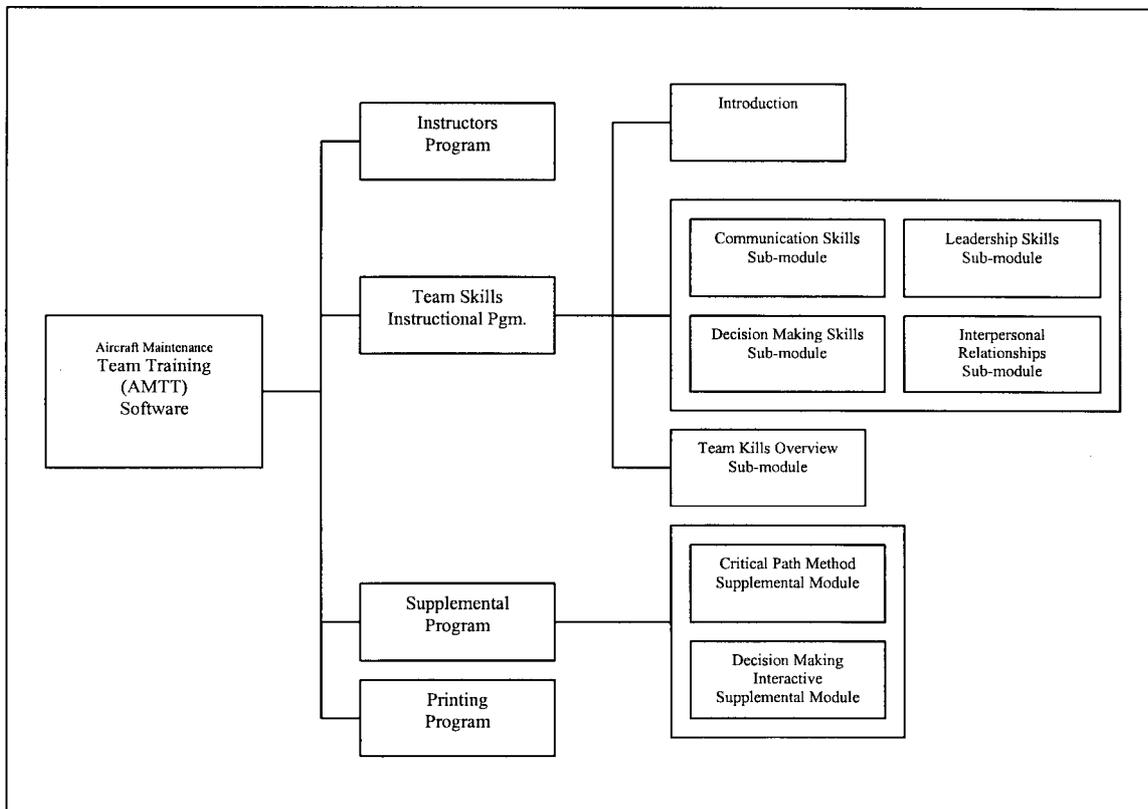

Figure 2. Layout of the AMTT software

of the main contextual material. Since the software was developed as a training and research tool, the software facilitates the collection of pretraining and posttraining performance data.

AMTT is divided into four major programs (Figure 2): (1) team skills instructional program, (2) instructor's program, (3) printing program and (4) the supplemental program. The team skills program and the supplemental program have been designed for use by the aircraft maintenance technician undergoing team training, but the remaining two programs are for use by the instructor or supervisor. An aircraft maintenance technician interacting with the AMTT software first uses the team skills instructional program, which initially provides an introduction to the software. Following this step, the AMT is provided with instruction on basic team skills through four separate team skill submodules: communication, leadership, decision making and interpersonal relationships. These submodules not only emphasize and cover generic material related to these skills but also relate the importance and use of the specific skills within the aircraft maintenance environment. These are the same four skills emphasized in an earlier FAA (1995) report which looked at the role of team training in the aircraft maintenance environment.

Figure 3 shows a prototypical layout of a team skills submodule. The right-hand side of the screen is dedicated to key points being discussed in the voice-over, whereas the left-hand side of the screen provides supporting material. This supporting material comes in a variety of formats which include, but are not limited to animation, video, photographs, diagrams and flowcharts. Buttons on the command line at the bottom of the screen can be clicked on to exit, advance, back up, stop and replay audio, replay video, and access the navigation map. Each of the team skills submodules has a similar structure.

3. METHODOLOGY

3.1. Test Site
The controlled study was conducted at the Aircraft Maintenance Technology Center of Greenville Technical College (GTC). The center houses classrooms for A&P training and a fully equipped hangar for conducting aircraft maintenance and repairs. The classrooms at the Aircraft Maintenance Technology Center provide seating for 20 students. Each classroom was equipped with a 25-inch color

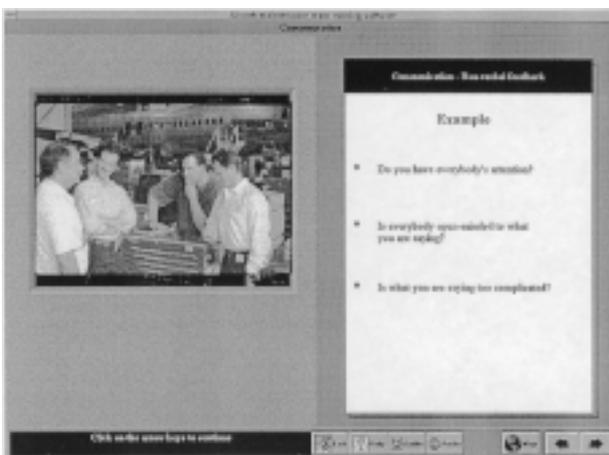
Figure 3. Prototypical layout of a team skills submodule

television, video player, overhead projector, whiteboards and blackboards, and a lectern. In addition, the classrooms were equipped with four Pentium 75 MHz computers and 15-inch color monitors (1024 ¥ 768 resolution) installed with multimedia packages.

3.2. Test Subjects
The subjects for this study consisted of 12 students from a local aircraft maintenance technology program and 24 licensed A&P mechanics from a local aircraft maintenance facility. The subjects were compensated for their participation. The 36 subjects were assigned to two groups: IBT for instructor-based training, and CBT for computer-based training. Each group had equal number of subjects from the aircraft maintenance technology program and the maintenance facility.

3.3. Experimental Procedure
3.3.1 Instructional phase
Subjects in the IBT group were trained on team concepts using a traditional instructor-based training delivery system, whereas those in the CBT group received similar training on a computer using the AMTT software. Every effort was made to maintain a constant curriculum and presentation sequence for both groups. The only difference in the training between the two groups was the type of delivery system. The team skills training focused on four separate skills: communication, decision making, interpersonal relationship and leadership. More details on the structure and content of the team training program can be found in Gramopadhye *et al.* (1995). Note that in the instructional phase, team training was provided to individuals, and teams were not formed until the evaluation phase.

3.3.2 Evaluation phase
This phase examined the transfer effects of team training (IBT and CBT) on AMT performance. Upon completion of the instructional phase, subjects in each group were assigned to six three-member teams. Following the assignments, the teams were given two tasks representative of normal aircraft maintenance: a routine maintenance (RM) task to determine the center of gravity of an aircraft, and a nonroutine maintenance (NM) task to troubleshoot an electrical problem on an aircraft. The order in which the tasks were performed was balanced within each group.

4. DATA COLLECTION
4.1. Instructional Phase
Before the training was initiated, all subjects completed a team skills perception questionnaire for each team skill being taught (communication, decision making, interpersonal relationships and leadership); figure 4 shows an example. The questionnaire used elements from the crew resource management/technical operations questionnaire (CRM/TOQ), a modified version of Taggart's questionnaire (1990), Taylor's questionnaire (1990) and the critical team behavior form (CTBF) (Glickman *et al.* 1987). Each questionnaire consisted of 10 questions on a seven-point Likert scale, and each was designed to measure the subject's perception of a particular team skill. In addition to the team skills perception questionnaire, each subject completed a 20-question multiple-choice knowledge test before training (figure 5). The objective of the knowledge test was to measure each subject's knowledge on the different team skills before training.


1. Good communication and team coordination are as important as technical proficiency for aircraft safety and operational effectiveness

| Very strongly disagree | 1 | 2 | 3 | 4 | 5 | 6 | 7 | Very strongly agree |

2. Crew leaders and supervisors should encourage questions during work and in special situations

| Very strongly disagree | 1 | 2 | 3 | 4 | 5 | 6 | 7 | Very strongly agree |

3. The start of shift team meeting is important for safety and effective team management

| Very strongly disagree | 1 | 2 | 3 | 4 | 5 | 6 | 7 | Very strongly agree |

Figure 4. Sample questions from team skills perception questionnaire: communication

After completing the team skills perception questionnaire and the knowledge test, the subjects received team skills training using the appropriate delivery system. Upon completion of the training, the same team skills perception questionnaires and the knowledge tests were readministered to the subjects. The purpose in repeating the same perception and knowledge tests was to measure the changes in perception and knowledge that had occurred during training. Each subject also completed two sets of usability questionnaires. The questionnaires collected subjective satisfaction ratings on the training delivery system using a seven-point Likert scale, where 7 indicated strong agreement and 1 indicated strong disagreement. The first questionnaire, called the general questionnaire (figure 6), contained questions relevant to both the training delivery systems; it was completed by subjects in both the groups. The general questionnaire addressed usability issues related to content, mechanics of presentation, format and usefulness. The second part of the usability questionnaire was specific to the training delivery system; it addressed usability related to presentation and format.

4.2. Evaluation Phase

As the teams performed the routine and nonroutine tasks, their performance on the tasks was evaluated by three independent evaluators on measures of speed, accuracy and safety. In addition, at the conclusion of the routine and nonroutine maintenance tasks, the evaluators (instructor's evaluation) and each individual subject (self-evaluation) completed a questionnaire evaluating their team on the application of various team skills

(communication, decision making, interpersonal relationships and leadership). The evaluation consisted of a questionnaire with seven questions on each of the team skills, wherein the evaluator rated the team on their application of the team skill on a seven-point Likert scale.

5. RESULTS

5.1. Analysis of Instructional Phase

5.1.1 Knowledge test.

The knowledge test was analyzed to understand the effect of team training on the subject's knowledge of team skills. The knowledge test analysis used a 2 ¥ 2 design – two delivery methods (CBT, IBT) by two trials (pretraining, posttraining) – with 18 subjects nested within each group. The method of training delivery was the between-subjects factor and the trial was the within-subject factor. A comparison of the pre- and posttraining knowledge test showed that in every skill category there was a significant increase in the test scores after training. The fact that both training programs showed comparable increases in test scores probably indicates the effectiveness of both methods of delivering team training. These results are encouraging about the potential of the team training program in imparting team skills knowledge. The fact that the CBT (specifically the AMTT software) was able to achieve the same scores as IBT (an equally well-developed classroom team training program) bodes well for the role of computers in imparting team skills knowledge. In other words, given equivalent content of the team training program, a well-

Your crew chief is talking to the team and when he says something significant and you nod your head in agreement…
    A. It displays a lack of desire to communicate.
    B. You are communicating with body language.
    C. You should keep very still so as to not confuse the speaker
    D. You should remain quiet since verbal and non-verbal communication do not mix.

When a supervisor summarizes what he said and then asks several questions of the team member, he is…
    A. Grading the team members.
    B. Using an investigative management technique.
    C. Using reverse psychology to get his team to work harder.
    D. Looking for feedback to see if he got his message across.

Figure 6. Sample questions from General usabiltiy Questionnaire

designed interactive computer-based team training program can be as effective as the traditional instructor-based team training program.

5.1.2 Perception

The team perception questionnaire was developed to quantitatively measure an individual's perception of team skills before and after training. The results of the pre- and postperception questionnaire on the four team skills showed that the training delivery system had comparable effects on the subject's perception of team skills. Figure 7 compares the perception scores for the two groups on each of the four skills.

5.2. Usability

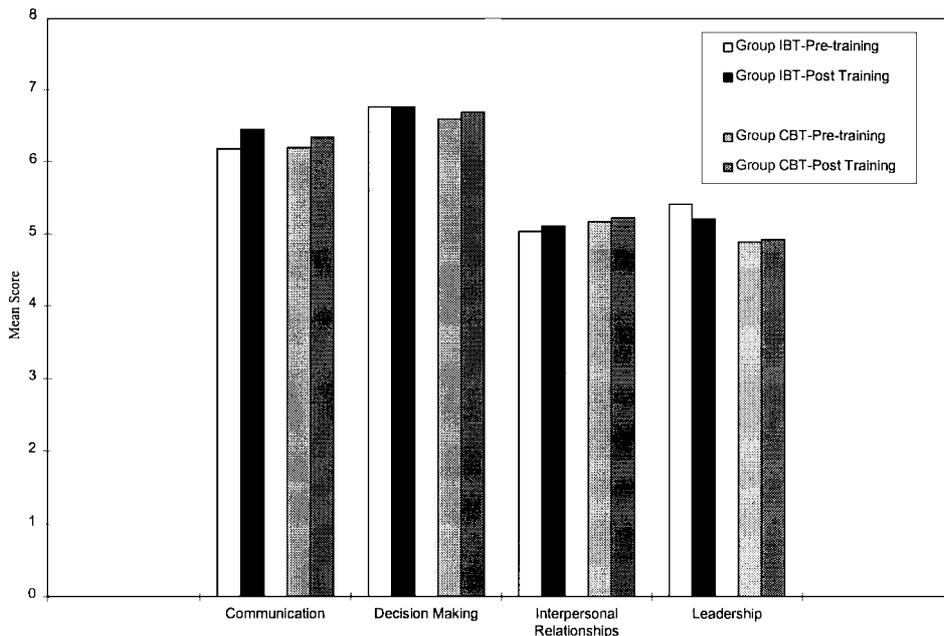
The development of the AMTT software followed an iterative design process to ensure that problems with the software design


Figure 7. Team skills perception pre and post training for groups IBT and CBT

were identified and corrected before implementation. The cycle of design, test, measure and redesign was repeated a number of times in the development process (e.g., Gould and Lewis 1985). The user interface capitalized on the following: graphical user interface technologies, human factors research (i.e., color, formatting, layout, etc.), ease of use, and information utilization (Chabay and Sherwood 1992). Thus the AMTT software was developed after understanding the needs of the AMT, discussions with experts from Lockheed Martin and Greenville Technical College, following a process of iterative design and development, and eventually resorting to detailed user testing (with instructors, supervisors and AMTs).

Figure 8 shows the results of the general usability questionnaire with mean score for the four separate usability issues: content, mechanics, format and usefulness. For the various usability issues, there were no significant differences in the levels of satisfaction between the groups. Also, when the four usability issues were consolidated (combined average score), there was no significant difference between the groups. Both of the training delivery systems had high scores on system-specific usability issues. These results were encouraging since they indicated that the users were equally satisfied with either a highly interactive computer environment or a traditional classroom environment.

5.3. Analysis of Evaluation Phase

On completion of both the routine and nonroutine maintenance tasks, the subjects in groups IBT and CBT scored their team on the application of the four team skills. As each team completed the routine and nonroutine maintenance tasks, the evaluators also scored the teams on their use of the four team skills. The instructor's evaluation did not reveal any significant differences between the groups in each of the team skills categories (figure 9). Thus, according to the evaluators' scores, the training delivery systems had comparable effects on the subjects' use of team skills in the performance of maintenance tasks. While the teams conducted the two tasks (routine and nonroutine maintenance), the evaluators recorded the performance of the teams on accuracy, speed and safety violations. Using all three performance measures, there was no statistically significant difference between the two groups on either the routine or the nonroutine maintenance task. Thus, the training delivery system had no significant effect on task performance measures.

6. DISCUSSION AND CONCLUSIONS

The goal of this research was to understand the role of computer-based team training specifically within the aircraft maintenance environment. Part of the research involved development of the AMTT software, a computer-based team training package And its usefulness was tested against a traditional classroom method of instruction in terms of team knowledge acquisition, usability issues and knowledge transfer. Here are the important conclusions:

1. Team training enhanced the knowledge of individuals on team skills However, the type of training delivery system did not have a significant effect on the individual's ability to acquire team skills knowledge. Thus, a well-designed computer-based team training program was equally effective in imparting team skills.

2. Many times CBT fails because software designers do not design interfaces and systems that users can understand. A user-centered design approach is required with an iterative process of design, test, measure, modify and retest. This procedure was used in the development of the AMTT software, and a user-friendly product was produced. There were no significant differences between IBT and CBT in terms of user satisfaction. Both training delivery systems reported a high level of user satisfaction on the general and delivery-specific portions of the usability questionnaire.

3. The results are unequivocal. CBT (i.e., AMTT) was as effective in delivering team training instruction as IBT. Finally, the iterative design methodology employed in this study proved to be useful in designing effective computer-based team training software. These results have obvious ramifications for the use of AMTT in team training within the aircraft maintenance environment. Besides being as effective as existing instructor-based methodologies, AMTT team training has other obvious advantages:

- *Standardization*: The AMTT software provides a standardized and systematic team skills training program which aircraft maintenance instructors (at certified repair stations, airline companies, general aviation stations and A&P schools) can use to provide team skills training.
- *Adaptability*: Maintenance training has traditionally been accomplished via on-the-job training or classroom training,

both of which are labor-intensive. It requires careful scheduling of personnel or encumbers others in the training process. AMTT is adaptive, self-paced and can be done at convenient times when trainees are available, and it need only involve the person being trained.

- *Record keeping*: The record-keeping capabilities of AMTT tracks the student's progress. This information can be used by the instructor/supervisor to design remedial training.
- *Cost-effectiveness*: Team training using AMTT can be cost effective because: (1) It can be delivered on-site thus eliminating travel expenses for the trainer and the trainee. (2) It can minimize downtime by providing training at times that are convenient to the trainee and the company's work schedule. In larger organizations, AMTT can be delivered to many people at multiple sites thus proving to be cost effective.
- *Use of advanced technology*: Many facilities (e.g., A&P Schools and fixed based general aviation facilities) do not have access to larger aircraft. The AMTT software provides team skills training against the backdrop of maintaining a DC-9. Thus the trainees not only acquire knowledge and skills on teamwork, but also gain an understanding of the importance of teamwork in the maintenance of wide-bodied aircraft.

Teamwork

C.H. Antoni

ABO-Psychologie, Fachbereich I, Universität Trier, Universitätsring 15, D-54286 Trier, Germany

1. INTRODUCTION

Effective teamwork has been crucial for mankind all throughout history. It has proven helpful not only when hunting mammoths in prehistoric times, but also in contemporary research projects or in high-tech industrial and service companies. The need for teamwork even grew with increasing task complexity, international division of labor and interdependence. In companies all over the world this development is reflected in the multitude and variety of teams at all levels and in all functions. Teamwork is, however, no guarantee for success. On the contrary, social psychologists have found it much easier to prove process losses rather than synergy gains due to teamwork. Potential pitfalls such as group think due to selective information processing, social loafing due to reduced individual motivation in groups or coordination losses can easily reduce group efficiency. Nevertheless, growing task complexity and interdependence require more and more teamwork in different settings and different types of teams. A better understanding of the basic concepts of teamwork, different team models and critical factors of team effectiveness might help to implement teamwork successfully.

2. CONCEPTS AND CRITERIA

The widespread discussion of teamwork did not reduce but rather has led to increased confusion about the concept. The managerial demand "we've got to be a team" refers to companies with thousands of employees as well as to boards of management comprising just a few people. The term "team" is used to stress corporate or team spirit. In other cases "team" is used to label an organizational entity of people having equivalent functions, such as security, or having complementary tasks, such as product development. In the latter case, "group" is often preferred whereas "team" is used to stress the importance or existence of common spirit.

In the scientific discussion and in this text, "team" or "group" are, in most cases, used interchangeably because a clear distinction can not be made. Social psychologists define "teams" as two or more persons who are interacting and influencing each other. Small-group research customarily considers at least three people, because group processes such as coalition formation start at this size. On the other hand, they restrict teams to ~20 people to have significant direct interactions and mutual influence. In addition to size, interaction and influence there are other criteria such as group roles, norms, cohesion and goals. They are not always included in definitions of "team" or group" because they evolve automatically in all kinds of teams due to the specific interaction and influence processes. Hence, these aspects differ in type and strength between teams.

In contrast to naturally developing informal teams, formal teams in organizations are defined by a common task, which is usually assigned by a supervisor. A team might be formed according to task requirements or a suitable task is assigned to an already existing team. However, teamwork requires not only the assignment of a common task, but also a shared and accepted notion of this task by the team members. To develop this mental model of what has to be done a communication process between the supervisor or client but also within the team is required.

Teams differ in the type of tasks they are assigned and in the way they work on these tasks. These aspects are crucial for the kind of teamwork which will develop. It is particularly important whether and how the assigned task can be split reasonably into different subtasks and whether these subtasks are interdependent or not. For example, one person usually types a letter. Hence, typists in a typing pool usually divide their labor by quantity and according to a "first in, first out" principle. In this case individual performance is independent of other team members.

One might reasonably question whether this can be called "teamwork" at all, since at first glance no common goal exists. Nevertheless, this pool of, for example, say five typists might be referred to as the typing team of the company. They might feel as a team as well, because they share one room, they chat with each other and help each other out, for example, to spell correctly or to solve computer problems. These aspects suggest team goals, which might be implicit or explicit, given or self set, such as we want team spirit and satisfaction, and we help each other out, to achieve top quality and efficiency. It is easy to set quantified goals even for such teams, for example to have all letters completed the day they come in. The core task for such a group is to organize their work in such a way that this goal can be achieved, whereas no cooperation is needed during the regular work (letter typing) itself.

Obviously this kind of teamwork is quite different from tasks that all team members have to work on successively or simultaneously. For example, on assembly lines, team members work individually as well but the product is built step by step along the line, and the team members depend on each other successively. Task interdependence is even stronger if team members simultaneously work on the same product, for instance at manufacturing cells, or deliver the same service such as a surgery team. Particularly the latter teams share not only the secondary (or indirect) tasks such as planning, coordinating and problem-solving, but also the primary (or direct) task. For these reasons the task immanent cooperation requirements are much stronger and therefore the need for shared mental models, including goals, strategies, norms and role expectations. These consequences of task assignment must be kept in mind if one wants to implement teamwork in a company.

3. TEAMWORK IN INDUSTRIAL AND SERVICE ORGANIZATIONS

In industrial and service organizations one finds quite different models of teamwork (Antoni *et al.* 1994). Their functions differ according to their use as regular work units or as specific problem-solving instrument.

3.1. Team-based Work Organizations

Teams have been used for a long time as a means to get the daily work done more efficiently. Examples for such classic work teams are the above-mentioned typist teams, construction teams or teams in a research and development departments, and so on. In manufacturing departments, teams were traditionally organized

according to Tayloristic principles, that is division of labor and functional specialization. For example, team members might perform the same specialized logistic or pre-assembly tasks, such as filling up supply boxes or inserting screws, or working on specialized positions on an assembly line.

In the past decade, functionally integrated work teams with multi-skilled members replaced classic work teams more and more following the paradigm of lean production. This proved much more efficient because multi-skilled team members can replace one another if one is absent. Also indirect labor costs, maintenance and other unproductive time are saved because the team members can do quality control and minor repairs themselves.

A supervisor might regulate these teams or be given some autonomy to regulate themselves, as proposed in the concept of "self-regulating" or "semi-autonomous" *work teams*. This concept is based on *socio-technical system theory* (Emery 1972) and is also theoretically well supported by the *theory of action regulation* (Hacker 1998). Socio-technical system theory proposes that self-regulated groups can respond faster and better to changing internal or external requirements, given the team has the needed know-how and other resources. This conception holds particularly well under dynamic environmental conditions and technical interdependent tasks, which require employee information processing. Furthermore, giving discretion to the team fulfills members needs for control and promotes skill and personal development (Emery 1972).

Team autonomy or participation in decision making has long been discussed from a motivational perspective only. Even more important might be that participation in decision making has important cognitive effects: task-relevant information is exchanged and task adequate action strategies are commonly developed. As a consequence, decisions rely on a broader information base and shared mental models can evolve. Team members learn to develop action strategies and to adapt them to changing task requirements.

Similar effects occur if "complete tasks" are delegated. Complete tasks require goal setting, planning, organizing, performance and control. They also require regulation processes not only on a motoric or perceptual, but also on an intellectual control level. These sequentially and hierarchically complete tasks further the development and elaboration of task adequate and efficient action strategies (Hacker 1998). Thus, task immanent learning processes can develop as well as preventive action planning to avoid scrap and to solve problems in advance (Hacker 1998). This problem-solving capacity of teams has even led to special types of teamwork which focus on unique and complex problems that can not be dealt with efficiently during daily business.

3.2. Problem–solving Teams

Besides routine task accomplishment, teams have proven themselves particularly helpful in complex problem solving. *Project teams* or *task forces* are set up to solve new, unique and complex problems affecting several organizational functions. For example, in Germany 87% of the top 100 organizations (in terms of revenue) used this type of teams in 1994. Depending on the kind of problem, experts from several organizational functions are sent to a project team for a limited period to solve this problem.

Typical occasions might be new product development, software implementation or re-engineering projects which affect complete process chains.

Project teams can differ whether the team leader or team members do their job part or full time. If team members still have duties on their regular job this often leads to conflicts in time resources between task forces and line functions. Since team members mostly still report to their functional supervisor at least in Germany, project teams are likely to run into serious difficulties and power conflicts. To prevent or resolve these conflicts, powerful clients are chosen for important projects, clear client–contractor agreements are made and steering committees are implemented to define boundary conditions and to control project progress. The importance of project teamwork can be stressed by additional measures, such as team-based bonus systems dependent on goal achievement or individual performance ratings by the team leader complementary to ratings done by the line manager.

Another critical factor for project success is team member composition. Ideally members have task relevant but complementary skills and expertise and strive cooperatively for the common goal. Hence, team members should not behave primarily as representatives of their home departments and stress those particularistic interests. Furthermore, qualification and not status should determine membership. Consequently project teams should rather encompass different hierarchical levels and the relevant functions of the process chain than to be restricted to staff departments.

Similar considerations that expert knowledge can be found at all hierarchical levels has led to the concept of "quality circles". Quality circles are traditionally small groups of blue-collar workers who meet voluntarily to discuss and solve their quality and other work problems. The primary goal of quality circles is quickly to detect and solve problems that directly affect team members. Particularly, in Tayloristic work structures, quality circles may be the only means for blue-collar workers to discuss and solve their problems commonly.

Quality circles usually meet twice a month for one or two hours but might increase meeting frequency or length in accordance with problem and production requirements. The time spent in meetings is regarded as regular work and paid regardless whether circles meet before, during or after regular working hours. Particularly assembly line and other sequential work structures often do not allow meetings during regular work time, thus demanding additional motivation to work overtime.

Although participants are experts in their special field of work they are usually not familiar with collective problem solving. Hence, it is useful to qualify a member in group dynamics and problem-solving methods to be able to organize and moderate quality circle meetings. If necessary, quality circles might invite experts from other departments to get necessary information or discuss problem solutions. To solve more complex cross-functional problems, members from different affected departments might as well form a cross-functional quality circle. Quality circles are well advised to start with simple problems, to get used to teamwork and to experience quick success. Success will not only motivate circle members but also might convince critics outside. Long response times, rejected problem solutions and delayed solution implementation by line management are

key causes of quality circle failure. Similar to project teams, the effectiveness of quality circles heavily depends on organizational context factors.

3.3. Models of Team Effectiveness

In the meantime a number of models of team effectiveness have been proposed. Most follow an "input–process–output" scheme (Guzzo and Shea 1992). Supporting empirical evidence still remains a problem. This might be due to model complexity as well as to practical difficulties in realizing (quasi-) experiments in field settings. Besides socio-technical system theory outlined above, one of the most prominent models is still Hackman's (1987) normative model of group effectiveness.

Hackman (1987) defines group effectiveness in terms of three aspects: (1) to get acceptable results for those who receive or evaluate them; (2) to improve ability of group members to cooperate on future tasks; and (3) to satisfy member needs. Acceptable results and member satisfaction reflect a stakeholder view on group effectiveness whereas ability for cooperation takes group resources into account. These output variables depend primarily on three process criteria: the amount of effort expended by team members; their knowledge and abilities; the adequacy of the task strategies applied by the team. In addition to these process aspects, sufficient resources are needed as well for group effectiveness (such as sufficient material, technical, and personnel resources).

The three process criteria are influenced by organizational context variables, group design and group synergy. Important organizational context variables are the reward, training and information system. Group design influences task performance by task structure, group composition and group norms. Group synergies support group interaction by reducing process losses, such as group think or social loafing and by creating process gains, for example, by a strong team spirit. Leadership factors are not explicitly considered but are nevertheless important. Group tasks, goals, feedback and rewards are influenced directly by leadership behavior or by decisions concerning task structure, reward or information systems. No specific recommendations are given concerning leadership behavior. Management decisions about group autonomy should take into account organizational factors, such as organizational culture, as well as task characteristics and employee expectations and abilities.

In this respect socio-technical system theory is more specific. Contingency factors supporting team self-regulation are high employee social needs and needs for growth, high technical interdependence of tasks and high technical uncertainty requiring employee information processing and decisions, as well as high environmental dynamics demanding quick system adaptation. In contrast, low needs for growth, low technical uncertainty and low environmental dynamics all call for externally regulated groups.

In other respects the two models have similar or complementary propositions. For example, both stress the importance of task design for team member motivation. They are complementary because Hackman's focus is on team interaction, whereas socio-technical system theory focuses on the relation between the social and the technical system. For these reasons, both models can be easily combined to deduce recommendations for implementing and improving teamwork.

4. RECOMMENDATIONS

Socio-technical system theory has shown that effective teamwork can only be achieved if both social and technical factors are considered. To analyze them, proven methods for socio-technical system analysis exist that focus on employee needs, technical, social and environmental system variances. These analyses and consequent system design should be done participatively, joining managers, employees and consultants in a project to implement teamwork.

Participative implementation strategies have cognitive and motivational effects. They ensure that relevant information is gathered and shared. The development and implementation of specific team models can be based on this information. During the implementation process employees and managers learn about one another. They also start learning teamwork on the job as they participate in project teams doing the analyses, team model development and implementation. Furthermore, their motivation to engage in this process as well as their acceptance of process results is likely to rise, if they are informed and experience influence, and control.

Team effort, knowledge and task strategies as crucial variables for team effectiveness can be influenced by the way teams and their organizational context are designed. Teams need interdependent tasks. Otherwise common team goals cannot be set, and teamwork cannot develop. Task requirements have to be matched with employee skills and abilities. In a constant process of dynamic task design, task requirements can be increased with growing employee qualification. When teams are composed of members who have heterogeneous skills they can easily qualify each other on the job. Management has to ensure that sufficient resources in manpower are provided to handle daily business and on the job training.

In addition, management can support team effectiveness by designing the organizational context (Antoni *et al.* 1994). For example, pay systems considering employee qualification will reward team members efforts to qualify for new tasks. Team oriented pay systems can strengthen team resources as well as customer orientation. Customer focus can be supported by performance components in pay systems, for example, by rewarding improvements in timely delivery or reducing customer complaints. Pay systems, however, should avoid too much team pressure. This can be achieved if individual differences are considered and if individual salary is not too much dependent on team performance.

Performance based pay systems are only useful if they rely on a team based goal setting and feedback system. Otherwise teams have no chance to plan and to control their actions. Specific, challenging, group goals direct team member actions in the same direction, increase their effort, and stimulate the development of adequate task strategies. The pursuit of common goals requires shared mental models of what has to be achieved and how it can be done cooperatively. Team-building efforts can speed up this process, especially if teams get a kind of "kick-off" training.

Team development training can be used to clarify role expectations, to shape group norms, and to increase team spirit. These measures promote group synergy and reduce process losses. Similar effects can be achieved by assigning subgoals to team members and providing individual as well as team feedback. Furthermore, process gains can be attained if group working

techniques such as moderating and visualizing team meetings are used.

These recommendations will not guarantee effective teamwork but if they are kept in mind, teamwork might be implemented more effectively. Although teams are not the only building blocks of organizations, teamwork might become even more crucial for future company success.

Technology Transfer

H. Shahnavaz

Division of Industrial Ergonomics, Department of Human Work Sciences, Luleå University of Technology, 971 87 Luleå, Sweden

1. INTRODUCTION

Technological development over the past century and especially since the Second World War has contributed enormously to economic growth and social progress in the industrialized world. It is beyond doubt that technological advancement has elevated the standard of living of mankind and has contributed greatly to the reduction of many sources of occupational accidents, injuries and stresses. However, advanced technology has also brought new sources of work stress and injuries. The complexity of the modern technology and the changing nature of work, work organization and production systems are placing extra high demands on the workforce. As a result, the degree and pattern of problems at work are changing along with the technological changes.

Further, competition at the global market imposes higher challenges on productivity, and product quality, which in turn require a knowledgeable workforce with broader skills, flexibility, good motivation, and self-regulation. As a result, progressive firms are shifting from a technology- to a human-centered approach, regarding people as central to all development initiatives. This notion highlights the importance of ergonomics in the development and application of technology to ensure that the technology is accepted and fitted to its users and the operating environment for safe and effective use. Only by considering ergonomics in the design, introduction and utilization of technology can system performance be optimized, achieving higher productivity as well as improved worker health and satisfaction.

2. ERGONOMICS: AN INVALUABLE TOOL FOR TECHNOLOGY DEVELOPMENT IN INDUSTRIALIZED COUNTRIES

Among industrialized countries (IC), the present technological advancement has likewise contributed to the growing awareness and recognition of the importance of ergonomics. It has become common experience that the same engineering and technical breakthroughs that propelled the current surge of industrialization can be harnessed to bring about technical innovations, answers and solutions to numerous work/work environment problems accompanying such growth. Consequently, the sphere of ergonomics, occupational health and industrial safety has expanded to help apply these realizations. For example, legal demands for risk assessment and preventive programs, when planning and organizing work have been initiated. Joint efforts of employers and employee organizations, as well as the establishment of joint industrial safety councils, have contributed a great deal to the improvement in industrial safety, occupational health and ergonomics' services. Even the development of recommendations, directives and standards concerning these issues has become an important part of work environment activities. Issues dealing with people and how they perform are considered as important as the technology *per se* and they are now linked to the overall company policies. At the same time, cooperation between managers and employees in participative problem-solving process has become a successful practice in many workplaces.

Thus, it can be said that IC are trying to keep pace with the technological advancement through the development of know how and legal and administrative structures for protecting the work force by making optimum use of technology.

3. INDUSTRIALLY DEVELOPING COUNTRIES: THE PREVAILING SITUATION

Even today, industrially developing countries (IDC) share some common problems of poverty, low productivity and low product quality. In their strive for an overall improvement of the quality of life through economic growth, an *industrialization* based mostly on importation of advanced technology is often considered as the best solution. Moreover, most of the IDC a rapid pace of industrialization — a speeded-up version of the historical process of industrial development in IC — is assumed to be the best way to overcome the economic problems. This concept of industrialization has, in fact, become for many synonymous with national development and social progress. Unfortunately, due to several complex socio-cultural, economic, human and technological factors, such policy is not always successful in terms of leading to any significant improvement in the countries' economy or the people's quality of life. In so doing, inappropriate technology transfer (TT) is considered as one of the reasons for the current situation that has contributed to unemployment, chronic ill-health, high rate of accident, low motivation level and increased physical and mental stress.

How such problems occur in TT will be closely examined. It is generally accepted that technology's characteristics are mostly determined by the prevailing conditions of the technology-producing country. They usually reflect the specific requirements and availability of both human and material resources, income level, resource costs, organization and political system, infrastructure, human factors/ergonomics and socio-cultural conditions of that country for which technology is designed. Then, when the very same technology is transferred from an IC to an IDC characterized by a vastly different set of requirements and characteristics, some kind of *adaptation* is imperative to fit the transferred technology. However, due to reasons ranging from ignorance to lack of demand from the technology receivers, very seldom do companies take the initiative to adapt their technology to the conditions of the recipient countries.

The developing countries, possessing 80% of the global workforce, usually gain access to advanced technologies without having sufficiently developed their technology-absorptive capacities, or even their legal or administrative infrastructures to control the adverse consequences of imported technology. (Here, the term technology pertains to the technology in use by IDC depending on their communication ability and selection mechanism.)

For TT to be successful and industrial development to occur,

they require, first, a conscious and rational selection of technology from the available world of technology. Second, there is need to prepare the local conditions for optimum absorption of the technology and to adapt the society and its social services to the changes required by the new technology for optimum use. Yet, many social functions in IDC are incompatible with the demand of industrial progress as developed in the IC. Lack of a safety-conscious culture, low educational standards, inadequate training in handling the new technology, inappropriate policies and organizational structure are but a few of the contributing factors to the failure of TT. In most cases, the rapid and hasty rate of change that takes place in some IDC is often too quick to suit either the individual or the society, threatening a failure to establish the required infrastructure and social structure for making maximum use of technology.

4. TECHNOLOGY TRANSFER PROCESS: THE NEED FOR A MORE HOLISTIC APPROACH

In the TT process emphasis is usually laid on the engineering aspect of technology (technoware). As a result of this narrow approach many IDC are struggling with a low rate of technology utilization, loss of production and low product quality, as discussed above. There is also ill health of the work force due to poor working conditions and other social problems.

To avoid the past mistakes, a more holistic and systematic approach that considers all the interacting components of technology should be adapted with regard to TT. Technology comprises of four interrelated components (Figure 1).

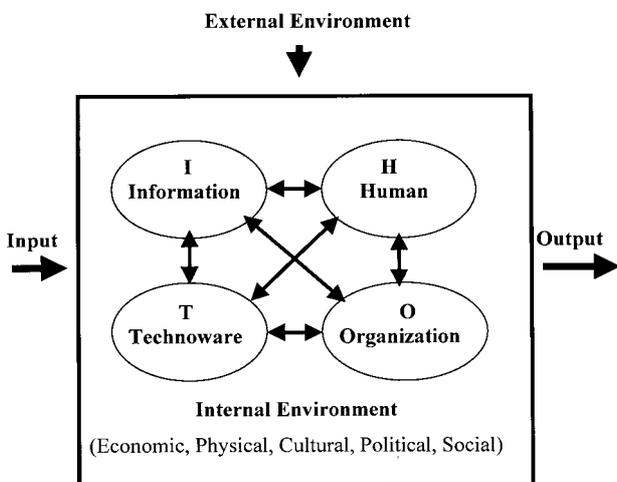
1. Technoware: tools, capital, intermediary goods, products, machinery, physical processes, etc.
2. Human: human labor, capacity for systematic application of knowledge, know-how, skills, ideas, problem solving capacity, etc.
3. Information: scientific and other organized knowledge, technical and social information, specifications, standards, soft wears, etc.
4. Organization: organization of products, processes, tools, services for use by people, social arrangement, means for using and controlling factors of production, etc.


Figure 1. Integrating components of the technology transfer process.

The four components of technology are complementary to one another and are required for the production of goods and services (TAT 1987, Sharif 1988). Depending on the nature of activity, the relative importance of each of the four components may differ. Not only must the four components be fully considered, but also their interactions within the operating environment (technology climate). A change in one factor can affect the others and ultimately the system output. The technology climate includes both external and internal factors. The external environment pertains to factors such as physical infrastructures, support facilities, R&D institutions, political system and legal systems as well as country's culture and administrative institutions. The internal factors include the local firms' cultures, physical environment and economic condition as well as the social and political conditions of the firms. Thus, a system-based approach rather than a reductionist functional approach is required to optimize the system out put.

5. ROLE OF APPROPRIATE TECHNOLOGY

Technology, defined in terms of physical products, techniques, know-how, information, skill, labor and organization, is an integral part of a country's structure. Any changes in technology can have an impact on the social, political and economic system. The solution to many of the problems associated with industrialization in IDC lies in the analysis of their causes. By adapting better development policies, choosing appropriate technology and exerting a more efficient control, IDC can solve many of their problems and provide better living and working conditions for their population.

An appropriate technology is one consistent to the needs and resources of the country: it is suited to its user population, is sensitive to its operating environment. It takes into consideration the local infrastructures, as well as the educational, social, cultural, economic and political aspects. Technology should therefore not be regarded as the objective of development, but rather as the principal means for its attainment.

With regards to the large variety of circumstances that exist among countries, there is no uniform prescription or single system that can be regarded as the appropriate technology for all IDC at all times. It differs according to place and stage of development. The crucial issues that should be fully considered with regards to industrial development is to keep in balance these substantial laws:

1. Economy (basic needs and equality).
2. Ecology (environment and protection).
3. Energy (material and human resources).

It is also important for IDC to identify which technology to acquire, how to transfer it and how to implement it. They need to learn how to adapt it to its users' and its operating environment, how to maintain it and how to build upon it. In this process *ergonomics* is the missing link in the quest for appropriate technology.

6. ERGONOMIC CONSIDERATIONS

Technology can be inappropriately transferred in three ways:

1. Incomplete transfer: not considering all aspects of the technology in the transfer process, e.g. leaving out (neglecting) the maintenance system.
2. Imperfect: not considering the user's characteristics in the transfer process, e.g. not translating manuals and instruction

books into local language or not considering the anthropometric dimensions (body size) of the technology users.

3. Inadequate: not considering the environmental conditions of the recipient country such as the climate, infrastructure of society, finance, technology and culture, etc., e.g. transferring products such as protective wears made for cold countries to tropic ones.

Ergonomics considerations ensure appropriate transfer of technology. They result in a 'good fit' between technology, its users and the operating environment. Thus, ergonomics should be considered in the process of TT both at the micro and macro levels.

6.1. Microergonomic Level

Microergonomics is concerned with the design of product or system with the objective of creating a 'usable' user–machine–environment interface. Issues that need to be considered from an ergonomic point of view in the process of TT at a microergonomic level are given below.

6.1.1. Anthropometry

Differences in body size, reach and shape of different populations may mean that many products and machines imported from IC do not fit the anthropometric dimensions of the user population in the IDC.

Areas where these differences apply and need to be considered are in the design and use of workstations, machinery, equipment, tools, safety equipment and protective devises. Failure to do so may result in poor working postures — a major risk factor causing musculoskeletal disorders, accidents and low efficiency at workplaces. With regards to misfits of protective devices, they may expose operators to environmental hazards (Shahnavaz 1992).

6.1.2. Physical work capacity

This is the capacity of people to perform prolonged physical (manual) work and it is related to individual health, age, weight, sex, fitness, level of nutrition and the environmental conditions. Physical working capacity of the average worker in most IDC is much less than his counterpart in IC because of inadequate nutrition, poor physic, lower quality of life in general and harsher working conditions.

Considering the high workloads in IDC and the lower physical work capacity of the workers, it is not difficult to find that work demands in levels equal to that in IC are in many cases too high for IDC operators. These lead not only to higher rates of accidents and injuries but also to lower productivity. These and other factors that affect people's physical performance and well-being in IDC (e.g. longer working hours, improper shift-work schedules, hazardous work environment, nutrition inadequacies and the effects of tropical climate) are often not taken into account when technology is introduced. The total working time in IDC is usually much longer than 40 h a week. Taking into account the transport time to and from work (which can be very long and highly stressful) and often the extra work people do to earn their living, daily work can add up to 14–16 h, especially among females who also have domestic responsibilities at home.

The realities of the situation in IDC should therefore be considered and consequent changes made; for example, when introducing manual work schedules, rest pauses and welfare facilities that are originally designed for IC.

6.1.3. Functional ability

This pertains to differences in generation of force and muscular function. The average maximum force generated by the workers in IDC is often much lower than those from IC. This can be due to differences in weight, health and nutrition. The designs of equipment, tools, mechanical interfaces such as hand and foot controls, as well as manual handling procedures must consider these differences for a safe and efficient work.

6.1.4. Physical working environment

The typical physical environment of an IDC is generally that of a tropical or subtropical climate. Consequently problems of heat and ventilation will be encountered. The indoor climate at workplaces is also not usually regulated and is more severe than in IC. Furthermore, there is the additional heat produced by the hard physical work usually performed in IDC. Subsequently, if the working environment is such that this excess heat is not removed and the worker is unable to retain normal body temperature, then it can be very uncomfortable and dangerous (e.g. causing heat collapse).

Other physical environmental factors of similar importance that need to be taken into consideration are lighting, noise, vibration, air quality, chemical hazards, etc. Environmental problems are usually very common and severe in IDC. They need to be taken cared of when introducing technology and when designing work places, work organizing, jobs, working methods, work–rest schedules, protective wears and plant design. Failure to do so will result in reduced performances in both physical work and mental activity. In extreme cases the working environment can also cause serious health problems. There are also instances of transferring dangerous technology. For example, technologies and their products, such as asbestos, already banned in the IC are unfortunately still being transferred to IDC. For IDC purchasing technology, it is vitally important to lay special attention to their environment. It is necessary to make sure that industrial development is not harmful to their working and natural environment to achieve a sustainable development.

6.1.5. Cognitive differences

These refer to variations in skills and differences in perception and cognitive complexity. It has been observed that people from IDC have a different internal model (mental model). They have different operational images and population stereotypes and there is a difference in their pictorial perception and information-processing behavior. These differences will affect the operator's decision-making, action and performance. In areas such as communication design (verbal, written, pictorial), display design, training programs, organization of work and skill, system design (particularly complex systems) and system operation, these differences need to be considered.

6.1.6. Cultural differences

Proper application of technology depends to a large extent on the compatibility of the user's culture with the design specifications and operational procedures. Compatibility must exist at all levels of culture — at the social, organizational and

professional levels. In turn, cultural compatibility can have a strong influence on people's preferences and aptness to utilize a technology. It must be mentioned that there exists no uniform culture in IDC. Nevertheless, some very broad distinctions can be made regarding social, organizational, professional and individual cultural-based differences that can influence technology utilization in general.

At the microergonomic level, the usability of a product, which involves not only its functionality and reliability but also its product safety, comfort and acceptance, depends on the compatibility of the product specifications and the user's characteristics and preferences wherein the user's culture plays an important role. In areas such as products, icons, symbols and interface design (regarding shape, form, color), control/display compatibility design, workplace design (regarding sitting posture, working height and gender issues), as well as protective clothing (regarding religion and custom constrains), these differences must be accounted for.

6.2. Macroergonomic Level

Macroergonomics refers to the design of organization–machine interface technology (soft-system technology). It concerns the proper design of organization and management systems and optimization of the technical and personal subsystems. Evidence exists showing that because of differences in culture, socio-political conditions, educational and technological levels, several of the successful management and organizational methods developed in IC cannot be successfully applied to IDC. On the other hand TT is not just a transfer of technoware, but together with the hardware systems it also becomes the soft system technology. Organization and its structure, values and behavior are usually cultural products, and are more strongly emphasized in the traditional societies of IDC. In most IDC, an organizational hierarchy characterized by a down-flow of authority structure within the organization is the common practice. It has little concern for Western notions such as democracy or power-sharing in decision-making, which are regarded as key issues in modern management, being essential for proper utilization of human resources as regards intelligence, creativity, problem solving potential and ingenuity.

A major problem of many transferred technologies is the lack of macroergonomic consideration. Macroergonomic issues are more complex than microergonomics ones because they are widely influenced by the firm's culture, which in turn is much affected by the socio-cultural structure of the country.

A problem pertaining to the implementation of macroergonomics is the lack of awareness regarding its benefits. The concept is regarded as new and a Western product and therefore mostly resisted by IDC managers. For making macroergonomics acceptable, it is better to find justifications for the macroergonomics ideas and its principles within the national culture, such as in religion, folk tales, stories, phrases and expressions. According to McWhinney (1992), 'conflict is avoided by making changes in accordance with the path of the myth and stories that guide our lives. Changes are most effectively accomplished when we have uncovered the core stories of the relevant culture and use our skills and courage to advance along the paths that are natural to the person, the organization, and the culture'.

The macrolevel actors such as government, business organizations and organized labor are the major determinants of macroergonomics at work. The higher their knowledge and commitment to these issues the better will be the firm's organization from a macroergonomics viewpoint.

6.2.1. Organizational design and management

Organization is a social structure wherein employees play a decisive role in improving its performance. Higher demand on productivity and intensive production require a workforce with high and broad skills, flexible, well motivated and self-regulated. Decision-making and action-taking should be concentrated to the heart of operation. This is to reduce the risk and duration of system failure and better to utilize resources as well as to increase system reliability and availability. However, organizational changes are difficult, time-consuming and an expensive process. Cultural factors, including the way people interact with each other in an organization and commit themselves to organizational goals, are complex matters that have significant bearings on the success of an organizational change. It is therefore necessary to match the management methods and techniques to the local conditions. Combining bottom-up and top-down approaches, macroergonomics takes full advantage of utilizing broad participation within the organization. This will create a shared vision and a program for change acceptable to both employees and management. This is especially essential with the view towards development of more complex and sophisticated systems.

The organization should regard employees as its future problem-solving agent, and must thus allow for enhancement of their skills and preserving their innovative capacities. To facilitate employees' participation in solving technical and psychosocial problems at work and to create a safe and productive environment, management has to institute a vigorous program of education, training and self-improvement.

In IDC, narrow, tightly controlled, fragmented jobs and hierarchical organization are still common practice. They are usually the cause of low motivation among workers, having adverse effects on both the individual and organizational performances. On the other hand, advanced technology requires a human-centered organization for its effective operation. Introducing organizational changes and new management systems could be easily achieved in IDC through a process of training and education in macroergonomics for both management and employees. These will bring about awareness and action, aiding in the introduction of necessary changes. It has been shown that the synergistic effect of a macroergonomics approach is significant. It improves not only the employees' productivity but also their quality of working life.

6.2.2. Workers' participation

Studies have emphasized the significance of worker participation in the introduction of new technology since technology needs to be legitimized by both management and workers. Worker participation can help improve the quality of the decision and implement the technology to its fullest.

In this competitive world, a company cannot survive without the total involvement of its workforce. Although participation is a culture-free concept, political as well as socio-cultural factors

must be considered for its proper applications in IDC's workplaces. Participation is needed at all stages of TT. It should start at the design conceptualization stage and continue throughout the life cycle of TT to the actual utilization of technology.

6.2.3. Communication and action

Culture is the key to effective and clear communication and dialogue, which is the means of information flow between the technology supplier (S) and technology receiver (R). Since technology utilization is a continuous process, proper communication and interaction of the two partners (S&R) are essential. Bridging cultural differences and learning to understand each other is a key for successful TT and building a long-term relationship (Figure 2). Clear and effective communication plays a decisive role in all five phases of TT (i.e. initiation, analysis, selection, implementation, utilization). In each phase, the information necessary for making a mutual decision is exchanged between the two partners. Information is invaluable to assess the environmental characteristics of the technology receiver, e.g. the capacity to absorb a new technology. It is needed to predict the cultural differences as well as to provide knowledge about a firm's characteristics and the current conditions of macro- and microergonomics and the necessary actions for a successful transfer.

Meshkati (1986) described the systematic integration of economic and ergonomics analysis needed to be performed in each phase of TT through a joint action of technology supplier and receiver. According to him, each partner should perform the following ergonomic activities:

1. In Phase 1 (mutual conviction — TT may be mutually beneficial):
S: recognition of technology receiver's needs and abilities to absorb and use technology.
R: identification of relevant human factors considerations affecting intended technology.

2. In Phase II (preliminary formulation of TT project and identification of appropriate choice):
S: macro- and microergonomics study of man, machine and environmental factors of intended technology.
R: functional analysis and evaluation of human resources, environment and working condition.

3. In Phase III (final decision on choice of technology and determination of needed adjustments):
S: final identification and selection of major ergonomics requirements and decision on modification.
R: developing ergonomics checklists and guidelines, technical adjustments and ensuring its appropriateness.

4. In Phase IV (implementing technology and initiating start up process):
S: design and development of operational and maintenance manuals in local language; determine staff training requirements.
R: work place design, job design, personnel selection and training, organization and management system design.

5. In Phase V (TT is running. Compile relevant data regarding operation effectiveness and total system performance):
S: monitor operational system, oversee procedural issues and evaluate total system performance.
R: monitor safety, productivity and performance of the system, improve working conditions.

7. TOWARDS A SUCCESSFUL TRANSFER OF TECHNOLOGY

The transfer of a technology from a firm in IC to a firm in IDC depends on the decisions taken both by the technology supplier (IC) and the technology receiver (IDC), as well as the dynamic interaction and communication between the two partners. The environment surrounding the TT is likewise another major component in this process. The environment influences the development of a particular relationship between the partners. The success of the process is determined by the cooperation between partners, something that can only be developed during long-term contacts. Furthermore, it is generally agreed that three characteristics of the technology recipient's environment are decisive for successful TT: government policy, technical absorptive capacity and cultural distances (Robinson 1988). Figure 2 illustrates the model of TT between two partners.

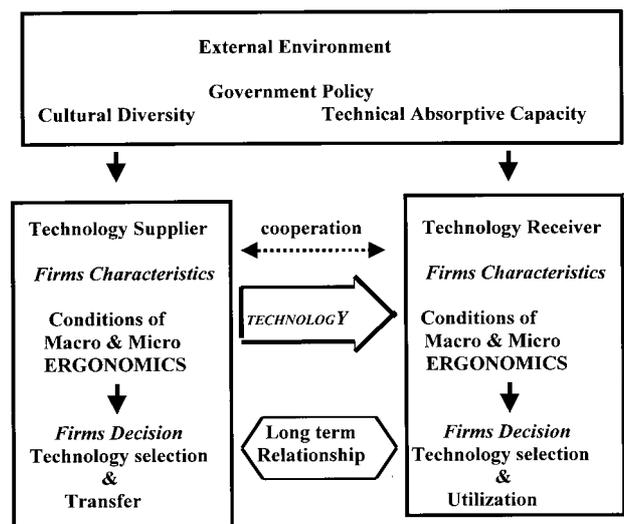
Regarding the appropriateness of the transferred technology, the level of ergonomic awareness by the technology supplier and receiver firms as well as their commitment to ergonomics issues will greatly influence their decision regarding how such appropriateness will be put into reality. These can be analyzed by closely examining the firm's characteristics and attitudes since they generally reflect the firm's micro- and macroergonomic conditions. The better the ergonomics conditions of a company and the firmer its commitment to it (both at micro and macro levels), then the better the choice and utilization of technology, leading to a more appropriate TT. With regards to the environmental factors, government policies should consider several macroergonomic parameters. These involve proper assessment of the recipient countries' needs with regards to the nature and type of technology, further establishment of relevant


Figure 2. Technology supplier and receiver's decision-making and action.

research institutes and support organizations for the development of national statistics and data banks, as well as formulating recommendations, promotions, control and implementation of ergonomics at work. Since many factors influence the nature, extent and diversity of TT, problems are specific in each IDC and it is necessary for each country to make research and training an indispensable part of its industrialization/development policy. Likewise, proper legislation and inspection policies have significant roles in the encouragement of considering ergonomics issues and in creating a crucial impact on companies in the maintenance of ergonomics. Further, it is an important way of ensuring a healthy, safe and ergonomically sound workplace, contributing towards the national aims of prosperity and higher quality of working life.

In the context of technology absorption capacity, one of the main problems of IDC is the lack of scientific and technological infrastructures and training facilities for improving the level of education and skill of the workforce for safe and effective operation, maintenance and development of the imported technology. These are important since technology will be absorbed better at the local environment if it is in harmony with its users and its operating environment. Certain concrete steps can be taken to meet this problem. For example, in most cases the necessary ergonomics knowledge for making the right choice with regards to purchasing a new technology or its proper utilization does not exist among companies in IDC. In such cases assistance can be sought from an ergonomics consultancy or research organization. A well-established support system for providing ergonomics information at a country level would ensure proper choice and utilization of the imported technology.

Vis-à-vis cultural distances, the local culture of the technology-recipient firm and its similarities with the technology-producing firm greatly influence the success of the transferred technology. Cultural values and behavioral patterns have a direct bearing on the peoples' willingness and ability to adapt and absorb technology. A successful transfer requires, therefore, that the cultural barriers are overcome and that cultural issues are considered in the life cycle of the TT process. However, it should be remembered that the ultimate responsibility for successful TT rests with the technology receivers — the recipient country's policy-makers involved in development planning as well as the firms importing the technology.

At the national level, effective institutions are needed for the formulation and implementation of sound policies. It is vital that they support the local firms and conduct inspections and control to ensure appropriate TT and utilization. At the firm's level, serious consideration of macro- and microergonomics, on the proper interaction between technology suppler and technology receivers will greatly help not only in selecting the right technology, but also in utilizing it efficiently in the long-term.

8. CONCLUSION AND RECOMMENDATION

In conclusion, the criteria for selecting appropriate technology and utilizing it successfully are:

Selection criteria:
- Relevance to basic needs of local population.
- Availability of local resources.
- Protecting local environment (air, water and soil).
- Contribution to improving quality of life of the local population.
- Sound ergonomics design (both at macro and micro level), considering local conditions.
- Availability of skills, information, services and infrastructure for optimum utilization of the technology.
- Creation of job and income opportunity for local population.

Factors to be considered with technology utilization:
- Human factors and ergonomics.
- Civil work.
- Raw material and energy.
- Trial production.
- Technical exchange and net working.
- Quality efforts.
- Market support.

Institute of Work Psychology, University of Sheffield, Sheffield S10 2TN, UK and *Psychology Department, University of Leeds, Leeds, UK

1. INTRODUCTION

This article describes a set of tools that have been developed to help organizations design and evaluate new forms of work organization, especially when introducing new technology. This is important given the typical lack of attention to human and organizational issues when implementing new technology, and the paucity of practical guidance on how to implement new work designs. The existing literature describes various principles, but does not help practitioners decide which ones they should use (Section 1.1). We focus on a scenarios tool which enables planning of the work organization. The outcomes of using this method can be incorporated into questionnaire and interview tools, which can be used to evaluate the change. The tools are illustrated by a case study of group work design in a large organization which accompanied a major investment in new technology. The implications and conclusions from using the tools are also considered.

1.1. Work organization and new technology

The literature on work organization, sociotechnical systems, and teamworking offers an array of general principles for workgroup design which practitioners may find rather bewildering when considering how they apply to their own organization. For instance, a workgroup or team should have boundaries, shared goals, and interdependence among members and tasks, and although skills and tasks should be broadly related, there is likely to be some role differentiation (Alderfer 1977). A workgroup needs to be of manageable size, and although team size will vary, it is likely to be smaller than 20 members (West 1996) and perhaps more typically between 2 and 7 members (Bettenhausen 1995). A workgroup is a meaningful unit that is identified as a team from both inside and out (West *et al*. 1998). However, these units can be changed; for example, engineers may not have originally been considered as part of a team with machine operators, but such boundaries may move (Parker and Wall 1998). As can be seen, principles for team design are not necessarily hard and fast.

Sociotechnical theory (Cherns 1976, 1987) proposes the need for the joint optimization and parallel design of the social and technical subsystems. This theory advocates (among other things) that employees should deal with variances (breakdowns, changes in product requirements, etc.) at source. Work roles should be multifunctional and multiskilled; jobs should have variety; and methods of working should be minimally specified (Cherns 1976, Emery 1959). One way to optimize the social and technical systems is through autonomous workgroups or self-managing teams (Pasmore 1988, Goodman *et al*. 1988). Such teams are able to decide upon their own methods of working, and are responsible for handling any operational problems they encounter

(i.e., these teams are not under traditional supervision). In order to do this, barriers to effective interaction within the group need to be removed, and employees need to have access to relevant information and resources in order to carry out their work. Work may take on more of a process flow, with people moving from machine to machine to produce the whole product, rather than being based on one particular machine and completing only a small part of the product.

In a similar vein, the job characteristics model (Hackman and Oldham 1976, 1980) specifies that jobs should be designed so they have skill variety, task identity (whole and complete tasks), task significance (important tasks), autonomy, and feedback. With regard to workgroups, it is advocated that not only should group members have collective responsibility and accountability for completing group tasks, but also for monitoring and managing their own work and interpersonal processes (Hackman 1987). Clear goals should be set for all dimensions of performance that contribute to the overall effectiveness of the group, and feedback (from usable, measurable indexes) should be provided on the group's progress towards it's goals (Hackman 1989). In addition, individuals should feel that they are important to the fate of the group, to minimize social loafing (Guzzo and Shea 1992).

Although the supervisory level is often removed when creating autonomous workgroups, some organizations opt for having a team leader. This role is different to the traditional supervisory role, in that the team are coached and facilitated by the team leader, but the group as a whole still has responsibility for the work, and autonomy and involvement in decision making (Parker and Wall 1998).

Sociotechnical theory advocates that work redesign processes should be compatible with desired design outcomes (i.e., they should be highly participative), and that work redesign should be a continuous process, rather than a single event. Consequently, roles do not stand still, but evolve as employees become more skilled and learn more about how to improve performance. Indeed, jobs should offer opportunities for continuous learning (Thorsrud 1972).

There are different constraints and varying contexts within organizations which will affect the application and impact of work design principles. For instance, internal political considerations will need to be taken into account, as autonomous or empowered teamworking can change existing power distributions within an organization, such as including engineers in a team of operators, or removing the supervisory level (Clegg 1984). However, if organizations can be encouraged to consider some of the barriers and contingencies faced within their own organizations, they should be able to plan effective ways of dealing with them.

Despite a plethora of literature on the design of work, reports are less clear on how these principles are translated into practice, given the varying constraints and contexts. The two main approaches offer no easy methods and simple tools to help with design and evaluation (Clegg 1993, Mumford 1987). And the Ethics tool (Mumford 1986) or key variance analysis (Davis and Wacker 1987) may not be appropriate in all circumstances.

Clearly a gap in the literature exists because work design principles, although laudable, have in practice been difficult to implement in the absence of clear pragmatic guidance. Moreover, organizations rarely evaluate the outcomes of initiatives they

implement (Clegg *et al.* 1997), so they find it difficult to chart their own progress. Here are some pertinent questions which the following sections try to answer by describing a set of tools and their use in a particular case:

- How do organizations generate ideas for new practices in a participative manner?
- How does the theory translate into the division of responsibilities and individual tasks that team members undertake within a particular organization?
- How can organizations be helped to make decisions about integrating theory and practice?
- How can implementers deal with the constraints within their organizations?
- How should they measure and evaluate the progress of work design changes?

2. THE SCENARIOS TOOL

The scenarios tool has been developed by Clegg and colleagues since 1986 (Clegg *et al.* 1996). It is a structured and systematic technique for developing and evaluating a range of choices for how an organization (or part of it) works. The tool is used in a workshop setting involving all the relevant stakeholders, with the discussions, choices and outcomes recorded (on paper) for later use. Although it is preferable to involve frontline employees in these workshops it may not always be possible. Then the tool can be used without frontline staff, but it is recommended to use alternative mechanisms for employee participation (e.g., employee opinions sought in representative workshops before implementation; or local adjustment of the overall scenario).

First, the members of the workshop describe the current scenario (for benchmarking and comparisons) and then generate a range of explicit alternatives. The tool itself does not generate the best choice, but it does provide a systematic method through which users can determine a range of possibilities to consider. Seven standard headings are used to describe each scenario (Table 1) although additional or alternative headings can be used. The headings do not necessarily have to be considered in order, but the vision does help to guide the description of the rest of the scenario (i.e., the vision should be consistent with it). An example is a vision based on the idea of employee empowerment. Describing the logic clarifies the reason or theory behind a particular vision (e.g., empowered workers are better performers). The vision has implications for the organizational structure and employee roles, which can be considered in detail. The benefits of the scenario can then be explored. Consideration of the costs and implications highlight the disadvantages, allowing reflection on the constraints and the organizational context; this encourages preventive planning.

Table 1. Standard headings for the organizational scenarios tool.

1. Vision (of how the system works)
2. Logic (underlying this choice)
3. Organizational structure (that supports this way of working)
4. Roles (that exist within the structure)
5. Benefits (associated with the scenario)
6. Costs (associated witht he scenario)
7. Implications (of making that choice)

3. CASE STUDY

The case study took place within three sites of a large organization within the UK, which was implementing advanced processing machinery (APM) across numerous sites. The new technology was highly complex, integrating several existing processes and was computer controlled. Tailor-made for the organization, the machinery was strategically important for the business and represented a massive financial commitment (in the region of £200 million). The organization was a traditional one with specialist roles for employees, and a preference for a standardized work organization across the different sites. However, there was an interest in taking a different approach.

The organization was already taking steps to introduce various initiatives. They were planning to implement teamworking, total productive maintenance (TPM), and associated engineering initiatives (such as condition-based monitoring, zero defects, and engineers having more responsibility for strategic management of machinery). In addition there was a large focus on management behavior with initiatives planned for training managers in coaching, devolving responsibility, and involving employees in decision making. Another development in management thinking in the organization had been whether it would be appropriate for team structures to follow a cell-based process flow model rather than the current machine-based model (Figure 1).

The new technology had already been bought but not implemented, and the organization wanted help in organizing the work around it. Specifically they wanted help answering these questions:

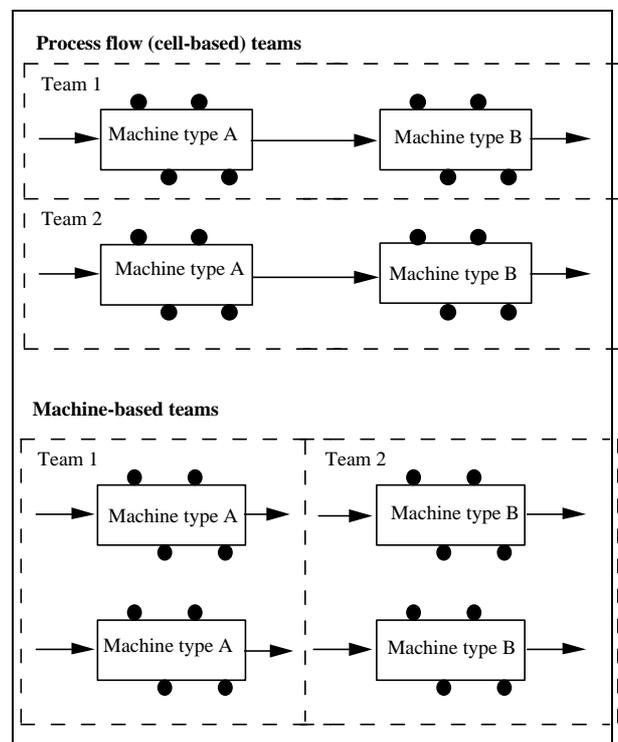
- How should work be organized to get the most out of the machinery?
- What should be the job role boundaries?
- What tasks will employees need to conduct?


Figure 1. Process flow and machine based groupings.

- How many operators and managers will be required to run the APMs?

4. USING THE SCENARIOS TOOL

The scenarios tool was administered and facilitated by three of us over the course of two workshops. The workshops were attended by several people:

- The group of people responsible for implementation and policies surrounding the APM.
- A senior manager from the site where the new machinery would be piloted.
- Managers who had experience of previous technology implementations within the organization.

The focus of the first workshop was to consider the roles of employees working with the APM (e.g., how to organize work to optimize the use of the technology, job role boundaries, and the tasks employees undertake). The second workshop considered in more detail the management configuration (e.g., how many machines a supervisor should be in charge of, how to combine old and new machinery).

When considering employee roles, four possible organizational scenarios were developed (Table 2); scenarios 1, 3, and 4 were developed during the workshop and scenario 2 was developed later on. Although scenario 2 was developed later on, it is covenient to put it in the same table. The choices of scenario were strongly influenced by the existence of the initiatives described in Section 3. Consequently, the four scenarios were based on these visions:

- *Scenario 1*: the current situation with specialist operator, engineer, and management work boundaries based around single machines.
- *Scenario 2*: partial empowerment with only slight broadening of roles (assuming only partial implementation of the initiatives) and team structures based around machine grouping and work areas.
- *Scenario 3*: flexible working with empowered, multiskilled

operators (assuming full implementation of the initiatives) and team structures based around machine grouping and work areas.

- *Scenario 4*: flexible, empowered, multiskilled working (scenario 3) but with team structures designed around process flows rather than machine groupings.

Scenarios 3 and 4 are almost exactly the same except for the way in which the machines are grouped. Scenario 4 has a process (cell) flow, whereas scenario 3 is organized around individual machines or functions .

During the workshop the facilitators were able to input their knowledge of theory and their experiences in other organizations to help the group describe the scenarios and consider their benefits and costs. The benefits that were felt to be associated with the more empowered scenarios (3 and 4) were greater machine efficiency and utilization. They were also considered to lead to increased employee satisfaction and well-being due to employees having well-designed jobs.

The costs (or requirements) of scenarios 3 and 4 meant that considerable outlay and effort would be needed in order to convince members of the organization and unions to accept the new initiatives. Moreover, there would be the expense of ensuring people were trained in the appropriate skills (e.g., TPM, decision making, teamworking) and that appropriate supports were put in place (e.g., pay, appraisal, information).

The implications of moving towards scenarios 3 or 4 were that they would rest on the success of the new initiatives. It was recognized that both these initiatives would require a considerable shift in the organizational culture, as the organization was very large and traditional and there would a considerable amount of inertia to overcome. Although there was doubt about whether the organizational initiatives would be ready in time for the new technology's implementation, the group felt that their long-term aim should be a scenario based on these initiatives.

During the workshop, the group decided that, because scenarios 3 and 4 would require the success of the organizational

Table 2. The four scenarios (illustrative not comprehensive).

	Scenario 1	Scenario 2	Scenario 3	Scenario 4
Vision	specialist roles and machine groupings	partial empowerment and machine grouping	full empowerment and machine grouping	full empowerment and process flow
Logic	specialist roles are cheap and effective	partial multiskilling is better than specialist working	complex machines need skilled operator control	complex machine need skilled operator control and process management
Structure	hierarchical	flatter hierachy	flatter hierarchy	flatter hierarchy
Roles	narrow and simple jobs with close supervision	partial skilling with some empowerment, e.g., operators have more responsibility but no TPM	multiskilled, empowered operators have responsibility for orgainzing own work and conducting TPM	multiskilled, empowered operators have responsibility for organizing own workflows and conducting TPM
Benefits	cheap and fits with employee expectations	only requires small outlay to get slight increase in job satisfaction	more machine efficiency and increased job satisfaction	more machine efficiency, more process knowledge, and more job satisfaction
Costs	unlikely to give improvements in machine efficiency	won't get much improvement in machine efficiency	hard work to persuade others; needs training and supporting services (e.g., information appraisal)	even harder to persuade others; needs training and supporting services (e.g., inforamtions appraisal)
Implications	requires no change in culture	only requires partial change in culture	requires big change in culture	requires big change in culture; the process flow may be too complex

initiatives, they would have to plan the detailed breakdown of tasks related to the new machinery within the existing specialist scenario (scenario 1) as well as scenarios 3 and 4. This was because some of the tasks on the APM would be different to those conducted on the old machinery, due to the greater complexity of the new technology.

A detailed description of the roles was undertaken. For instance, within scenarios 3 and 4 the roles were described as being multiskilled with empowered operators who organize their own work, breaks, etc., and who maintain the machinery. Engineers would be highly skilled and able to concentrate on strategic management, machine development, etc. Managers and supervisors would be able to concentrate on managing boundaries and overall goals rather than closely supervising their staff. This stands in stark contrast to the specialist model (scenario 1) in which operators have very narrow roles where they just operate machinery and are closely supervised.

One outcome of the discussion about roles during the workshop was a matrix showing the breakdown of broad tasks for operators, managers, and engineers within each of the scenarios. The general description of roles was decomposed and the workshop participants listed and allocated the key tasks they had generated. This matrix was a useful mechanism for comparing the division of responsibilities across the different scenarios. For instance, "fix faults" was an engineering task in scenario 1 and an operator task in scenarios 3 and 4 (Table 3). Table 3 illustrates scenario 2, although this scenario was not devised during the workshop.

The group felt they needed input from others to decide which routine maintenance or fault-fixing tasks operators could perform on the APM. After the first workshop, the group of stakeholders used the scenarios tool themselves with some other managers (from engineering and operational areas) to refine the division of responsibilities matrix. This represents another strength of the tool, in that the stakeholders felt able to use it themselves. Within this refined matrix, tasks were more detailed (particularly those relating to TPM) so that "fix minor faults" became tasks like "replace faulty drive belts," "check print quality," and "change ink bottles."

At the same time the group used the tool to come to a decision about how many operators were needed to operate the APM, based on the description of the tasks and the vision of multiskilling. They decided on four operators, fewer than typical for scenario 1, but this allowed a broader range of responsibility for each operator. The group agreed that the number of operators would be reviewed after the pilot.

The scenarios can be elaborated by considering potential

Table 4. Criteria to assist in the configuration of teams.

CRITERIA FOR TEAMS
1. Size (perhaps the maximum number of people is about 12)
2. Proximity (consider trade-off between physical location and communication needs)
3. Interdependence (of inputs and outputs of each member)
4. Logical grouping (meaningful unit that matches mental model of members)
5. Complete task (conducted by team from begining to end)
6. Self-contained responsibility (so can stand alone and manage selves to meet targets and responsibilities)
7. Performance measurement (members have measurable contribution and usable performance indexes)
8. Mix of tasks (so good and bad tasks can be shared out)
9. Related skills (members have broadly related skills and competencies)
10. Internal politics (team should be consistent with important internal political considerations)
11. Natural grouping (for communication purposes, with shared information needs)

NOTES
There are no hard and fast rules
Several of the above items are interrelated
There may also be trade-offs (e.g., you may want to change the existing logical groupings and mental models)
The general trend is towards a product or process flow organization, rather than a machine-based organization
Teams in the form of autonomous workgroups provide a very effective and flexible way of working but can be difficult to manage
The role of team leaders needs very careful consideration (not equivalent to supervisor)

subscenarios. For instance, the group wanted to consider the management structures and team boundaries that would fit into the ideal scenarios 3 or 4, so we set up a second workshop to do this. A list of criteria to assist configuring teams was drawn from the literature and used to help the group make their decision (table 4). This list was not exhaustive but included some useful points for consideration by the stakeholders. In particular, the criteria could be used to assess the benefits and costs of the scenarios.

Seven possible management configurations were developed using the scenarios tool. They were based around different types of machine or process flow groupings which outlined particular combinations of machines or functions that could be managed under one supervisor at the pilot site. The number of managers required for particular machine or functional groupings was considered an important issue for the organization, who wanted to get the balance right between allowing operators autonomy and having enough supervisory support. Consistent with the themes of scenarios 3 and 4, we assumed a team leader model (rather than a traditional supervisory model). However, the group

Table 3. Illustrative excerpts from the division of responsibilities matrix.

Task	Scenario 1	Scenario 2	Scenario 3,4
Prepare work area	supervisor	operator	operator
Allocate tasks among selves	supervisor	sup/op	operator
Generate/write reports	supervisor	sup/op	operator
Brief the team	supervisor	supervisor	operator
Fix minor faults	engineer	engineer	operator
Monitor machine operation	engineer	eng/op	operator
Clean APM	engineer	engineer	operator
Call engineer if problem	supervisor	sup/op	operator
Fix major faults	engineer	engineer	engineer

did not want to consider a scenario where engineers were part of the team at this stage, partly due to political considerations.

A key initial decision was whether to adopt a cell-based process flow or a machine-grouped structure. The benefits and costs of each configuration were listed. It was decided that the idea of cell process groupings (which would involve team leaders being in charge of the APM and old machinery covering the whole process from beginning to end) should be abandoned as the full operation was too fragmented, with several different machines involved, and unpredictable levels of material collected and processed from hundreds of different customers. This ruled out scenario 4. Scenario 3 then became the overall aim. The chosen management configuration model that would fit into this (figure 2) depicted one team leader in charge of two of the APM machines (8 people or 2 teams). This represented a move away from the current scenario (scenario 1) where one supervisor was usually in charge of just one machine.

The logic behind the groups final choice was a management configuration considered the best compromise between the criteria for successful teams (i.e., manageable team size, clear boundaries, good groupings for communications) and consistency with the vision of reduced number of managers, multiskilled and empowered teams, etc. However, a cost of the chosen scenario was that the group felt it would not be consistent with employee mental models (or perspectives) of the work, particularly with regard to confusion over how to divide raw materials between the APMs and old machinery, the reduced number of managers, and a relatively small number of staff on the new technology. Therefore, the group recognized that the organization would need to carefully plan how to obtain employee acceptance and prevent this scenario from failing. However, this was not discussed in detail during the workshop.

The decision was made by the stakeholders to pilot the chosen organizational scenario (scenario 3) and associated management structure as part of the technical evaluation and pilot of the APM. It was recognized that careful negotiations with the unions would be required in order to achieve this. After the workshop, members of the group extended the new management structure themselves, to enable it to fit different sites with varying configurations of old versus new machines (i.e., some sites may have an odd number of APMs rather than multiples of two).

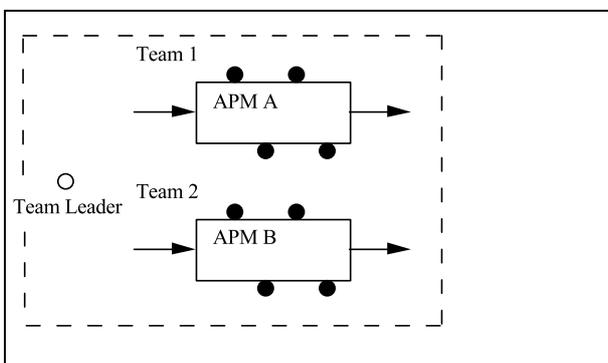
Scenario 2 was devised at a later date by members of the group. The realities of the organizational context meant that several months after the initial workshops, opposition to TPM


Figure 2. The chosen management and team structure.

and teamworking by staff and unions made the group rethink their options. By that stage, it became clear that only partial implementation of the organizational initiatives would be achieved. Thus, the scenarios tool helped the group develop a contingency plan, given the constraints within the organization. They used the division of responsibilities matrix to develop an interim goal (scenario 2). This scenario removed the TPM and teamwork activities that had been allocated to operators within scenario 3. So, although scenario 3 had originally been chosen due to the sense it made (for machine utilization, job satisfaction, etc.), it was felt that due to changing circumstances (i.e., politics within the organization) scenario 2 would be a good compromise and would now be used in the pilot of the APM.

But the long-term aim was still to reach scenario 3. Part of the power of the scenarios tool is that it enabled the group to think beyond the constraints of their organization (to some future state, i.e., scenario 3 or 4) and also allowed them to consider contingency plans given the reality. Moreover, it allowed them to contemplate how they would migrate from the current scenario to the desired one through the detailed discussions and outcomes of the workshops, and also via a substage (scenario 2).

5. OUTCOMES FROM THE SCENARIOS TOOL

Using the scenarios tool during a workshop produces a clear description (in the form of a table or similar document) of a range of possible organizational scenarios, the reasons behind them, the form they will take, and the pros and cons of each one. This helps the people using the tool to make decisions based on several different indexes. Another outcome of the scenarios tool is a detailed document or matrix which describes the roles, tasks, and division of responsibilities that different job grades will undertake in the new work organization.

5.1. Development and use of evaluation tools

Although the scenarios tool is primarily for planning, it is also valuable because its outcomes can be used to guide the development and structure of evaluation tools or instruments. Work redesign is a continuous process, so it requires evaluation and feedback on how work practices change in reality. The division of responsibilities matrix can be adapted for use within questionnaire and interview formats in order to measure and evaluate the extent to which the work organization has been met or modified in the light of changing circumstances. For instance, to help measure the distribution of tasks between different levels in the organization, employees can be asked to rate the extent to which they think different parties get involved in particular work-based activities. Besides that, perceptions and attitudes can be measured with regard to the properties of the existing work design using questionnaire scales. By the time evaluation took place it was obvious that the move towards scenario 3 would be limited and scenario 2 had become the interim goal. But it was still considered necessary to evaluate elements of scenario 3, just in case it was realized in the long term and people wanted to map out the route which had achieved it.

5.1.1. Questionnaire

A key element of scenario 3 was a broadening and empowering of operator roles. A questionnaire was developed to measure role breadth and empowerment. It was based on a measure of workgroup autonomy (Gulowsen 1972) and the division of

responsibilities matrix (operator and management tasks) generated from the first workshop. It began "To what extent do you and your immediate colleagues get involved in the following" and example items were "allocation of jobs amongst yourselves," "generating reports," and "applying the conduct code."

A measure of machine maintenance was also developed. It used the division of responsibilities matrix, including both operator and engineering tasks. This measure included key tasks such as Do you clean your own machinery? Do you fix minor faults? These measures used a five-point response scale: not at all, just a little, a moderate amount, quite a lot, a great deal. These tools may be unique to particular situations or scenarios. For more information on these measures, see Pepper *et al*. (1999).

The questionnaire was administered to all those involved in working with the APM at two different sites, around the time it was introduced (time 1) and again approximately one year later (time 2). Time 2 was after the pilot of the APM and shortly after some further successful negotiations with unions on progress towards scenario 3.

5.1.2. Interview

A structured interview was also developed to map the division of responsibilities between operators, managers, and engineers. This schedule asked the interviewee the extent to which each grade was involved in conducting certain tasks. These tasks included, machine maintenance, organization of work, and general use of the APM. The interview was derived from the division of responsibilities matrix as well as theory, so it could be unique to a particular scenario or situation. The interview enabled a more detailed and in-depth analysis of the existing work scenario and allowed us to investigate more of the specific tasks in the division of responsibilities matrix. It also allowed interviewees to comment on whether they felt that certain grades (such as operators) could potentially (or would like to) take over particular tasks (Figure 3). Therefore, the interview not only captured the status quo but also orientations towards change. A small selection from each grade were interviewed just before the APM became fully operational (to provide a benchmark at time 1) and again approximately one year later (time 2). This process was conducted over the two sites where the questionnaire was administered. The interview was also conducted at a third site several months after the new technology was implemented (time 2).

6. OUTCOMES FROM EVALUATION TOOLS

As expected, the findings from the interview and the questionnaire showed that movement towards scenario 3 was slow but scenario

2 looked promising. Previous union opposition meant that work roles were still fairly narrow and specialist but with some increases in variety and responsibility (consistent with scenario 2). Recent negotiations towards scenario 3 (e.g., regarding TPM) had not filtered through into organizational practice at that stage. However, where other initiatives were starting to be introduced (such as the management initiatives) there was change in line with scenario 2. Notably there were some improvements in general skill use, involvement in decision making, coaching, and management communication.

One problem with adopting scenario 2 was the many technical difficulties during implementation of the machinery and for some time afterwards. At the pilot site this meant there was not enough time to test out the work organization element before other sites started to use it. This prevented full evaluation or experimentation with scenario 2 and meant that frontline employee input was only on fairly minor work organization or design issues (e.g., delineating walkways around the machinery, design and arrangement of auxiliary equipment and communication devices).

From the information gathered using the evaluation tools, it also became apparent that the three sites worked with the APM in different ways and there was resistance to sticking to the one best way that the planning group had chosen. For instance, at one site the agreed number of team members was boosted by having an extra member of staff who did not work on the APM itself, but took on the tasks of fetching and removing materials for operators. Moreover, at another site the management structure had not been adhered to, because of local operational needs and the requirement for some additional machinery to process local material. This meant the evaluation tools gave an insight into change processes at the different sites.

Despite the slow start towards the ideal of scenario 3, there were employees who had attitudes consistent with it, as they showed a willingness to take on some of the duties such as machine maintenance. In general, managers were more positive towards the changes, followed by engineers and operators; this might be expected in a gradual shift in culture and attitudes. The interview evaluation tool was more sensitive at identifying these attitude shifts from scenario 1. The questionnaire was useful for gross measures across a large number of employees, but it was less detailed and less sensitive to smaller changes. We would expect the questionnaire to be especially useful when more substantial shifts in actual job content are made. So, although the scenarios tool was the driver, the evaluation tools were able to identify how well the ideal was being realized.

7. IMPLICATIONS AND CONCLUSIONS

This section outlines some theoretical and practical implications and conclusions from the use of the tools within this case study. There is a clear need for tools and methods to help organizations plan new work organizations. The scenarios tool was extremely useful for planning and enabling the clarification of key issues and tasks. It helped to identify a range of possibilities, a long-term objective (scenario 3), and the changes necessary to reach that objective; it also helped to structure some evaluation tools.

The scenarios tool provided the means to specify an interim solution (scenario 2) by enabling the group to consider the pragmatic "what are we able to do now" against the long-term

Figure 3. Some interview questions.

objective. In other words, it helped to make explicit the link between designing shopfloor jobs and the political context, and enabled the planning group to eliminate aspects of the new work organization that were politically sensitive.

Although progress towards the full scenario (scenario 3) was slow (as shown by the evaluation tools), it would appear that the plan and aims were compelling enough to ensure the scenario was merely delayed and could remain on the agenda. The evaluation tools also prevented false claims of success as there was a systematic and measured assessment. Without these systematic planning and evaluation tools, the group may have had much more difficulty deciding what to do and evaluating their progress.

There are several implications for practical use of the scenarios tool. For instance, it was used in a nonsociotechnical way, as the technology had already been bought, and consideration was exclusively about the work organization that would fit around the given technology. Although the scenarios tool can provide several benefits even at this stage, it would be particularly useful for considering the work organization issues that arise during the design of new technology. Hence it would be beneficial to use the scenarios tool much earlier in the process (i.e., before the technology is purchased).

It may be fairly difficult for people in organizations to consider several different scenarios. But within this case study the participants were able to consider more alternatives in the second workshop. This may be due to the fact that the group was more open-minded about the possible machine groupings or the immediate management structures. One potentially problematic issue in the first workshop was that the existence of the long-term organizational initiatives (TPM, management training, etc.) prevented alternative (and perhaps better) scenarios from being considered for working with the APM. This occurred even though the group were encouraged to think more broadly, hence it highlights the possible effects of the organizational context on the ideal use of the tool.

The participants in the workshops were policy makers rather than frontline implementers, union members, or frontline employees. Again, this highlights the effect of the organizational context, for although the tool emphasizes the need to involve other stakeholders in the decision-making and implementation process, past involvement was low within this organization. However, a key point is that the scenarios tool can be used both online and off-line. The organization was not ready to use the tool online with frontline staff, but a great deal of progress could still be made by using it off-line with the planning group.

Moreover, the difficulty of involving a representative cross-section of frontline staff within a large multisite organization may mean that off-line use is sometimes more appropriate as long as employees are involved in other ways. Related to this are employee acceptance and the need for greater consideration (greater than occurred here) of preventive planning within or after the scenarios workshop. This planning might be for greater involvement of the unions in the initiative, or forums for educating and fine-tuning the responsibilities matrix involving employees and union staff at the relevant sites.

The findings from using the tools also reveal the slow and evolutionary nature of work organization implementation. The scenarios tool enabled the organization to devise small steps and

helped to provide structure and coherence to a cycle of planning, change, evaluation, and back to planning. The evaluation tools enabled the organization to observe the extent to which the goals were being met and identified small shifts in attitude towards the new scenario.

The scenarios tool raises awareness that there is not necessarily one best option. This is of theoretical and practical interest and was initially highlighted for the organization during the workshops when several possible scenarios were developed. And subsequently, at the individual sites, the preference for one best method has not yet worked in practic. Variations in local needs and requirements contribute to this, as well as employee adjustment towards a less specialized and leaner way of working. This suggests it may require some local control and flexibility in translating principle into practice at the different sites.

Indeed, the work organization literature advocates the empowering of sites or individuals to have some control over the way they work, within certain boundaries (e.g., broadly within a particular organizational scenario in which methods are minimally critically specified) (Cherns 1976, 1987, Hackman 1989). Moreover, local involvement and adjustments to the new ways of working would help to enhance ownership of them. These variations suggest that particular forms of work organization should not be considered as fully generalizable (i.e., slotted into place anywhere). We need to know more about the contingencies, circumstances, or boundaries under which these principles will be successful (Parker and Wall 1998).

Other issues relate to the local tailoring of the tool itself. The stakeholder group suggested some changes to the headings within the scenarios tool to make it more organization friendly. They suggested that the heading "logic" should be replaced by "reason for vision"; the heading "roles" should be expanded to "roles—who does what?" Alternative and additional headings have also been suggested elsewhere (Nadin 1996, Hesse 1998). We think the scenarios tool can easily be modified to particular organizations or problems in this way, as it is a guide to thinking through various issues, rather than a rigid, inflexible dogma. And we feel this is one of its strengths.

Ongoing research has updated the interview evaluation tool. Useful additions have come to light as TPM negotiations have progressed, as employees have gained more experience with the technology, and as ideas have become clearer about the detailed nature of the jobs and the division of responsibilities. This will allow further and more detailed mapping of the change in the organizational scenario (towards scenario 3).

In conclusion the scenarios tool seems to be robust within the realities of an organization undergoing a massive change, with all its cultural and political implications. The evaluation tools (questionnaire and interview) were useful for assessing the progress of the change and provided a necessary link between design and evaluation. Finally, the case study demonstrates that a multimethod range of tools can help with the planning and evaluation of change and therefore helps to fill the gap between principle and practice.

Training System Development in Ergonomics

M. M. Robertson

Liberty Mutual Research Center for Safety & Health, 71 Frankland Road, Hopkinton, MA 01748, USA

1. INTRODUCTION

Ergonomics training is recognized as a critical element in effective ergonomics, health and safety programs. When ergonomics training is part of a comprehensive, systematic approach to integrating ergonomics into an organization, it can play a key role in enabling an organization to link corporate goals with ergonomics practices, enhance organizational effectiveness and facilitate the change process. Training programs can modify how people work together, solve work-related problems and actively fulfill their role in ergonomics implementation. When a successful office ergonomics training program is implemented, the result is an increased ability for the worker to change his/her work environment, reduce the exposure to work-related risk factors and promote healthy work practices. High quality ergonomics training incorporates a "participatory" approach, in which end users, managers, engineers, designers, health professionals and others are involved. A participatory approach assures that each employee learns and develops the knowledge, skills and motivation to provide suggestions for improvement and change into the organization. It is this participatory aspect, along with the ergonomics training and work system design, that forms the basis for creating an improved work environment and continual change in the company.

Training alone does not constitute an ergonomics program, and it is not a panacea for reducing work-related musculoskeletal disorders (WMSD). Generally, work-related disorders include WMSD, such as low back pain, and other health disorders arising from exposures to hazardous conditions in the workplace. Typically, ergonomics training programs are designed to address these disorders as well as the contributing workplace risk factors. Further, training provides the mechanism by which workers' performance and well-being are enhanced to maximize an organization's investment in people and technology. Owing to the multifaceted nature of these workplace risk factors, a work system design or macro-ergonomics approach should be taken effectively to address the associated WMSD.

Training is an integral part of a larger work system with the individual or end user in the center. It is important that the entire work system be taken into account, including the balance of the interrelated system elements. These work system elements include: job design factors, work organization, environmental design, technology and organizational structure. All of these integrally related system elements should be considered effectively to minimize the negative health effects arising from poorly designed work systems. These training elements, processes and models are applicable to other work environments and conditions, such as aviation maintenance (Robertson 1998), and industrial ergonomics (McKenzie *et al.* 1985). Results of these training programs' effectiveness vary depending on several issues, like the social and organizational culture; however, significant and positive effects of training programs have been demonstrated on workers' ergonomics knowledge, reducing discomforts and increasing healthy work practices.

This chapter will focus specifically on the design, implementation and evaluation of office ergonomics training programs with the goal of reducing WMSD as related to office technology work environments. The importance of office ergonomics training programs, the elements necessary for successful programs, training models for designing and evaluating the effectiveness of training programs, and organizational examples of the application of these models are presented.

2. IMPORTANCE OF SYSTEMATIC OFFICE ERGONOMICS TRAINING PROGRAMS

2.1. Need for Training

Owing to the health effects, such as WMSD experienced in office environments, office ergonomics intervention strategies have been proposed and implemented throughout organizations (e.g. Sauter *et al.* 1990, Robertson and Robinson 1995). These strategies include: ergonomics training, re-design of workspaces, environmental re-design, biomechanics and physiological interventions (work–rest cycles); enhancement of user control, job and organizational re-design. All of these intervention strategies are critical elements that must be taken within a systems perspective to effectively minimize the negative health effects arising form the intensive use of office technologies (e.g. Robertson and Rahimi 1990, Robertson and O'Neill 1995, Hendrick 1997).

Several researchers and practitioners have established the need for and the importance of office ergonomics training (e.g. Verbeek 1991). A successful ergonomics training program should be incorporated into the overall organizational strategic plan for health and stress reduction programs. The linking of the ergonomics training program objectives to the organizational goals ensures the integration of ergonomics in the organizational culture. Based on organizational performance measures, it also is important to establish an evaluation plan to track the effectiveness of the ergonomics training program.

While engineering controls such as workstation re-design or the use of adjustable furniture are frequently suggested (Verbeek 1991), administrative controls, such as training must accompany them so that employees and management understand the need for change using video display terminals (VDT) and related new office technologies. In addition, training can assist in ensuring both managerial and employee support for the introduction and implementation of an ergonomics program. In addition to the basic principles of office ergonomics and approaches for incorporating them into work methods, training also is a necessity in order for employees to understand workstation set-up and the use of proper postures to avoid discomfort and WMSD (Gross and Fuchs 1990, Kukkonen *et al.* 1983, Robertson and Robinson 1995, Robertson and O'Neill 1995).

Without training employees on these ergonomics concepts, the presence of other administrative and engineering controls will result in only limited success. For instance, it was found the availability of adjustable furniture alone did not prevent the onset of overuse injury in some users. Verbeek (1991) did implement

a training program for use of adjustable furniture, and found that it significantly improved user posture when compared with an untrained group. Kukkonen *et al.* (1983) also were able to reduce neck and shoulder tension through education of workers who were found to be unfamiliar with the proper adjustment of their furniture and, as a consequence, were using poor working positions. Therefore, by providing employees with flexible, adjustable office workstations and environments, coupled with the knowledge of office ergonomics, the necessary elements can then be put into place to realize the benefits of a comprehensive, systematic office ergonomics program.

3. COMPONENTS OF A SUCCESSFUL OFFICE ERGONOMICS TRAINING PROGRAM

3.1. Using an Instructional Systems Design Approach

The design of an effective training program should include several processes and activities involving: (1) conducting a needs analysis, (2) designing the training materials, (3) developing the training materials, (4) implementing and delivering the training and (5) evaluating and measuring the effectiveness of the training. There are several instructional system design models, and each incorporates these basic processes and phases to create effective training programs (e.g. Gagne *et al.* 1988, Goldstein 1993). For each instructional system stage, different types of information are conveyed and different techniques are used to analyze the collected information. See Figure 1 for the instructional system design model and phase activities.

3.2. Needs Analysis

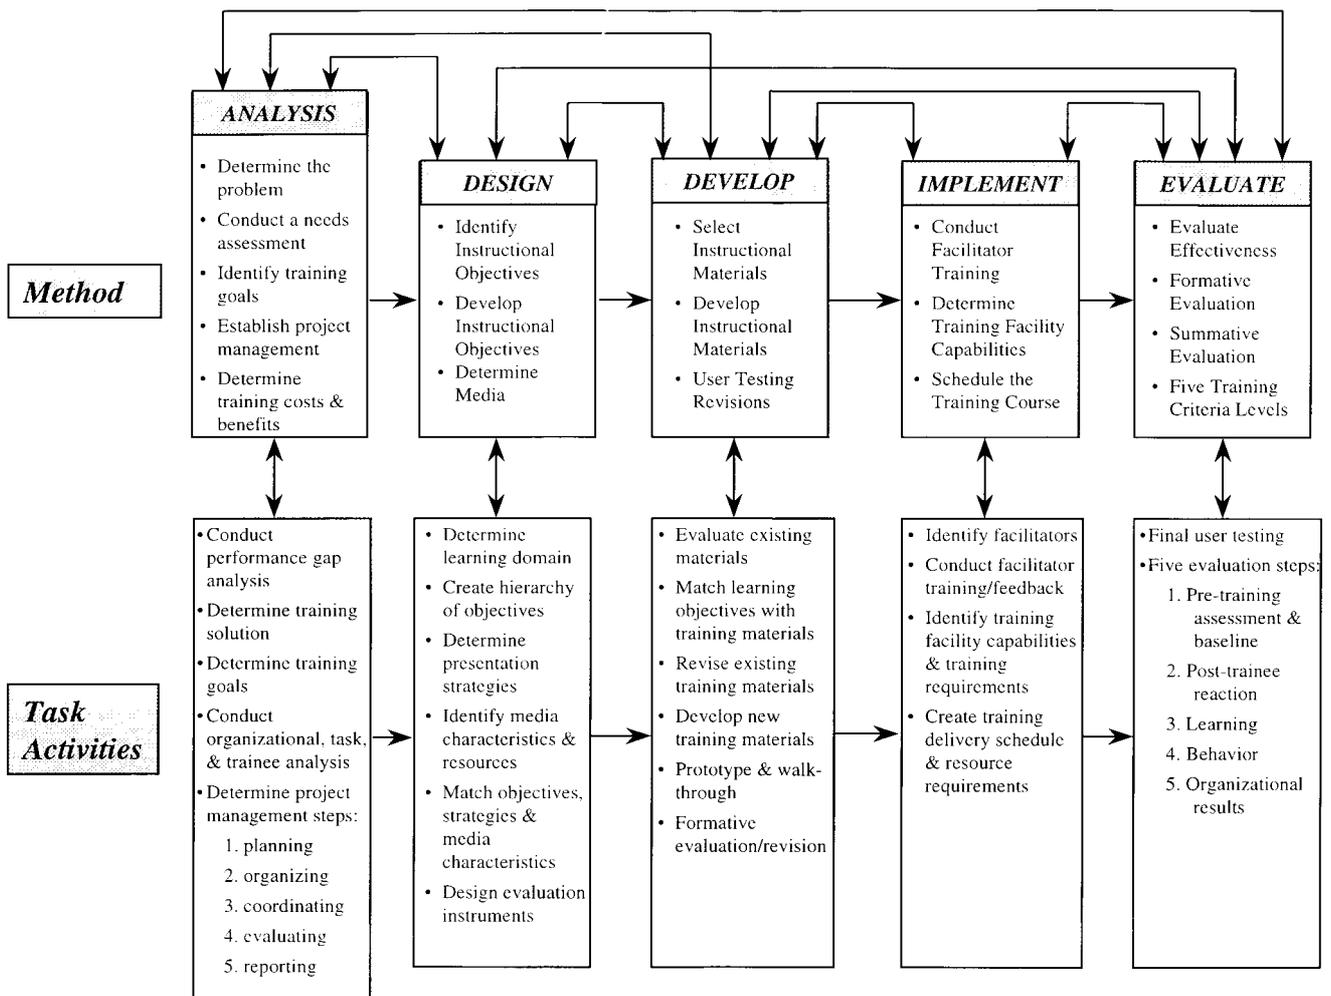
In the needs analysis phase, an organizational, task (job) and person analysis is conducted. Two questions need to be answered: what is the *current* performance of the organization and the workers? and what is the *desired* performance for the organization and the workers? The derivation of the training objectives and their linkage to the corporate goals are accomplished at this stage. If the performance problem is identified as a lack of knowledge, skill or ability of the workforce, then a training program should be designed as a necessary intervention strategy. However, if through the needs analysis it is discovered that the performance problem is due to a poorly design work system (e.g. workstation design, work demands), then training is not the *only* intervention solution. This phase also includes the development of the criteria for evaluating and measuring the training effectiveness. These criteria are linked to the training objectives and are established at the trainee, supervisor, departmental (strategic business unit) and organizational performance levels.


Figure 1. Instructional system design phase, activities and feedback.

3.3. Design

In the design phase, the needs analysis results are used to determine how the training objectives are going to be met. This involves establishing:

- training prerequisites;
- trainee population;
- desired learning outcomes (e.g. knowledge, skills, and abilities in cognitive; affective and psychomotor domains);
- training media and techniques;
- training environment;
- learning conditions (e.g. individual differences);
- instructional strategies; and
- learning principles.

Contextual factors involving organizational, environmental, and social issues, such as designing training for newly hired workers versus experienced workers are determined in this phase. Since training occurs within an organizational culture, how the organization values the training and its integration, including the link to corporate strategy, must be accounted for in this design phase. Information derived from the needs analysis phase is used to identify these factors.

Instructional strategies must be selected before developing the training materials themselves in order to outline how the instructional activities will relate to the accomplishment of the training objectives and goals. Gagne *et al.* (1988) proposed a series of nine instructional events that must occur for learning to take place which apply learning theories to the development of training. These nine events include:

- gaining attention of the trainee;
- informing the trainees of the training objectives;
- using recall or transferring from existing experience of the trainee;
- presenting training material to be learned;
- providing learning guidance or elaboration;
- eliciting desired performance;
- providing feedback;
- assessing performance; and
- enhancing retention and facilitating transfer of training to actual task performance.

Different instructional media have different capabilities and strengths for providing the various events (components) of instruction. Optimal selection of the training delivery system is achieved by matching the training media strengths with the training objectives as determined in each instructional event. In developing a strategy for instruction, the choice of the training delivery system can be assigned by event-by-event, objective-by-objective to accomplish the training goals.

3.4. Development

Development of training materials in whichever media are selected is the next phase in the instructional system design process. It is important to note that the instructional design process itself determines the effectiveness of a training program not the training media and technology. If sound instructional design principles are used, the instructional designer will choose instructional or other technologies that meet the functional and training requirements. Since various media interact with certain instructional methods, the development phase involves piloting and walkthroughs of all training modules. During this phase,

instructional strategies are applied sequentially to each training activity, then the most effective media delivery techniques are selected. Additionally, the training delivery format is determined. It may be instructor/facilitator controlled, performance-controlled or trainee self-paced style.

3.5. Implement

Implementing the training is the next phase consisting of scheduling how and when the training is to be delivered. Also, train-the-trainer or facilitation skills are developed and need to be taught and practiced before the trainers and/or facilitators present the training. It is important that the facilitator learns and practices how to lead and control active and interactive discussions among the trainees.

3.6. Evaluate

Evaluating the effectiveness of the training program and providing feedback to the organization and trainees is the last phase in the instructional system design. When the training results match the training goals and objectives, the training program can then be concluded to be effective. There are five major purposes for conducting training evaluation (Ford and Sego 1990). These purposes and definitions are:

- content validity: the relevancy between training content and the job;
- training efficiency: under or over training by the training program;
- training validity: the extent of the trainees' learning of the training material;
- transfer validity: trainees' job performance after training; and
- predictive validity: predicting job performance by training performance.

A systematic, multiple measures, four level training evaluation model can be used for evaluating training effectiveness (Kirkpatrick 1975). This four level evaluation model process includes:

- Level I: Reaction to the training program (How well did the trainees like the training program? How relevant, useful was the training?).
- Level II: Learning of principles, facts, techniques, and attitudes (What principles, facts, and techniques were learned? What attitudes were changed?).
- Level III: Behavior relevant to job performance (What changes in job behavior resulted from the training program?).
- Level IV: Organizational Results of the training program related to organizational objectives. (What were the tangible results of the training program in terms of reduced cost, improved quality, improved quantity, reduced injuries and lost work days, etc?).

Measurements that may be taken at each of these training evaluation levels are as follows: Level I: post-training questionnaire asking the trainee to evaluate the value and usefulness of the training; Level II: pre–post-questionnaires/tests assessing how well the trainee learned the information taught as well as observations/ interviews with the trainee; Level III: assessment of the trainees' behavior on the job — how well was the trainee able to transfer the knowledge and skills to the job — this may be completed by observations and/or interviews; and Level IV: results and impacts

of the training program on organizational performance measures, benchmarking and tracking of organizational performance measures.

4. OFFICE ERGONOMICS TRAINING PROGRAM EVALUATION MEASURES

For evaluating an ergonomics training program, the following measurements may be incorporated at each of the evaluation levels. Level I measurements may include questions on the post-training questionnaire regarding the usefulness and value of the training as well as the relevancy of the training to the workplace. For Level II, a paper and pencil *pre-knowledge* office ergonomics training test may be given as well as various measurements may be taken *before* the training such as an observational analysis of posture and work habits, and postural discomfort surveys. Also included in Level II, a *post-training* ergonomics knowledge test as well as a *post-training* discomfort survey identical to the pre-training survey measures may be administered. Level I and II also may serve as a type of formative evaluation of the instructional materials indicating if the training program was well received, the training materials were clear and understandable, and the training objectives were met. For Level III: various measurements may be taken *after* the ergonomics training to evaluate the transfer of the training by the trainee to the workplace. These may include an observational ergonomics analysis and interviews of what the trainee changed or did not change in their workplace as a result of the training. Additionally, on the post-training ergonomics knowledge test, open-ended questions may be asked of the trainee regarding how they are going to *use* the training when they return to work. For Level IV, various organizational performance measurements may be taken related to the results of office technology work environments, such as reported WMSD, time off work, worker's compensation rates, and health and stress-related costs. Pre- and post-training organizational health and safety performance measurements should be benchmarked and tracked over time. Tracking these pre- and post-health and safety performance measures, as well as other training costs, determines the basic variables for calculating a return on investment (ROI) of the training program.

4.1. Having Senior Management Support and Commitment

The foundation of any successful organizational program is senior management support. Senior managers must have the vision and commitment to reduce adverse health effects and increase quality of life and performance through the use of office ergonomics. When top decision-makers clearly support the mission and purpose of an office ergonomics program, an organizational culture and safety climate change can occur. Without such a commitment, a pervasive organizational change is unlikely.

4.2. Training for Supervisors and Middle Managers

Linked to senior management support, is training for supervisors and middle managers. These individuals interact daily with the workers who are ultimately responsible for implementing the new strategies. Mid-level mangers also need the support of upper-level management in implementing the new office ergonomics skills, knowledge and practices in the field. This support can

take many forms, but certainly includes the time to attend appropriate office ergonomics training courses. With this commitment, supervisors will have the opportunity to use their own ergonomics skills and knowledge in addition to managing a cultural safety and organizational change.

4.3. Creating a Responsive Environment

Training of managers and supervisors also is necessary in order to provide a responsive environment in which employees are encouraged through reinforcement and reward to utilize their training skills and knowledge. Since supervisors have more influence on the daily performance of individual employees, their participation in the training process is essential for the success of the ergonomics training program. It was found that supervisors responded best to training that emphasized situations over which they had some measure of control, and that such training made them more cooperative and supportive of change. This type of training assures that supervisors learn to respond effectively to suggestions regarding office ergonomics given by employees.

4.4. Supporting Active Participation

Participating in the creation, development and implementation of an office ergonomics training program stimulates a feeling individual ownership. Active involvement creates a sense of commitment to supporting the training program goals and a willingness to engage in the required cultural change process. Being a member of a team — that is designing and implementing an office ergonomics training program — is motivating, rewarding, and beneficial to the individual and the organization. Working together on a cross-functional, interdisciplinary team provides a unique strength in designing and developing a training program. If there is a lack of active worker participation in the training program, the worker's motivation for and understanding the material presented is low and their resistance to change is high (Luopajarvi 1987).

4.5. Developing Active Learning Experiences

More effective instructional methods, sometimes called "inquiry" or "discovery" learning, emphasize the involvement of learners. These methods involve students by having them participate in problem-solving activities and group discussions. The strength of this approach is that the use of group exercises and office ergonomics related case studies promotes an active and motivating learning environment. It creates an interactive, highly motivating approach, since students are doing more than just passively receiving the information – they are actively applying and using the concepts and skills. To strengthen further this approach, training courses can be co-facilitated by knowledgeable trained workers in office ergonomics and specific work processes. These facilitators can encourage students to participate, by bringing "real world" experiences into the classroom, and are viewed as relevant and valid experts. Also, if the class make-up consists of individuals from various job positions in the organization, active and interactive discussions can occur providing an ideal opportunity to discuss "real" problems together.

4.6. Continuous Learning and Improvement

Every work system changes over time. In the systems approach, office ergonomics training and practice must be viewed as part of the overall health, safety and ergonomics program. As such,

the training program must be adapted to changes that occur elsewhere in the system, as well as to changes in health and safety practices and technology. The idea of continuous change and adaptation is fundamental to making any system responsive to the needs of the workers. Financial and organizational resources must be committed actively to support the safety culture change process. This includes the commitment of human resources within the company, such as administrators, trainers and curriculum developers, and media and computer application developers. Continuous improvement is not a short-term activity. Rather it requires long-term management commitment to continuously adapt and improve the program.

4.7. Providing Continuous Feedback

Performance improves more quickly when people are given feedback concerning their successes (or lack of them). It is vital that timely feedback is given to all workers and managers about the results and effects of the office ergonomics training program. Feedback provides information to accomplish two performance improvement goals: (1) improve the program and identify necessary corrective actions and (2) reinforce the positive outcomes and benefits of using office ergonomics skills in the workplace.

5. OFFICE ERGONOMICS TRAINING CASE STUDIES

5.1. Background of the Office Ergonomics Training Programs

Two telecommunications companies designed, developed, implemented and evaluated an office ergonomics training program to (1) reduce adverse health effects from computer intensive work and (2) impart knowledge about how to effectively use their new ergonomically designed VDT workstations. Company 1 involved a large telecommunications company where 3500 telephone information operators, customer service representatives and supervisors were trained (Robertson and Robinson 1995). Company 2 involved 20 engineer designers, system engineers and manufacturing engineers who used office technologies extensively for their work at a large telecommunications company (Robertson and O'Neill 1995). In both companies, ergonomically designed workstations were provided with a moderate to high level of environmental control allowing for a high level of user control.

5.2. Office Ergonomics Course Content

The content of these office ergonomics training programs included: definition of ergonomics, basic physiology of the upper extremities, causes of discomforts and injuries, ergonomics principles regarding workstation layout, techniques on how to adjust and use their workstations properly, recommendations for analyzing the employees workstation, procedures to follow when they feel uncomfortable (management's policies on who to contact), and relaxation and exercise techniques to relieve office technology stress. For company 1, a three-tiered training program was designed for senior managers, supervisors and employees. Each training program included specific content areas related to their job responsibilities including how they were expected to respond when employees approached them with ergonomics problems. This allows the opportunity to support interaction and

participation between employees and managers to support the changes in the work environment. For company 2, a similar approach was taken; however, there was more focus on how to allow for a high level of user control as the ergonomics workstations were designed with the intent to allow for high flexibility and mobility. Managers involved in this training program were faced with different change issues as employees were applying their ergonomics knowledge in a more systematic manner by re-arranging their workstations and work environment components.

5.3. Office Ergonomics Training Evaluation Results

Overall, significant and positive effects of the ergonomics VDT training for both companies were demonstrated. For company 1, all four levels of the evaluation model were applied and clearly documented. Significant results of the training program was accomplished for all 3500 individuals included in the training program. Company 2 demonstrated positive results for three of the evaluation levels and results of the fourth level showed positive results in that there were significant decreases in self-reported musculoskeletal discomforts for the 20 individuals involved in the training.

5.3.1. Level I: Reaction

For Level I evaluation, the trainees from both companies rated the training highly favorable, useful, and informative. Over 90% of the trainees from both companies reported that the course material was relevant to their current office workspace design.

5.3.2. Level II: Learning

For Level II evaluation, there were significant changes in the amount of knowledge gained by the trainee's concerning office ergonomics as measured by pre- and post-training knowledge tests for company 1 and company 2.

5.3.3. Level III: Behavior

For Level III evaluation, significant positive behavioral changes of the trainees as measured by self-reported behavioral changes and observed changes were found and reported for both companies. For company 1, > 80% of the trainees reported that they had applied the ergonomics knowledge to their jobs, which included the correct placement of the VDT screen, the position of their wrists at the workstation, and their sitting posture. Follow-up observations and interviews by the corporate ergonomist and staff confirmed these self-reported behavioral changes. For company 2, all participants exhibited a high level of user control as they continually adjusted their workstations to meet various job demands. This involved arranging the workstation for sitting and standing postures. In addition, a significant decrease in overall discomfort was found in this group. Follow-up interviews and observations by the ergonomist supported these results, as > 80% of the trainees said that they were able to apply many of the principles taught in class to their workplace. Of the changes to the workplace reported, most were adjustments to the chair, placement of the monitor, workstations configuration and layout, and height adjustments of the keyboard and working surfaces. Many of the participants reported that the awareness developed from training led to changes in posture and an increase in the number of breaks for exercises or movement. In company 1, there

was some ability to change the workstation configuration within some defined constraints that provided some means of user control at the individual level. For company 2, the workstations were highly mobile and groups of workers were able to change not only the configuration of their individual workstation, but the overall configuration of the group's work area. One manager was very supportive and encouraged his workgroup to change their workstation configurations within certain boundaries to support their varying job processes.

5.3.4. Level IV: Results

For Level IV training evaluation, a ROI analysis for the office training program for company 1 revealed that the program resulted in a positive payback for the individuals trained and their company. The ROI analysis involved calculating the direct and indirect costs of company-defined WMSD, the training development and implementation costs, the workstation redesign costs, the ergonomics workstation evaluation costs as well as the number of reported WMSD that occurred after the implementation of the office ergonomics training program. Company 1 experienced a significant decrease of 16% in reported WMSD as well as a significant decrease of 21% in lost work days in the year following the office ergonomics training program. Additionally, in years 2–4 after the implementation of the office ergonomics training and workstation changes, this significant decrease in the number of WMSD continued.

For company 2, as the knowledge of control of their workstation increased, overall self-reported stress decreased. A significant reduction of 31% in self-reported upper/lower back discomfort was reported by the engineers who received the office ergonomics training and the highly adjustable workstation. For this same group of engineers, a 56% reduction in self-reported upper limb discomfort was found.

5.3.5. Successful components

Other successful components of the training were the commitment by top management to the ergonomics program itself, active involvement of the employees, positive response by management to employee's requests regarding office workstation redesign or reconfiguration, and continuous support of management in applying the office ergonomics principles to the work environment. Furthermore, an essential part of sustaining the results of a successful ergonomics training program is awareness by the supervisors in knowing what employee behaviors to reinforce. This was effectively completed in company 1 as part of the overall strategic plan to address health issues associated with office technology work. For company 2, a comprehensive ergonomics program is being designed and is planned to be implemented in the future.

6. SUMMARY AND CONCLUSIONS

In these two studies, overall significant and positive effects of the office ergonomics training programs were demonstrated for each of the training evaluation levels. These studies also support the contention that the combination of user control and training are important — since they can provide the worker with a high degree of environmental control through an increased knowledge of office

ergonomics and the ability to effectively apply ergonomics principles to their office work environment.

With an increase in office ergonomics knowledge as well as the implementation of an evaluation process the value of office ergonomics training can be demonstrated. A well-designed ergonomics program, coupled with an ergonomically designed work environment provides the foundation for creating a responsive environment for the employee and manager. As individuals interact with one another, applying and seeking ergonomics solutions, a sense of participation is created forming the basis of a positive change management process. Research and case studies show that a systems approach can decrease health and stress effects as well as reduce office ergonomics problems associated with WMSD. Coupling an effective training program with other engineering, work organizational factors provides a systematic approach to alleviating the multifaceted negative health effects experienced in office technology environments. Ergonomics training programs and environmental control can be successful intervention strategies at both the individual and organizational level in preventing WMSD, related office environment job stress and enhancing organizational effectiveness.

Usability and Product Design

P. W. Jordan

Human Factors, Philips Design, Building W, Damsterdiep 267, 9700 AE Groningen, The Netherlands

1. INTRODUCTION

Perhaps the most important reflection on how seriously usability issues are now being taken is the sharp increase in the number of professionals employed by industry who are charged with ensuring that products are easy to use. These include human factors specialists and interaction designers.

Usability may be one of the few areas left to manufacturers where it is still possible to gain a significant commercial advantage over the competition. Manufacturing processes have now reached a stage of sophistication whereby any possible advantages in terms of manufacture quality or cost savings are likely to be marginal. Offering customers "user-friendly" products can be seen as something new in markets where the technical and functional specifications will vary little between brands.

Aside from the commercial implications, lack of usability can have effects that range from annoying the users to putting the users' lives at risk. While lack of usability in a video cassette recorder (VCR) may result in the user recording the wrong television program, lack of usability in a car stereo may put lives at risk by distracting drivers attention from the road.

2. USABILITY

Informally, usability issues can be thought of as pertaining to how easy a product is to use. They are, then, to do with the "user-friendliness" of products. More formally, the International Standards Organisation (ISO) defines usability as "the effectiveness, efficiency and satisfaction with which specified users can achieve specified goals in particular environments."

Effectiveness refers to the extent to which a goal, or task, is achieved. In some cases, the distinction between a task being achieved successfully or not may simply be success or failure on that task. However, there are also situations where effectiveness could be measured in terms of the extent to which a goal was achieved. Consider, for example, an industrial production machine. If the machine operator's goal were to produce 100 components per day, then if s/he were able to produce 80 per day, then this might be seen as an effectiveness level of 80%.

Efficiency, meanwhile refers to the amount of effort required to accomplish a goal. The less the effort required, the higher the efficiency. Effort might be measured, for example, in terms of the time taken to complete a task or the numbers of errors that the user makes before a task is completed. Consider the example of creating a new file with a word-processing package. If the user is able to create the new file instantly at the first attempt, then the package would be considered more efficient than if the user had to spend a couple of minutes thinking what to do, or than if s/he had activated several inappropriate commands before eventually finding the right one.

Satisfaction refers to the level of comfort that users feel when using a product and how acceptable the product is to users as a means of achieving their goals. In general, satisfaction might be seen as the most important aspect of usability for products whose use is voluntary. For example, if users of consumer products do not find them satisfying to use, they do not have to use them. Perhaps more importantly from a commercial point of view, they do not have to buy any more products by the same manufacturer. Conversely, in situations where people are "forced" to use products, such as manufacturing equipment or products used in professional environments (e.g. software packages), it might be argued that effectiveness and efficiency are equally or more important — at least from the point of view of the employers!

An important thing to note about the ISO definition of usability is that it makes clear that usability is not simply a property of product in isolation, but rather that it will also be dependent on who is using the product, the goal that they are trying to achieve and the environment in which the product is being used. Usability is, then, a property of the interaction between a product, a user and a task, or set of tasks, that s/he is trying to complete.

Examples of people characteristics that may have an effect on usability include:
- Experience (previous experience of the particular product).
- Domain knowledge (previous experience of similar products).
- Cognitive abilities.
- Physical abilities.
- Age and gender.

3. COMPONENTS OF USABILITY

Most of the user characteristics mentioned above may be thought of as comparatively stable. They are characteristics that, if they change at all, will probably change over a comparatively long period. The exception to this is "experience" — users' performance with a product is likely to improve significantly the more that they repeat particular tasks with a product. Thus, the usability of a product for a particular person completing a particular task may change very quickly as the task is repeated. To reflect this five separate components of usability have been identified.

3.1. Guessability

Guessability is a measure of the cost to the user in using a product to perform a new task for the first time — the lower the cost (e.g. in terms of time on task or errors made) the higher the guessability.
- *Guessability*: the effectiveness, efficiency and satisfaction with which specified users can complete specified tasks with a particular product for the first time.

3.2. Learnability

Learnability is concerned with the cost to the user in reaching some competent level of performance with a task, but excluding the special difficulties associated with completing the task for the first time.
- *Learnability:* the effectiveness, efficiency and satisfaction with which specified users can achieve a competent level of performance on specified tasks with a product, having already completed those tasks once previously.

3.3. Experienced User Performance (EUP)

This refers to the relatively unchanging performance of someone who has used a product many times before to perform particular tasks. Although performance may not always level off at an asymptotic level, there will probably come a stage with most products where significant changes will only occur over comparatively long time scales.

- *EUP*: the effectiveness, efficiency and satisfaction with which specified experienced users can achieve specified tasks with a particular product.

3.4. System Potential

System potential represents the maximum level of performance that would be theoretically possible with a product. It is, then, an upper limit on EUP.

- *System potential:* the optimum level of effectiveness, efficiency and satisfaction with which it would be possible to complete specified tasks with a product.

3.5. Re-usability

This component of usability refers to the possible decrement in performance after the user has not used the product for a comparatively long period of time.

- *Re-usability*: the effectiveness, efficiency and satisfaction with which specified users can achieve specified tasks with a particular product after a comparatively long period away from these tasks.

The comparative importance of the various components of usability will depend on the context of use of the product. For example, guessability and learnability will be important where there are a high proportion of one-off users or where users must familiarize themselves with a product within a comparatively short time. EUP will be important where a high level of expert performance is required and system potential is important when it is a limiting factor on performance. Re-usability is important when a product is used in intermittent "bursts."

Each of the components of usability is loosely associated with a different section of a notional learning curve. An example of such a curve is illustrated in Figure 1.

4. DESIGNING USABLE PRODUCTS

Ten principles of usable design have been identified and are summarized below. Products which display these characteristics will support superior levels of usability. Detailed descriptions of each of these characteristics are given in *An Introduction to Usability* (Jordan 1998).

- *Consistency*: designing a product so that similar tasks are done in similar ways.
- *Compatibility*: designing a product so that its method of operation is compatible with users' expectations based on their knowledge of other types of products and the "outside world."
- *Consideration of user resources*: designing a product so that its method of operation takes into account the demands placed on the users' resources during interaction.
- *Feedback*: designing a product so that actions taken by the user are acknowledged and a meaningful indication is given about the results of these actions.
- *Error prevention and recovery*: designing a product so that the likelihood of user error is minimized and so that if errors do occur they can be recovered from quickly and easily.
- *User control*: designing a product so that the extent to which the user has control over the actions taken by the product and the state that the product is in is maximized.
- *Visual clarity*: designing a product so that information displayed can be read quickly and easily without causing confusion.
- *Prioritization of functionality and information*: designing a product so that the most important functionality and information is easily accessible to the user.
- *Appropriate transfer of technology*: making appropriate use of technology developed in other contexts to enhance the usability of a product.
- *Explicitness*: designing a product so that cues are given as to its functionality and method of operation.

5. EVALUATING PRODUCTS FOR USABILITY

There is an ever increasing selection of methods available for evaluating product designs for usability. Seventeen of the most commonly used ones are described *in An Introduction to Usability* (Jordan 1998).

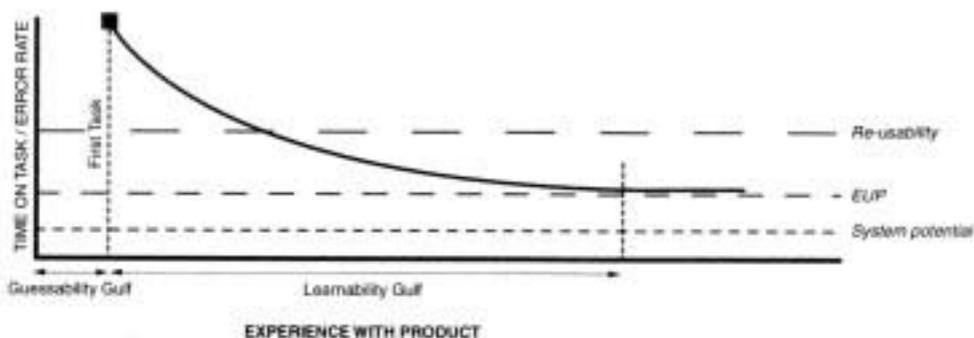
Broadly, methods can be classed as either empirical or non-empirical (Table 1). Empirical methods involve observing users interacting with products or asking users to comment on their perceptions of a product's usability. Non-empirical methods involve an investigator making an expert judgement about a product's usability or a structured check of a product's design qualities. As a rule, it may be preferable to take an empirical approach — there is no substitute involving users when it comes to learning about how to optimize user-product interaction. Nevertheless, there are circumstances where it may be preferable to take a non-empirical approach — for example, where it is


Figure 1. Idealized learning curve illustrating the five components of usability.

Table 1. Usability evaluation methods.

Empirical methods	Non–empirical methods
• Private camera conversations	• Task analyses
• Co-discovery	• Property checklists
• Focus group	• Expert appraisals
• User workshops	• Cognitive walkthroughs
• Think aloud protocols	
• Incident diaries	
• Feature checklists	
• Logging use	
• Field observation	
• Questionnaires	
• Interviews	
• Valuation method	
• Controlled experiments	

difficult to get hold of users for a test, where confidentiality is an issue, or where there are severe financial or time constraints on an evaluation.

Another option, where the circumstances of the evaluation present tight constraints, is to apply an empirical method, but in a "stripped down" form. This means setting aside some of the checks, balances and sampling techniques that would be included when a method was applied in its most rigorous form. The penalty of such informal (or "quick and dirty") approaches may be a reduction in the veracity of the data generated. Nevertheless, where the option is between a stripped down empirical evaluation and no empirical evaluation at all, the quick and dirty test can be a sensible approach. Indeed, compared with practice in research and academic environments, much of the empirical testing carried out by industry-based practitioners is informal in nature. The art of conducting an effective informal evaluation lies in knowing which elements of the test design can be relaxed without rendering the evaluation invalid. This is a complex and context dependent issue. For a comprehensive discussion of industry-based usability evaluation, including examples of best practice with respect to conducting evaluations within tight constraints, see (Jordan *et al.* 1996).

6. USABILITY EVALUATION IN THE PRODUCT CREATION PROCESS

6.1. Iterative Design and Prototyping

The principle of "iterative design" is that product concepts evolve through a design/evaluation cycle. This means that the first design idea will be evaluated in terms of how well it meets the users' needs. The strengths and weaknesses will be assessed and a further design developed on the basis of this. This in turn is evaluated and so on until a product is created that conforms to pre-specified levels of usability.

There are different prototyping options of differing degrees of realism and sophistication that can be used in the design/evaluation cycle. Some examples are given below.

6.1.1. *Product specification*

Perhaps the most basic form of prototyping is simply to give a verbal or written description of the form and functionality of the proposed product.

6.1.2. *Visual prototypes*

These are simply visual representations of a product. They could be paper-based sketches or drawings or on-screen representations created using drawing or computer-aided design packages. They may be supplemented with written or verbal descriptions of a product's functionality or procedures for operation.

6.1.3. *Models*

Sometimes physical representations or models of the product are created. Typically, these will be made of wood or of polystyrene foam. Sometimes they will include additional materials to weight the model so that its weight is representative of the proposed product.

6.1.4. *Screen-based interactive prototypes*

These are software-based representations of products. They offer simulated interactions — for example, by clicking the mouse on a representation of one of the product's controls. The screen-based representation will then change state to represent how the product would react to a particular interaction.

6.1.5. *Fully working prototypes*

These are prototypes that — at least from the point of view of the user — are barely distinguishable from a fully manufactured product. In the case of software products these will be the same as screen-based interactive prototypes — software that supports interaction and responds in the same way that the final product would do. However, where the product has physical dimensions then the prototype will also have these.

7. CONCLUSION

Usability is a "hot" issue at the moment. Users are demanding usable products and manufacturers are beginning to see designing for usability as bringing a competitive advantage. Certainly, usability is a commercial issue. However, it is more than just that. Providing adequate standards of usability is part of the responsibility that those producing products owe to those who use them. We live in a high-technology era and live with technology that has the power to enrich our lives — in our homes, workplaces and communities. Yet, all too often this technology proves difficult for us to control. The consequences of this can range from mild annoyance to serious injury or death. Usability is about giving control back to the user — producing useful, pleasurable, safe and helpful products that will enhance the quality of our lives.

User-centered Systems Analysis in Aircraft Maintenance

D. A. Mitta

Georgia Tech Research Institute, GTRI/SEV, Georgia Institute of Technology, Atlanta, GA 30332-0840, USA

1. INTRODUCTION

This chapter documents the final results of a systems analysis of the task environment under which depot maintenance technicians perform their jobs — specifically, the programmed depot maintenance (PDM) environment for F-15 aircraft. This effort yielded a detailed functional breakdown of PDM activities from which an understanding of the PDM process, specific major jobs within the process and the types of support necessary for successful job completion were identified. The US Air Force, with all of Department of Defense (DoD), is under continuing pressure to reduce operational costs. One area offering the potential for significant cost reduction pay-offs is the preparation and presentation of technical and management data for aircraft maintenance. Previous assessments have demonstrated that the integrated presentation of technical and management data can reduce operational costs in flightline environments.

Recently, the Deployment and Sustainment Division of the Air Force Research Laboratory (AFRL/HES) directed a program of research focused on enhancing the task environment for aircraft maintenance, in particular PDM, technicians. One aspect of the program, referred to as Integrated Technical Information for the Air Logistics Centers (ITI-ALC), was to insert advanced technologies into the PDM task environment. Examples of such technologies include wearable computers, speech-to-text and text-to-speech interfaces, electronic technical orders, intelligent agents, web browser presentation systems, audio and video consultation capabilities, and a bar code capability to facilitate parts tracking. A second aspect of ITI-ALC was to demonstrate the insertion of advanced technologies into the PDM process.

One challenge for AFRL/HES was to identify those PDM functions for which the insertion of ITI-ALC technologies would be most beneficial, where in this context benefits have been defined in terms of a set of Business Process Improvements (BPI). The most pressing need was to introduce advanced technologies into those aspects of PDM functionality for which the greatest advantages would be realized. Identifying PDM functions in this manner would also allow AFRL/HES to identify the maintenance task scenarios most appropriate for ITI-ALC demonstrations.

The objective of this research was to demonstrate how a traditional human factors-based systems analysis enabled the identification of PDM functions and at the same time considered the end user, i.e. the maintenance technician. Research results reinforced the benefits of a traditional system analysis approach — one of the core analytical methodologies available to human factors specialists. Proponents of such analyses (e.g. Meister 1985, Chapanis 1996) have come from among leading researchers and practitioners within the field of human factors. This chapter shows how the results of a detailed systems analysis, when applied to the PDM task environment for F-15 aircraft, allowed the identification of the PDM functions most appropriate for the insertion of technologies anticipated within ITI-ALC. The systems analysis included a functional specification, detailed task breakdown and specification of the types of support required by the technician for successful task completion.

2. SCOPE

In this effort, we focused on the specific needs of maintenance technicians across several skill types and a range of PDM jobs. In focusing on technicians' needs, we identified areas of the PDM task environment that would most benefit from the insertion of ITI-ALC technologies. To identify the PDM functions most appropriate for ITI-ALC technologies, the following sources of information were used:

- Results of engineering analyses — in particular, Integrated DEFinition (IDEF) functional models developed as a means of documenting depot operations across all Air Force Air Logistics Centers (SRAC 1995a, b).
- A set of BPI derived from simulations of IDEF models.
- Analyses, insights and feedback provided by maintenance personnel from the Warner–Robins Air Logistics Center (WR-ALC) during on-site consultation sessions.
- A set of support requirements derived directly from the systems analysis effort, where the systems analysis included a specification of PDM functionality and a detailed breakdown of PDM jobs.

3. APPROACH

In analyzing data specific to the PDM task environment, the following four-step process was applied.

3.1. Specify PDM Functional Areas

- Assign each major PDM job to an appropriate functional area.
- Derive detailed breakdowns of critical path jobs, i.e. conduct a task analysis.
- Specify support requirements for critical path jobs, i.e. determine the types of support maintenance technicians will require to complete major jobs successfully (e.g. equipment, specialized knowledge, procedures, documentation, data).

Results obtained during steps 3 and 4 were validated against data obtained during on-site consultation sessions held at WR-ALC. These sessions provided an opportunity for questions and answers on the analysis results and allowed the elimination of any remaining analysis "holes."

The identification of critical path jobs was the result of an engineering effort completed at WR-ALC under the Multi-stage Improvement Program (MSIP). MSIP identified 52 major jobs within the PDM process. Of these, 15 jobs were defined as critical path jobs, regarded as so because they were known to create process bottlenecks if not completed according to schedule requirements. Ultimately, noncompliance with the job completion schedule will delay an aircraft's delivery to functional testing. The decision to focus on critical path jobs was based on our interest in analyzing the most important PDM activities.

Once the support requirements for each critical path job were specified in step 4 (where all major jobs were assigned to a

functional area), they were consolidated across functional area. In this manner, each function, and the jobs assigned to that function, were identified with a set of support requirements. Once consolidated, the support requirements were considered with respect to 10 BPI. By considering the relationships between support requirements and the BPI set, we assessed the extent to which advanced technologies would enhance the successful execution of PDM functions and, thus, determine where in the PDM process the greatest benefit would be realized.

4. RESULTS: ANALYSIS OF THE PDM PROCESS

To gain a more detailed understanding of the PDM process, as well as the types of jobs that contribute to process delays, we conducted a detailed analysis of PDM jobs — specifically, the 15 critical path jobs.

4.1. Functions and Critical Path Jobs

Seven areas of PDM functionality were specified: REMOVALS, MODS, BUILDUPS, INSTALLATIONS, CHECKS, INSPECTIONS and FACILITATIONS. Within each function, major jobs (including critical path jobs) were performed by five technician skill types: AC (aircraft), AE (electrician), AH (hydraulics), AN (weapons), AS (sheet metal). These skill types, specified in written documentation of the PDM process (WR-ALC 1997), were also identified during on-site data collection sessions held with WR-ALC personnel.

The process flow chart of figure 1 reflects the general sequence in which PDM functions are executed. The feedback loop has been included to indicate that various checks and inspections are included as tasks during BUILDUPS and INSTALLATIONS jobs. They might be considered as "mini" checks or inspections. In other words, they are distinct from the major PDM jobs assigned to the CHECKS and INSPECTIONS functions.

4.2. Support Requirements

Once each critical path job was decomposed into specific tasks and subtasks, a set of support requirements was specified. That is, each job was defined in terms of the types of support that would promote successful performance of job tasks by respective maintenance technicians. These support requirements facilitated job performance and were consolidated within each PDM function (i.e. across the major jobs assigned to each function). In defining support types, *generic* and *specialized* types of support were specified. Generic support referred to information requirements applicable to all jobs within a given functional area, while specialized support referred to requirements specific to a particular critical path job.

4.3. Targeting PDM Functions for ITI–ALC Technologies

Among the sources of information considered in identifying those functions to receive the greatest benefit from ITI-ALC technologies were each function's support requirements and the BPI that could be addressed by these support requirements. The 10 BPI identified below were considered. Specifically, each support requirement was evaluated in terms of the BPI to which it could contribute, and the support requirements for each functional area were mapped to BPI.

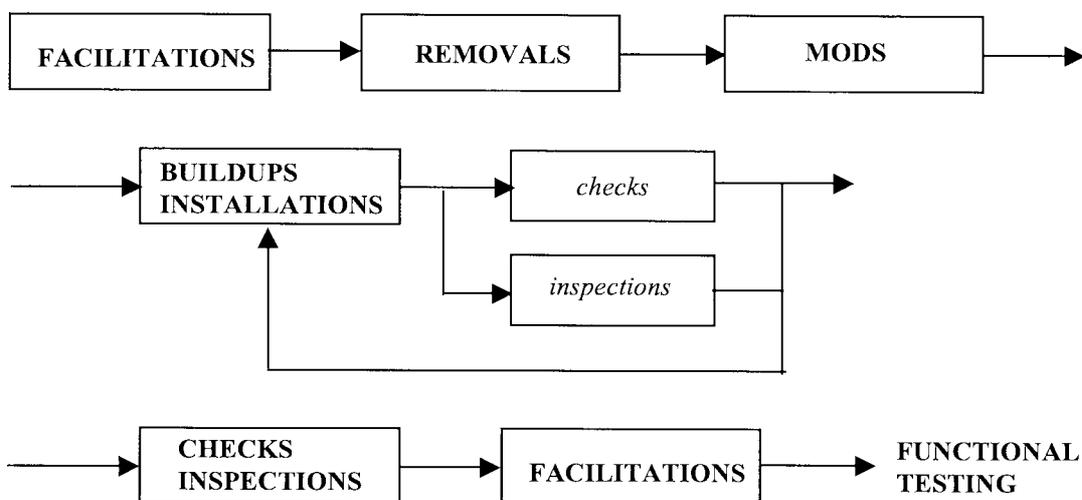
- B1. *Planning Process Enhancement*: application of previously developed plans, lessons learned, and fully defined work operations.
- B2. *Acquire Parts*: providing technicians with a kit containing all parts required for a specific maintenance repair.
- B3. *Electronic Signatures*: use of electronic signatures for "signing-off" that a task or inspection has been completed.
- B4. *User Technical Information Presentation System*: providing access to accurate and current technical information.
- B5. *Integrated Technical and Diagnostics Information*: facilitating automatic receipt of information required for the performance of maintenance activities — at required levels of detail.
- B6. *Visibility into Part Availability*: providing ready and reliable access to data on part availability.
- B7. *Multi-skilled Technicians*: certification in a broader range of skills.
- B8. *Data Sharing Among all Levels of Maintenance*: ready availability of accurate organizational level information to depot personnel.
- B9. *Performance Metrics Based on Actual Data*: maintaining data representative of actual task and process performance.


Figure 1. PDM process.

- B10. *Preplanned Over and Above/Unpredictables*: electronic cataloguing of planning packages for unpredictables and over and above discrepancies.

Table 1 provides an example of the support requirement-to-BPI mapping for the function REMOVALS. As one means of identifying the PDM functions for which advanced technology insertion would be most beneficial, one might examine the frequency with which BPI are addressed within a given function. That is, by analyzing the type of information contained in table 1, one can measure the extent to which the BPI set is addressed by the support requirements defined for each function. In effect, table 1 represents a *support requirement _ BPI* matrix M with elements m_{ij}. Furthermore, each *X* entry indicates that support requirement *i* addresses BPI *j*. By considering the data in table 1 (i.e. the number and location of matrix entries), one can determine — for each function — the range of BPI coverage by that function's respective support requirements. In other words, one can assess the frequencies with which BPI are addressed by the set of support requirements, as well as the proportion of matrix cells containing an entry. This proportion is referred to as the extent to which support requirements contribute to the BPI set. Note that the extent to which support requirements contribute to BPI is provided in the summary information of table 1.

5. IMPLICATIONS

The primary objective was to identify PDM functions that would receive the greatest benefit from ITI-ALC technologies. This type of identification required a ranking of the PDM functions according to a given set of criteria. In this effort, a single criterion was proposed: the extent to which each function's respective set of support requirements addresses the BPI set. One means of measuring this extent of coverage is to calculate the proportion of matrix cells that reflect a support requirement-to-BPI mapping.

As this proportion increases (i.e. as the density of the matrix representing a given function increases), greater benefit will be obtained through the insertion of ITI-ALC technologies into that particular function. In other words, satisfying the function's support requirements through the application of ITI-ALC technologies will effect greater improvement to the PDM process. Table 2 ranks PDM functions according to the extent-of-coverage measure. According to this measure, the REMOVALS function receives the greatest benefit, followed by BUILDUPS. The proportions offered in table 2 indicate that CHECKS, INSTALLATIONS, FACILITATIONS and INSPECTIONS benefit to a lesser extent.

One means of readily identifying the BPI addressed most (and least) often by the support requirements defined for a given PDM function is to examine the frequency with which each BPI is addressed by the support requirements defined for that function. By examining such a frequency distribution, one can identify the BPI most likely to be realized if the corresponding support requirements for the PDM function of interest are satisfied. Frequency based data are readily available from the support requirement-to-BPI mappings completed with respect to a given PDM function (table 1). Table 1, for example, indicates that for REMOVALS, the BPI addressed most frequently by the function's respective support types are *Visibility into Part Availability* (B6) and *Data Sharing Among all Levels of Maintenance* (B8).

The results of this work reinforce the value of human factors-based systems analyses — demonstrating how a detailed systems analysis enhanced our ability to identify those PDM functions for which the insertion of ITI-ALC technologies would be most beneficial. Our results also provided a means of targeting maintenance task scenarios most appropriate for ITI-ALC demonstrations. Specifically, the ranking of PDM functions (table 2) was driven directly by the mapping of support requirements (an outcome of the systems analysis) to a set of process improvements. Based on results of this work, AFRL/HES personnel were better informed about PDM functionality, the benefits of applying advanced technologies to a given PDM function, and the types of task scenarios in which to demonstrate the use of such technologies.

Table 1. Support Requirement-to-BPI Mapping: REMOVALS.

REMOVALS: AE Removals, AN Removals, AC Remove Fuel Tanks

	B1	B2	B3	B4	B5	B6	B7	B8	B9	B10
Generic

User-centered Design: Needs Analysis

N. Marmaras

National Technical University of Athens, Department of Mechanical Engineering, GR-15780 Zografou, Greece

1. INTRODUCTION

A user-centered approach for the design of information technology (IT) systems puts the future users of the system at the center of the design process. The aim is to create computer systems that support the user within a working environment (WE) rather than the user supporting the system. The typical phases of the user-centred design are (1) user needs analysis or user requirements analysis, (2) system specification, (3) system design and (4) system evaluation. In what follows, the first phase of the design process, the user needs analysis, is dealt with.

User needs analysis can be carried out in the context of two different design paradigms: the technology-driven design paradigm and the problem-driven design paradigm.

The design of systems under the first paradigm is guided more by already existing IT solutions, as well as theoretical models and techniques of the domains of application, than by the problems and difficulties met by human problem solvers or operators. The main scope of these systems is either the automation of certain subtasks, or to offer some form of problem solution by stand-alone machine experts. In this case, the designers carry out a rather quick and superficial analysis of the domain of application and the future users' tasks (what they formally have to do), identify the tasks or subtasks that could be supported or automated by already existing IT solutions, and then start the development of the system. For example, in the domain of telematics, the designer, after identifying the formal data to be used by the future users of the system and the flow of these data, may develop a system to capture, transmit and store these data. Questions such as which is the most appropriate form or sequence of presentation of the data, what is the relative importance of these data for the users and for the different situations they cope with, what data treatments are required, etc. are more often addressed by the designers, based on their knowledge of the domain, their experience from previous applications and considering the constraints of the IT chosen to be used.

The technology-driven design paradigm has been proved efficient for the design of IT systems addressing simple, well-defined and repetitive tasks. In contrast, many systems developed under this paradigm and addressing complex cognitive tasks such as decision making, design and control, have had to be abandoned or used in a suboptimal way, not because they did not work, but because the users could or would not use them. More specifically, these systems:

- often do not provide the information that is really needed, or produce information in a form that is undesirable or incomprehensible to the user. On the other hand, these systems often provide information that is not required;
- can appear confusing to the users;
- sometimes do not provide the functions the user requires, and more often provide functions that the user does not need;
- force the users to perform tasks in undesirable ways; and

- can cause unacceptable changes in the structure and established practices of organizations, creating dissatisfaction and conflict.

Furthermore, the development of IT systems following the technology-driven paradigm increases the required time, effort and iterations at the systems' evaluation phase.

In the problem-driven design paradigm, the task requirements and constraints, as well as the way domain experts cope with them, would drive the choice of IT to be used and the design of the systems. The main scope of IT systems developed under this design paradigm is:

- to address the cognitive difficulties met by potential users in performing cognitive tasks;
- to improve their potential users' performance; and
- to achieve compatibility with potential users' competencies and work environment. This compatibility permits the user to remain in full control of the support provided by the system and ensure high usability, i.e. effectiveness, ease of learning and ease of use.

The design of systems under the problem-driven paradigm requires a much deeper and more extensive user needs analysis. The aim of the analysis being to identify (1) the cognitive difficulties potential users meet in performing their tasks, (2) the factors determining their performance and (3) possible ways to alleviate task difficulties and improve users' performance. This design paradigm has been proved particularly appropriate for the design of IT systems supporting complex cognitive tasks such as process and traffic control, medical diagnosis, design, managerial and production planning, computer programming, etc. (Pavard *et al.* 1990, Laios *et al.* 1992, Marmaras *et al.* 1992, 1997, Pougès *et al.* 1994, Nathanael *et al.* 1997).

Below is presented a methodological framework for user needs analysis in the context of user-centred design and under the problem-driven design paradigm.

2. CONCEPTUAL MODEL OF COMPLEX COGNITIVE TASKS

Complex cognitive tasks share some common characteristics both at the cognitive level and the environments within which they are performed. At the cognitive level, these tasks require different types of problem solving such as decision making, diagnosis, planning, and complex cognitive activities such as anticipation, monitoring, mental calculations, etc.

As far as the environments within which and for which these tasks are performed, they may have one or more of the following characteristics:

- they consist of many interrelated and interacting dynamic components and factors assuming different values each time;
- events can occur at undetermined times and the nature of the problem to be solved can change;
- there is uncertainty regarding the time at which one or more events occur, and the severity of changes they cause to the work system;
- there are multiple quantitative and qualitative objectives to be achieved, often conflicting, and with no predetermined hierarchy;
- they impose severe time constraints to the human operators;
- they are risky; and
- human errors may have serious consequences.

It could be concluded, therefore, that the difficulty of complex cognitive tasks is due both to the complexity of cognitive processes required for their completion, and to the complexity of the environments within which and for which they are performed.

To cope with the cognitive constraints and demands of their WE, domain experts develop and use specific cognitive skills or *competencies*. Elements of these competencies are:

- selective use of formal and informal sources of information;
- development and use of specific mental representations of the WE, or operative images;
- use of problem-solving strategies and heuristics such as problem decomposition, bounded rationality, satisfying and search costs, opportunistic thinking;
- ability to change appropriately between skill-, rule- and knowledge-based performance level, depending on the characteristics of the situation at hand; and
- use of components of the WE as memory supports.

3. FRAMEWORK FOR USER NEEDS ANALYSIS

Considering the above conceptual model, user needs analysis has to identify the main cognitive constraints and demands posed to the domain experts, as well as the main elements of the competencies they develop and use to cope with them. Given that the constraints and demands are determined by the WE's situations presented to the human agents, typical situations also need to be analyzed. Finally, the analysis of undesirable work outputs (e.g. systematic errors, suboptimal or erroneous decisions) will point out the situations where human experts' competencies fail. Figure 1 presents a framework for user needs analysis.

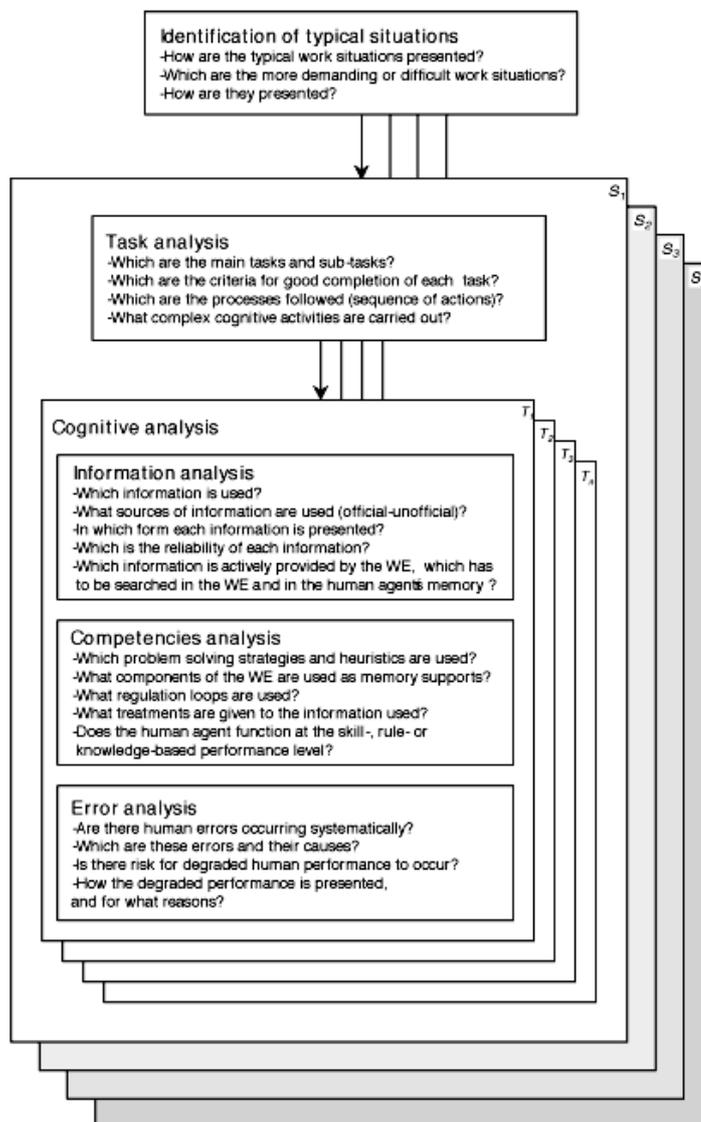
At a first phase the analyst, with the aid of domain experts, identifies the *typical work situations*. By this is meant both normal and characteristic exceptional situations. The way these typical situations are presented to the human agents as well as the cognitive demands, constraints and difficulties associated with them, are also investigated.


Figure 1. Framework for user needs analysis.

Task analysis is carried out at a second phase, for every work situation (S_1, S_2, S_3, … S_n) identified at the first phase. The main tasks and subtasks, the criteria for good completion of each task, the processes followed as well as the activities (both cognitive and physical) carried out for the accomplishment of each task, are identified and described.

The third phase deals with *cognitive analysis* of the tasks (T_1, T_2, T_3 … T_n) identified at the previous phase. Cognitive analysis comprises analyses at the levels of information, competencies and errors. *Information analysis* looks for the information used for the completion of each task, the sources providing the information (both formal and informal), the form each information is presented, its reliability and classifies them according to whether they are actively provided by the WE or whether they have to be found in it or the human agent's memory. *Competencies analysis* deals with the problem-solving strategies and heuristics used by the human agents, the components of the WE used as memory supports, the regulation loops eventually used, the mental treatments given to the information, as well as the performance level at which the human agents function, i.e. skill-, rule- or knowledge-based. Finally, *error analysis* looks for human errors occurring systematically and their causes, as well as for possible degraded human performance leading to suboptimal actions or decisions, and their causes.

The type of support that could be provided by an IT system can then be investigated, based on the results of the user needs analysis. This can be done by answering questions such as:

- What other information would be useful to the operators?
- Is there a more appropriate form to present the information already used as well as the additional new information?
- Is it possible to increase the reliability of information?
- Could the search for information be facilitated, and how?
- Could the treatment of information be facilitated, and how?
- Could we provide memory supports, and how?
- Could we facilitate the complex cognitive activities carried out, and how?
- Could we promote and facilitate the use of the most effective problem solving and decision making strategies, and how?
- Could we provide supports which would decrease mental workload and mitigate degraded performance, and how?
- Could we provide supports which would decrease human errors occurrence, and how?

Support of users' memory, computational aid, communication support, de-biasing, support to visualize or to make concrete the abstract and uninspectable, aid to the formation of a better global representation of the situation at hand, support to actions' planning, and support to evaluate alternative decisions are examples of possible functions of a system supporting complex cognitive tasks.

4. ACTIVITIES' ANALYSIS FOR USER NEEDS ANALYSIS

To carry out the user needs analysis described above, analysis of future users work activities is required. *Activities' analysis* deals with the responses human agents give to the tasks imposed on them or they wish to carry out, the tasks being goals to be attained within a set of conditions.

Activities' analysis is an iterative process, comprising the following stages:

1. Systematic observation and registration of observable activities, in relation to the implicated elements of the work environment. The observed activities may be body movements and postures, eye movements, verbal and gesture communications, etc.
2. Inference of cognitive activities, processes and strategies.
3. Formulation of hypotheses about competencies, by interpreting the cognitive activities and referring to the work environment's demands, constraints and supports, as well as to the limits of cognition.
4. Validation of hypotheses by repeating stages 1 and 2.

The iterations end-up when the developed model of human agents' competencies explains sufficiently and satisfactorily their behavior and performance.

Video- and tape-recording, paper and pencil or other specially designed displays (e.g. eye movement recorder) can be used for data gathering at stage 1. Consecutive or retrospective verbalizations supported by the data gathered at stage 1 (autoconfrontation) can be used at stage 2. Protocol analysis is the main method for stages 2 and 3.

Besides direct on-site observations, alternative scenarios and simulation methods may be used to analyze activities in rare or risky work situations. However, before using these methods, sufficient analysis of the work environment as well as selection and examination of historical data concerning the studied work are required. Comparative activities' analysis of equally experienced operators, who nevertheless demonstrate different performance (experts and super experts), is also useful in many cases.

Theories and models for human cognition and behavior, offered by cognitive psychology, artificial intelligence, ethnology, psycholinguistics, neuroscience, organizational psychology or philosophy, can be used for the inference of operators' cognitive activities and the formulation of hypotheses concerning their competencies. Examples of such theories and models are Newell and Simon's (1972) human problem-solving theory, Theureau's (1992) theory of action's course, Hutchins' (1990) and Hutchins and Klausen's (1992) theory of distributed cognition, Rasmussen's (1986) 'ladder' model of decision-making and Reason's (1990) model for human errors. However, these theories and models must have a rather hypothetical than a normative value for the analyst. They constitute his/her background knowledge and support the interpretation of observable activities and the inference of cognitive activities. Activities' analysis may confirm these models totally or partially, or it may indicate their limits or reject them.

5. EPILOGUE

The proposed user needs analysis may be difficult and time-consuming to carry out, requiring the use of specific work analysis methods and techniques, as well good cooperation between the analyst and the IT specialists who develop the system. These weaknesses are, however, counterbalanced by the fact that it ensures the design of systems which (1) improve their future users performance by decreasing the cognitive constraints and alleviating the cognitive demands imposed to them, (2) eliminate or mitigate error-prone and degraded performance situations, (3) facilitate the use of effective human experts competencies and eventually enrich them and (4) achieve compatibility with these competencies and the work environment. This compatibility will ensure the usability of the future system.

Furthermore, this way of analyzing user needs minimizes the risk to ignore the more demanding and therefore difficult and error-prone aspects of the target work, as well as providing sufficient data permitting to decrease the required time and iterations at the system's evaluation phase.

Finally, the outcomes of the proposed user needs analysis provide also sufficient data to specify the main features of the human–computer interface, ensuring compatibility with users' competencies. The way task's objects have to be represented by the system, the type of man–machine dialogues to be used, the procedures to be proposed and generic or customizable elements of the system are examples of human-computer interface features that can be specified, using the acquired data.

Work Design: Barriers Facing the Integration of Ergonomics into System Design

1. INTRODUCTION

Many industrial injuries and illnesses can be attributed to poor design features. Mishaps are often the unintended consequences of either using or misusing designed products. At times these mishaps result in fatalities that are attributed to "human error." The question is error on whose part, the victim's or the designer's? The designer's job is to forecast potential uses and misuses of products through design. The integration of ergonomics principles at the product or process development phase helps to minimize unintended consequences. This attention at the design phase reduces and even prevents injuries and illness among end users. If ergonomics is to be integrated into the design process, however, organizational principles must be integrated into the design factors. This process is difficult and the barriers are multiple.

2. RELEVANCE

The main goals of any design effort are that the product works as it is intended to, trains easily, and performs safely when used (Broberg 1997). A product needs not be only beneficial but must possess no harmful side effects. Sometimes even these goals are not met. The automobile air bag is a good example. The goal was to protect automobile occupants during sudden impact. *Product requirements* documents spell out how the product will function. *Product specifications* stipulate the product's construction and performance. From an engineering standpoint, when the product meets these two sets of criteria it is considered a success. The air bag does function exactly as the design parameters said it would except that it sometimes kills small women and children. Any repercussion will not come back on the designer, but rather stops at his/her project manager. The design engineer is isolated from feedback until information for new specifications is received. The organization writes off its liability until the public or government becomes involved. This process, including the assignment of work roles and administrative procedures that shape the organization's social culture and conduct of work activities, is part the overall organizational structure.

Organizational structure and the thinking that reflects it play a major role in shaping the product development process. Broberg (1997) described the multistage and interconnected manner in which a concept becomes a product. Product requirements and specifications guide the development mechanism. These two basic design inputs were described earlier. What is missing from the process is a third document that sets forth *use parameters*. Dekker and van den Bergen (1996: 301) suggested that "integrity, reliability, efficiency, and usability" must all be characteristic of an interface that protects humans and optimizes their performance. Yet, the product–human interface does not show up in company standards governing the design process. Therefore, designers may continue working within their normal organizational framework and face little pressure to develop products with ergonomic input. What they do experience is social encouragement to repeat design approaches that have worked in the past (Broberg 1997).

The purpose of this chapter is to provide insight into barriers facing the integration of ergonomics into design. It is also intended to create an awareness of consequences that can result from ignoring ergonomics during the design process. Mistakes made by users are often invited by the way the process or product was designed (Chapanis 1996). Working through these implications and understanding how design engineers function may help determine how to expand the design approach to include ergonomics criteria.

3. ENGINEERING APPROACH TO THE PROBLEM

Typically, a design engineer is presented with a deadline to build a product that will do something. S/he conceptualizes it, and gathers whatever resources are necessary to achieve this goal. The designer will focus mostly on whether the product does what it is supposed to do. The concern is to make a product that is used according to the ideal manner in which it will be demonstrated. A designer's success or failure is measured by whether the product does what it was supposed to do and whether it was delivered in a timely manner. Such design approaches overlook the fact that ultimately, people use products. A typical engineering process does not consider this until the end of development, during usability testing. The product's team develops this testing with limited knowledge of the human element and in a controlled environment. They possess the same knowledge they had when designing the product, and, because of their familiarity with it, may be shortsighted as to how the product should be tested. Under such conditions, human interface problems will be hidden rather than highlighted.

4. BARRIERS TO INTEGRATION

The organizational structure is not supportive of ergonomics in comparison to other design parameters, and the lost benefits of such support are not recognized. Often designers are working under severe time constraints, and project managers assume that if the product functions as it was planned to function, ergonomics will work itself out. At best, the design can only be "tweaked" after completion. Design engineers may be lacking ergonomics knowledge or training, and simply not know the right questions to ask. Unless the organization's expectations reflect a necessity for ergonomics, their thinking will remain the same. Designers will continue to use the same tried and true methods for development. When there are product failures or customer complaints, design engineers are the last to know. When a developed product is determined to work but there are still usability problems, these issues are often blamed on the end user's inability to use the product properly. Products are almost never evaluated for their intended and unintended consequences. Sound ergonomics methods can be used to predict uses and misuses.

Unintended consequences are not brought back to the designer unless a re-design is demanded. The problem created is that the designer never gets a chance to build a database of

ergonomic knowledge or cause for failure. Therefore, s/he believes the design process works well and will use this belief in future designs. This practice encourages a "tunnel vision effect" because the designer is using a one-dimensional approach based on his/her previously tried and true algorithms. This thinking supports "blind spots" by not allowing peripheral information to enter. Blind spots keep the engineer from asking the right questions and allows him/her to ignore "extraneous" information. Most organizational structures tend to encourage this type of thinking. In the long run, though, the earlier human engineering is introduced into the design process, the better the product will be. Redesign for usability is more costly after production.

5. CASE ANALYSIS

Some of the ideas mentioned above can be illustrated by a program, begun in the early 1970s, to develop an oxygen breathing apparatus for US coal miners. There were some scientific and engineering principles that could not be violated during development and the process seemed to rely on past successes. Because there was little or no ergonomics involvement, it cannot be known how much impact ergonomics might have had on up front engineering design. However, it could reasonably be deduced that some user problems could have been avoided.

> Barrier: Because people are considered to be adaptable, there is no demand for use parameters. Users are therefore forced to adapt to designs that "make sense." A failure to understand that ergonomics is not just "commonsense" leaves the interface problem unrecognized.

Since its creation in 1910, the US Bureau of Mines was active in setting requirements and performing certification tests on oxygen breathing apparatus. These were intended to help workers survive irrespirable mine atmospheres. The weight and size of the devices proved to be too much for the typical mine worker and the daily apparatus came to be used only during rescue attempts. A succession of deaths among would-be rescuers underscored the fact that miners had little or no training in apparatus usability. The loss of lives led to the adoption of mine rescue standards in 1921. These standards provided a baseline for instruction. The schedule for initial training, which required 20 h over 5 days, included 9 h of practice wearing the device. The Bureau recommended additional instruction and practice every 6 months (Parker *et al.* 1934). Over time, mine rescue apparatus became more refined and rescue team members better trained in its use.

> Barrier: Even when a problem with the machine/human interface is recognized, the tendency is to believe it can be "trained out." Training then becomes the stopgap for product inadequacies.

In 1924, to encourage miners to wear the breathing device continually, the Bureau approved a different type of apparatus. This one measured 3 x 4 x 6 inches and weighed just 2.5 lb. Since then, the basic design has remained unchanged. Although the "filter self-rescuer" or "FSR" can easily be carried on the miner's belt, it does not provide oxygen. It converts carbon monoxide (CO) to carbon dioxide (CO_2) and provides some protection from hydrogen chloride gas. The FSR is of no use in oxygen deficient or highly toxic mine atmospheres.

> Barrier: The perceived solution to a complicated user problem, from an organizational standpoint, may be to make tradeoffs.

> Many times, the tradeoff criterion is arrived at non-inclusive of all critical parameters.

With passage of the 1969 Coal Mine Health and Safety Act, money became available to develop a self-rescue apparatus that supplies oxygen. During the requirements phase, officials established that the unit must be small, durable and weigh < 4.5 lb. Finally, the device had to provide complete respiratory protection. Performance specifications for the proposed apparatus were contained in Schedule E of the Federal Register. Schedule E set stringent metabolic requirements for oxygen delivery. In sum, the Bureau was aiming at an acceptable tradeoff that would supply oxygen like the mine rescue apparatus (for at least 1 h) but be worn like the filter self-rescuer. Lockheed Independent Development built a KO_2 (potassium super oxide) prototype under contract. According to Lockheed's Senior Research Engineer, human factors considerations heavily influenced the development of this device. "When an emergency situation arises, the unit can be activated quickly, even by an untrained and/or excited person. Once deployed, the breather is comfortable to wear, does not interfere with the user's activity, and gives the user confidence that it is working properly" (Perry and Wagner 1973). The Lockheed rescuer caught fire during a demonstration, leading to further research and development, as well as a need to defend similar apparatus. Another KO_2 unit widely used by Russians supposedly was used underground without any known problems. Also, the Chemox unit had been used for 30 years without technical problems in the unit itself. However, it was mentioned that there were problems with training and usage of it (Stein 1978).

> Barrier: When there are no carefully controlled studies, one is likely to see what one wants to see. Outside studies and suggestions helpful to building more sound designs are not welcomed by the organization research team leading to repeated designs that are ineffectual.

Despite the Lockheed engineer's endorsement of human factors, there is little evidence that the human/product interface was explored much beyond metabolic concerns. Lockheed never went to production with their rescuer but sold the technology to another manufacturer. In 1981, a federal law mandated that mines would provide miners with a one-hour oxygen delivery device. By the time of the Wilberg mine disaster in 1984, there were two types of oxygen delivery apparatus (chemical and compressed oxygen) and five different brands in US coalmines. All came to be commonly called "self-contained self-rescuers" or "SCSR." SCSR were readily available to the 27 miners who died at Wilberg, but investigations suggested they had not been able to use them. Since the suspect apparatus functioned properly when tested after the fire, inadequate training emerged as a determinant in the workers' deaths. Only later did the general question of usage emerge.

> Barrier: Time pressure and regulatory or other constraints might lead to solutions that seem neat and expedient, but are inappropriate and ineffective.

In 1986, researchers at the University of Kentucky (UoK) began a project in cooperation with the Bureau, several other agencies, and original equipment manufacturers. This study started with a task analysis and soon turned into a full-scale scientific investigation of worker proficiency with SCSR. In the study it

became clear that none of the apparatus was user-friendly. These devices were different in design, but all shared some traits with the earliest mine rescue apparatus that the Bureau had felt compelled to set stringent training standards for. Oxygen was activated manually, by either pulling a cord or turning a knob, each device had a mouthpiece with bite lugs and a flange that fit between lips and teeth, a nose clamp was affixed to the mouthpiece by means of a cord, and goggles were stowed inside the case. The notion that a unit "can be activated quickly, even by an untrained and/or excited person" was put to the test at a cooperating coal company. A group of surface workers (who are not required to carry SCSR) was brought into a training room where the device's function was explained in detail. Each person was then asked to don the apparatus while being videotaped. Only the company pilot was able to figure out the SCSR well enough to isolate his lungs, though he did not get the wearing straps tied nor goggles in place. No one else in the group of 14 was able to activate the device. Researchers concluded there are few built-in cues to help people activate SCSR, nor did it appear that the interface was characterized particularly well by the "integrity, reliability, efficiency, and usability" Dekker and van den Bergen (1996: 301) considered essential for an ergonomically correct product.

> Barrier: Claims are often not put to real-world tests. Without end user testing in the design phase, one's knowledge base limits his/her perception. The tendency is to see only confirmatory evidence.

The UoK study team noted that SCSR were the result of engineering research and development that had taken years. Nowhere, however, could they find evidence that ergonomic or cognitive studies had been conducted to determine what human design features the devices should have (Vaught *et al.* 1996). After the apparatus had tested out as reliable in field trials, been shown to function well mechanically, and to have a fairly long shelf life, they were placed in the mines. From that point workers must accommodate the SCSR in order to use them effectively. Training would have to be a large part of that accommodation, but the training research focused narrowly upon donning proficiency rather than on overall usability.

> Barrier: If a product is working according to specifications, any subsequent failures are likely to be blamed on the human user.

Lack of capability is clear in an account given to the UoK researchers by a safety instructor who had 96 trained workers don their SCSR and travel through theatrical smoke at a mine. His observations: (1) workers had to be helped to don their devices; (2) about one-quarter of the miners forgot to put on their nose clamps; (3) roughly a dozen individuals omitted their goggles; (4) nine people did not get their oxygen turned on; (5) several workers became entangled in the wearing straps; and (6) at least two miners failed to insert their mouthpieces correctly. Focusing upon this problem the study team, over the next 5 years, developed a rationalized donning sequence that could be used with all SCSR then on the market. Next, the researchers designed an evaluation method that would allow them to observe donning attempts and chart each miner's performance. Then, they constructed low cost training apparatus and tested them against the more expensive models offered by equipment manufacturers.

Finally, the study team employed their innovations in the field, training miners to proficiency and plotting their forgetting curves. One group of coal miners was trained to proficiency (able to perform five perfect sequences in a row) so that samples could be evaluated through the following year. Of those evaluated after 90 days, only 30% had retained enough knowledge to get their lungs isolated and the SCSR secured. It was apparent that there was little or nothing intuitive about the design of SCSR that will prompt a trained person's memory. Current guidelines are such that these miners had 9 months to go before they would be retrained.

> Barrier: A patchwork pattern of training and usability instructions developed when problems are encountered is not a substitute for anticipation of design problems prior to implementation.

Although they were committed to finding training solutions for the use of an apparatus that requires practice to master, under a standard that mandates little practice, researchers did encounter other usability issues. In interviews with 46 workers who used SCSR while escaping underground mine fires, the study team found 29 who reported having had breathing difficulties. Twenty-seven miners, though in smoke, removed their mouthpieces to breathe. As one individual stated, "I know there's a lot of CO … but I can't breathe. If I can't breathe in this thing [SCSR], I'm just going to collapse anyway" (Brnich *et al.* 1992). Potential breathing problems became greater when a second generation SCSR was introduced in the early 1990s. During the requirements phase it was decided that if these devices were made only twice the size and weight of a filter self-rescuer, they could be worn rather than carried or stored as the larger units had been. These size and weight specifications were met partly by crowding the metabolic limits for oxygen delivery. Where the first SCSR provided excess oxygen under certain conditions, the person-wearable SCSR (PWSCSR) measured it out more carefully. It can be imagined that if a miner decided s/he was not getting enough oxygen from a first generation apparatus, the problem would be magnified by a device designed to deliver a lesser quantity per minute.

> Barrier: A product may meet physiological requirements, yet fail to meet psychological ones. This must be recognized and attended to, or the device may not be successful.

A second usability problem related to the size and weight issue was wearability. It had been assumed by those establishing requirements that a device only twice the size and weight of a filter self-rescuer could replace the FSR on a miner's belt without undue complications. This reasoning might seem valid unless one applies the concept to more familiar objects replacing one's glasses with a pair twice the size and weight; or, exchanging the car in one's driveway for one twice the size and weight. In both instances, it might be expected there would be problems with mobility and physical impairment, among others. Such seems to have been the case at a mine where accident data collected over 10 years were reviewed by company personnel. They reported a dramatic increase in accidents due to fatigue and balance after introduction of the person-wearable units. In an investigation conducted by researchers at this mine, a sample of 51 workers was asked their opinions about wearing the PWSCSR. The miners' answers to a set of objective statements about the PWSCSR and FSR suggest the following: (1) they felt pain and soreness after

wearing the PWSCSR all shift; (2) they did not feel pain and soreness after wearing the FSR all shift; (3) they did not think wearing either device posed a danger of injury; (4) the weight of their belts, however, has at some time caused a fall due to loss of balance; and (5) given a choice, they would switch back to wearing the FSR even though it offers less protection.

> Barrier: Sometimes design tradeoffs are made arbitrarily without controlled studies based on proven principles. This may lead to unintended consequences, such as having workers who are adequately protected but uncomfortable or visa versa.

6. CONCLUSIONS

In general, the ignoring of human factors in the design phase constitutes an organizational blind spot. This blind spot has usually been recognized after the fact in partially failed attempts to "reinvent" organizations. A recent example is the result of re-engineering efforts here and abroad: "the basic assumption is that if you get the engineering right the human factor will fall into place. … As a result, the re-engineering movement has encountered exactly the same problems and failures experienced by older style classical management principles" (Morgan 1997: 22). The integration of ergonomics into system and product design is not accomplished by just putting an ergonomist on the project but requires a change in the cultural thinking of the designers and the organization. The *use parameters* document needs to be considered as important as the *product specification* and *product requirements* documents. An organization's social framework must be structured to accept ergonomics as part of the design criteria. That would increase the amount of interest design engineers need to have in ergonomics. Further, the design team should be educated about how to recognize and apply ergonomic principles during all development stages. This would help reduce the barriers to ergonomics integration. Methods used to assess ergonomic design criteria can be found in Chapanis (1996) and Ainsworth (1992). Chapanis (1996: 294) addressed

the difficulties and rewards of ergonomics integration, but clarified that "even the best efforts of human factors professionals and system designers cannot guarantee that a system will be successful because of the many factors over which they have no control." The way to move toward control over the system is to recognize that barriers do exist and the organizational structure may be part of the problem. Then, begin a culture change by using sound ergonomics and design principles to predict product usability and safety.

1. INTRODUCTION

The use of new technology in occupational settings has created changes in work tools, work methods and working conditions. These changes are likely affecting employee stress, health and quality-of-working-life (QWL) (Carayon and Lim 1994). Upper extremity work-related musculoskeletal disorders (WRMD) are increasingly becoming more prevalent among the US workforce (BLS 1997) and this trend seems to be related to the introduction of computer-based technology in the service sector. The introductions of new technology, and the accompanying changes in job design and work organization, have often failed to incorporate human factors principles of organizational design and management (ODAM) and socio-technical principles of job design and stress reduction. Accumulated research evidence has shown a relationship between the nature of work organization and various stress-related diseases (Cooper and Marshall 1976, House 1981), and there has recently been an interest in the potential relationship between work organization, psychological stress and WRMD (Smith and Carayon 1996).

There are theoretical reasons to believe that work organization factors can play a role in the report and development of WRMD (Sauter and Swanson 1996, Smith and Carayon 1996). Work organization is defined as "the way in which work is structured, supervised and processed" (Hagberg *et al.* 1995: 393–4). The model presented in Figure 1 (Carayon *et al.* 1997) suggests the potential relationship between work organization and WRMD. Mediating this relationship are (1) ergonomic risk factors (e.g. postures, force), (2) psychosocial work factors, that is "the individual subjective perceptions of the work organization factors" (Hagberg *et al.* 1995: 395) and (3) stress load, as well as the interactions among these factors. Organizational, ergonomic and psychosocial factors can produce a "stress load" on the individual: this stress load can have both physiological and psychological consequences (i.e. strain), such as biomechanical loading of muscles or joints, increased levels of catecholamine release, or adverse psychological mood states (Smith and Carayon-Sainfort 1989, Hagberg *et al.* 1995). These various concepts of work organization, ergonomic and psychosocial work factors, stress load, strain, musculoskeletal discomfort and WRMD are hypothesized to describe various stages of the chain of events that link work organization to WRMD.

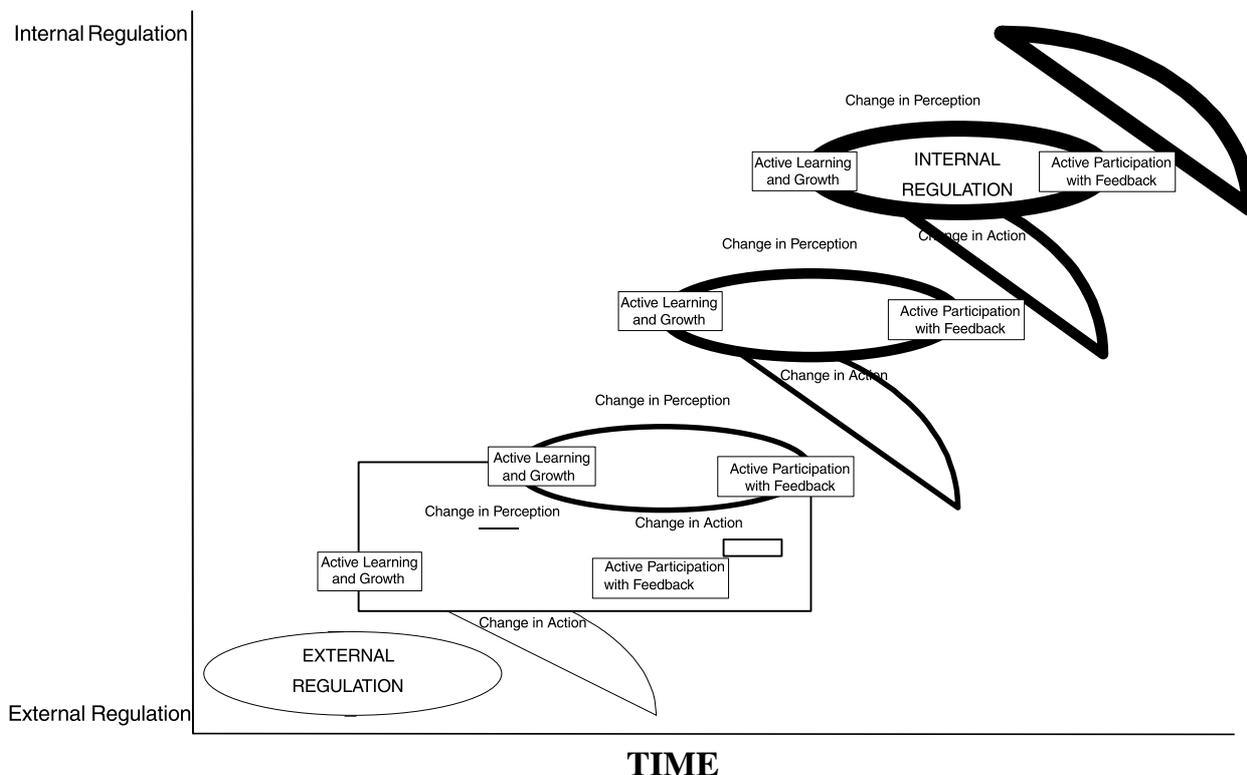
Traditionally, physical ergonomic factors have been considered the primary risk factors for WRMD (e.g. Putz-Anderson 1988). Recent studies, however, have found associations between psychosocial factors and WRMD even after adjusting for physical demands, suggesting that the effects of these factors may be, in part or entirely, independent of physical factors (Kerr *et al.* 1997, NIOSH 1997, Wahlstedt *et al.* 1997). This research justifies the


Figure 1. Model of the relationship between work organization and WRMD

exploration of the effects of interventions that go beyond changes to the physical aspects of work environment and job design. Work organization interventions encompass a systemic approach for improving QWL and health by taking into account macro-level organizational variables and both ergonomic and psychosocial work factors.

2. WORK ORGANIZATION INTERVENTIONS

Several work organization strategies have been proposed to improve QWL and health, and to prevent or reduce WRMD (Carayon 1996, Smith and Carayon 1996). Different types and examples of work organization interventions are listed in Table 1.

With respect to time management, various types of rest break schedule have been proposed to reduce exposure to ergonomic risk factors. Also, in order to reduce the QWL and health problems associated with shiftwork, different forms of work scheduling have been proposed: flextime, compressed work weeks and other alternative work schedules. More recently, with the use of new information and communication technology, new forms of work schedule have appeared, such as telework and job sharing. Increased job variety has long been recognized as a means for reducing exposure to ergonomic risk factors: workers are rotated and/or exposed to tasks with different physical requirements. From a psychosocial point of view, however, job rotation and job enlargement are of limited value because the basic tasks are not enriched and often do not add dimension, interest or challenge to work. Work organization interventions aimed at increasing

job content and responsibility or at changing the basic structure of work (e.g. team work and organizational design) are potentially more effective from a psychosocial point of view. Whereas job rotation and job enlargement are horizontal strategies (i.e. increasing the variety of jobs), job enrichment strategies, aimed at increasing job control and team work, are vertical strategies: employees are given more responsibility within their jobs. Team-work has different facets, such as temporary versus permanent teams and level of participation or involvement. Different forms of organizational design can contribute to improved QWL and health. Flat organizations and decentralization can help promote increased job content and responsibility for workers,, therefore, increasing satisfaction, motivation and QWL. Total quality management and other quality improvement strategies can be aimed at "internal customers", i.e. the employees, and can, therefore, foster improvement in working conditions. Finally, work organization interventions can target management, and indirectly contribute to better psychosocial and ergonomic work conditions.

It is important to recognize that these different forms of work organization have the potential to improve QWL and health, but may also have some negative effects on employees (e.g. increased workload and work pressure). Recognizing these negative effects and preventing or reducing them should be part of any work organization intervention.

3. PROCESS FOR WORK ORGANIZATION INTERVENTIONS

If not well managed, changes in work organization can become a source of employee stress. Change can lead to feelings of uncertainty, increased workload and feelings of decreased job control, all well-known psychosocial factors related to stress (Hagberg *et al.* 1995). It is crucial to develop appropriate processes for planning, implementing and monitoring intervention changes. One of the greatest challenges for successful interventions is overcoming resistance to change among various individuals and groups within an organization. Effective approaches for overcoming resistance include participation/involvement and knowledge/communication (Hagberg *et al.* 1995).

Participation has been used as a key method for implementing various types of organizational changes, such as ergonomic programs (Wilson and Haines 1998), continuous improvement programs (Zink 1996) and technological change (Eason 1988). Haims and Carayon (1998) have developed a model for the implementation of participatory work organization interventions (Figure 2) and have conducted several research efforts toward better understanding how to implement effective participatory work organization interventions and for defining best practices and design principles. The model is based upon the behavioral cybernetic theory of learning (Smith and Smith 1966) and asserts that effective participatory programs are developed through continuously providing opportunities for employee involvement linked with feedback and control mechanisms, which leads to continuous learning and the ability of employees to take increasingly higher levels of control over the intervention efforts over time. The model suggests that gradual increases in participation, learning, feedback and control that occur over time allow for the gradual transfer of the participatory program

Table 1. Types and examples of work organization interventions.

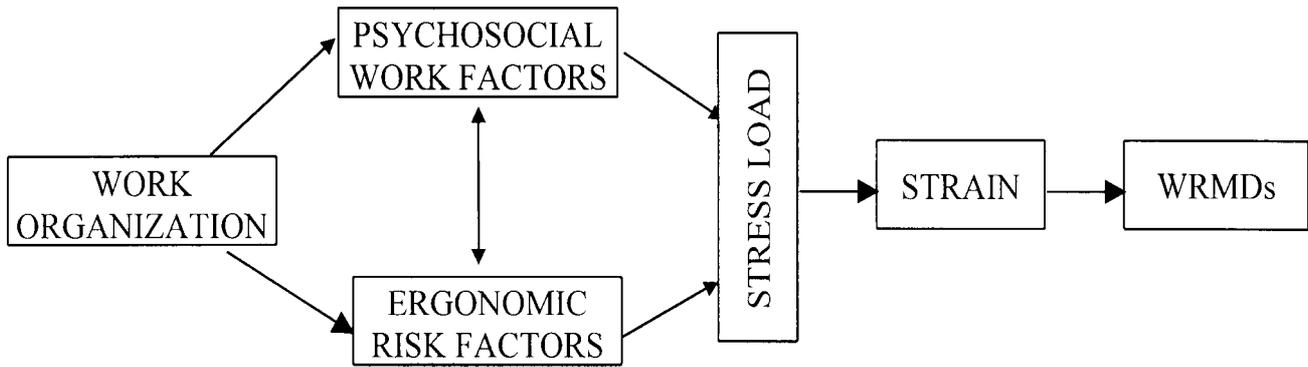
Types of work organization interventions	Examples	
1. Time management	Alternative rest break schedules	Compressed work week
	Flextime	Job sharing
	Self-scheduling	Telework
	Alternative work schedules	
2. Increased job variety	Job rotation	
	Job enlargement	
	Cross-functional training	
3. Increased job content and responsibility	Job enrichment	
	Vertical job loading	
	Control over work place	
4. Team work	Semi-autonomous work groups	Autonomous work groups
	Project teams	Self-managing teams
	Participatory ergonomics	Suggestion programs
	Quality circles	
5. Organizational design	Flat organization	
	Decentralization	
	Design of electronic performance monitoring systems	
	Total quality management	
	Healthy organizations	
6. Management	Supervisory training	
	Increased communication, feedback, information exchange	
	Just-in-time scheduling	


Figure 2. Research model for the implementation of participatory work organization interventions (from Haims and Carayon 1998).

from external regulation by outside experts to internal regulation by organizational members. We argue that this model can be used for the effective implementation of work organization interventions.

Several authors have proposed design principles and best practices for the process of implementing participatory work organization interventions (Spencer 1989, McLagan and Nel 1995, Mohrman and Mohrman 1997, Haims and Carayon 1998), and together they represent a "toolbox" for human factors and ergonomics professionals to use in the field. The subsequent list by no means is all-inclusive, but rather represents what these authors have expressed as key components for effective, continuous improvement work organization interventions.

- Collect data for identification of problems and identification of criteria and goals. Intervention design and assessment should "match up with" the data and established criteria and goals.
- Include all key stakeholders in the process, along with those who bring the necessary knowledge, skills and perspectives "to the table."
- Develop a staged process plan, including design/development, implementation, evaluation and continuous improvement phases.
- Strike a balance between structure (e.g. project management and adhering to the process plan) and flexibility (e.g. making necessary changes along the way).
- Ensure the necessary resources are available to carry out the process plan.
- Secure "buy-in" and commitment (including time) from top management.
- Share information by communicating all process plans to all organizational members.
- Use a systems approach to bring about change. That is, change should not be isolated, but rather widespread and embedded within the organization.
- Incorporate individual and organizational learning into the process. That is, treat change as a learning process and design for self-design.
- Adhere to established training principles, such as experiential learning through action, feedback and feedback control and staged levels of learning.
- Be a flexible, dynamic outside expert willing to wear many different hats throughout the process of intervention development and implementation.

4. EFFECTIVENESS OF WORK ORGANIZATION INTERVENTIONS

When examining the effectiveness of work organization interventions, it is important to consider both the process and content of the intervention (Haims and Carayon 1998). An effective process is one that reduces resistance to change, reduces stress related to change and leads to long-term, continuous improvements. Effective content (including the content of the process) leads to improved QWL and employee health. In this section, several examples of work organization interventions, using different processes and/or contents, are provided, along with discussion of their effectiveness and/or limitations.

Westlander *et al.* (1995) conducted a field study to examine the effects of an ergonomics intervention program in two different workplaces. The aim of the intervention was to create an ongoing intervention program, involving participatory problem solving, to deal with current and future ergonomics problems. Implementation of the interventions was not successful, and Westlander *et al.* (1995) discuss the environmental and organizational barriers they encountered in implementing such programs. Specifically, they found that turbulent economic conditions and concurrent organizational changes contribute to the difficulty of implementing interventions initiated by outside researchers. Åborg *et al.* (1998) also report organizational factors as limitations to the effectiveness of their reorganization of data entry work, such as lack of communication of changes, insufficient employee involvement in decision-making related to work organization changes and employee expectations of positive change not being achieved.

Smith (1994) used worker participation in a meat processing plant as a means for defining ergonomic problems and implementing improved work methods. Ergonomic training was provided to plant supervisors and employees, and an employee was named as a full time ergonomics coordinator to implement solutions, facilitate focus groups, and keep awareness levels of ergonomics high. Another component of the program was to involve all employees in ergonomic focus groups for recommending engineering controls, better work methods, and job enrichment strategies. Preliminary results showed a reduction in ergonomic risks, reduction in psychosocial stress and the "institutionalization" of ergonomics as part of daily life within the plant (Smith 1994).

The National Institute of Occupational Safety and Health reports on an additional three case studies of participatory ergonomic interventions in meatpacking plants (NIOSH 1994). Each

project used a participatory approach involving front-line workers, supervisory personnel and others organized into teams for problem-solving purposes. Findings from these case studies included: (1) successful participatory ergonomics programs require strong in-house direction, support and ergonomic expertise, (2) training programs must develop both team work and ergonomic skills among participants, (3) teams should include supervisors, maintenance and/or engineering staff (who actually implement the recommended changes), as well as production workers engaged in the jobs being studied, (4) realistic and measurable goals need to be set and communicated and (5) evaluation criteria must be planned.

Haims and Carayon (1998) implemented a participatory ergonomics program in a public service agency in the Midwest US with the aim of ergonomic and job redesign for reducing stress and improving health. A group of 13 employees, representing a total of 450 employees throughout the organization, directly participated in the program. Participants were provided with "hands-on" training and feedback and were encouraged to actively participate throughout the process. Findings indicated that participants in the program experienced a great deal of learning over time, increased levels of communication and information and gains in control over the program. Preliminary data showed a general trend of upper body discomfort, hand/arm discomfort and postural stressor complaints decreasing over the study period in one of the represented work groups within the organization. Results were positive but suggested the importance of increased consideration of macro-level organizational variables. For example, management support was crucial for providing participants with time, access and opportunities to exercise their gained knowledge and expertise for improving ergonomic work conditions and continuing program initiatives over time.

Haims (1998) reports on a longitudinal study of the implementation of a participatory work organization intervention among a group of office workers to examine the effects of the process and content of the intervention on both direct participants (project team (PT) members) and indirect participants (non-PT members) over time. The intervention process combined the approaches of participatory ergonomics, behavioral cybernetics and action research. The intervention content consisted of adherence to a document that specifies how work is to be organized and continuously improved. Data were collected using questionnaires (PT and non-PT members) and interviews (PT members only). Interview results suggested positive changes in participation in decision-making, communication, feedback and learning for both the PT and non-PT groups. However, work demands generally increased. Although non-PT were not directly involved in the participatory intervention process, they seemed to experience "spill over" effects, through interaction with PT and the process itself. It appears that learning among the PT was transferred or diffused to the non-PT over time. Owing to limitations, the questionnaire was generally unable to detect changes in either psychosocial factors or outcome stress and health measures. A multitude of outside environmental factors "overpowered" any effects of the intervention at the global level of questionnaire measurement. Results suggested the need for intervention research to focus at the global, work system level and for the development of methodologies and measures to examine the participatory learning process.

5. CONCLUSION

An inherent problem in intervention research is the plethora of uncontrollable organizational and environmental factors that always exist in concert with the intervention being put into place (Åborg et al. 1998). This, along with time issues (Carayon 1997), makes the measurement and assessment of interventions difficult. Solutions are not easy, but several are suggested. First, work organization interventions must adhere to a systems approach to change and focus at the global work system level (i.e. upper-level management) for making changes to the overall organizational structure. A work organization intervention will only be successful if a structure and culture are in place to support it. Second, work organization interventions must be designed for continuous self-design in order that the organization be capable of responding effectively to the reality of today's turbulent environmental conditions. This can be achieved by incorporating widespread involvement, participation and (individual and organizational) learning into both the process and content of work organization changes. Lastly, in terms of methodology, it is suggested that organizational variables (e.g. organizational climate and culture) be measured so that they can be controlled for, that quantitative and qualitative data be collected to provide both "hard results" and "contextualization" of the change process and that long-term longitudinal study designs be adopted to examine a variety of short- and longer-term effects over time.

1. INTRODUCTION

The purpose of this chapter is to provide an understanding of how work organization features can lead to stress and adverse health effects. It will discuss the working conditions that produce stress, and organizational interventions to reduce adverse health effects due to stress. The physiological basis of stress theory lies in the work of Selye (1956) who described a pattern of physiological reactions to environmental stressors which he called the "general adaptation syndrome" (GAS). This GAS was activated in a non-specific, stereotyped form by any environmental demand (Selye 1956). One of the characteristic features of this theory was that stress was understood as a stimulus–response phenomenon. The organism's reaction was activated in the same manner by any environmental demand which was called a stressor. Later theorists believed that this response-based definition was limited because the same reaction pattern could be evoked by a wide array of stimulus conditions.

Lazarus (1977) developed a cognitive theory of stress in which individual differences in cognition intervene between the stressor (stimulus) and the reaction (response) to define the nature of the reaction. These cognitive processes determine the quality and the intensity of the reaction to the stressor. A stressor will not have an effect unless it is recognized and assessed by the person in an appraisal phase. Three different kinds of stress situations are acknowledged, which are harm, threat and challenge. Harm refers to psychological damage that has already taken place, such as an irrevocable loss like the death of a loved one. Threat is the anticipation of harm that has not yet taken place but may happen. Challenge results from difficult demands that one feels confident about overcoming by the effective mobilization of resources.

Current stress theories usually involve the concept of a transaction between the environment and the individual. Some theories characterize the development of stress as an outcome of an imbalanced interaction of the environment and the person (poor "fit"). If the environmental demands are greater than the person's capacities and/or if the person's expectations are greater than the environmental supplies, then stress responses will occur (Smith and Sainfort 1989, Kalimo *et al.* 1997). These theories do not see the environment, such as work, only as a source of stressors. They see work as a source of a full range of demands and supplies that may match the individual. Thus, work can be a source of life satisfaction as well as a source of distress.

Work makes demands on the person regarding for instance workload and participation. The person responds to these demands according to her/his skills, motivations and other characteristics. The person has expectations regarding work, such as decision-making, opportunity for development and support. Work may present the opportunity for the achievement of such goals to a varying degree. In the case of a positive "fit" the working conditions put manageable challenge to the person, which results in positive satisfaction, feelings of competence, well-being and positive health. A poor "fit" causes stress responses and a series of negative reactions begin to develop. Negative emotions including frustration, dissatisfaction, fear and anger appear at first. These lead into the development of physiological changes involving the autonomic nervous system and the hormonal and immunological systems. If coping processes fail then the stress responses may change into a chronic state and eventual mental and/or physical disorders develop.

2. WORK ORGANIZATION AND JOB DESIGN

It is important to recognize those psychosocial characteristics in work, work organization and the environment which are potential contributors to stress and which adversely influence the health and well-being of individual workers, groups and the whole organization. The characteristics of the work and of the organization are overlapping and not independent. Their stress effects depend on their mutual interaction and on the specific characteristics of the individual (personality, capacity). We are interested mainly in the health relatedness of the psychosocial characteristics of work and work organization, but they can be also be important contributors to job satisfaction, work motivation and work performance.

2.1. Characteristics of Work Organization

Cooper (1986) has categorized organizational stress factors as those that are intrinsic to the job, role in the organization, career development, the relationships at work, as well as the organizational structure and organizational climate. In this section factors related particularly to the physical work environment and task demands are described. Factors intrinsic to the job are: (1) physical working conditions, (2) workload, both quantitative and qualitative, and time pressure, (3) responsibilities (for lives, economic values, safety of other persons), (4) job content, (5) decision-making and (6) perceived control.

Many blue-collar jobs entail a high physical energy expenditure or difficult work movements and postures. Ergonomic factors, such as repetition, posture, and force can contribute to the development of musculoskeletal problems (e.g. musculoskeletal discomfort or fatigue), and the features of a psychosocial work environment can also contribute to their development. The ergonomic aspects of the work place interact with the psychological factors to influences stress responses.

The most obvious job characteristic is workload. This describes both quantitative and qualitative aspects of the task. Stress can be due to overload (over work) or underload (boredom). Quantitative overload means that there is too much to do or the person has to work under time pressure or meet strict deadlines. Also, requirements to work excessive hours increase quantitative workload. Too much workload has been associated with stress in many occupations from assembly-line workers to nurses to computerized clerical staff.

Control at work can be defined as the ability of a person to exert some influence on one's environment and/or some

characteristic of the task or the work organization. In a work situation the person can have control over various job demands, like the task itself, pacing of the work, work scheduling, the physical environment, decision-making, other people or mobility. As such, and in combination with work demands, a lack of job control or decision latitude has been found to be an important contributor to stress and ill-health. When job control is high, the other job demands such as workload tend to have less potential for adverse stress effects.

Uncertainty or lack of clarity is closely related to a lack of control because it implies a lack of needed information for control. Uncertainty exists when that knowledge about events requiring action is experienced as being inadequate. Uncertainty has been emphasized as one of the most predominant single sources of occupational stress. It arises from job insecurity, task ambiguity, lack of knowledge of results of performance and unanticipated slowdowns in work production. With increasing use of computer technology, this kind of unpredictability has become more frequent and quite stressful.

Responsibility at work can be related to the success and safety of other persons or to material resources. These issues are prominent in customer or client-related operations. Responsibility is also associated with occupational roles and organizational hierarchy, such as being a supervisor or manager. High responsibility can lead to high stress levels.

2.2. Organizational Structure and Culture

Organization that fail to have a commitment to employee welfare, career stability and personal development have been shown to influence employee stress. Job insecurity is a primary issue for stress in many workers, particularly when work life is undergoing major structural changes associated with new technology, downsizing, mergers and business process re-engineering.

Supervisory style is important from the occupational health perspective. A hierarchical, authoritative management style in general has been found to have negative effects on workers' well-being and stress, whereas a participatory leadership style has been found to be advantageous.

In a job design context, the following characteristics of job content are of main interest: the variety of tasks and task identity, feedback about job performance, perceived personal contribution to the product or service, challenges and opportunities to use one's skills, and individual autonomy. If these characteristics are perceived negatively by the employee then the level of stress increases.

Three types of problems have been observed in the organizational role setting: role ambiguity, role conflict, and role overload. Role conflict is defined as a condition of incompatible role expectations placed on a person. Role ambiguity means a lack of clarity regarding the role expectations, and an uncertainty concerning the outcomes of one's role performance. Role overload means a scope of tasks that is too wide with too many different kinds of role expectations. Recently, role underload has been recognized as a problem. It is caused by too low and too few expectations placed on a person who would be capable of a greater contributions.

Interpersonal conflicts are a source of stress which can lead to violence at work. Recent research about interpersonal relations has been focused on aggravated conflict situations and bullying.

Bullying, mobbing or psychological harassment, are a form of expression of the problems in the interaction between people at the workplace. A person is being bullied when s/he is exposed repeatedly and over time to negative actions on the part of one or more persons at the workplace. It means teasing, pressure and unfair treatment of a person in situations where the target cannot defend him/herself.

2.3. Extra-organizational Influences

Work and private life were recognized as two interdependent spheres of life in work-related stress and health. This relationship can be characterized by: (1) a spillover effect of stress from one sphere to the other, (2) role conflict between work and family responsibilities, (3) a cumulative effect of work and family stressors and (4) the buffering effect of one sphere against stress in the other.

3. SOCIAL SUPPORT

Social support is a resource which has been shown to influence the effects of stress. Social support can include: (1) social integration, which is the size and structure of one's social network, (2) the availability of satisfying relationships characterized by love, trust and esteem, and (3) the actual receiving of supportive acts from others when in need. House (1981) emphasized the importance of the actual receiving of social support as the key factor for the beneficial impact. He defined four forms of such support: (1) emotional support such as care giving and affectionate concern, (2) appraisal support through evaluative feedback and affirmation, (3) informational support by giving suggestions or guiding, and (4) instrumental support through organizing opportunities.

Social support is a beneficial factor for well-being and job satisfaction and lowered stress. There are direct effects in which social support is positively related to person's health independent of environmental circumstances or stress level. In addition, social support provides a protective function during conditions of stress, that is to "buffer" a person against the harmful effects of the social environment. As a whole, evidence for the beneficial effect of social support is conclusive enough to merit the promotion of efforts aimed at the improvement of interpersonal interaction at the work place. The role of the supervisors as sources of support seems to be stronger than that of colleagues and work mates.

4. IMPROVING WORK AND ORGANIZATIONS

Improving work and work organizations is usually a practically oriented activity supported by consultants and other specialists from inside and/or outside the organization. The intervention traditions and models are also strongly dependent on current social and cultural values of the company and the employees. The goal of a specific intervention or program at work is to improve the functioning of an organization, its productivity, profit, quality of production and services, and to promote workers' health, aspiration and competence, by making work and its characteristics favorable.

4.1. Healthy and Productive Work Organization

The organizational health approach reflects the capability of an organization to function effectively in relation to various economic and market factors within the context of a supportive work

environment for employees. This provides the ability respond effectively to environmental changes. A value-based organization using the healthy company model involves strategies for profit-making and valuation of people. The management plays a key role in the implementation of these strategies, which are open communication and employee involvement, learning and renewal, valued diversity, institutional fairness, and equitable rewards and recognition, and general economic security. People-centered technology as well as a health-enhancing environment and meaningful work are important. The balance between work and family life is also emphasized.

4.2. Improving Environmental and Ergonomic Conditions

Ergonomics is the science of fitting the environment and activities to the capabilities, dimensions and needs of people. Good ergonomic practice suggests that all aspects of the work system be included in job redesign improvements. From an ergonomic perspective the design of the environment, workstations, tasks, work organization and the tools/technology should reasonably accommodate the employees' capacities, dimensions, strengths and skills. Critical aspects of the success of ergonomic interventions for providing psychosocial benefits are a strong management support for the ergonomics program; the involvement of managers and supervisors in the ergonomics program; the involvement of employees in the program and their willingness to participate in defining problems, proposing solutions and improving their work practices; and the application of engineering improvements to reduce biomechanical and physiological loads.

4.3. Strategy for Job Redesign

The following section will define a strategy for redesigning jobs to reduce job stress, but will not elaborate the specific characteristics of job elements needed to achieve proper job design. Smith and Sainfort (1989) have proposed a balance among various elements of the work "system." The essence of this approach is to reduce the negative health consequences caused by stress by "balancing" the various elements of the work system to reduce unwanted loads. It goes without saying that proper work organization and job design can best be achieved by providing those characteristics of each individual work system element that meet recognized criteria for proper physical loads, work cycles and job content, and that provide for individual physiological and psychological needs. The best designs will eliminate all sources of stress, job dissatisfaction and discomfort.

For instance, proper workload can be established by use of appropriate methods of work analysis, while aspects of job control can be developed through the use of worker participation. The negative influences of inadequate skill to use new technology can be offset by increased training of employees to acquire the needed skills. Or the adverse influences of low job content that creates repetition and boredom can be balanced by an organizational supervisory structure that promotes employee involvement and control over tasks, and job enlargement that introduces task variety if not complexity.

A major advantage of this model is that it does not highlight any one-job factor such as job content, or a small set of factors such as autonomy and social relations. Rather it examines the design of jobs from a holistic perspective to emphasize the potential positive elements in a job that can be used to overcome the adverse elements when such adverse elements cannot be eliminated or modified.

4.4. Organizational Change Management

All planned changes and development interventions should follow the developmental cycle. They start with problem or goal definition, and the committing and informing of all interest groups at the workplace. They then proceed to analysis of the present situation, based on survey results, and to joint planning of the intervention. The intervention itself needs clear goals, subgoals, steps, a time schedule, duties for people, and ways to overcome obstacles and problems during the process. The process seldom proceeds as planned, it needs reevaluation and checking of the methods and even the goals during the process. The intervention process and the outcome should be evaluated. This helps the organization to learn about its experiences for the next project. This part is usually left out because very often changes and projects are already arising before the end of the former changes and projects.

The successful implementation of changes in work processes, and subsequent enhancement of worker health, performance, and satisfaction requires organizations to have a transition policy that includes worker participation in all stages of the change process. That is, workers should participate in the planning, then in the selection of equipment, and finally in the daily operation of the work system.

5. SUMMARY

Psychosocial aspects of the workplace can have profound influences on the individual's health and well-being, satisfaction with work and productivity. There are various characteristics of working that have generally been shown to have negative physical and/or psychological consequences, for example, machine paced work, a lack of task control, high job demands, shiftwork, poor supervisory relations, and organizational downsizing. The extent of the negative consequences varies from individual to individual depending on the perceived threat, individual constitution and coping mechanisms. When the person is vulnerable, substantial harm can occur including disability and death.

Several organizational behavior (OB) approaches that can be applied which will diminish or eliminate the harmful effects of poor workplace design that leads to psychological distress. Examples of these approaches include removal of the sources of stress (stressors) through job redesign, balancing the positive and negative aspects of work to provide an acceptable level of stress, developing a corporate culture that promotes self worth and productive employment (the "healthy organization"), and enhancing employee skills and career development.

If the psychosocial aspects of work design are properly developed and implemented, there can be benefits for employee's health and performance, and a "healthy corporation" will emerge. If job stress is not properly controlled, then the consequences can be reduced employee job satisfaction, health, and morale, and reduced employee and corporate performance.

Part 10

Health and Safety

Agriculture

D. H. O'Neill

Silsoe Research Institute, Silsoe MK45 4HS, UK

1. INTRODUCTION

More people gain their livelihoods through agriculture (including horticulture) than any other industry. About 50% of the world's economically active population produce food, most working at the subsistence or small-scale level as a family enterprise. This makes agriculture the world's largest industry, with > 3.5 billion people depending on it. Agriculture is also one of the most labor-intensive and energy-demanding occupations, alongside mining and construction work. This is true for all farming systems, whether small or large in scale, extensive or intensive. In terms of human effort agriculture is the most important industry on the planet and the ergonomics issues are as wide and varied as the industry itself. Different aspects of ergonomics will be prominent in different farming systems, but the design and use of equipment and associated working practices are the underpinning issues.

Agriculture is also one of the most hazardous occupations at whichever level it is practiced, but the risks and hazards depend on the farming system and these change with the degree of mechanization. Environmental and other stresses, such as caused by weather conditions, long working hours and isolation, are also likely to be more extreme in agriculture than in other industries.

Table 1. Three types of agriculture

	Small-scale	Intermediate	High input
Main locations	rainfed areas, hinterlands, most of SSA	irrigated and stable rainfall, high potential areas in the Third World	industrialised countries and specialised enclaves in the Third World
Main climatic zone	tropical	tropical	temperate
Major type of farmer	small and poor farm households	large and small farmers	highly capitalized family farms and plantations
Use of purchased inputs	low	high	very high
Nature of farming system	complex	simple	simple
Production stability	high risk	moderate risk	moderate risk
Priority for production	raise	maintain	lower
Production level relative to sustainability	low	near limit	too high
Environmental diversity	varied	uniform	uniform

Adapted from Chambers *et al.* 1989

Table 2. Contrasting characteristics of small-scale and high input farming

	Small-scale	High input
1	underproduction	overproduction
2	low yields	high yields
3	starvation	overeating
4	low body weight	obesity
5	poverty	affluence
6	crop product consumption	meat consumption
7	muscle powered	oil powered
8	high percentage of young people	high percentage of old people
9	79% of population rural	22% of population rural
10	poor hygiene	good hygiene
11	contaminated water	clean water
12	poor control (over conditions)	good control
13	food processed domestically	food processed industrially
14	poor infrastructure	sophisticated infrastructure

All these factors demand major ergonomics inputs to improve the productivity of the agricultural industry and the welfare of its workers in all countries of the world. Some examples of the problems and possible solutions are presented below for the main types of farming systems.

2. FARMING SYSTEMS

Farming systems may be categorized in a variety of ways but, from the ergonomics perspective, it is convenient to consider the level of mechanization. Three levels can be identified, described as (1) subsistence or small-scale farming, (2) intermediate mechanization and (3) high-input and high-output farming. The lowest level predominates in the poorest countries of the world, mainly in sub-Saharan Africa (SSA), while high-input–high-output farming is found in the richest countries of the world (typically Europe, North America, Japan and Australia), although not all the farmers in these countries operate at this level. The intermediate level of mechanization is found among the more successful farmers in countries with emerging industrial economies, typical of South-East Asia and South America. On average, farmers' potential to invest in mechanization reflects the local industrial situation. The main characteristics of these three significant types of farming system, described by Chambers *et al.* (1989), who referred to these systems as "Industrial," "Green Revolution" and "Third/CDR" (complex, diverse, risk-prone), are summarized in Table 1. Some contrasts between small-scale and high-input farming systems are given in Table 2.

Several of these factors have ergonomics implications, particularly those numbered 4, 7, 12, 13 and 14. Nutrition and body size have implications for work capacity, endurance and equipment design. Anthropometric differences may exist over and above those observed in national or ethnic populations. Oil- rather than muscle-powered equipment confers a role of control

rather than energy (mechanical) provision by the farmer. The final three all implicate contrasting levels of equipment design and use, including power tools, production lines, information processing, environmental hazards and transportation. The contrast, relating to age, indicated by the eighth factor may be diminishing in the late 1990s because of migration of younger people to cities to avoid the drudgery of agriculture and to find more rewarding work. Recently, issues relating to the first factor for high-input farming have become more prominent, with the sociological problems associated with overproduction achieving similar significance to those of poverty alleviation and sustainability of small-scale and subsistence farming.

3. WORKLOAD

Women do the majority of the work in the small-scale farming sector (Figure 1). This work is added to their domestic tasks, to which the male contribution is ~5%. Thus, for women problems of workload, in terms of both energy (and therefore nutrition), and time are amplified in the small-scale sector and must be considered alongside the other gender issues (e.g. income generation, decision-making).

For both men and women in small-scale agriculture the greatest constraints on crop production and productivity are land preparation and weeding; the former because of the energy required and the latter because of the time required. Workloads in small-scale agriculture in industrially developing countries may exceed energy intake, particularly during land preparation when food reserves are often depleted.

Typical levels of work intensity range from ~12 kJmin⁻¹ (at ~30% VO_{2max}) for simple weeding tasks to ~20 kJmin⁻¹ (at ~50% VO_{2max}) for digging in hard soil. Work intensity may also be expressed as PAL (physical activity level), a multiple of BMR (basal metabolic rate). When PAL > 2, as may be demanded for sustained periods in agriculture, considerable motivation is required to maintain work output. A PAL > 2 should be avoided by pregnant and lactating women.

4. ERGONOMICS FACTORS

In all farming systems, the principal ergonomics factors are the (1) design and use of equipment, particularly ensuring physical, economic and cultural compatibility, (2) information processing and consequent decision-making and (3) health and safety. The levels of engineering and technology increases from small-scale to high-input farming, but that does not necessarily mean that the complexity of the ergonomics issues increases, merely that it changes. The design criteria can be just as stringent for a low-cost, multi-purpose and durable handtool as for an engine-powered piece of equipment, such as a hedge-cutter or a power tiller. However, because of the value of the market (rather than the size) for the more sophisticated equipment, more research and development resources have been applied in that direction.

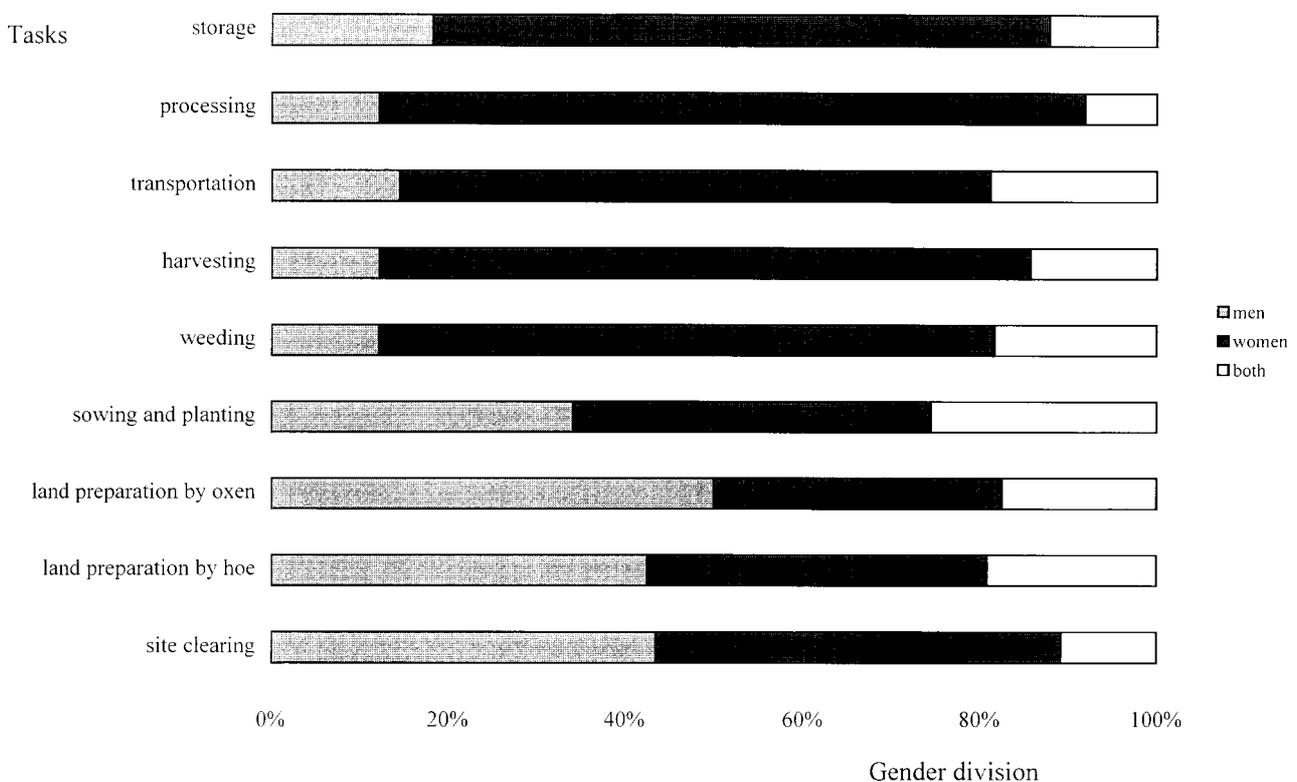
In the progression from small-scale to high-input farming, the most obvious changes in the characteristics of the equipment are the reduction in human energy expenditure and the increase in information processing required for operation. The


Figure 1. Typical gender division of labour in Africa

information-processing demand of the latest, most sophisticated equipment aimed at the high-input market has now been acknowledged and recent developments incorporate features to reduce the mental workload or to facilitate decision-making. Thus, modern high-specification tractors have automatic transmission and draught devices, controlled by signals from sensors to relieve the driver/operator from constantly having to make adjustments to achieve optimum performance. The use of computers, for both vehicles and fixed plant, from sprayers and combine harvesters to grain dryers and glasshouses, is rapidly increasing to leave the operator free to make and implement decisions at the highest (and most important) level. These applications have generated ergonomics effort aimed at making information technology and software packages more "user-friendly" for farmers.

The intensive raising of livestock and the production of milk are both prominent in commercial farming enterprises. The efficient raising of healthy stock depends on appropriate feeding, environmental control and waste management. Farmers need well designed interfaces to monitor herd (etc.) performance, initiate regular routines as effectively and safely as possible and to maintain an optimum working and living environment for both human and animal occupants of livestock buildings.

4.1. Ergonomics Case Study — Tractor Design

The ubiquitous tractor has been the target of most ergonomics research and development with efforts to alleviate the effects of noise, vibration, overturning, air quality and heat stress (Chisholm *et al.* 1992). Tractor ergonomics presents a complex array of issues: the adopted method of protecting the driver from some of the stressors can introduce additional ones, so careful design is required to achieve the best (and affordable) compromise. For example, enclosing a driver in a strong cabin with a suspended seat offers protection against overturning, noise, whole-body vibration and respiratory hazards but reduces the field of view, attenuates feedback from the machine, inhibits communication and can increase heat stress. Similar considerations apply to more specialist vehicles such as combine harvesters and sprayers.

As a case study, consider the reasons for and consequences of fitting a "Q-cab" (i.e. quiet cab) to an agricultural tractor. To protect the driver's hearing, an approved Q-cab must now be fitted to tractors that, in any operating condition, can generate a noise level of > 90 dBA at the driver's ear. Although there are a few special exemptions, this has led to almost every tractor with a power output > 25 kW (i.e. most tractors) being fitted with a cab. Historically, the cab was an adaptation of the mandatory rollover protection — a frame fitted over the seat to protect the driver in the (not uncommon) event of the tractor overturning. With the frame in place, it became popular to attach panels to protect the driver against bad weather (particularly in Northern Europe). These panels, usually of sheet metal and Perspex, were simply fixed to the frame and had the effect of amplifying the tractor noise to the extent of causing the drivers to suffer hearing loss (initially temporary, but permanent after sustained periods). When this problem was identified and it became clear that tractor drivers did not wish to lose their weather protection, cabs were developed, based on the ROPS (rollover protective structure), but these cabs had to meet the noise exposure at work restrictions. The resulting engineering design had the effects of reducing the

Table 3. Advantages and disadvantages of enclosed cabs

Advantages	Reasons
Less risk of ear damage Less stressful working environment	Reduced exposure to noise
Improved air quality	Protection from dusts and chemicals
Less protective clothing needed Opportunity to fit heater	Protection from cold and wet
Fewer postural problems	Potential to improve work-place layout
Greater safety of personal effects	Secure enclosure
Disadvantages	
Access to workplace impeded	Cab structural members and panels
Access to external controls impeded	Cab structure, panels and windows
Excessive temperatures in sunshine	Glazed enclosure acting as 'greenhouse'
Reduced field vision	Cab structure and panels
Isolation from useful auditory information	Necessary cab attenuation properties

driver's field of view, isolating the driver from other auditory (and sometimes important) auditory signals and, during periods of sunshine, making the driver uncomfortably hot (through the "greenhouse" effect). In other words, the solution to one ergonomic problem created new ergonomics problems. The main advantages and disadvantages are shown in Table 3.

As time has progressed, Q-cab design has improved to eliminate as far as possible the undesirable effects without compromising the benefits and, furthermore, to extend the range of potential benefits afforded by the presence of a cab. These include better vibration isolation than can be provided by a simple suspended seat, selective attenuation to improve the transmission of important auditory information, the fitting of climate control systems, greater proportion of glazed area to improve visibility and better design and location of hand and foot controls. Without such improvements, such as to the thermal environment, drivers would choose to avoid the immediate discomfort of heat stress and expose themselves to the potentially more damaging and insidious effects of noise and respiratory hazards (e.g. dust and chemicals). Vibration on tractors is a specific problem because the natural frequency of the large tires typically fitted to the rear of tractors is ~2–4 Hz. This form of mechanical energy, transmitted through the rigid tractor frame and seat, subjects the driver to relatively high amplitude low frequency vibrations which are particularly damaging to the human body. The latest designs of tractor display many engineering refinements, achieved through considerable research and development effort, such as suspended axles, air conditioning, electronic controls to improve man–machine performance over the long periods that tractors are driven day after day.

Enclosing the driver in a cab and reducing the information available, notably auditory and tactile (less so for visual information on modern tractors), concerning behavior of the machine and its attachments can reduce the perception of danger or hazards, so, despite the improvements described above, the incidence of overturning accidents has remained almost constant. This is likely to be reduced only when the driver can be provided with better, readily assimilated information about the stability of

the tractor, especially on slopes. While this remains an ongoing ergonomics challenge, the fitting of ROPS continues to save lives.

4.2. Livestock

The need to work with animals, often with body weights and strengths exceeding those of a typical human, sets agriculture apart from most other industries. The difficulties of handling and generally managing farm animals, from the shearing of sheep to the milking of cows, create ergonomics problems specific to agriculture. Irrespective of the degree of mechanization or automation, equipment designers must consider not only the human–machine interface but also the human–animal interface and, preferably, the animal–machine interface in pursuing complete system compatibility. Milk production is the principal enterprise for many farmers and the activities involved pose wide-ranging ergonomics problems. These include milking the cows (particularly equipment and workplace design), monitoring their health and productivity (identifying and responding to relevant indicators) and designing livestock housing to minimize human health risks. The design of milking parlors must minimize postural problems, promote safe and efficient work routines and provide an acceptable thermal environment. Satisfying all these demands within the prevailing economic constraints generally involves ergonomics and engineering compromises. Monitoring health and productivity becomes more difficult as herd size increases and can be facilitated by information technology, but care has to be taken that such technology is "user-friendly." Current research and development is moving towards robotic milking, which will reduce problems associated with the workplace but, with greater isolation of the herdsman, will place greater reliance on effective information systems to facilitate the husbandry of individual animals.

The growing concern for animal welfare in some developed countries, especially concerning the transport of animals (often to abattoirs), has often been based on ergonomics principles. The techniques for monitoring and evaluating whole-body vibration and thermal stress have been particularly useful. Techniques for assessing work performance and efficiency (e.g. the use of heart rate, oxygen uptake) have also been applied to draught animals (e.g. oxen, horses, camels) to improve productivity.

5. HEALTH AND SAFETY

There are many health and safety concerns in agriculture, apart from those associated with tractors (and other vehicles) and animals referred to above. These include:

- hand–arm vibration from power tools;
- entering hazardous situations (e.g. oxygen depleted atmospheres in store-places);
- slip and fall injuries associated with working on poor surfaces, ladders, roofs or in trees;
- diseases communicated from animals (zoonoses);
- respiratory diseases from exposure to organic or inorganic dusts, or chemical sprays;
- injuries from inadequate machine guarding; and
- environmental noise (annoyance) from fixed agricultural plant (e.g. grain dryers).

Although ergonomics alone can not deal with all these problems, acceptable solutions will not be realized without significant ergonomics and systems contributions.

POSTCRIPT

In so diverse an industry as agriculture, particularly with such a large informal sector worldwide, it is impossible to cover all the ergonomics issues in a few pages. The purpose of this chapter is to give an indication of the major issues and to emphasize the importance of the systems approach, fundamental to sound ergonomics practice. There is probably no other industry in which interactions with economic constraints, cultural factors and engineering design are so critical to the development of "ergonomics solutions," and in which participative approaches are so crucial to their implementation.

Anthropometry for the Needs of Rehabilitation

E. Nowak

Institute of Industrial Design, świĺtojerska 5/7, 00-236 Warsaw, Poland

1. INTRODUCTION

At present there appears a new direction of ergonomics aimed at the needs of disabled people. This is *rehabilitation ergonomics* (Kumar 1992, Nowak 1992, 1996), roughly defined as an interdisciplinary field of science that aims at adjusting tools, machines, equipment and technologies as well as material work and life environments including objects of daily use and rehabilitation equipment to the psychophysical needs of the disabled. Rehabilitation ergonomics takes part both in the rehabilitation process and in equalizing chances.

Anthropometry plays an important role in rehabilitation ergonomics. It is defined as a set of measuring methods and techniques that allow to investigate exactly the differentiation of the measurements of the man and their changeability during ontogenesis and phylogenesis.

As ergonomics develops and in compliance with its needs anthropometry develops new methods that can be called ergonomic anthropometry. Many of these methods, concerning both classical and ergonomic anthropometries, can be applied to the rehabilitation ergonomics that can be divided into two parts:

- The first part is strictly connected with ergonomics, where anthropometry provides data for designing and shaping work and life environment of the disabled.
- The second part embraces all methods and measuring techniques that assist the rehabilitation process.

2. ANTHROPOMETRIC RESEARCH OF THE DISABLED — DATA FOR DESIGNING

2.1. Somatic Characteristics

Defining the possibilities and necessities of the disabled is a necessary condition for designing the material work and life environment for this population. Data that characterize the somatic structure constitute basic information.

The influence of disabilities on shaping the body structure was studied by many anthropologists (Pheasant 1986, Molenbroek 1987, Nowak 1989, 1996, Das and Kozey 1994, Jarosz 1996). The largest disproportions between the healthy and the disabled population can be found in a group of people with motor dysfunction. This is understandable since dysfunction results from the past or currently developing diseases that lead to joint disturbances of the osseous, ligament and joint, muscular and nervous systems. These disturbances lead to deformities and somatic changes of particular parts of the body. This then affects the final shape and dimensions of the body and its motorics.

Other factors that restrain the development and growth of the body include restriction of motion activities, neglected nursing, unproper or lack of rehabilitation, as well as stresses connected with pains, frequent stays in hospitals and rehabilitation centers and which accompany the pathological process. Descriptions of investigations of people with the lower

extremities dysfunction are usually found in the literature. They are usually wheelchair users. It should be realized, however, that this group embraces people with various degrees of motor-efficiency limitations. This depends not only on a type and stage of a disease, but also on time of its appearance. Therefore, researchers dealing with this problem face great difficulties in selecting subjects, and in describing results scientifically. This may be the cause of the small number of studies undertaken in this field. This particularly concerns studies where the results are to provide data for designing.

Not only anthropometric measurements of the disabled are important for the needs of design, but also differences between the disabled and healthy population. The majority of authors indicate that the body structure of disabled men and women differs significantly from the able-bodied population (Nowak 1989, Das and Kozey 1994, Jarosz 1996). This problem was illustrated in the example of data on the Polish population, girls and boys (Nowak 1989, 1996). It appears that these measurements show smaller values for the disabled than for healthy people (Figure 1).

2.2. Elements of Anthropometry in Clothing Design

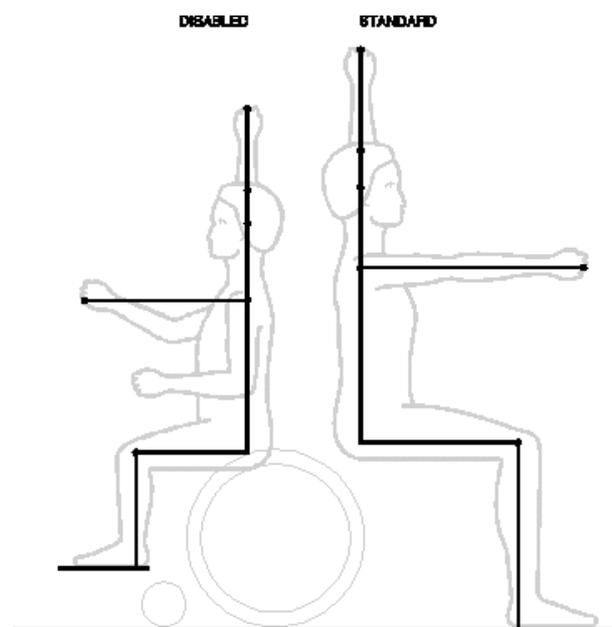
Somatic characteristics are important for clothing design and the fact that its values are bigger in case of the disabled is of importance for designers. A person suffering from disability or permanent illness should get such clothing that makes his/her life easier, is functional, meets his/her emotional needs and, at the same time, is adjusted to the limitations caused by a disability. People with motion dysfunction have the most problems with clothes. Clothing designed for this group of people should assure appropriate physiohygienic properties, heat comfort, as well as ease of manipulation. Concepts of model-constructions solutions should take into account not only the usefulness of products, but also the economic effect. Designs must be simple in


Figure 1. Comparison of body dimensions of the disabled and the able-bodied.

construction and easy to manufacture. The form of clothing is to integrate the group of the disabled with society, to conceal a disability, and to give the feeling of satisfaction at possessing clothes appropriate to needs and expectations. In addition to the body dimensions, determination of motor abilities is of vital importance. Basing on ergonomic investigations, assumptions for clothing design are determined. For example, clothing for the wheelchair user must fulfill (among others) the following requirements: (1) appropriate clearance allowing the hands to move easily up and forward and appropriately larger shoulder breadth. This is ensured by the special construction of sleeve and armpit cut. (2) Increased transverse dimensions related to the enlarged, muscular chest. (3) Widened sleeve finish related to the considerably enlarged biceps and triceps. (4) Adjustment of the bottom part of clothing length and cut (in case of a blouse, shirt, and vest) to the sitting position of its user. This is attained through the removal of excess fabric in front.

People with Down's syndrome (DS) require clothes of different construction (Harwood 1997). This group of people is always offered oversized garments to fit their large hips and thighs; as a result all of the features and proportions do not lie in their correct locations. Some of the common problems can be summarized: (1) when the waist of a garment fits, the bust/chest does not; (2) trousers that have the correct waist measurement are too tight on the hips and thighs; (3) dresses and coats that fit the shoulders are too long, i.e. sleeves, trouser legs and coats are too long; as a result many garment features are at the wrong level of the body; (4) bust contour features are below the bust line, trouser pockets are too low for inserting hands; (5) the full crotch measurement is never long enough to accommodate the over-developed abdomen of the wearers; (6) the overall effect of using standard size garments and adapting them to a reasonable fit is obviously unsatisfactory in terms of both their aesthetic and functional characteristics; maternity garments offer a closer approximation to the size requirements and are often used by DS females. The lack of provision is disappointing particularly when block patterns, based on DS body dimensions, are available from which garments could be designed for industrial production.

Many investigators and designers of clothing for the elderly and the disabled underline the fact that in the process of clothing design they are governed by the idea that clothing, in addition to its functional characteristics, should give its user physical comfort. The disabled want to live and work among healthy people. Therefore, they have to accept the clothes they wear. Clothing should not deform the shape of the body, but just the opposite, it should cover anatomical defects.

2.3. Workspace Measurements

Essential characteristics exerting an influence on workspace shaping are functional characteristics of the upper extremities, i.e. reaches. Values observed in these characteristics are significantly lower in persons with the lower extremities dysfunction, although their upper extremities are qualified as 'efficient'. Lower values of reaches result not only from lower values of the arm and forearm length, but also from limitations in shoulder and elbow joints. In connection with the above, the disabled have difficulty in performing the movements of abduction and extension (Nowak 1989). Many authors found that in case of persons suffering from rheumatoid arthritis

workspace of the upper extremity is 7–10% lower if a shoulder joint is constrained and 25–33% lower when there is the constraint of the elbow joint movements. It is obvious that disorders of these two joints increase the limitation of the upper extremity movements, and thus the efficient workspace is significantly reduced. This is confirmed by investigations conducted by Nowak (1989) and Jarosz (1996). It should be pointed out that particular values of reaches of the disabled refer to the straight position of the body. Thus, they can be increased through the trunk movements forward and lateral.

Nowak (1989), basing on the Das and Grady's method (1983) developed a simple method of defining workspace for arms. This space was determined for disabled young people with the dysfunction of lower extremities, using the wheelchair.

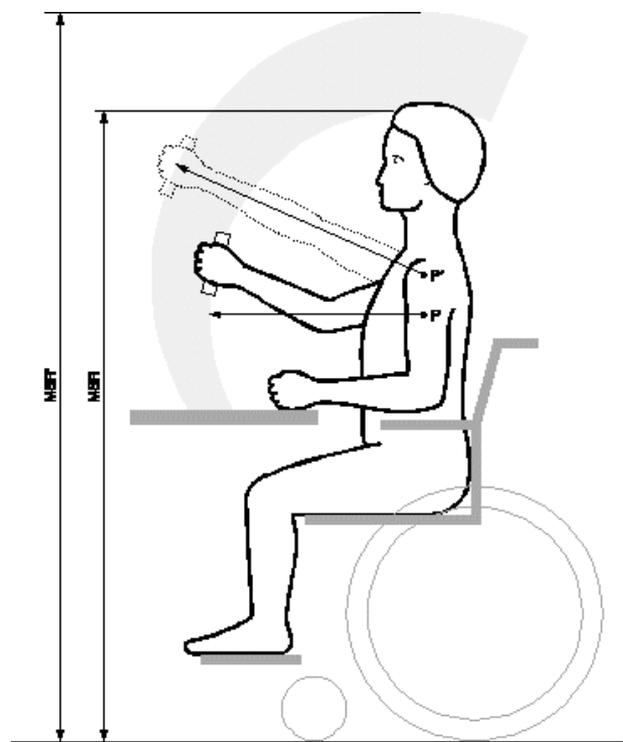
Figures 2a and b show the graphic way to determine this space in the sagittal plane (maximum sagittal reach, MSR) and in the transverse plane (maximum transverse reach, MTR). They show the difference for both reaches between disabled and healthy young people. Differences in maximum reach measurements were


Figure 2a. Maximum sagittal reach for the all-Polish population (MSR') and the disabled population (MSR).
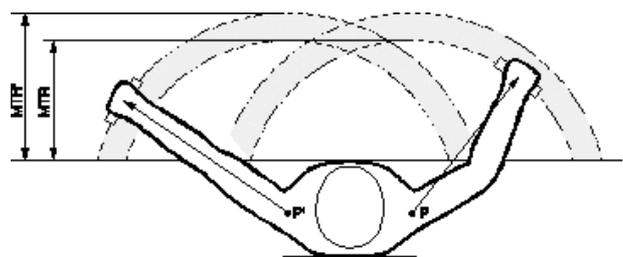

Figure 2b. Maximum transverse reach for the all-Polish population (MTR') and the disabled population (MTR).

significant and amounted for the 5th percentile to 300 mm. Results of the study were used to ergonomic analysis at school and to designing school workshops, laboratories and rehabilitation centers. This method can be recommended for workspace design for the disabled. It is simple and easy to use. Using only five anthropometric characteristics one can obtain the graphic representation of workspace of any population or an individual person.

According to Pheasant (1986), a wheelchair user (whose upper extremities are unimpaired) can reach a zone from ~600 to 1500 mm in a sideways approach, but considerably less 'head on'. It may well be that the location of fittings within this limited zone will prove entirely acceptable for the ambulant users of the building, but in case of working surface heights no such easy compromise is possible.

As the review of investigations has proved, the body structure of disabled men and women differs considerably from that of the healthy population. Anthropometry, providing data concerning the body structure of disabled people, makes it possible to adjust designs of products and spatial structures to the possibilities and predispositions of this group of users.

3. ANTHROPOMETRY FOR THE NEEDS OF REHABILITATION

Anthropometric data and methods can be used for the evaluation of the disabled children development and the rehabilitation process of the impaired organ or function.

To check and assess the process of children's physical development biological reference systems, the so-called standards, are developed. The values of standards are determined on the basis of the population investigations, embracing people qualified as 'normally' efficient. Standards are prepared with the use of mathematical and statistical methods.

For the needs of pediatrics two border regions of developmental standards are distinguished:

- The so-called narrow developmental standard, comprising values between the 25th and the 75th percentile and covering 50% of all observations.
- The so-called wide standard, comprising values between the 10th and the 90th percentile and embracing 80% of the observations (children included within these limits need observation and concern of a pediatrician).

Developmental standards can also be used to assess the physical development of disabled children. Rehabilitation activities include, among others, the monitoring of somatic development, aimed at the assessment of the child's biological potential. The development of a child depends not only on his genetic potential, but also on the environmental conditions.

As the result of disadvantageous events, which can take place during the ontogenesis, injuries inducing disturbances in the nervous system activity, growth or functioning of the whole body or its part can occur. Biological reactions of the body depend first on the releasing factors, that is, diseases and personal injuries. These factors have a direct effect on the development of the body, but reactions of the body are also indirectly influenced by other factors, such as the type of medicine and the schedule of its application, as well as undertaking of rehabilitation. Important factors, which influence the process of development, are the time of disorder occurring and the kind of factor that caused the disorder. Approaching the assessment, one should analyze and determine possible ways of the child's physical development. Developmental standards can be helpful in a single assessment of a child, as well as in continuous investigations; they can also be used in determining the differences between the development of the body structure characteristics of the children with deviation and this of the healthy children of the same age. The assessment is usually done with the use of the percentile nets representing the height and body mass characteristics. In a single assessment of the child's development one determines the position of the child on the percentile net for the above characteristics and the channel in which this point is located.

Based on the values of the two characteristics one can determine normality or disorders in the body proportions, for example, the child can have the big body mass (it is in the channel between the 97th and 90th percentile) and low height (between the 10th and the 25th percentile). If one tests the child regularly, the individual curve of their development can be obtained.

Children with motor dysfunction are shorter, they have very narrow hips and laterally flattened chest. They are similar to healthy children in that they have the same shoulder dimensions. They have a low body mass, and this deficiency increases with age.

Anthropometry can be particularly useful in diagnosing and assessing the motor efficiency of the human body. Rheumatic diseases and mechanical injuries result in pathological changes in joints, ligaments, tendons, muscles and lead to considerably restricted movement ranges. Thus, the assessment of motor efficiency of the affected joints is essential for monitoring the rehabilitation processes.

The simplest way of assessing motor efficiency is by comparing a restricted motion range of an affected joint with its initial range of motion, that is before injury or disease. Unfortunately, after injury or disease has already prevailed, it is impossible to determine what was the initial motion range in the healthy patient. It may hardly be expected that a rehabilitated patient had his initial motion ranges measured just before the injury.

Thus, motor efficiency of a rehabilitated patient can only be assessed based upon data of the healthy population. A method based upon this kind of data and allowing the quantitative assessment of rehabilitation progress was developed by Nowak (1992).

Based on the investigation of the ranges of motion of arm, leg, hand, foot and head standards for the healthy adult population were developed (Nowak 1992). These standards were developed in three motion classes: wide (W), average (A) and small (S). The maximum and the minimum movement ranges were developed for particular classes.

Three age categories are subordinated to the classes of movement shown. The youngest persons, aged 18–30, belong to class W, characterized by the maximum values. Class A includes adults aged 31–40, and class S includes the eldest subjects, aged 41–65, whose movement range in particular joints has the smallest values.

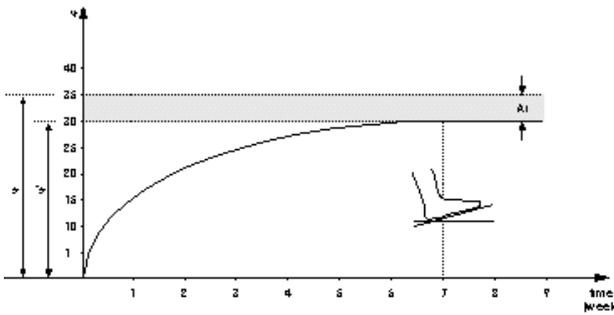
Knowing the standard value of particular age classes (f) and the values of movement ranges after the rehabilitation process (f') one can calculate the absolute decrease (Ar) and a percentage decrease (Pr) in the movement range. Using a four-grade scale one can calculate a degree of efficiency.


Figure 3. Example of the ankle joint rehabilitation.

- Very good: decrease up to 20% — efficiency from 80%.
- Good: decrease up to 40% — efficiency from 60%.
- Poor: decrease up to 60% — efficiency from 40%.
- Very poor: decrease > 60% — efficiency < 40%.

The application of the method above is presented on a graph (Figure 3).

Assessing the Risk of Upper Limb Disorders

E. N. Corlett

Institute for Occupational Ergonomics, University of Nottingham, Nottingham, NG7 2RD, UK

1. INTRODUCTION

The preliminary assessment of a problem to understand the key areas where attention should be focussed is a frequent activity for the practicing ergonomist. It is not satisfactory, at least for the client, to state a view based solely on a judgement unless, of course, the problem is clear and can be adduced from the visible evidence when demonstrated to the client by the ergonomist. More usually both ergonomist and client are more confident if some measured data can be given that can identify the dimensions of the problem, and show how the attack on the problem will counteract the effects arising from the causes identified by that evidence.

Early attempts to achieve this situation without using a full-scale research program depended on checklists. In spite of considerable refinement these have major flaws. Among them are that they analyze the problem within the structure of the list, thus perhaps missing any new features present in the problem; they can be so exhaustive that they are counter-productive because of the time involved in their use and analysis, or they just serve as a checklist to assure the user that no item has been missed.

Undoubtedly valuable as this last point is, it is not enough. A skilled ergonomist's use of feature checklists (Sullivan and Corlett 1998), supported by other appropriate methods, can reduce these problems and serve to estimate the influence of the major factors affecting a situation. This technique, first illustrated by Shackel *et al.* (1969), sets out all the influencing factors in a given situation and requires the subject to assess each on the basis of its level of adequacy or unsatisfactoriness. This results in a profile of the contribution of each factor to the overall condition of the situation under study, from which a decision can be taken on which point of inadequacy should be attacked first.

2. UPPER LIMB DISORDERS

When it comes to assessing the situation surrounding the occurrence of work-related upper limb disorders (WRULD), the investigator is faced with the same problem, where to start. The understanding of the causation of WRULD has increased considerably over recent years and it is too simple to assume that it is purely a physical cause. Nonetheless, the physical situation is frequently the major causative factor and rarely would an attack on the presence of WRULD be successful without modifications to the workplace or work routine.

Faced with the situation where the causes of WRULD in a major industry had to be tackled rapidly, and in an economic manner it was necessary to develop a systematic procedure that would cover the major known areas contributing to such problems and identify the causes which, when attacked, would most effectively minimize or eliminate them. The context of the work was the requirement of the UK Health and Safety Executive, responding to a Directive of the European Union, that companies

should be proactive in identifying unsafe situations and show that they had undertaken safety assessments should injuries have taken place. Hence, the investigation had to include the development of a company system to monitor the ongoing situation, together with appropriate training courses for company personnel.

Within this whole investigation, which covered work organization, work attitudes and company recording systems (McAtamney and Corlett 1992) a prime need was to assess the work places and activities of operators, in factory and office, so that work and engineering changes could be carried out to reduce any existing hazards. Furthermore, this had to be done using existing personnel, primarily from the company's methods engineering group.

The approach to this was to devise a rapid survey method using the concepts underlying the OWAS procedure (Karhu *et al.* 1977). In this method, for the analysis of work postures, each major body part is assessed for its displacement and a number is allocated according to the increase in the departure of that body part from a defined neutral position. From combined values for the various body parts, achieved by the use of tables, ultimate values are found that indicate the severity of the posture and the level of urgency for change.

To utilize the idea for the assessment of hazards relevant to WRULD causation it was necessary to identify from the literature those postures of the upper limbs, and the contributory postures of the whole body, which had been identified as contributing to the disorder. Diagrams were then developed, on the lines of those used for OWAS, to provide the investigator with guidance when making an assessment (Figure 1). The assessment was done for the upper limb and for the whole body postures separately, groups A and B respectively in Figure 1. The results of the estimates of postural angles, after adjustment for force exertions and muscle activities, were combined to give a final score from which the likely level of hazard and the urgency of action could be obtained. The structure of the method also permitted the user to see what must be done to reduce the hazard.

3. RULA

RULA stands for rapid upper limb assessment and it is emphasized that it is an assessment method. There will be occasions when the results merely point the user in the direction of the required changes but where further analysis is needed before a full understanding of the problem is achieved.

The first part of the procedure is to decide where, in the work activities, are the tasks that give the most extreme angles of the upper limbs and where the forces occur which may aggravate the effect of the angles. These are the points where a RULA assessment should be done. Assistance in this task may come from the use of a body part discomfort diagram (Corlett and Bishop 1976) which will demonstrate the growth of discomfort over the working period in different parts of the body, and highlight possible sources of the most serious muscle loadings.

Having extracted those tasks in which the suspect postures and loads occur, the analyst then uses the ranges of the angles shown in Figure 1 to obtain the numbers to go into the tables of part A of Figure 2. Each of the boxes for upper arm, lower arm, wrist and wrist twist are completed in part A, for the upper limb. The muscle and force scores should then be estimated, using the

	2	8	8	8	8	8	9	9	9
	3	9	9	9	9	9	9	9	9

TABLE B   Neck, Trunk, Legs Posture Score

NECK POSTURE SCORE	TRUNK POSTURE SCORE 1		2		3		4		5		6	
	LEGS 1	2	LEGS 1	2	LEGS 1	2	LEGS 1	2	LEGS 1	2	LEGS 1	2
1	1	3	2	3	3	4	5	5	6	6	7	7
2	2	3	2	3	4	5	5	5	6	7	7	7
3	3	3	3	4	4	5	5	6	6	7	7	7
4	5	5	5	6	6	7	7	7	7	7	8	8
5	7	7	7	7	7	8	8	8	8	8	8	8
6	8	8	8	8	8	8	8	9	9	9	9	9

Figure 4. Tables that combine the values identified from the observations into a single score, for later combination into an estimate of the risk. Tables A and B give scores that should be entered into the 'score C' and 'score D' boxes respectively in Figure 2.

in part B of Figure 2. Again the force and load scores should be added, taking the values from the same tables on Figure 3 as before.

The necessary data has now been collected from the workplace. The analyst should now refer to table A of Figure 4. Taking the values for upper arm, lower arm and wrist posture the table should be entered, selecting one of the two columns given under each wrist score according to the value of the wrist twist score. The value thus identified in the body of the table should be entered in the space on the score sheet of Figure 2 marked posture score A. The two values for muscle use and force can now be added to posture score A, giving score C.

Repeat this procedure for the whole body score, but using table B of Figure 4, to give posture score B. Again add this to the muscle use and force scores to arrive at the number for score D, to be entered in the appropriate space in the score sheet of Figure 2.

To combine the two scores so as to arrive at a score representing the hazard value of the posture under study, combine scores C and D by using table C of Figure 5, giving the grand score. This value, from the body of the table, represents the probable hazard, and should be assessed by the recommended action levels given below table C at the bottom of Figure 5. Note

SCORE D (NECK, TRUNK, LEGS)

	1	2	3	4	5	6	7+
1	1	2	3	3	4	5	5
2	2	2	3	4	4	5	5
3	3	3	3	4	4	5	6
4	3	3	3	4	5	6	6
5	4	4	4	5	6	7	7
6	4	4	5	6	6	7	7
7	5	5	6	6	7	7	7
8	5	5	6	7	7	7	7

SCORE C (UPPER LIMB)

<u>TABLE C</u> Grand Score Table

ACTION LEVEL 1 A score of one or two indicates that posture is acceptable if it is not maintained or repeated for long periods.

ACTION LEVEL 2 A score of three or four indicates further investigation is needed and changes may be required.

ACTION LEVEL 3 A score of five or six indicates investigation and changes are required soon.

ACTION LEVEL 4 A score of seven or more indicates investigation and changes are required immediately.

Figure 5. Here, table C gives a final score to evaluate the potentially hazardous nature of the posture under study and its muscular activity. Scores C and D from the score sheet are combined using this table and the grand score found. Action Levels listed at the foot of the figure indicate the appropriate action to take as a result of the score found from this table.

that table C of Figure 5 is graded from light to dark to give some indication of increasing hazard with the darker area

4. USING THE RESULTS

Inspection of the procedure will show that the more serious is the posture, the larger is the number that is registered in the analysis. This gives a clue to what may be done to improve the situation, since any changes which will reduce the magnitude of the number will probably result in improvements in the postures and consequent reduction of the hazard. However, a change of one or two in one box is unlikely to change the hazard score significantly, major changes to body postures and forces are usually required.

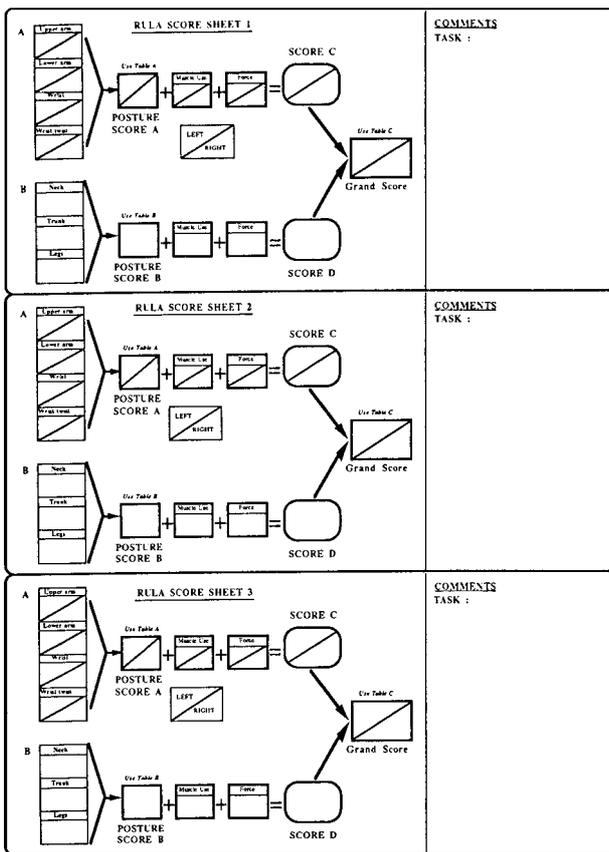
If it is considered that both the upper limbs should be analyzed, the left and right upper limbs should be scored separately, and the diagram of Figure 6 shows how an economical score page may be laid out, with the left and right scores on the same diagram. When defining the grand score, there will be two, one for each of the two upper limbs. Decisions concerning what action to take will then depend on a study of the particular situation, bringing into


Figure 6. Score sheets may be combined as shown here. Diagonal lines within the boxes for the upper limb allow both left- and right-hand values to be entered on the same figure.

consideration the actual activities being undertaken, but the same point given above will apply, lower numbers arising from changes will most probably lead to lower risks to the operator.

After changes have been made RULA can again compare results with the state before the intervention. Confirmation of the effectiveness of the intervention, at a later stage, can be obtained from reports from workers or by using other measures such as the body part discomfort diagrams mentioned earlier. The use of such measures gives an independent validation of the decisions arising from the RULA analysis and confidence in the use of the method.

When new workplaces are being proposed a mock-up of the workplace can give opportunities to simulate the work activities and RULA can be used before any expensive decisions are made. Thus, the common situation, of finding that problems exist after equipment has been installed, can be avoided.

Of course, the use of RULA does not exclude the need to

consider other basic ergonomic points. What kind of grip is being used and what reaches are needed in the workplace? Are handles too big, hard-edged, too small or in difficult places? Are the hands or fingers doing pounding, long periods of gripping, doing stretching or twisting actions? Are the work postures aggravated because the worker cannot see easily, or reach or exert the necessary forces in advantageous postures? All such points should be noted and taken into account both during the study and when the remedial actions are decided upon.

5. CONCLUSIONS

Users of RULA will find that it can be easily learned, although some revision will be valuable at intervals to ensure that all users are consistent. It can be added to a normal methods engineering tool-kit and undertaken as a regular part of the methods engineer's activities. Experience shows that most findings of existing hazards can be reduced or eliminated immediately and at no expense. Some 20% may require some delay but very few problems require major costs for material or time.

The method has been taught to workers and they have subsequently made improvements to their own workplaces. The recognition by them that this can be done, and the increased understanding it generates about the possible causations of WRULD give an extra dimension to the safety program of the company.

Finally, it should be stressed that the implementation of a comprehensive program with recording of industrial injuries and assessments of management–worker relationships can add to the better reduction of WRULD. Although biomechanical factors may be the most readily identified of all the causative factors the psychosocial problems are real, and important. Hence, the need for the comprehensive program under which RULA was developed, described in McAtamney and Corlett (1992).

Assessment of Combined Occupational Low Back Disorder Risk Factors

F. A. Fathallah

Liberty Mutual Research Center for Safety and Health, 71 Frankland Road, Hopkinton, MA 01748, USA

1. INTRODUCTION

The proper quantification of risk factors in occupational settings is an essential part of controlling occupational injuries and illnesses. Commonly, the first step in ergonomic interventions is to assess the problem at hand by quantifying the "known" potential risk factors identified through prior epidemiological evidence and/or through ergonomic guidelines and practices. For example, there is epidemiological evidence that an increase in the weight beyond a certain level in manual materials handling (MMH) jobs may lead to an increase in the likelihood of a low back-related disorder. An ergonomist evaluating an MMH job with historically high incidence of low back injuries would consider the weight of objects that workers handle as a primary factor for the observed high incidence of back injuries. In many instances this approach may prove successful. However, there are instances where simply reducing the weight of the object may not be sufficient substantially to reduce the injury experience of a given job, or may not be a feasible approach. This could be due to the fact that there are factors that may be interacting with the object weight. It is the simultaneous or combined effects of the object weight with other risk factors that may better explain the link between the job exposures and the injury outcome. When such an interactive relationship is ignored or poorly quantified, intervention measures that rely solely on reducing the weight may prove to be ineffective.

The purpose of this article is to highlight the importance of the simultaneous or combined quantification of risk factors in occupational injuries with special emphasis on occupational low back disorders (LBD) risk factors.

2. GENERAL GUIDELINES FOR QUANTIFYING COMBINED RISK FACTORS

The approach of quantifying combined risk factors attempts to answer the following two questions: Did a given risk factor simultaneously occur with other risk factors?; and What are the frequency and magnitude of these observed combined, or simultaneously occurring, risk factors? Challenges to answering these questions lie partially in the level of risk factors' measurement type. Within the context of this article, measurement type may be classified into two main classes: direct and indirect measurements. In general, direct (or semi-direct) measurement would indicate the measure of a risk factor via an instrument or an apparatus (e.g. an electrogoniometer to capture posture). On the other hand, indirect measurement usually entails observation workers and/or the use of questionnaires/self reports (e.g. asking a worker to estimate push force when pushing a cart). When assessing risk factors in occupational settings, it is desirable to obtain direct (continuous) measurement of these factors since the approach provides the most comprehensive level of information. However, several issues may limit the use of direct measurement, including cost, lack of technology and feasibility/practicality. Hence, indirect measurement has been alternatively used to overcome some of these limitations. In assessing combined risk factors, a hybrid of direct and direct measurements may be required, depending on the financial and technological limitations as well as practical issues. The following sections will discuss some examples of how hybrid (direct/indirect) measurements could be assessed within the context of combined risk factors related to occupational LBD.

3. COMBINED RISK FACTORS IN OCCUPATIONAL LOW BACK DISORDERS

LBD are considered the most prevalent musculoskeletal disorders in occupational settings. Lifting, in particular, has been implicated most often as an occupationally related low back disorder risk. A clear understanding about the underlying mechanism(s) that lead to back disorders would provide a means for minimizing LBD in industry. However, the current state of knowledge about such mechanisms is still incomplete. Thus, quantifying risk factors associated with occupationally related LBD is an important step towards a better understanding of the etiology or cause(s) of such disorders.

The spine (especially the lumbar region) undergoes complex motion patterns when performing dynamic lifting tasks in occupational settings. The sources of these complex motions can be attributed to both the inherit complexity of the spinal structure and its supporting elements (muscles, ligaments, etc.), and to task demands (weight of object, origin and destination, etc.). These complex spinal motions generate complex loading patterns experienced by the spinal elements (e.g. combined lateral shear and compressive loading). There is significant epidemiological and biomechanical evidence that implicates combined motions and loading as important risk factors for LBD. Unfortunately, few studies have quantified combined or simultaneously occurring motions and loading (in conjunction with other workplace factors) which could help in reducing the risks of occupational LBD.

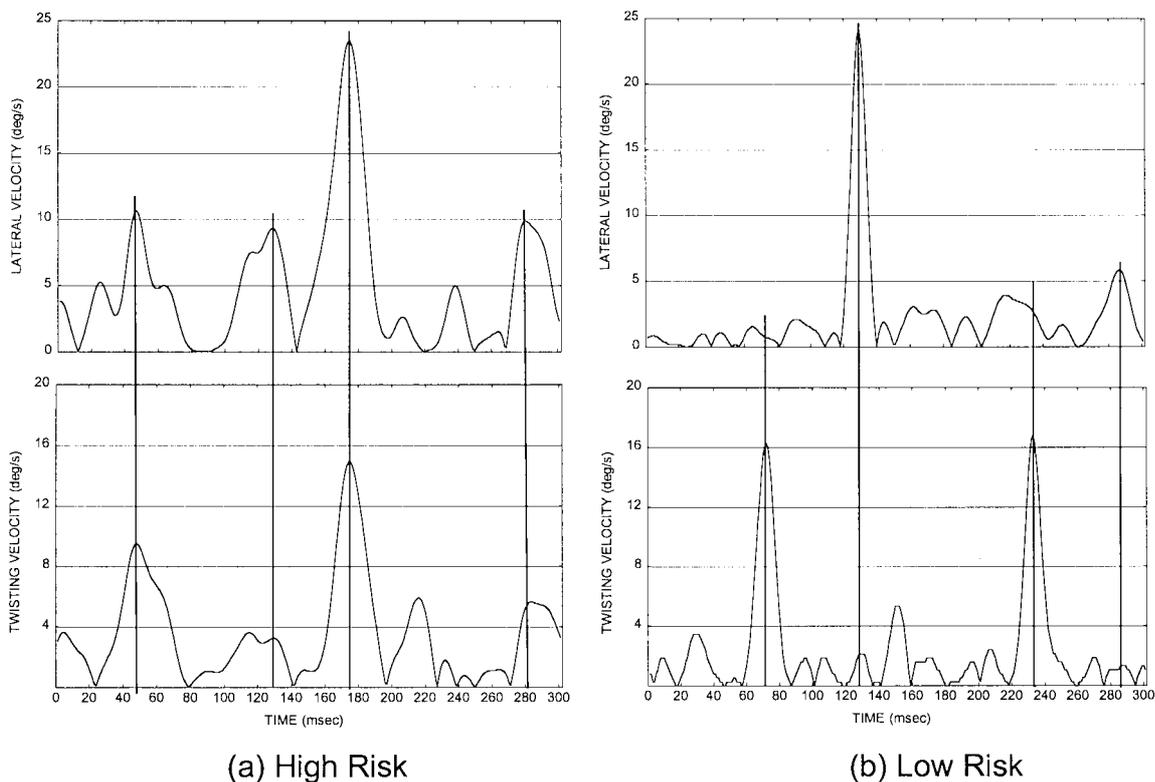
Figure 1 operationally defines combined motions and demonstrates the potential significance of these motions in identifying high-risk situations. The captured continuous motion profiles were obtained through the use of a triaxial electrogoniometer, the Lumbar Motion Monitor (LMM), developed at the Ohio State University Biodynamics Laboratory (Marras *et al.* 1992). Figure 1 shows trunk motion components obtained from actual task cycles of two typical MMH jobs; one job had no history of LBD (low risk), and the other had several (> 12 per 200 000 man-hours) recorded back disorders (high risk). For a sample pair of jobs, the figure depicts the temporal occurrence of simultaneous magnitudes of trunk lateral and twisting velocities. If one considers the statistical profiles of each motion variable as temporally *independent*, the parameters for both jobs are rather similar. For example, the magnitude of maximum lateral velocity attained for the "low-risk" job was very close to that of the "high-risk" job. However, the *timing* of the maximum lateral velocity value for the high-risk job occurred simultaneously with the maximum twisting velocity. Whereas,


Figure 1. Simultaneous lateral and twisting velocities of actual MMH high-risk (a) and low-risk (b) jobs.

for the low-risk job, the maximum lateral velocity occurred at a distinctively different instant in time than the occurrence of the maximum twisting velocity. Similar observations can be made for submaximal values under which simultaneous high magnitudes of both velocities were occurring in the high-risk job.

3.1. Assessing Combined LBD Risk Factors

The preceding example emphasized the importance of quantifying the simultaneous occurrence of high velocity magnitudes in multiple planes of the trunk. In past studies involving the LMM in industrial settings (e.g. Marras *et al.* 1993), there were five risk factors identified as being related to the risk of occupational LBD. Two of these factors are task related, namely, the load moment (load weight times distance from the base of the spine) and lifting frequency (lifts per h). The remaining three factors were summary statistics obtained from the LMM. These included maximum sagittal (forward) flexion (deg), maximum lateral (side to side) velocity (deg/s), and maximum twisting velocity (deg/s). However, the combined effect or simultaneous occurrence of these motion risk factors was not documented. The following strategy provides one possible approach to quantify such a combined effect.

For each task within an MMH job, the continuous trunk motion of at least five task cycles should be captured. Data from these representative cycles are combined into *one* task motion profile. Finally, it is necessary to determine the proportion of the total time spent in situations where the sagittal flexion is > 20° combined with lateral and twisting velocities > 10 deg/s. These cutoff values represent the corresponding average values from the "high risk" group defined in Marras *et al.* (1993). The objective

is to minimize the percent of time spent in this region of combined sagittal flexion and lateral and twisting velocities. For the entire job, data from all the captured tasks could be combined into one representative data set and the proportion of time spent in the region defined above would be recalculated.

One potential way to incorporate the two task factors with the continuous combined motion factors is to determine the proportion spent in combined motion within various combinations of load moment (or weight) and frequency (Fathallah *et al.* 1998). The levels for each factor correspond to a low ($\geq$ 25th percentile), medium (> 25th percentile and $\leq$ 75th percentile), and high levels (> 75th percentile) of either the moment or frequency. Again, the objective is to minimize the percent spent in combined motions within a given moment/frequency combination.

Another way to quantify the combined motion is to take the average of the continuous product between sagittal position, lateral velocity and twisting velocity. This combined motion variable could be again linked with the task factors in a similar fashion as described above or through logistic regression approach, as described by Fathallah *et al.* (1998), where a probability of high risk group membership could be determined.

4. SUMMARY

When dealing with occupational injuries, especially LBD, risk factors are commonly assessed in an independent fashion where there is no indication of the temporal or combined relationship(s) among these factors. This article attempted to highlight the importance of addressing the issue of combined or simultaneously occurring risk factors since it could play an important role in explaining the occurrence of occupational injuries. The main

question to raise is: does a given risk factor simultaneously occur with other identified risk factors? The article discussed two potential ways of quantifying combined occupational LBD risk factors.

Back Belts

S. M. McGill

Occupational Biomechanics and Safety Laboratories, Faculty of Applied Health Sciences, Department of Kinesiology, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1

1. INTRODUCTION

Debate over the use of abdominal belts (also known as back belts, back braces (*sic),* lumbar supports) in industrial settings continues. The premier question still remains "Should abdominal belts be prescribed to workers in industry to perform manual materials handling tasks?" Abdominal belts continue to be sold to industry in the absence of a regulatory requirement to conduct controlled clinical trials similar to that required of drugs and other medical devices. Many claims have been made as to how abdominal belts could reduce injury. For example, some have suggested that the belts remind people to lift properly. Some have suggested that belts may possibly support shear loading on the spine that results from the effect of gravity acting on the hand-held load and mass of the upper body when the trunk is flexed. Compressive loading of the lumbar spine has been suggested to be reduced through the hydraulic action of increased intra-abdominal pressure associated with belt wearing. Belts have been suspected of acting as a splint, reducing the range of motion, and thereby decreasing the risk of injury. Still other hypotheses as to how belts may affect workers include (1) providing warmth to the lumbar region, (2) enhancing proprioception via pressure to increase the perception of stability, and (3) reducing muscular fatigue.

A NIOSH (1994) publication entitled "Workplace Use of Back Belts", contained critical reviews of a substantial number of scientific reports evaluating back belts and concluded that back belts do not prevent injuries among uninjured workers nor do they consider back belts to be personal protective equipment. While this is generally consistent with our position stated in 1993, my personal position for belt prescription is somewhat more moderate.

The following sections have subdivided the scientific studies into clinical trials and those that examined biomechanical, psychophysical, and physiological changes from belt wearing. Finally, based on the evidence, guidelines are recommended for the prescription and usage of belts in industry.

2. CLINICAL/FIELD TRIALS

Many clinical/field trials that were reported in the literature were fraught with methodological problems and suffered from the absence of a matched control group, no post-trial follow-up, limited trial duration, and insufficient sample size. While the extreme difficulty in executing a clinical trial is acknowledged, only a few trials will be reviewed in this chapter.

One trial divided 81 male warehouse workers into three groups: a control group (n = 27); a group that received a half-hour training session on lifting mechanics (n = 27); and a group that received the one-hour training session and wore low-back orthoses while at work for the subsequent six months (n = 27). Instead of using more common types of abdominal belts, this research group used orthoses with hard plates that were heat molded to the low-back region of each individual. Given the concern that belt wearing was hypothesized to cause the abdominals to weaken, the abdominal flexion strength of the workers was measured both before and after the clinical trial. The control group and the training-only group showed no changes in abdominal flexor strength nor any change in lost time from work. The third group, which received both training and wore the belts, showed no changes in abdominal flexor strength or accident rate, but did show a decrease in lost time. However, it appears that the increased benefit was only to those workers who had a previous low-back injury.

In a larger field trial 642 baggage handlers who worked for a major airline were divided into 4 treatment groups; a control group (n = 248); a group that received only a belt (n = 57); a group that received only a one-hour back education session (n = 122); and a group that received both a belt and a one-hour education session (n = 57). The trial lasted eight months and the belt used was a fabric weight lifting belt, 15 cm wide posteriorly and approximately 10 cm wide anteriorly. There were no significant differences between treatment groups for total lumbar injury incident rate, lost workdays, or workers' compensation rates. While the lack of compliance by a significant number of subjects in the experimental group was cause for consideration, those who began wearing belts but discontinued their use had a higher lost-day case injury incident rate. In fact, 58% of workers belonging to the belt-wearing groups discontinued wearing belts before the end of the eight-month trial. Further, there was an increase in the number and severity of lumbar injuries following the trial of belt wearing. This general paradigm has recently been repeated in Europe where similar results were found in that no difference in injury rates were observed between the belt wearers and the non-belts. Interestingly, a small subgroup of pained workers reported less pain when wearing belts.

One large retrospective study administered questionnaires to 1,316 workers who performed lifting activities in the military. While this study relied on self-reported physical exposure and injury data over six years prior to the study, the authors did note that the costs of a back injury that occurred while wearing a belt were substantially higher than if injured otherwise.

A most recent study that has been widely reported, by Kraus and colleagues (1996), surveilled the low back injury rates of nearly 36,000 employees of the Home Depot Stores in California from 1989 to 1994. As reported, the company implemented a mandatory back belt use policy. Although the authors claim that belt wearing reduced the incidence of low back injury, analysis of the data and methodology suggests a much more cautious interpretation may be warranted. The concern is based on two issues: the lack of a robust effect and co-interventions (in addition to belts). The data suggest that the beneficial effect was limited to men with 1 to 3 years of employment (but not for longer or shorter lengths of employment) and limited to women employed 1 to 2 years - this is a very narrow band of effected employees. However, of greatest concern is the lack of scientific control over co-interventions to ferret out the true belt wearing effect - there was no comparable non-belt wearing group which is critical given that the belt wearing policy was not the sole intervention at Home Depot. For example, over the period of the study, the company increased the use of pallets and forklifts (altering physical demands), installed mats for cashiers, implemented post-accident

drug testing, and enhanced worker training. In fact, the company made a conscious attempt to enhance safety in the corporate culture. This was a large study and the authors deserve credit for the massive data reduction and logistics. However, despite the title and claims that back belts reduce low back injury, this uncontrolled study cannot answer the question about the effectiveness of belts.

In summary, difficulties in executing a clinical trial are acknowledged: the placebo effect is a concern, as it is difficult to present a true double-blind paradigm to workers since those who receive belts certainly know so; and there are logistical constraints on duration, diversity in occupations, and sample size. However, the data reported in the better-executed clinical trials cannot support the notion of universal prescription of belts to all workers involved in manual handling of materials to reduce the risk of low-back injury. There is weak evidence to suggest that those already injured may benefit from belts (or molded orthoses) with a reduced risk of injury reoccurrence. However, there does not appear to be support for uninjured workers wearing belts to reduce the risk of injury, and in fact, there appears to be an increased risk of injury during the period following a trial of belt wearing. Finally, there appears to be some evidence to suggest that cost per back injury may be higher if the worker was wearing a belt than if injured otherwise.

3. BIOMECHANICAL STUDIES

Biomechanical studies have examined changes in low back kinematics, posture and issues of specific tissue loading. Some studies have suggested that wearing an abdominal belt can increase the margin of safety during repetitive lifting but these studies generally did not measure this parameter directly. It was generally assumed that intra-abdominal pressure is a good indicator of spinal forces, which is highly contentious. Nonetheless, they assumed the higher recordings of intra-abdominal pressure (IAP) indicated an increase in low-back support which, in their view, justified the use of wearing belts. Spinal loads were not directly measured or calculated in these studies.

Several studies have questioned the hypothesized link between elevated intra-abdominal pressure and reduction in low-back load. There is no debate that IAP is increased but so too is concomitant abdominal wall activity (a build-up of intra-abdominal pressure requires additional activation of the musculature in the abdominal wall), resulting in a net increase in low-back compressive load and not a net reduction of load as had been previously thought. Therefore, it would seem erroneous to conclude that an increase in intra-abdominal pressure due to belt wearing reduces compressive load on the spine. In fact, it may have no effect or may even increase the load on the spine.

Several studies evaluating belt wearing and changes in muscle activity have noted no change in muscle activation amplitude of the low-back extensors nor in any of the abdominal muscles (rectus abdominis or obliques). Furthermore there has been no evidence for changes in muscle strength or endurance. Generally belt wearing appears to add stiffness to the torso particularly about the lateral bend and axial twist axes but not when subjects were rotated into full flexion. Thus, it would appear from these studies that abdominal belts assist to restrict the range of motion about the lateral bend and axial twist axes but do not have the same effect when the torso is forced in flexion, as in an industrial lifting situation.

Posture of the lumbar spine is an important issue in injury prevention for several reasons, but in particular the compressive strength of the lumbar spine decreases when the end range of motion in flexion is approached. Therefore, if belts restrict the end range of motion one would expect the risk of injury to be correspondingly decreased. While, the splinting and stiffening action of belts occurs about the lateral bend and axial twist axes, stiffening about the flexion-extension axes appears to be less. Some data have suggested that some belt styles are better in stiffening the torso in the manner described above, namely the taller elastic belts which span the pelvis to the rib cage. However, even in well controlled studies, it appears that belts can modulate lifting mechanics in some positive ways in some people and in negative ways in others. It remains to be seen if belts perturb the motor control system including the kinesthetic apparatus in the future.

4. PHYSIOLOGICAL STUDIES

Blood pressure and heart rate have been monitored in a few studies. Generally, both systolic and diastolic pressures can rise when wearing belts, over a wide variety of tasks from quiet sitting to heavy lifting. Given the relationship between elevated systolic blood pressure and an increased risk of stroke, some authors have concluded that individuals who may have cardiovascular system compromise are probably at greater risk when undertaking exercise while wearing back supports.

Over the past three or four years I have been asked to deliver lectures, and participate in academic debate on the back belt issue. On several occasions, occupational medicine personnel have approached me after hearing the effects of belts on blood pressure and intra-abdominal pressure, and have expressed suspicions that long term belt wearing at their particular workplace may possibly be linked with higher incidents of varicose veins in the testicles, haemorrhoid and hernia. At this point in time, there has been no scientific and systematic investigation of the validity of these claims and concerns. Rather than wait for strong scientific data to either lend support to these conditions, or dismiss them, it may be prudent to simply state concern. This will motivate studies in the future to track the incidents and prevalence of these pressure-related concerns to assess whether they are indeed linked to belt wearing.

5. PSYCHOPHYSICAL STUDIES

Studies based on the psychophysical paradigm allow workers to select weights that they can lift repeatedly using their own subjective perceptions of physical exertion. Generally, it has been observed that wearing belts increased the load that subjects were willing to lift by up to 20% in some cases. There has been some concern that wearing belts fosters an increased sense of security, which may or may not be warranted. This evidence may lend some support to this criticism of wearing abdominal belts.

6. BACK BELT PRESCRIPTION

My earlier report (McGill, 1993) presented data and evidence that neither completely supported, nor condemned, the wearing of abdominal belts for industrial workers.

Definitive laboratory studies that describe how belts affect tissue loading and physiological and biomechanical function have yet to be performed. In addition, clinical trials of sufficient scientific rigor to comprehensively evaluate the epidemiological risks and benefits from exposure to belts must be done. The challenge remains to arrive at the best strategy for wearing belts. Therefore, the available literature will be interpreted and given placement, and also combined with "common sense" to derive the most sensible position on prescription.

Given the available literature, it would appear the universal prescription of belts (i.e., providing belts to all workers in a given industrial operation) is not in the best interest of globally reducing both the risk of injury and compensation costs. Uninjured workers do not appear to enjoy any additional benefit from belt wearing and in fact may be exposing themselves to the risk of a more severe injury if they were to become injured and may have to confront the problem of weaning themselves from the belt. However, if some *individual* workers perceive a benefit from belt wearing then they may be allowed to conditionally wear a belt, but only on trial. The mandatory conditions for prescription (*for which there should be no exception*) are as follows:

(1) *Screen for cardiovascular risk*. Given the concerns regarding increased blood pressure and heart rate, and issues of liability, all those who are candidates for belt wearing should be screened for cardiovascular risk by medical personnel.

(2) *Enlist candidates in education programs*. Given the concern that belt wearing may provide a false sense of security, belt wearers must receive education on lifting mechanics (back school). All too often belts are being promoted to industry as a quick fix to the injury problem. Promotion of belts, conducted in this way, is detrimental to the goal of reducing injury as it redirects the focus from the cause of the injury. Education programs should include information on how tissues become injured, techniques to minimize musculoskeletal loading, and what to do about feelings of discomfort to avoid disabling injury.

(3) *No belts will be prescribed until a full ergonomic assessment has been conducted of the individual's job*. The ergonomic approach will examine, and attempt to correct, the cause of the musculoskeletal overload and will provide solutions to reduce the excessive loads. In this way, belts should only be used as a supplement for a few individuals while a greater plant-wide emphasis is placed on the development of a comprehensive ergonomics program.

(4) *Enlist candidates in a mandatory exercise program that must continue well after belt wearing has ceased*. Belts should not be considered for long-term use. The objective of any small-scale belt program should be to wean workers from the belts by insisting on mandatory participation in comprehensive fitness programs and education on lifting mechanics, combined with ergonomic assessment. Furthermore, it would appear wise to continue vigilance in monitoring former belt wearers (together with structured exercise) for a period of time following belt wearing, given that this period appears to be characterized by elevated risk of injury. Advice for exercise program development together with evidence to justify specific components has been provided in McGill, 1998).

1. GENERAL

Building and construction are among the oldest activities of mankind. Important improvements in history were the invention of nails and screws, the introduction of ceramic building materials and the invention of prestressed concrete. The first important step in the field of work organization was the introduction of professional tradesmen. Specialization of trades was introduced in the early middle ages. In the second half of this century many new specialists arose, mainly as jobs were split up into several new trades, which often only consist of one or just a few tasks. In most cases the only change for the construction process was the appearance of several tradesmen in a sequential order. Teamwork still does not exist in road construction and other civil work. As we look at the pace of innovation in other sectors of industry, the construction industry can be characterized as conservative. Work is still physical straining and work organization and working methods are traditional. Koningsveld and van der Molen (1997) described the history and future of ergonomics in building and construction at the First International Symposium of Ergonomics in Building and Construction, which was part of the 13th triennial congress of the IEA in Tampere in 1997. There it was concluded that radical changes in working methods, work organization, and working conditions are necessary for a secure future for companies and a safe and healthy future for the workers. Ergonomists can help in the improvement process on evidenced-based ergonomic knowledge.

In the Netherlands, the last decade has shown growing attention to working conditions. In the construction industry *physical workload* and *work stress* are the two most important causes of absenteeism and disablement from work. Two-thirds of all health complaints are caused by these two working factors.

Section 1 describes the guidelines for assessing all aspects of physical workload of construction tasks in the construction industry. The assessment of physical workload on the basis of an adequate task analysis is, especially for ergonomists, a basic step in reducing the physical workload. The selection of technical solutions is easier than the assessment of physical workload. Section 2 describes the causes and relevant measures of work stress in the construction industry. Since, by comparison with physical workload, there are no validated and reliable guidelines available for work stress in the construction industry, this section focuses on causes on the basis of qualitative assessments. The different directions for solutions are also described. These more complex organizational solutions are, in most cases, primary preventive measures for eliminating physical overload and work stress.

2. GUIDELINES ON PHYSICAL WORKLOAD

In general, more than 50% of sick leave among Dutch construction site workers is a result of musculo-skeletal complaints and disorders, mostly related to the lower back region (Arbouw 1990–5). According to Hoonakker *et al.* (1992), in a group of about one thousand Dutch construction workers, the following hazards were mentioned: repetitive work (61%), heavy materials handling (59%), poor working postures (52%) and high force exertion (49%). In addition, occupational profiles based on the results of periodic health examinations show a high percentage of complaints concerning the musculo-skeletal system (Broersen *et al.* 1992). To reduce or eliminate health risks concerning the back, neck, and limbs, one needs to know which tasks in particular overload construction workers, and so guidelines and/or standards on physical workload are essential.

2.1. Background

Most guidelines on physical workload focus on the lifting of materials. The collective labor agreements for the construction industry in the Netherlands generally specify a maximum weight of 25 kg. In countries such as Australia, the United Kingdom and the USA it is common practice not to consider the object weight as the only risk factor in quantitative guidelines. The so-called Arbouw guidelines therefore follow this multi-factor approach by also taking into consideration, for instance, handling frequencies, task duration, or whatever is known to most affect physical load in particular work activities. Quantitative guidelines concerning lifting and carrying, pushing and pulling, static postures and repetitive work have been developed at the request of the parties involved in negotiating the labor agreements. The first edition of the Arbouw guidelines was based on a literature review and discussions among experts on physical workload in 1992 and 1993. Subsequently, 10 health and safety professionals evaluated the guidelines by actually working with them. In 1996 the guidelines were slightly revised in order to include the latest information from standards, reviews, etc. The health limits in the revised version of the Arbouw guidelines are based on Waters *et al.* (1993), Mital *et al.* (1993), Kilbom (1994a, 1994b), ISO/DIS 11226 (1999), NF X 35-106 (1985), and prEN 1005-4 (1998).

2.1.1 Evaluation scheme

All construction guidelines are based upon the following evaluation scheme:

green zone: basic, i.e. non-increased health risk for ≥90% of males (P90);

yellow zone: increased health risk; action may be planned in stages; immediate action is to be preferred. For the guidelines on external force exertion, such as for lifting and carrying, pushing/pulling and repetitive arm work, this zone denotes that between 25% and 90% of males (P25–P90) are able to exert a certain force. Static postures and repetitive movements associated with an increased health risk are included in this zone in the case of a task duration of between 1 and 4 hours;

red zone: strongly increased health risk; immediate action is necessary. For the guidelines on external force exertion (refer to above) the zone denotes that ≤25% of men (P25) are able to exert a certain force. Static postures and repetitive movements associated with an increased health risk are included in this zone in the case of a task duration of >4 hours.

The boundary between the green zone and the yellow zone is called the Action Limit (AL), whereas the boundary between the yellow zone and the red zone is called the Maximum Arbouw Limit (MAL). The AL-MAL concept has been used earlier for manual lifting (i.e. in terms of AL-MPL by NIOSH 1981), while the green-yellow-red concept has also been described before, e.g. for repetitive work (e.g. Hedén *et al*. 1993). The Arbouw guidelines use both concepts as one, with their own definitions, and in a consistent way for all kinds of physical workload.

2.1.2 Criteria for AL and MAL

AL represents a health limit, i.e. it should be the ultimate goal for action programs to get working conditions into the green zone. MAL was introduced for setting priorities within these programs. Strongly increased health risks (red) are to be tackled first, followed by those conditions associated with an increased health risk (yellow). Nonetheless, it should realized that an essential element of priority setting is also to check whether possible actions are reasonably practicable in economic, organizational and technical terms.

The MALs for external force exertion (lifting and carrying, whole body pushing/pulling and repetitive arm work) are set to a level at which a majority of the workers (75%) are not even able to exert that particular force. Employers do not desire such a situation in particular as it excludes far too many workers from doing the jobs. Thus there is a strong motivation for setting in motion a process of change, in addition to the obvious reasons for reducing health risks. Currently, most Dutch construction workers are male, and so the guidelines on maximum forces are based on male population data. It would be possible to formulate guidelines for females as well.

For static postures and repetitive movements, task duration was used to set AL and MAL. Primarily, tasks lasting more than 1 hour a day are included in the risk assessment procedure, based on the results of a review by Kilbom (1994a, 1994b). For repetitive work primary attention is on movement frequencies ≥ 2 per minute. Positions of body segments and joints are evaluated based on CEN and ISO standards. Those postures and movements observed that are associated with an increased health risk are classified in the yellow zone if the task lasts between 1 and 4 hours, and classified in the red zone if it lasts more than 4 hours. As a matter of course, durations of tasks loading the same body region are to be added together. It is recommended that each evaluation should be interpreted in relation to the level of complaints for the associated body region for the group of workers involved. Although the 4-hour limit, and to a lesser extent also the 1-hour limit, are arbitrary, the authors are of the opinion that the current procedure does at least, to some extent, take the risk factor task duration into consideration.

If application of the guidelines does not disclose an increased health risk, while an increased level of physical complaints for the group of workers involved exists, further analysis is considered necessary.

2.2 Application of the Guidelines

The Arbouw guidelines are meant for health and safety professionals. The guidelines show the user the most effective way to get to the green zone, or, for the time being, to the yellow zone. That is, they provide guidance as to whether actions are best directed towards the workplace (fixtures, transport, machines, tools/objects), the work organization and/or the workers. The results of analyses regarding a certain profession or job are discussed with employers and employees in order that a decision may be taken concerning actions that are reasonably practicable. Then a straightforward document is written for employers, employees, commissioners of work, architects or manufacturers of equipment and tools. Various so-called A(rbouw) documents (state-of-the-art documents) are available, e.g. for paving, scaffolding, and installing windowpanes. More than 20 such documents are available; in addition, a solutions database contains hundreds of technical solutions for reducing physical workload.

2.3 Guidelines for Five Areas of Physical Workload, i.e. Lifting, Pushing/Pulling, Carrying, Static Load, and Repetitive Work

2.3.1 Guideline on lifting

(mainly based on NIOSH, 1991, Mital *et al*. 1993, and NF X 35-106, 1985)

The following conditions are *red*:

- weight more than 25 kg when in a standing position;
- weight more than 10 kg when in a sitting, squatting, or kneeling position;
- weight more than 17 kg when lifting one-handed;
- horizontal location (H) more than 63 cm;
- asymmetry angle (A) more than 135°;
- vertical location (V) more than 175 cm or less than 0 cm;
- frequency (F) more than 15 lifts/minute.

Tables 1 and 2 below distinguish between symmetric and

Table 1: Lifting index for *symmetric* lifting (asymmetry angle (A) 0°), vertical location (V) 175 cm, vertical travel distance (D) 175 cm, work/lifting duration 8 hours and no recovery time. The figures in brackets are for lifting under optimal symmetric conditions, i.e. vertical location (V) 75 cm, vertical travel distance (D) 0 cm, work/lifting duration 1 hour and recovery time 7 hours. A lifting index ≤1 is *green*, a lifting index 1-3 is *yellow*, and a lifting index ≥3 is *red*.

| Weight | horizontal location (H) | Frequency | | |
		5–9 lifts/ minute	1–5 lifts minute	<1 lift minute
0-5 Kg	≤25 cm	2.8 (0.5)	1.2 (0.3)	0.5 (0.3) green
	25-40 cm	4.2 (0.7)	1.9 (0.5)	0.9 (0.4)
	40-63 cm	7.1 (1.7)	2.9 (0.8)	1.4 (0.6)
5-10 Kg	≤25 cm	5.9 (0.9)	2.3 (0.6)	yellow 1.1 (0.5)
	25-40 cm	8.3 (1.5)	3.7 (1.0)	1.7 (0.8)
	40-63 cm	14.2 (2.3)	5.9 (1.5)	2.7 (1.3)
10-15 Kg	≤25 cm	8.3 (1.4)	3.5 (0.9)	1.6 (0.8)
	25-40 cm	12.5 (2.2)	5.6 (1.4)	2.6 (1.2)
	40-63 cm	21.4 (1.9)	8.8 (2.3)	4.1 (1.9) Red
15-20 Kg	≤25 cm	11.1 (1.9)	4.7 (1.2)	2.2 (1.0)
	25-40 cm	16.6 (2.9)	7.4 (1.9)	3.5 (1.6)
	40-63 cm	28.5 (4.7)	11.7 (3.0)	5.4 (2.6)
20-25 Kg	≤25 cm	13.8 (2.3)	5.8 (1.5)	2.7 (1.3)
	25-40 cm	20.8 (3.7)	9.3 (2.4)	4.3 (2.0)
	40-63 cm	35.7 (5.8)	14.7 (3.8)	6.8 (3.2)

Table 2: Lifting index for *asymmetric* lifting (asymmetric angle (A) 135°), vertical location (V) 175 cm, vertical travel distance (D) 175 cm, work/lifting duration 8 hours and no recovery time. The figures in brackets are for lifting under optimal asymmetric conditions, i.e. vertical location (V) 75 cm, vertical travel distance (D) 0 cm, work/lifting duration 1 hour and recovery time 7 hours. A lifting index ≤1 is *green*, a lifting index 1-3 is *yellow*, and a lifting index ≥3 is *red*.

Weight	horizontal location (H)	Frequency (F) 5-9 lifts/ minute	1-5 lifts minute	<1 lift minute
	≤25 cm	4.6 (0.8)	2.0 (0.5) yellow	0.9 (0.5)
				green
0-5 Kg	25-40 cm	7.1 (1.3)	3.3 (0.8)	1.5 (1.7)
	40-63 cm	12.5 (2.0)	5.0 (1.3)	2.4 (1.1)
	≤25 cm	9.1 (1.6)	4.0 (1.1)	yellow
				1.9 (0.9)
5-10 Kg	25-40 cm	14.2 (2.6)	6.7 (1.7)	3.0 (1.4)
	40-63 cm	25.0 (4.0)	10.0 (2.6)	4.8 (2.3)
	≤25 cm	13.6 (2.5)	6.0 (1.6)	2.8 (1.4)
			yellow	
10-15 Kg	25-40 cm	21.4 (3.9)	10.0 (2.5)	4.6 (2.1)
	40-63 cm	37.5 (6.0)	15.0 (4.0)	7.1 (3.4)
	≤25 cm	18.1 (3.3)	8.0 (2.1)	3.8 (1.8)
15-20 Kg	25-40 cm	29.1 (5.1)	13.3 (3.4)	6.1 (2.9)
	40-63 cm	50.0 (8.0)	20.0 (5.3)	9.5 (4.5)
	≤25 cm	22.7 (4.1)	10.0 (2.7)	4.7 (2.3)
20-25 Kg	25-40 cm	35.7 (6.4)	16.6 (4.2)	7.6 (3.6)
	40-63 cm	62.5 (10.0)	25.0 (6.6)	11.9 (5.7)

asymmetric lifting, where a lifting index ≤1 is *green*, a lifting index 1–3 is *yellow*, and a lifting index ≥3 is *red*.

In the case of limited headroom the lifting index found in one of these tables has to be multiplied by a multiplier taken from Table 3 below.

Table 3: Limited headroom multiplier

	multiplier
fully upright	1.00
95% upright	1.67
90% upright	2.50
85% upright	2.60
80% upright	2.78

An index greater than 1 means an increased health risk, concerning musculo-skeletal complaints/disorders in particular. A greater index means a higher risk. Table 4 presents the guidelines for lifting in a sitting, squatting, or kneeling position or for lifting one-handed.

Table 4: Guidelines for lifting in a sitting, squatting, or kneeling position or for lifting one-handed infrequently

	Weight green/yellow limit	yellow/red limit
sitting, squatting or kneeling	4.5 Kg	10.0 Kg
one-handed	7.5 Kg	17.0 Kg

For frequent lifting (≥2/minute) and longer durations (>1 hour/day) the guidelines on repetitive work apply.

2.3.2 Guidelines on pushing/pulling
(mainly based on Mital *et al.* 1993, and NF X 35-106, 1985)

2.3.2.1 Pushing/pulling with the whole body while walking

The tables below distinguish between pushing to set an object in motion (initial force exertion), pulling to set an object in motion (initial force exertion), and pushing or pulling to keep an object in motion (sustained force exertion). The guidelines are valid for two-handed pushing/pulling for a whole working day (8 hours), and an optimal height of the hands during force exertion (95–130 cm). A detailed analysis is necessary if slipping is likely to occur (or actually occurs) or in the case of high movement speed, awkward posture, asymmetric force exertion (one-handed, course changes), or a bad view of the surroundings (surface, obstacles, etceteras). All cells of the tables contain a pushing/pulling-index, besides the green, yellow, or red evaluation result. An index greater than 1 means an increased health risk, concerning musculoskeletal complaints/disorders in particular. A greater index means a higher risk.

2.3.2.2 Pushing/pulling with the whole body while staying on the spot

The guidelines for setting an object in motion (refer to tables 1 and 2 in section 2) also apply to pushing/pulling with the whole body while staying on the spot.

2.3.2.3 Pushing/pulling with the upper limbs

The guidelines below are valid if the postures of the trunk and the upper limbs are evaluated as green (refer to the guideline on repetitive work), if the hands do not reach further forwards than three-quarters of the maximum reach distance (trunk upright), and if the hands are between pelvis height and shoulder height.

Table 5: Pushing to set an object in motion (initial force exertion)

force	frequency 2.5x/minute– 1x/minute	1x/minute– minutes	1x/5 minutes– 1x/8 hours	≤1x/8 hours
0-25 kgf	1.0 green	1.0 green	0.9 green	0.8 green
25-30 kgf*	1.2 yellow	1.2 yellow	1.1 yellow	1.0 green
30-45 kgf*	1.8 yellow	1.7 yellow	1.6 yellow	1.5 yellow
45-50 kgf*	2.0 red	1.9 yellow	1.8 yellow	1.7 yellow
50-65 kgf*	2.6 red	2.5 red	2.3 red	2.2 yellow
>65 kgf*	>2.6 red	>2.5 red	>2.3 red	>2.2 red

Note: * = usually not possible because slipping is likely to occur

Table 6: Pulling to set an object in motion (initial force exertion)

force	frequency 2.5x/minute– 1x/minute	1x/minute– 1x/5 minutes	1x/5 minutes– 1x/8 hours	≤1x/8 hours
0-25 kgf	1.0 green	1.0 green	1.0 green	1.0 green
20-40 kgf*	2.0 yellow	2.0 yellow	2.0 yellow	2.0 yellow
40-45 kgf*	2.3 red	2.3 red	2.3 yellow	2.3 yellow
45-50 kgf*	2.5 red	2.5 red	2.5 red	2.5 yellow
>50 kgf*	>2.5 red	>2.5 red	>2.5 red	>2.5 red

Note: * = usually not possible because slipping is likely to occur.

Table 7: Pushing or pulling to keep an object in motion (sustained force exertion)

force	distance	frequency 2.5/minute–1/minute	1/minute–minutes	1/5minute–hours	≤1/8 hours
0-5 kgf	2–15 m	0.8 green	0.4 green	0.4 green	0.3 green
	15–30 m	-	0.8 green	0.4 green	0.3 green
	30–60 m	-	-	0.6 green	0.4 green
5–10 kgf	2–15 m	1.5 yello	0.9 green	0.7 green	0.6 green
	15–30 m	-	1.5 yellow	0.8 green	0.6 green
	30–60 m	-	-	1.2 yellow	0.9 green
10–15 kgf	2–15 m	2.3 red	1.3 yellow	1.1 yellow	0.9 green
	15–30 m	-	2.3 red	1.3 yellow	0.9 green
	30–60 m	-	-	1.8 yellow	1.3 yellow
15–20 kgf	2–15 m	3.1 red	1.7 red	1.5 yellow	1.2 yellow
	15–30 m	-	3.1 red	1.7 yellow	1.2 yellow
	30–60 m	-	-	2.3 red	1.7 yellow
20–25 kgf*	2–15 m	3.8 red	2.2 red	1.9 yellow	1.5 yellow
	15–30 m	-	3.8 red	2.1 yellow	1.5 yellow
	30–60 m	-	-	2.9 red	2.2 red
25–30 kgf*	2–15 m	4.6 red	2.6 red	2.2 red	1.8 yellow
	15–30 m	-	4.6 red	2.5 red	1.8 yellow
	30–60 m	-	-	3.5 red	2.6 red
>30 kgf*	2–15 m	>4.6 red	>2.6 red	>2.2 red	>1.8 red
	15–30 m	-	>4.6 red	>2.5 red	>1.8 red
	30–60 m	-	-	>3.5 red	>2.6 red

Notes: * = usually not possible because slipping is likely to occur.

- = combination of frequency and distance is not realistic.

2.3.3 Guidelines on carrying

The following condition is *red*:

- weight more than 25 kg;
- weight more than 10.5 kg for infrequent one-handed carrying.

The guidelines below are valid for two-handed carrying for a whole working day (8 hours), and the hands at an optimal height (knuckle height, arms hanging down). All cells of the tables contain a carrying-index, besides the evaluation result green, yellow, or red. An index greater than 1 means an increased health risk, concerning musculoskeletal complaints/disorders in particular. A greater index means a higher risk

2.3.4 Guidelines on static postures

It is recommended to use the guidelines below to begin with on tasks lasting longer than 1 hour (continuous or a total of distinct periods) per working day (note: shorter task durations cannot be considered safe in all cases). In the case that two or

Table 8: Guidelines for infrequent pushing/pulling with the upper limbs

	force green/yellow limit	yellow/red limit
A	7.5 kgf	17.0 kgf
B	19.0 kgf	43.0 kgf

Notes: A and B refer to the various types of force exertion distinguished in the guideline on repetitive work.

For frequent pushing/pulling (≥2/minute) and longer durations (>1 hour/day) the guidelines on repetitive work apply.

Table 9: Guidelines on carrying (mainly based on Mital *et al.* 1993)

weight	distance	frequency 3/minute–1/minute	1/minute–1/5 minutes	1/5 minutes–1/8 hour	≤1/8 hour
0–10 kg	≤2.0 m	0.5 green	0.5 green	0.4 green	0.4 green
	2–8.5 m	0.8 green	0.6 green	0.5 green	0.4 green
10–15 kg	≤2.0 m	0.8 green	0.7 green	0.7 green	0.6 green
	2–8.5 m	1.2 yellow	0.9 green	0.8 green	0.6 green
15–20 kg	≤2.0 m	1.1 yellow	1.0 green	0.9 green	0.8 green
	2–8.5 m	1.5 yellow	1.2 yellow	1.0 green	0.8 green
20–25 kg	≤2.0 m	1.3 yellow	1.2 yellow	1.1 yellow	1.0 green
	2–8.5 m	1.9 red	1.5 yellow	1.3 yellow	1.0 green
>25 kg	≤2.0 m	>1.3 red	>1.2 red	>1.1 red	>1.0 red
	2–8.5 m	>1.9 red	>1.5 red	>1.3 red	>1.0 red

Table 10: Guideline for infrequent one-handed carrying (standing or walking up to 90 meters)

	weight green/yellow limit	yellow/red limit
infrequent one-handed carrying (standing or walking)	6 kg	10.5 kg

more tasks load the same body region (through static postures and/or repetitive work), the durations of these tasks are to be taken together. It is recommended to interpret the results of guideline application in relation to the complaints and disorders of the particular body region found for the group of employees involved. An evaluation result yellow/red becomes yellow in the case of a task duration of between 1 and 4 hours, whereas it becomes red in the case of a task duration >4 hours.

The guidelines on low back, shoulder and shoulder girdle as well as on neck and upper back are based on a description of the actual posture (observed/measured) with respect to a reference posture, i.e. a sitting or standing posture with a non-rotated upright trunk, a non-kyphotic lumbar spine posture, and the arms hanging freely, while looking straight ahead along the horizontal. Guidelines on sitting also include raised sitting.

- Asymmetric trunk posture (axial rotation and/or lateral flexion): *yellow/red*
- For sitting: kyphotic lumbar spine posture (valid for: trunk inclination between 0° and 20°): *yellow/red*

Table 11: Guidelines on static postures (mainly based on ISO/DIS 11226, 1999): *low back*

trunk inclination <0°	0–20°	20–60°	>60°
yellow/red**	green	green/yellow/red*	yellow/red

Table 12: Guidelines on static postures (mainly based on ISO/DIS 11226, 1999): *shoulder and shoulder girdle*

upper arm elevation		
0–20°	**20–60°**	**>60°**
green	green/yellow/red*	yellow/red

- • * = with full trunk support: green; without full trunk support: consult an expert for evaluating holding time — recovery time regimes (see ISO/DIS 11226); if that is possible, the evaluation result is *yellow* in the case of a task duration of between 1 and 4 hours, whereas it is red in the case of a task duration > 4 hours (expert guess of the authors); if two or more tasks load the same body region, the durations of these tasks are to be taken.
- • ** = with full trunk support: *green*
- • Upper arm retroflexion (i.e. elbow behind the trunk when viewed from the side of the trunk), upper arm adduction (i.e. elbow not visible when viewed from behind the trunk), or extreme upper arm external rotation: *yellow/red*
- • Raised shoulder: *yellow/red*
- • = with full arm support: green; without full arm support: consult an expert for evaluating holding time – recovery time regimes (see ISO/DIS 11226); if that is not possible, the evaluation result is *yellow* in the case of a task duration of between 1 and 4 hours, whereas it is red in the case of a task duration >4 hours (expert guess of the authors); if two or more tasks load the same body region, the durations of these tasks are to be taken together.

2.3.4.1 Neck and upper back

Green:
- head inclination 0°–25° and neck flexion (i.e. head inclination minus trunk inclination) 0°–25°.

Green/yellow/red:

- head inclination 25°–85°:
- with full trunk support, consult an expert for evaluating holding time — recovery time regimes (see ISO/DIS 11226); if that is not possible, the evaluation result is yellow in the case of a task duration of between 1 and 4 hours, whereas it is red in the case of a task duration >4 hours (expert guess of the authors); if two or more tasks load the same body region, the durations of these tasks are to be taken together;
- without full trunk support, the holding time for trunk inclination is critical, and should be evaluated.

Yellow/red:

- head inclination <0°:
- changing to *green* in the case of full head support;
- head inclination >85°;
- neck flexion (head inclination minus trunk inclination) <0° (i.e. neck extension) or >25°;
- asymmetric neck posture, i.e. axial rotation and/or lateral flexion of the head versus the upper part of the trunk.

2.3.4.2 Other joints

The following conditions are *yellow/red*:

- extreme joint positions;
- for a kneeling position: no adequate knee protection;
- for standing (except when using a buttock rest): flexed knee;
- for sitting: knee angle >135° (180° = the upper leg in line with the lower leg), unless the trunk is inclined backwards and fully supported (as in car driving);
- for sitting: knee angle <90° (1) (180° = the upper leg in line with the lower leg).

2.3.4.3 Pedal operation

The following conditions are *yellow/red*:
- standing;
- sitting, leg-actuated;
- sitting, ankle-actuated, force exertion >5.5 kgf;
- sitting, ankle-actuated, pedal operating already by merely supporting foot weight.

2.3.4.4 General

The following conditions are *yellow*:
- standing continuously ≥1 hour/day;
- standing for a total of distinct periods ≥4 hours/day.

2.3.5 Guidelines on repetitive work

It is recommended to use the guidelines below to be begin with on tasks lasting longer than 1 hour (continuous or a total of distinct periods) per working day (note: shorter task durations cannot be considered safe in all cases). If two or more tasks load the same body region (through static postures and/or repetitive work), the durations of these tasks are to be taken together. It is recommended to interpret the results of guideline application in relation to the complaints and disorders of the particular body region found for the group of employees involved. An evaluation result yellow/red becomes yellow in the case of a task duration of between 1 and 4 hours, whereas it becomes red in the case of a task duration >4 hours.

Table 13: Guidelines on repetitive work (mainly based on NF X 35-106, 1985, and prEN 1005-4, 1998): *low back*

trunk inclination		
<0°	**0–20°**	**>20°**
yellow/red[1]	green	yellow/red[1]

Asymmetric trunk posture (axial rotation and/or lateral flexion): *yellow/red*

Note: 1 An increased health risk is present if ≥2/minute an evaluation result yellow/red is found (N.B. lower frequencies cannot be considered safe in all cases).

Table 14: Guidelines on repetitive work (mainly based on NF X 35-106, 1985, and prEN 1005-4, 1998): *shoulder and shoulder girdle*

upper arm elevation		
0–20°	**20–60°**	**>60°**
green	green	yellow/red 1

Upper arm retroflexion (i.e. elbow behind the trunk when viewed from the side of the trunk), upper arm adduction (i.e. elbow not visible when viewed from behind the trunk), or extreme upper arm external rotation: *yellow/red* 1

Raised shoulder: *yellow/red* 1

neck flexion (i.e. head inclination minus trunk inclination) 0°–25°.

Note: 1 An increased health risk is present if ≥2/minute an evaluation result yellow/red is found (N.B. lower frequencies cannot be considered safe in all cases).

2.3.5.1 Neck and upper back

Green:
- neck flexion (i.e. head inclination minus trunk inclination) 0°–25°.

Yellow/red:
- neck flexion (head inclination minus trunk inclination) <0° (i.e. neck extension) or >25° (1);
- asymmetric neck posture, i.e. lateral flexion and/or extreme axial rotation of the head versus the upper part of the trunk (1).
1 An increased health risk is present if ≥2/minute an evaluation result yellow/red is found (N.B. lower frequencies cannot be considered safe in all cases).

2.3.5.2 Other joints

The following conditions are *yellow/red*:
- extreme joint positions (1);
- for a kneeling position: no adequate knee protection;
- for standing (except when using a buttock rest): flexed knee (1);
- for sitting: knee angle >135° (1) (180° = the upper leg in line with the lower leg), unless the trunk is inclined backwards and fully supported;
- for sitting: knee angle <90° (1) (180° = the upper leg in line with the lower leg).
1 An increased health risk is present if ≥2/minute an evaluation result yellow/red is found (note: lower frequencies cannot be considered safe in all cases).

2.3.5.3 Pedal operation

The following conditions are *yellow/red*:
- standing;
- sitting, leg-actuated.

2.3.5.4 Force exertion

1 General force limits, i.e. one-handed or two-handed, sitting or standing, almost all directions.

Table 15: General force limits

| A | force | |
frequency	green/yellow limit	yellow/red limit
≥2 and <3/minute	3.0 kgf	6.5 kgf
≥3 and <4/minute	2.0 kgf	4.0 kgf
≥4 and <5/minute	1.5 kgf	3.0 kgf
≥5/minute	1.0 kgf	2.5 kgf

1 Specific force limits: fore/aft direction; upward/downward direction; force limits are also valid for combined fore/aft and upward/downward directions. For one-handed pinching and pedal operation: see NF X 35-106.

Table 16: Specific force limits

| B | force | |
frequency	green/yellow limit	yellow/red limit
≥2 and <3/minute	8.0 kgf	18.0 kgf
≥3 and <4/minute	5.0 kgf	11.5 kgf
≥4 and <5/minute	3.0 kgf	7.0 kgf
≥5/minute	2.0 kgf	4.5 kgf

3. WORK STRESS IN THE CONSTRUCTION INDUSTRY

In the Dutch construction industry over half of the employees experience considerable pressure of work, and they think that measures should be taken either to prevent high work pressure or reduce it. Employers also admit that work pressure is sometimes high. One quarter of the employers taking part in a Dutch Monitoring Study on Stress and Physical Workload admitted that work pressure is indeed high. However, only 3% of the employers say that this causes serious problems.

3.1 Causes and Consequences of Work Pressure in the Construction Industry

The ultimate cause of high work pressure in the construction industry lies above all in the (economic) demands which are imposed on (the employees of) construction firms. The current system of public tenders (contracts) and the intense competition among construction firms compels such firms to try to achieve maximum production at minimum cost. This means being as efficient and flexible as possible and adapting quickly to the constantly changing demands.

This has several consequences for the organization (of the work). The activities are split up into parts which are small and standardized (Taylorism). This marked division of labor results in adjustment problems; creates organization of work which is more prone to disruption (interruptions) and increased control problems. It is the lack of decision latitude, in particular, that creates a high work pressure. The causes and consequences of work pressure are illustrated in Figure 1.

3.1.1 The division of labor

The division of labor refers to the way work is organized.

Figure 1: The causes and consequences of work pressure

Minimum division of labor means that successive items of work are performed as part of one job or in one department. Maximum division of labor means that successive items of work are divided between different jobs or departments. Division of labor in the construction industry occurs at two levels:

3.1.1.1 The organization of the overall construction process

The activities in the building process are distributed between different parties. The building process starts with the customer (client). The client, nowadays, has a choice between various forms of real estate development. Traditionally, the design has been produced by the architect. Work preparation is done by the contractor. The suppliers take care of the materials and the subcontractors carry out the work.

3.1.1.2 The organization of construction companies

The organization of building companies is based upon division of labor. Different activities make up different functions. Before a construction worker starts his activities, the cost accountant, the planner, the project manager, the foreman, and the person responsible for the working conditions have already been involved in the process. Moreover, there are many construction companies which specialize in specific activities of the building process. Examples of these include companies specializing in foundation work, concrete formwork, bricklaying, carpentry, painting, roof laying, plastering, ceiling assembly, glazing etc.

A characteristic feature of the division of labor is the interdependence between the different parties involved. The later a party is involved in the process, the stronger its dependency on other parties and the smaller its influence on decision-making.

Maximum division of labor entails certain risks (see figure 1): standardization problems in the building process, adjustment problems, greater risk of disruption, low commitment of employees and a lack of decision latitude (autonomy). These effects reinforce one other and are important causes of work pressure.

The large number of parties involved in the building process demands standardization of the work process and rigid planning. Consequently, problems are often identified at the last moment and solved on an ad hoc basis. Little attention is paid to the solution of structural problems because the building process is characterized by unique collaborations: another characteristic of the construction industry is the project-based organization of work. The construction of each building is a project involving different parties. Because of this variety of buildings and parties involved, each project is unique and requires specific collaborations and organizations.

The complex organization of the building process demands good coordination between the parties involved. Coordination problems are very common. For example, in the process design phase decisions may be made which result in a working method that is difficult or presents unusual or even increased risks to the firm which has to carry it out.

Another consequence of the high division of labor is that the building process is very sensitive to disturbances. An example of such a disturbance is the failure to deliver materials on time. Employees have to wait unnecessarily in order to continue working. As a result, the sub-contractors at the end of the building process often have to work under high work pressure. Indeed, they are the most likely to have to cope with the negative consequences of high work pressure.

Because many parties are involved in the building process, it is difficult for people to feel responsible or be committed to the work as a whole. Construction companies and individual employees have a tendency to concentrate solely on their own interests. As a result there is little feedback.

The high division of labor means that employees have little decision latitude. Decision latitude is the opportunity for employees to solve problems themselves with the aid of their colleagues or in consultation with others. In the construction industry, employees are dependent on the decisions of their managers, who in turn are dependent on the choices made earlier in the building process.

The consequences of the high division of labor are interdependent and amplify one another. The splitting up of the activities makes the companies involved in the building process more and more dependent on each other. As a consequence, the building process is very prone to disruption. And these disruptions (for example; the late delivery of materials, the failure of subcontractors to show up) often interfere with the planning.

Apart from that, the division of labor considerably reduces the decision-making latitude. To increase the latter, excellent co-ordination is required between the parties involved in the building process. This is often difficult. The need to increase the decision latitude often requires standardization of the work processes. This higher standardization often means greater division of labor. And thus the wheel comes full circle.

3.1.2 New technologies

The process described above may be intensified by the development of new technologies. The development of such new technologies means that a great deal of work is being transferred from the construction site to factories and suppliers. Hard physical work is often being replaced by mechanization (for example, the more frequent use of heavy machines). The development of new technologies also affects the division of labor and increases work pressure. Because machines take over much of the work, only minor activities are left to be carried out by human beings. These minor activities are often short-term and monotonous. As a result of the introduction of new technologies, employees may be subjected to unilateral and sustained stresses both mental and physical.

3.1.3 Consequences for employees

For the (individual) employee this can upset the balance between the workload and his capacity to cope with it. Research has shown that several important factors play a role in this process (e.g. Warr, 1990). The figures reported here for the building industry are taken from research performed by the Economisch Instituut voor de Bouwnijverheid, the EIB (the Netherlands Economic Institute for the Construction industry) and from the Arbouw database which contains data for over 60 000 construction workers who took part in a routine company health survey (PBGO).

3.1.3.1 Overload

We speak of overload when the activities carried out by an employee overtax his capacities to cope with them. Overload

often occurs when there is not enough time to recover from a very demanding situation. There is a difference between overload due to *the amount of work* and overload caused by *the nature of the work*. In the first case, the work pressure is too high, simply because there is too much work to be done, or because the work tempo is too high (quantitative workload). In the second case the work is too complex or too difficult. This is known as the qualitative workload.

3.1.3.2 Underload

It is well known that overload can cause stress. But the reverse situation, underload, can also be a cause of stress. Stress can arise because an employee has too little to do, or because the work is too simple, too monotonous or is not demanding enough. This can be "soul-destroying".

Overload and underload can increase stress. In both cases the balance between workload and work capacity is disturbed.

3.1.3.3 Taxing physical working conditions

Overload can also occur as a result of very taxing physical working conditions. Examples include noise, vibrations, toxic substances, temperature and humidity. This not only has physical effects but also increases the mental stresses. A very specific demanding situation — especially in the construction industry — is working in hazardous situations.

3.1.3.4 Role ambiguity and role conflict

When it is not absolutely clear what one's responsibilities are, or what one is expected to do, we talk about role ambiguity. When there is a lack of specific procedures, it is impossible to know whether one has done a good or a bad job. This insecurity about the results of the work can cause a lot of stress; no one knows down to the very smallest details what is expected of them, and this insecurity sometimes becomes too great. It can result in job dissatisfaction; people feel redundant and experience a lack of self-confidence. Sometimes jobs are clearly described (on paper), but then bear little resemblance to the work that has actually to be carried out. Also, work in which there are a lot of conflicting demands can be harmful to well being. It creates a situation full of conflict and insecurity (what am I supposed to do?) and this in its turn can be a cause of stress.

3.1.3.5 Excessive responsibility

Excessive responsibility for other people's health, safety and job security can also be a cause of stress.

The same goes for excessive responsibility for (valuable) materials.

3.1.3.6 Insufficient opportunities for consultation and participation

Stress can also be caused when there are too few opportunities to participate or make decisions concerning the job that has to be done. The employee has little influence on the activities that have to be carried out and is at the mercy of others. A regular discussion of progress can be one way to exercise an influence on the decisions that are being made.

3.1.3.7 Insufficient social support

Lack of social support from colleagues can also be a cause of stress. Two sorts of social support are important: instrumental

and emotional support. Instrumental support means that colleagues or the management can actually give help to solve problems. This can be advice on how to solve the problem, but may also be an offer of practical assistance. Emotional support is also very important. This implies respect and consideration for one another, commitment, understanding and sympathy. It creates a situation of security and trust.

When people get enough social support, they are better equipped to deal with other stress factors. An important aspect of social support is the person who gives it. One's immediate boss and colleagues are important "supporters".

Table 17: Percentage prevalences of stress factors in construction employees

Source:: EIB: 1995, PBGO: 1993–1994, Arbouw

Overload	
– tasks are complex	18%
– much knowledge of materials required	67%
– work requires a lot of improvisation	54%
– much professional knowledge required	87%
– many professional skills required	90%
– work is mentally demanding	25%
– high work tempo	55%
Underload	
– work lacks interest most of the time	21%
– work too simple	10%
– work not challenging enough	6%
Taxing physical working conditions	
– toxic substances	17%
– climate	26%
– safety problems at work	16%
– physical demands	32%
– noise	37%
– vibrations	19%
Role ambiguity and role conflict	
– does other work than his 'own job'	40%
– unclear responsibilities	4%
– doesn't know what others expect	8%
Much responsibility	
– responsible work	78%
Lack of consultation and participation	
– insufficient consultation	10%
– insufficient participation	15%
Lack of social support	
– bad day-to-day management	19%
– bad social climate	9%
Unresolved conflicts and bad social climate	
– annoyed by others	20%
– annoying absence of others	11%
– tension on the work site	20%
Job insecurity	
– insufficient security	19%
– unfavourable changes	10%
– unfavourable prospects	13%
Lack of decision latitude	
– insufficient opportunities to take decisions	41%

3.1.3.8 Unresolved conflicts and bad work relations

If one lacks social support and is forced to work in a situation full of irritations and conflicts, this can also cause stress.

3.1.3.9 Job insecurity

Because of the project-based organization of work one of the factors which has always played an important role in the construction industry, and especially now in these days of mergers, reorganizations and cutbacks, is insecurity about the future. This relates mostly to the availability of work and career opportunities. The threat of losing your job or the insecurity of not knowing whether there will be work after the latest project creates a lack of job security. This can have serious social and financial consequences. Research has shown that job insecurity is as bad as actually being sacked (Dekker and Schaufeli 1995).

3.1.3.10 Lack of decision latitude

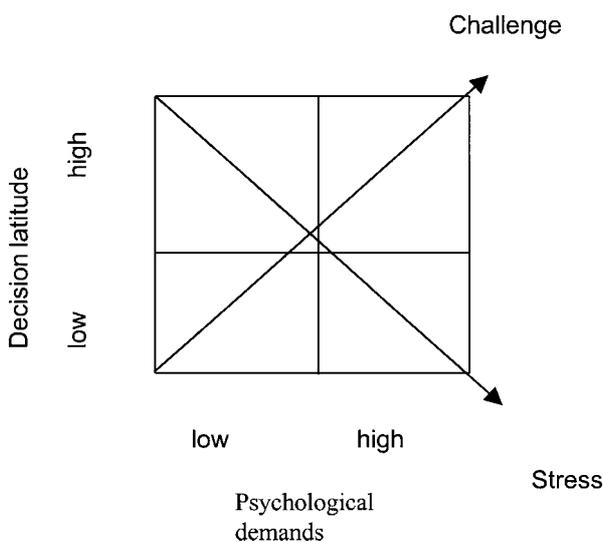
When someone finds it impossible to exert an influence on their work, for example affect the work tempo, take breaks or organize the work in the way he (or she) prefers, we talk of the lack of decision latitude or autonomy. Lack of control over the work situation can also be a serious cause of stress.

The reason is that the employee is not able to intervene to adapt the work to his own situation (e.g. to work more slowly when he is tired, work faster when he is fit).

The construction industry has conducted research into these aspects. For example, the research carried out annually by the EIB and by Arbouw is looking at these aspects. Table 17 below shows some of the results.

Research has shown (e.g. Karasek 1979; Karasek and Theorell 1990) that the combination of (high) demands and (low) decision latitude, in particular, is important in preventing work pressure and the strains resulting from it. Figure 2 below illustrates the model:

Explanation of the model:

1. There are low (psychological) job demands, the job is not too difficult and employees have little decision latitude. It is a passive job.


2. Despite the low job demands, employees have a lot of decision latitude. These are jobs with a risk of underload.

3. Job demands are high, but the job contains a lot of autonomy (decision latitude). This is an active job, with a lot of challenges, in which the employee can grow and develop his skills.

4. Much is asked of the employees: job demands are high. However, employees have little decision latitude. They are bound by procedures and obligations. In this situation there is a high risk of stress.

The above factors, which create excessively high work pressure and resultant stresses, are caused by the organization of work. The stresses can, in some cases, create health risks.

3.1.4 Consequences of high work pressure in the construction industry

As Figure 1 shows, high work pressure can result in stress. This stress can lead to various complaints: complaints of a behavioral, psychological and physical nature. Examples of behavioral complaints include: sleeping problems, reduced appetite, greater use of medication, increased smoking, drinking more alcohol, increased restlessness and avoidance behavior. This can, in certain cases, result in (higher) absenteeism and (higher) turnover. At the psychological level, high work pressure can result in the employees feeling stressed, tense, anxious and insecure, having concentration and decision-making problems, and creating depression. Physically, high work pressure can result in complaints of fatigue, nausea and dizziness, chest and stomach pains, headaches, painful muscles, especially in the neck and shoulders.

Everyone can occasionally suffer from the above complaints. And they don't have to be a problem. They start becoming a problem when they occur too often, persist or get worse and worse. They then can become a serious health risk. It is important, of course, to prevent this from happening.

Complaints like these are also occurring more and more frequently in the construction industry. They are one of the biggest reasons for sickness and absenteeism of foremen in the construction industry. But they are also becoming more and more of a problem for the other employees on the construction site. Analyses of periodic health examinations show that psychological problems have occurred more often in the last few years, and that they are the fastest growing reason for absenteeism and incapacity for work.

When stress complaints occur too often, it is important to ascertain whether employees are suffering from high work pressure.

Figure 2: Model illustrating some pyschological demands of work

Table 18: Measures to reduce high work pressure

Measures	Affect created	Prevention	Implementation
Adjustment measures	Little	Low	Easy, quick
Improvement measures	Medium	Medium	Relatively easy
Redesing measures	Large	High	Difficult, time-consuming

3.2. Measures to Reduce High Work Pressure

In this section we outline measures which can be taken to reduce high work pressure in the construction industry. There are three sorts of measures (see Table 18): adjustment measures, improvement measures and redesign measures. They differ from each other in a) the extent to which they affect the organization of work and the employees involved; b) the effectiveness (the degree of prevention) and c) the speed and complexity of implementation.

The different measures all have the same aim: to create an optimum match between the work demands and the ability to cope with these demands. The measures are characterized by several critical success factors. Practice in different branches of industry has shown that every measure should contain the following elements. The elements are also embodied in the Netherlands Working Conditions legislation.

- Clarity and identification of tasks
- An employer must be properly informed about the demands asked of him and about the purpose and content of the work.
- Cooperation and support
- Employees must be able to cooperate with and support one another.
- Autonomy
- Employees must have the opportunity to solve problems independently, without being dependent on others.
- Feedback
- It is very important to give employees feedback on the quality of work and the way the work is carried out. Feedback provides opportunities to learn. Learning has a positive influence on the motivation and involvement of employees. Apart from that, it makes optimum use of the potential of an organization.

The following sections explain the different measures in more detail. Examples from practice are used to illustrate how the various measures can be implemented in the building industry. The examples are taken from "Welfare measures in the building industry: analysis and discussion" (Manshanden 1996). The section concludes with the result of the scientific research into the implementation of the measures.

3.2.1 Adjustment measures

These measures are important, but usually have a low prevention value. The aim of the measures is to create "realistic" work demands. The organization of work is not changed, but employees are better equipped to cope with work demands. The probability of work pressure is reduced.

The measures can be taken relatively quickly and easily. Foremen can carry out these measures independently from the rest of the organization. It is important, in the preparation of the measures, to involve as many employees as possible. Some examples are given below.

Clarity about goals and results of work:
- clear two-way communication: employees can indicate what their limits are;
- realistic scheduling and reasonable standards relating to quality and quantity;
- good training for inexperienced employees;
- clear orders that can be understood by everyone involved.

Materials:
- delivery of materials on time
- clear agreements on when and what materials are needed;
- a reserve stock that can be used as an extra buffer to keep employees going;
- an incoming inspection; to check when the materials arrive on site and to prevent the quality of materials from constantly changing.

Equipment:
- presence of the right tools and equipment;
- the tools and equipment store to be as close to the workplace as possible;
- regular inspection of tools and equipment, timely replacement of worn tools and equipment.

Reliable feedback of results:
- feedback, aimed at learning: not only negative feedback but also positive feedback is desirable;
- the possibility for employees to create their own feedback.

Working conditions:
- optimal protection from bad working conditions, i.e. protection against noise, humidity, rain, cold and from heavy work.

Cooperation:
- good coordination between the different activities and tasks;
- creating opportunities to discuss and tackle problems together; one way of doing this is by introducing regular and structured work meetings.

3.2.1.1 Adjustment measures: an example from practice.

In the last few years, (structured) work meetings have been introduced at several construction companies. The experiences of one of these construction companies are described here.

One of the purposes of introducing work meetings was: "to get things running better and more smoothly. This means you need clearly defined topics, which you can discuss with the men and the foremen. Sometimes there are situations being complained about. This can signal problems."

The results of introducing work meetings are said to be as follows: "if the work meetings go well, it means that you as a foreman can organize things better. You make everything clear and create a situation where the men put forward their experience. We are doing this in such a way, but . . . can we not do it better? They then come up with suggestions as to how to improve the work process. Much has happened as a consequence of the work meetings. The foremen get more feedback — also about the work of the subcontractors. The work is better coordinated, and matched to suit the different teams."

3.2.2 Improvement measures

Improvement measures are more preventive in nature. The central feature is the content of a job. There are various sorts of improvement measures, such as job enlargement, job enrichment and task (or job) rotation. Job enlargement means combining several tasks into one job. For example, employees on the

construction site carry out tasks relating to both foundation work, erection and roofing.

Task rotation is a variant of this measure. A job constitutes only one task, but employees change jobs every now and then. Examples include: concrete shuttering workers who work occasionally with steel reinforcement, or bricklayers who now and then install windows and door frames. The construction companies believe that the benefits of task enlargement and job rotation are as follows: variety of tasks for the employees, wider experience and multi-functionality of personnel; fewer hiatuses in planning; greater responsibilities of employees; greater commitment to the quality of work (and the results) and reduced numbers of mistakes and problems in the building process.

For the individual employees, combining tasks means greater responsibilities and more decision latitude when it comes to solving problems. Employees also get more involved because they have a better view of the end result.

The other measures are geared towards ensuring that jobs fulfil specific requirements. One of the most important elements which a job must embody is containing adequate latitude of decision. Second, a job must involve as few repetitive tasks as possible and have the maximum amount of variation in the degree of difficulty. The last requirement which can be demanded of a job is the opportunity to find out as much as possible about the result of the work. This can be achieved by a proper information supply and targeted feedback.

3.2.2.1 Sufficient decision latitude
Decision latitude relates to the opportunities granted to the employee of being able to solve problems in the job. A job must incorporate the possibilities of being able to influence (1) the tempo of work, (2) the working method, and (3) the sequence of working operations. The solving of problems is made easier if there is an opportunity for mutual contact and sufficient cooperation. Having decision latitude enhances the feeling of responsibility for the product being provided and also increases the opportunity to learn from mistakes made earlier. Employees who, for example, are not able to complete a work schedule (i.e. an organized task) drawn up by themselves feel more responsible for such a failure than when this schedule has been drawn up by their boss. Afterwards, they will prepare a different work schedule.

3.2.2.2 No repetitive tasks
A job must embody the minimum number of repetitive (short and repetitious) tasks. Instead of being assigned tasks for short periods to be performed at a fixed tempo, a worker can be given tasks for longer periods with greater scope to devise the schedule and fix the tempo and method of work to suit him- or herself.

3.2.2.3 Varying the degree of difficulty
Simple and difficult tasks will be alternated as much as possible in a job. Whether a task is perceived as difficult or easy depends on the person carrying out the task. On the other hand, it is possible to make a "difficult" task easier by getting workers to learn about their job. This can be done by proper instruction, tutoring by qualified instructors, training, work meetings and sufficient decision latitude.

3.2.2.4 Information and feedback
A worker needs information on the purpose and results of the work. This is required to help him understand the demands which are made on him and enable him to learn from this. The information must be available in full and when it is needed. Information is also needed about the ins and outs of the site where he works and his own particular department.

As regards the different sorts of improvement measures, it may also be said that a balance also needs to be found here between the load imposed on the employees and their ability to cope with it. For example, tasks may not be added to a job as the work stress on the employee increases.

3.2.2.5 Improvement measures: a practical example:
A specific form of job enlargement (in the construction industry) relates to so-called multi-functional working. Experience with multi-functional working has been acquired at a construction company in the west of the Netherlands. One of the aims behind the changeover to multi-functional working is described as follows: "We noticed that there was a demand for people in maintenance who, in addition to bricklaying, could also do the finishing work. For example, concrete formwork carpenters who could also carry out tiling or carpenters who could also lay bricks or glaze a window. Then we deliberately introduced multi-functional working via the sort of maintenance, which was being done at that time. Although maintenance work was being carried out on large numbers of houses, not much needed to be done in a particular house — for example, the replacement of kitchen units, bathroom fittings or a sash window. Does a glazier have to do ten houses once a week and make the inhabitants wait? Cannot this man of ours fit the window straightaway?"

> For maintenance and renovation work it was important to have fewer people moving in and out of the client's house. It would be better to deal completely with a few houses than to be doing the same job successively in a large number of houses. Because different specialist disciplines were being employed, there were often gaps in the planning. It was then a matter of working more efficiently for which the social aim — the broader use of people — also came into the picture.

Multi-functional working can also be used in the construction of new buildings: "At the moment, in new building work, we are attempting to get the people doing the foundations to also do the complete job. They are both laying the foundations, doing the assembly work and roofing and thus advancing."

Multi-functional working can also be used when different companies are involved:

> In new building constructions we use our own steel benders. If a steel bender has to fit reinforcement grids on tunnel formwork or his walls, he can get help if he needs it. You can see here where the subcontractor sometimes helps our people. While our steel bender is fixing the grids, he can also, for example, be laying the electricity conduits. It becomes a joint operation. This is Cupertino and has developed over a period of time.

As for the results of multi-functional working it can be said that no computation has yet been made as to precisely what benefits it brings about. In various fields, however, the results of multi-functional working are clearly to be seen. Recently our company was awarded the "Consumer Building Prize", the prize

for the construction company capable of organizing the building process to the maximum benefit of the consumer, tenant or buyer. This Consumer Building Prize is an evaluation criterion; it shows that the occupants are happy with us. But that apart, you may be wondering whether things are better in the company. I believe they are because it is now possible to do things that would previously have been impossible or more difficult.

What is the actual difference?

Fewer people are involved and we work more quickly. I do not need to measure what the result is. You can see for yourself. We wish to optimize things still further and can hold our own in the market. Thanks to our added value we are frequently upfront in terms of negotiations and tenders. The results are geared to the market. In the company you will see motivated people created by job enlargement and greater latitude of decision-making.

And what's more:

the percentage of mistakes is small because the people work better. There is a greater readiness to think things over and to cooperate. Better quality and fewer mistakes help to save money. Also, people like working in the company; you can see this at all levels, and also on the construction site. We never need to advertise for recruitment.

3.2.3 Redesign measures

Another effective way of overcoming work pressure is to take so-called redesign measures. These measures, like the improvement measures, aim to increase the decision latitude. Working in teams is central to this. (The idea of autonomous teams arises from the social engineering field. It is a business trend, which creates links between the division of labor and the productivity of a company.)

A team consists of a fixed group of employees who are jointly responsible for (part of) the (total) process in which products or services are created. The team draws up the plans itself and monitors the progress of the process, jointly solves day-to-day problems and improves processes and working methods. When carrying out these tasks the team does not need to refer constantly to the management or supporting services. In summary, a team has executive, organizational, preparation and supporting functions.

Other names used for such teams are self-governing or self-reliant teams, autonomous task groups or independent construction teams.

The introduction of team-oriented working often means fundamental changes in the organization of the company. However, increasing numbers of companies and institutions in differing branches of industry are utilizing the principles of team working. A basic principle behind team-oriented working is that people are the most important resource in the company and that a team is a powerful means of nurturing and utilizing this resource.

In teamwork, control does not take place at individual level, but at team level. This means that each team has its own tasks, responsibilities and powers. Practice has shown that successful team working features various critical success factors. They are described as follows:

- The group task must be complete, have clearly defined limits and be linked to a measurable result. The group task is a complete whole. When carrying out the group task, the team is independent of its environment.
- The entire team must have sufficient decision latitude.

- Team members are interdependent.
- The team consists of a minimum of four and a maximum of twenty persons.
- The members of the team are available for several tasks within the team.
- The team has one or more fixed reference points for the outside world, but also for its own team.
- The team must have its own room, own production resources and own information.
- Planning and quality systems and the budgeting need to be adapted for working with teams.
- The wages system must be adapted for working with teams.

The decision latitudes of a team can relate to different tasks and powers. It is possible that a team will gradually take on more and more tasks while some tasks may continue to be performed to a limited extent. A team which, for instance, controls its own planning must take account of the existing executives drawing up the general plans. Listed below are examples of tasks and powers, which can be assigned to a team:

- Planning tasks, work preparation
- Training and induction of new employees
- Administration
- Timekeeping, price control and costing
- Quality assurance
- Looking after materials (ordering, maintenance)
- Looking after working conditions and environment (accident prevention, security, order and tidiness on the site, but also recording of absenteeism)
- Commercial responsibilities, budgeting
- Contact with occupants in maintenance and renovation projects
- Direct contact with (sub)contractors and suppliers
- Higher quality of labor with, as a result, lower work pressure, higher commitment and motivation among the workers, lower absence due to sickness and a lower turnover.
- Higher effectiveness (the degree to which an enterprise achieves its objectives): high quality, short delivery time, high technical flexibility, less time consumed by executives.
- Higher efficiency (the degree to which a company is capable of achieving optimum output at the minimum possible cost): higher productivity, reduced stock costs, lower material losses and, generally speaking, a shift in the types of costs (from fixed to variable and from indirect to direct).

When autonomous teams are introduced, however, allowance must be made for the fact that this will have an influence on *all facets of business management:* the organization structure, the organization culture, the production structure etc. It also concerns redesign measures. Some of these facets are set out below:

- Extra instruction and training courses are often part of the change process. Ultimately, employees are given new and sometimes more taxing tasks.
- Wages and job evaluation systems should be changed because the present system places little value on the ability to perform more than one task. For instance, individual wage-rate systems can be replaced by team wages systems.
- The present control systems (financial or logistics control, planning systems) usually inhibit the independence of teams. Frequently, plans are too detailed and leave no scope for independent action.

- The reduction of the indirect costs is an important effect of the introduction of autonomous teams. This enables the number of staff and support services and the number of executives to be reduced to a minimum. However, this advantage will be achieved only gradually.
- Working with autonomous teams requires another style of management. The team is central to this and the management supports the team.
- The period of change while autonomous teams are being introduced is frequently a long process during which simultaneous changes also occur to the division of labor, the overall control and contacts between people. There is no instant blueprint available for the process of change: every company has specific problems, which require a specific solution. The change process is a learning process for everyone in the company.

3.2.3.1 Redesign measures: a practical example

As part of its work on redesign measures a construction company in the south of the Netherlands has been using autonomous construction teams on a renovation project. This team was made up of carpenters, bricklayers, a painter, a tiler and a plasterer. The plumber and electrician of the specialized contractor were permanently assigned to the team. Without the workers ever really practicing a different trade, there were three things which differed from the "normal manner of working". First, a helping hand was given to the other specialist disciplines. This can be seen as job enlargement in several disciplines. Second, job enrichment was created by allowing the teams to also carry out preparatory and organizational tasks. The workers organized the work themselves. For example, arrangements were made with the occupants: "We'll come to you tomorrow to do this or that". They also were responsible for accepting and ordering materials and equipment. The organization, moreover, was under the control of the foreman. Third, there was the matter of learning. Workers in an autonomous construction team learn as a result of the control tasks and by organizing the work. The results show that working with autonomous construction teams has delivered both social and economic benefits.

The following are some figures based on (scientific) research in practice:

- A study at a Swedish construction company, which was organized on the principles of team-oriented working, has stated that the following benefits were obtained by working with teams. The productivity of the construction company rose by 15%, there were fewer disruptions, 20% fewer mistakes, 4% cost savings, the workers suffered less stress. Material losses were reduced from 10–15% to 3–4% and the team spirit increased markedly. Absence due to sickness fell, as also did the number of accidents.
- In 1993 the Arbouw and Bouw Research foundations undertook an experiment with the fabrication of plaster block partition walls in house construction. Despite the fact that this work is not complicated, there are a lot of operations and specialized activities involved. This experiment revealed that team working resulted in benefits both in terms of production efficiency and working conditions. The production time per m² wall surface and the total construction time were reduced and there were fewer

coordination problems. If, for example, the electrician was not present at the agreed time, the autonomous team could continue working at half strength. With a more conventional working method such a hold-up virtually puts a stop to the building process. The delay initiates a chain reaction causing things to get worse and worse. This can result in high costs. In the experiment, use was also made of new technologies, and improvements have been reported in the area of physical stress. During the experiment the team did not perform any organizational tasks in administration, budgeting, timekeeping, etc.

4. FUTURE

As we look at the pace of innovation in other sectors of industry, the construction industry should be characterized as conservative. Work is still physically straining and work organization and working methods are traditional. However, construction companies start more and more to experiment with different ways of work organization. And, as shown in this chapter, this can result in improving the working conditions, reducing physical workload and work stress.

1. INTRODUCTION

Seven million workers are employed in the US construction industry. As identified in many other countries (Holmstrom *et al.* 1995), the construction industry in the USA accounts for some of the highest rates of workplace injuries and deaths. High rates of work-related injuries and illnesses have traditionally been accepted as being part of the construction worker's job. According to the Bureau of Labor Statistics (BLS) Annual Survey of Occupational Injuries and Illnesses (BLS 1998), construction workers experienced > 189 900 illnesses and injuries causing lost work days in 1997. The actual number occupational injuries and illnesses in construction is probably under reported. For instance, the annual survey does not include companies with < 10 employees or self-employed workers, which combined account for ~80% of the construction establishments. Additionally, injury or illness underreporting in construction may be associated with injured workers' concerns about losing work and contractors concerns about their impact on workers' compensation premiums.

Although work-related musculoskeletal disorders among construction workers are less dramatic than traumatic injuries, they can be as debilitating and very costly. Many of these conditions have a long latency between initial exposure and symptom manifestation, which may contribute to their under reporting as an occupational illness. Chronic low-back pain and other musculoskeletal disorders like carpal tunnel syndrome cost millions of dollars in medical expenses, lost wages and workers' compensation payments. The disability and costs of these conditions has prompted federal agencies, trade unions, trade associations, contractors and researchers to investigate methods to prevent these disorders. Primary prevention efforts in the past 10 years have focused on the multidisciplinary field of ergonomics to assist in the reduction of the risk factors associated with work-related musculoskeletal disorders.

Although ergonomics is commonly associated with manufacturing facilities (electronics, meat packing, automotive industry) and the use of video display terminals, there has been considerable interest and research in construction ergonomics since the mid-1990s. Construction is a very broad field and the ergonomic challenges and solutions are difficult to summarize in a short review. There are many different types of construction work (residential, commercial, highway, industrial, demolition, etc.) and many different types of construction workers (carpenters, laborers, electricians, bricklayers, etc.). Clearly, there are ergonomic challenges everywhere in the industry and injury rates are high. The rate of back injuries and sprain and strain

injuries in construction is ~50% higher than the rates for manufacturing plants in the USA. Construction materials are heavy and often require considerable materials handling, frequently by hand. Building ceilings requires extensive overhead work for installation. Floors and roofs require work to be done at floor level.

Because the worker's job-site is constantly changing in construction, it is not possible to design a workstation as you would in an industrial facility, which may not change for several years. Most US construction companies are small, with 82% employing < 10 workers. Most job sites are multi-employer sites, where one contractor may create ergonomic challenges for workers working for another contractor. Construction workers change jobs sites frequently (one job may last a few days or several months) and often change employers frequently as well. Despite these differences, many of the same principles of ergonomics that apply to industrial ergonomic problems can be used in construction. The main approach that has been taken is to divide the construction worker's job into "tasks" and to look at the ergonomic problems and solutions for each task individually (Schneider 1995). Though solving task-specific ergonomic problems may have beneficial effects for individual workers, a systems approach involving workers, contractors, and owners may have a greater impact.

The purpose of this review is to provide a brief description of some of the physical demands, ergonomic challenges and ergonomic strategies that have been identified in several construction trades.

2. CONSTRUCTION LABORERS

In construction laborers end up doing many of the materials handling tasks and are, consequently, at perhaps the greatest risk of acute and chronic low back injuries. Laborers act as "mason tenders" handling all the materials necessary for bricklayers to perform their jobs. They do demolition work, where heavy construction materials are demolished and must be manually lifted, carried and thrown into refuse containers. Laborers use manual tools to dig trenches in pipeline work and to move asphalt in paving. All these tasks place them at great risk of injury. For most materials handling jobs there are carts, dollies and cranes that can be used to reduce the amount of manual handling stress. Unfortunately, little research has been done thus far on the ergonomic problems of laborers, in part due to the diverse nature of their work.

3. BRICKLAYING

Bricklaying, by contrast, has little task variation and consists of handling mortar, bricks, and blocks and moving scaffolding. There has probably been more work done on bricklaying ergonomics than most other trades. Bricklayers place mortar on the wall, lift bricks or blocks, set them in place, and remove the excess mortar. The ergonomic hazards of the job revolve around the placement of the mortar mix, the placement of the brick/block supply, the weight and size of the bricks/blocks, the location of the work (e.g. height of the wall), the work rate, rest cycle, and duration of work. Luttmann *et al.* (1991) measured muscle activity, time in awkward postures, brick holding time and productivity relative to wall height. They found that muscle activity and awkward postures were highest when bent over.

Holding time increased when the wall height was higher. Productivity was highest when the wall was low. They concluded that a wall height of ~80–100 cm is optimal for all factors.

Thus, one approach to improving ergonomics for bricklayers would be to maintain wall height, as much as possible, at 80–100 cm. The increasing use of adjustable scaffolding, which can be raised in ~30-cm increments, can help keep the wall height close to 80–100 cm. Studies done at the University of Texas have shown a 20% increase in productivity by using adjustable scaffolding. Bilevel scaffolds and mortar pan stands are also available to keep the brick and mortar supplies just below waist height.

The size and shape of bricks and blocks can also be modified. In Germany, block manufacturers worked together with contractors and unions to design a block with handholds to make it easier to lift and carry. In the US, the Army Corps of Engineers worked with the University of Nebraska to design the Nebraska A block, which weighs half as much as a normal block but with the same strength characteristics. Mechanical hoists are also available in Europe for lifting and placing blocks. Their use was spurred on by a law requiring any blocks weighing > 20 kg to be lifted mechanically. The Army Corps of Engineers in the US is also working on a mechanical arm to lift masonry blocks in place.

The other main ergonomic problem for bricklaying is the manual handling of bricks and mortar. Brick tongs are available for individual masons to use to handle small numbers of blocks. For bulk handling of bricks, the Dutch have developed an integrated materials handling system which includes special carts and dollies for handling bricks and new methods for packaging and shipping bricks allowing much of the handling can be done mechanically. Equipment is also available to pump mortar up to point of operation and apply the mortar pneumatically.

4. DRYWALL WORK

Drywall or plasterboard installation has been identified as one of the most hazardous occupations, according to workers compensation records from Washington State in the USA. Drywall installers have very high rates of back injuries and most people cannot perform this work for many years without injuring themselves. The job includes three main tasks: manual handling of boards, cutting boards to size and screwing the boards into the studs. Drywall installation is either vertical (for walls) or horizontal overhead (for ceilings).

Most of the ergonomic research on drywall tasks has focused on the handling of drywall boards. Drywall boards are heavy and awkward to carry. They are a minimum of ~30 kg and ~120 _ 240 cm in size. Often they are larger and heavier. Handling them outdoors, they can act as a sail and catch wind gusts, making them even harder to handle. There are several handles available for workers to use for carrying drywall. The handle merely hooks under the board and allows the worker to carry it with a much more comfortable, less extended grip closer to their body. Alternatively, carrying handles, which attach to either end of the board, allow two people to carry boards easily, which is probably a better solution for manual handling given the weight and size of the boards. Drywall carts are also available for transporting boards, but most require a flat surface, such as a finished concrete floor. A third option was developed in Sweden, where 90-cm wide boards were introduced. Research in Sweden and Finland showed the boards are much easier to handle, including allowing for more visibility during carrying, and reduced ergonomic risk. Research has not yet been done to look at the ergonomic tradeoffs of using 90-cm boards, e.g. they require more screwing.

Other interventions have focused on cutting and fastening drywall. Ergonomically designed utility knives with a bent handle are available for cutting the boards as are cutters that can be placed over the edge of the board and pulled. Screwing the boards into the studs has become much easier with the widespread use of powered screw guns, either electric or battery operated. Little attention has been paid thus far to the design of these tools. Workers often operate then by pushing on the back of the gun and using their little finger to operate the trigger. Automatic feed screw guns are widely available and extension handles allow for screwing drywall into the ceiling without an overhead reach.

The organization of the work is also important. One Swedish study showed that taking short rest breaks, "micropauses," while installing drywall reduces fatigue and increases productivity.

5. REBAR TYING/STEEL FIXING

Modern concrete is generally reinforced by the placement of iron reinforcement bars in the floor, bridge or column before pouring. The bars are tied together to make sure they maintain their position during and after the pour. Traditionally tying has been done by hand. Workers, called rodmen or steel fixers, tie the bars together at junctions using tie wire from a roll on their belts. They maintain a bent over posture for most of the day resulting in back problems and often have hand and wrist problems from twisting and cutting the tie wire. Finnish researchers first studied rodmen in the 1970s. Several different rod-tying machines have been developed in Europe, Japan and the USA for tying from a standing height. They eliminate the bent over posture and hand and wrist movements. While these machines have resulted in enormous interest among contractors worldwide, their use has not yet become widespread. There has been significant resistance to their use from workers who see the machines as deskilling their work, transforming their skilled and highly paid jobs into simpler, low paid work. Unlike the other ergonomic interventions previously described, this machine essentially changes the job completely. This makes the success of such interventions considerably more difficult, no matter what their ergonomic benefits.

6. WORK ORGANIZATION

Nothing is more important to the ergonomics of a construction site than proper work organization. The job superintendent and foremen must ensure that materials are delivered to the job site in a manner than minimizes manual handling. They must make sure that the proper equipment (cranes, hoists, dollies) is available, in good working order and easily accessible to the workers. They must plan the supply of materials so there is not a storage problem, i.e. materials get in the way of the work. They must make sure they have the right number of workers, i.e. they are not understaffed, and they have to plan the work to ensure that the various trades do not create obstacles to each others' work. Proper work scheduling to avoid excessive production pressures is also essential to good ergonomics. Walk-around checklists have been developed to help workers and management evaluate their worksites and improve ergonomics by addressing these issues.

7. PARTICIPATORY ERGONOMICS

Participatory ergonomics has long been an important part of ergonomics in industrial workplaces. During the past few years, it has also begun to be practiced more in the construction setting. The approach has been to develop a small ergonomics steering committee composed of workers, a management representative and a researcher to facilitate the process. Through a series of short meetings the committee develops a short list of problem tasks to address, a list of potential solutions, ranks those solutions and tests them out on the job site. Solutions are evaluated and the most successful ones adopted. The best example of this in construction has been a Dutch project to develop ergonomic interventions for scaffold erectors.

Scaffold erection had been identified as one of the highest risk trades. One of the major problems the committee identified was that scaffold parts arriving from the rental company were thrown disorganized into the back of a pickup truck. By insisting that the parts be placed in the truck in the order they were to be used, an hour of back breaking work was avoided. They also recommended the use of smaller ladders and planking. They recommended using a small electric winch to raise parts to the top of the scaffold construction. These interventions were evaluated by measuring heart rate, percentage of time in awkward postures and frequency of heavy materials handling (> 20 kg). The results displayed improved ergonomics and increased productivity. This participatory approach shows enormous promise in construction. Construction workers are generally very good problem-solvers. Every day construction activities result in problems that must be solved on the spot. Ergonomic problem solving is no different and should be a natural extension for construction workers.

8. OTHER ISSUES

8.1. Ergonomics Training

Training is an essential part of any successful ergonomics program. Workers need initial awareness training on the principles of ergonomics and methods for recognizing hazardous tasks. They also need training on how to identify potential solutions and solution implementation strategies. Several training programs are now available for construction workers in the US. Most focus on training apprentices, those just beginning their careers in the trade. Training would also be helpful for foremen and superintendents. They run the job sites and if they understand and are supportive of ergonomics change comes much easier.

8.2. Stretching Programs

During the past few years pre-work stretching programs have become popular. Workers go through a series of routine stretches each morning before the day begins. Studies in the USA and Sweden have shown these programs to be beneficial, particularly if they are mandatory and on paid time.

8.3. Personal Protective Equipment

Personal protective equipment, such as kneepads, is essential for construction workers, primarily to reduce the contact stresses from kneeling, etc. Some work in kneeling postures is unavoidable in construction as floors and roofs must be installed. Good kneepads can help although they can create pinch points in the back of the legs and may be uncomfortable to wear. Newer models are available which show some promise in reducing discomfort. Studies are underway to evaluate kneepads and their use. Carrying materials on your shoulder makes some sense ergonomically, in that you keep the materials close to your center of gravity and use your legs to support the weight rather than your arms. However, there is little padding on the shoulders. Shoulder pads are available for reducing contact stresses associated with carrying materials on the shoulder. Standing on a concrete floor all day has been associated with back problems. Rubber matting and shoe insoles can help reduce the pressure from standing on concrete and may help reduce the risk of back pain. Lastly, back belts have become popular in construction. Unfortunately, there have been few studies of their efficacy in preventing injuries and no studies in the construction industry. Recommendations on their use must wait the outcome of research currently underway.

9. CONCLUSION

The construction industry presents a high risk of musculoskeletal injury and many ergonomic challenges. Despite these difficulties, many strategies can be implemented to reduce the risk of injury (Schneider 1998). New materials, new tools and ergonomically designed equipment all have a role to play. As do stretching programs and personal protective equipment, such as kneepads. Improved work organization and better job planning are probably the most important ergonomic interventions in construction while training of workers and supervisors is also critical. Participatory approaches to ergonomics in construction hold great promise for making effective changes in work methods, work organization and injury prevention.

Diagnosis of Work-related Musculoskeletal Disorders

C. Dillon† and M. Sanders

†School of Medicine, University of Connecticut, Farmington, CT 06030, USA

‡Department of Occupational Therapy, Quinnipiac College, Hamden, CT 06518, USA

1. INTRODUCTION

The diagnosis of a cumulative trauma disorder (CTD) poses a challenge to practitioners who treat workers with prolonged exposure to workplace ergonomic hazards. Although controversy surrounding the diagnosis of a CTD is not unlike that of other areas of medicine, a coherent understanding of the problem is necessary since CTD have such wide reaching impact on industry, insurance and medical systems. This chapter discusses CTD from the perspectives of these various sectors and reviews the nomenclature used to reference CTD. It explains the major diagnostic criteria that identify the presence of a CTD and addresses specific diagnoses that typify CTD in the workplace. The controversial issues relative to CTD diagnoses are examined.

2. DEFINITION AND NOMENCLATURE OF CTD

2.1. Definition of CTD

CTD is a broad term that refers to injuries of soft tissue structures of the body such as muscles, tendons, nerves, blood vessels and joints which have identified causal link to ergonomic risk factors. As the name implies, CTD is not the result of a fall or a sprain that may have occurred in a single incident. CTD develops insidiously from prolonged exposures to repetitive motions, awkward postures, static posture, vibration and forceful exertions that injure soft tissues and prevent them from healing (Buschbauer 1994). While researchers equate CTD primarily with workplace ergonomic factors, central nervous system and psycho-organizational factors also contribute to the problem (Gordon *et al*. 1995, Sanders 1997).

CTD encompass specific medical diagnoses including tendinitis, epicondylitis and entrapment neuropathies. While diagnostically similar disorders result from ergonomic exposures in sports or avocational activities, or from inflammatory arthritis, endocrine disorders and certain hereditary syndromes, these conditions should not be confused with CTD resulting from workplace ergonomic exposures.

2.2. Nomenclature Used to Reference CTD

The scientific and popular literature is inconsistent with regard to nomenclature for workplace CTD. The various terms for this phenomena include CTD, repetitive strain injuries (RSI), repetitive motion disorders (RMD), work related musculoskeletal disorders (WRMSD), occupational cervicobrachial disorder (OCD) and upper extremity repetitive strain disorders (UERSD). Each term conveys important meaning, yet is inaccurate in the entire portrayal of the condition. For example, the term "injury" is misleading since these disorders are characterized by a gradual onset and exacerbation; "musculoskeletal disorders" lacks diagnostic specificity for the area targeted. Since no truly satisfactory term for CTD exists, the term CTD is chosen here for the greatest currency and recognition.

3. DIAGNOSTIC CRITERIA FOR CTD

An interconnected variety of clinical syndromes exist under this "umbrella" of CTD. Confusion surrounds the issue of diagnostic criteria for CTD due to a lack of clinical case definitions for many CTD; and, equally as important, the differing clinical and scientific diagnostic perspectives held by the various contributors (Rempel *et al*. 1998). A brief review of these different perspectives and accompanying criteria is presented.

3.1. Medical CTD Case Definitions

A medical diagnosis relates to a clearly defined disease process involving pathology of an anatomically defined region or physiologically defined process. The medical diagnosis determines the nature of the disease and enables appropriate treatment selection. Medical diagnostic criteria facilitate making the diagnosis and consist of a structured set of symptoms and physical exam signs. Ideally, a confirmatory lab-based test or "gold standard" acts as the ultimate objective test to verify the existence of a disorder.

The medical diagnostic criteria are combined with a medical diagnosis in a medical case definition which describes an instance of a disease with its accompanying circumstances. A medical case definition should be both sensitive and specific. That is, the case definition should identify the overwhelming majority of clinical cases, yet not falsely include those cases superficially similar to but inherently different than the condition of interest.

For most CTD rigorous case definition criteria are not met because the ultimate pathophysiology and manifestation of disorders are not thoroughly understood. For conditions such as carpal tunnel syndrome (CTS), consensus case definitions have

Table 1. Diagnosis and Classification of Cumulative Trauma Disorders

Surveillance Case Definition Used to Determine the Presence of a Cumulative Trauma Disorder

Interview

- Symptoms of pain, numbness, or tingling
- Symptoms lasting more than 1 week and/or occurring more than 20 times in the last year
- No evidence of acute traumatic onset
- No evidence of systemic disease
- Onset of symptoms occurring with present job

Physical examination

- Characteristic signs of specific muscle, tendon, or nerve disorders
- Rule out other conditions with referred symptoms

Sources: Adapted from SILVERSTEIN, B.A., FINE, L.J. and ARMSTRONG, T.J. 1986, Hand wrist cumulative trauma disorders in industry. *British Journal of Industrial Medicine*, 43, 779; and SILVERSTEIN, B.A., FINE, L.J. and STETSON, D. 1987, Hand-wrist disorders among investment casting plant workers. *Journal of Hand Surgery* (Am), 12, 838.

been developed, which identify typical cases and allow for standardized patient enrolment into medical and scientific clinical trials (Rempel *et al.* 1998). Consensus case definitions are designed to recognize the typical case and usually do not encompass the early, mild or atypical patients with an existing disorder. Additionally, published medical case definitions in the CTD literature may not accurately reflect the circumstances of an individual patient examined in everyday clinical practice. Table 1 summarizes the classic physical signs and symptoms associated with common medically defined CTD diagnoses.

3.2. Surveillance Case Definitions

Surveillance case definitions are primarily used in regulatory monitoring to track the impact of the workplace on the incidence of CTD. Surveillance case definitions may incorporate all or part of existing medical case definitions. These definitions may consist of brief symptom surveys likely to be attributed to CTD or may employ a full range of symptom, physical exam and laboratory testing data. A key characteristic of surveillance case definitions is the frequent inclusion of ergonomic exposure variables. For example, work-related carpal tunnel syndrome might be defined as a case with characteristic symptoms, exam findings, lab tests *and workplace exposure history* for surveillance purposes.

The Occupational Safety and Health Administration (OSHA) (1990) in the USA utilizes broad surveillance criteria for reporting, recording and tracking CTD as part of compliance with regulatory standards. According to OSHA, if a worker's symptoms are *caused or aggravated by exposure to work* and meet recordability criteria then the case is considered to be a work-related CTD. The recordability criteria specifies the presence of subjective or objective findings with action taken as a consequence. A condition qualifies as a "recordable" CTD, if the following conditions 1 *or* 2, AND condition 3 are met: (1) the worker must possess one or more physical findings such as redness, loss of motion, deformity, swelling, a positive Phalen's, Tinel's test, or other positive provocative tests *OR* (2) the worker must possess one or more subjective findings such as pain, numbness, tingling, aching, stiffness, or burning AND (3) actions were taken as a result of this condition such as medical treatment (including self-administered), lost workdays, loss of full-duty status or transfer to another job. The presence of work-related exposures is inherent in the definition of a work-related CTD.

If a worker's condition fulfils these parameters, the condition is considered to be an occupational illness and must be recorded on the OSHA 200 Log under the 7f column, "disorders associated with repeated trauma" (OSHA 1990). Table 2 provides an example of a more strict surveillance case definition utilized in the studies by Silverstein *et al.* (1986).

3.3. Epidemiological Case Definitions

Epidemiologic case definitions are a third type of case definition found in the CTD literature (Rempel *et al.* 1998). These are stricter scientific case definitions with more rigorous, reproducible protocols for research data acquisition and inference. Epidemiologic CTD case definitions are typically employed for investigations of etiologic factors and natural history of CTD as well as for clinical intervention trials. While many epidemiologic CTD case definitions attempt to achieve fidelity with clinical case definitions, this is not always the case. Epidemiologic case definitions typi-

cally avoid the inclusion of ergonomic exposure data for studies examining the etiology of CTD.

4. PERSPECTIVES ON CTD DIAGNOSES

Parties that routinely deal with workplace CTD include med-changes of the tendon occurring in the presence or absence of inflammation (Gordon *et al.* 1995). The most common sites for tendon injury from repetition or overuse are the tendon attachment to bone, the myotendinous junction (point at which tendon attaches to muscle) and sections of the tendon that pass beneath a tunnel or pulley such as in the wrist and fingers.

5.3.1.1. Factors affecting the healing process.

Factors such as age, disease, genetics and medications significantly affect the healing process and integrity of tendons. The tendon strength of a 70-year-old person is ~21% less than that of a 25-year-old person because the collagen stiffens (loses elasticity) which reduces tensile strength (Leveau 1992). It is unclear the extent to which reduced strength is due to intrinsic qualities of the collagen or due to years of repetitive use and microtears.

5.3.2. Nerve-related disorders

Nerves relay messages of intent from the brain to muscle and receive sensory information from the periphery about the environment that is delivered to the brain. Hence, nerves have motor and sensory components. *Peripheral nerve compressions* occur as nerves are compressed by adjacent tissues or an abnormality in tissue structures which reduce the space through which the nerve travels. A *peripheral nerve entrapment* is caused by repetitive trauma to the nerve, which results in inflammation and later fibrotic changes. *Double crush syndrome* refers to the concept that nerve entrapment may occur at several points along the nerve. Compression and entrapment are likely to occur together as a nerve that is already traveling in limited space may be especially vulnerable to repetitive trauma by adjacent tissue.

In the early stages of nerve compression or entrapment, intermittent tingling and parasthesias may be provoked by certain positions but that later resolve with rest. Over time, the numbness and tingling become more pronounced, with numbness occurring first occasionally then constantly. Later, motor changes ensue; these changes may begin with muscle aches that may progresses to weakness and atrophy if nerve damage persists. Proximal sites of nerve compression in the neck and shoulder may increase the susceptibility of nerve compression at more distal sites such as in the wrist and hand (Novak and Mackinnon 1997).

Certain joint positions increase the shear forces between nerve and surrounding structures causing the nerves to be more vulnerable to entrapment if these positions are sustained. For example, extremes of wrist flexion and extension increase tension and shear forces on the median nerve within the carpal canal; elbow flexion increases tension on the ulnar nerve within the cubital canal. Irritation of the nerve at these sights will lead to edema fibrosis of the nerve, decreased excursion, and potentially impaired blood supply.

6. CONTROVERSIAL ISSUES RELATED TO CTD
6.1. Causal Factors in CTD Diagnoses

Researchers debate whether CTD should be attributed primarily to psychosocial, organizational or biomechanical factors within

Table 2. Common diagnoses related to CTDs. Medical and lay terms for each dondition are included as well as a description of the condition, the classic signs and symptoms, and causes of common CTDs.

Common Term	Medical Term	Description	Signs/Symptoms	Causes
Tendon-Related Disorders				
Tendinitis	Tendinosis Tenosynovitis	Inflammation of tendon sheath; becomes thickened, and frayed	activity-related sharp pain specific to an anatomical location	Repetitive use of tendons especially in awkward positions; assembly work, VDT work, wiring, packaging
Trigger finger or thumb	Stenosing tenosynovitis of the fingers or thumb	Thickened synovium accumulates as a "nodule" on the tendon. Nodules may catch and prevent movement of tendon under A1 pulleys in palm	Finger becomes "locked" when attempting to extend. Motion occurs in a snapping fashion	Repetitive pinch and grip; operating a trigger, use of hand tools with edges that compress tissue
deQuervain's tenosynovitis	Stenosing tenosynovitis of the tendons at the radial wrist	Inflammation and entrapment of the extensor pollicis brevis and abductor pollicis longus tendons of the thumb under the extensor retinaculum	Pain with thumb extension and abduction; positive Finklestein's	Typing with frequent use of space key, buffing grinding, sanding, use of small tools, forceful hand wringing
Tennis elbow	Lateral epicondylitis	Degeneration of the extensor tendons originating at the lateral epicondyle of the humerus	Pain at lateral elbow; pain with resisted wrist extension and supination	Repetititve wrist extension and repetititve grasp; VDT work, hammering, meat cutting, small assembly, musical instruments
Golfer's elbow	Medial epicondylitis	Degeneration of the flexor tendons originating at the medial epicondyle of the	Pain at the inside of elbow; pain with resisted wrist flexion and pronation	Repetitive wrist flexion; wringing or twisting hands, VDT work, golf
Shoulder tendinitis	Rotator cuff tendinitis, Supraspinatus tendinitis	Inflammation of the rotator cuff tendons as they pass beneath the acromion process and/or insert into humerus	Pain at mid range of shoulder motions (painful arc) and with resistance to abduction and external rotation	Overhead work; work with the arms away from the body; electrical work, grinding, sanding, soldering
Nerve-Related Disorders				
Carpal tunnel syndrome	Carpal tunnel syndrome	Compression of the median nerve in the carpal canal at the wrist	Numbness and tingling in the thumb, index, third and radial aspect of fourth finger; difficulty with dexterity, loss of prehension strength; positive Phalen's and Tinel's sign	Repetitive or forceful grip and prehensile tasks especially in extremes of flexion, extension and ulnar deviation; dental hygiene, surgery, VDT work, scrubbing, hammering, cutting
Cubital tunnel syndrome	Ulnar nerve entrapment	Compression of the ulnar nerve at the inside of olecranon groove of the elbow	Tingling, numbness or pain at elbow radiating to the ring or little finger; intrinsic hand weakness	Resting the elbow or forearm on a sharp edge or hard surface; repetitive or static elbow flexion
Guyon tunnel syndrome	Biker's fingers	Entrapment of the ulnar nerve at the wrist	Tingling, numbness or pain in the ring and little finger; intrinsic weakness	Repeated/prolonged pressure on the outside of the palm; prolonged flexion and extension of the wrist; biking, carpentry, use of pliers, hammering
Neurovascular-Related				
Thoracic Outlet Syndrome	Brachial Plexus compression injuries	Compression of the neuro-vascular bundles between the clavicle and first and second ribs at the brachial plexus; scalene triangle	Numbness/tingling in the ring and little fingers; pain at the brachial plexus; cold hands; intrinsic muscle weakness	Work with arms overhead or in front of the body; mechanical stresses applied to the brachial plexus; office workers, electricians, cashiers, postal letter carriers, musicians, waitresses

the workplace. The predominant evidence suggests that bio-mechanical factors inherent in the performance of work tasks initiate the development of tissue damage and resulting CTD diagnosis; personal, psychosocial and organizational factors such as work style, control over one's job, machine pacing, and stress in the workplace further contribute to or exacerbate the physical stressors in the disease process (NIOSH 1997, Sanders 1997, National Research Council 1998).

A group of prominent physicians view sociopolitical, le-gal and worker's compensation issues as the primary causal factors in the development of CTD. This conviction is partly driven by investigation of the 1980–85 Australian "RSI epi-demic" — a time period in Australia when reports of repeti-tive strain injuries rose > 300% over 3 years. Researchers criticized the medical system for inconsistencies in diagnosing the source of pain and observed that the magnitude of injury did not always seem to correlate with the work being performed.

While disputes continue as to whether political inter-ests, strong union support, litigation and substantial work-er's compensation awards are major factors driving CTD claims (Hadler 1992) research shows that the pool of unre-ported CTD cases is much larger than those ever reported to worker's compensation systems. The more salient question to address is the relative contribution of biomechanical and psycho-organizational factors to the prevalence of workplace CTD.

7. CONCLUSION

CTD diagnoses require expertise in evaluating workers in light of the biomechanical, personal and work organzational factors that cause such a condition. Utilitarian variations on CTD case definitions exist, including those for traditional medical diag-nosis and treatment planning, case definitions for safety and reg-ulatory monitoring and case definitions for epidemiological research on the natural history of CTD. Although each definition has a different practical purpose, these seemingly distinct demarcations often overlap in content and have complementary roles in the common ultimate goals of treating or preventing the development of CTD.

‡Harvard School of Public Health, Boston, MA 02115, USA

1. INTRODUCTION

Epidemiology is a set of established and developing methodologies used to describe the distribution and determinants of adverse health outcomes in human populations. The subsequent evaluation of interventions to prevent injury or disease is the ultimate objective of epidemiology.

2. FUNDAMENTALS OF EPIDEMIOLOGY

2.1. Fundamental Aspects of Epidemiologic Methods

People who develop a health condition tend to be exposed to antecedent risk factor(s) more than persons who do not develop the condition. Epidemiologic methods have evolved to approximate the effects of potential risk factors (also known as exposures) on health outcomes (such as injuries, disorders, diseases) in groups of individuals. Associations between exposures and outcomes may be causal or due to alternative explanations such as study bias, confounding or chance.

In epidemiology, study bias refers to some systematic error in study methods that precludes a clear judgment about the nature of the association between the exposure and the disease outcome. For example, parents of children injured at home may recall certain exposures more thoroughly than parents of uninjured children. This *recall* bias may be estimated by comparing questionnaire responses to a "Gold Standard" source of information, perhaps a medical record or a direct observation of an exposure.

Confounding refers to the effect of an intermediary factor associated with both outcome and exposure. That is, the exposure–disease association may be artificially produced or obscured by this other factor. For example, cigarette smoking potentially confounds any observed association between alcohol use and lung cancer because many alcohol users also smoke.

Chance or sampling variability operates in most scientific research. It is a potential explanation for an observed association between an exposure and a disease outcome. It may be less likely, however, with larger sample sizes and as a study's findings are replicated by subsequent investigations.

2.2. Measures of Outcome Frequency

Important terms in interpreting and reporting outcomes in populations include incidence and prevalence. Incidence refers to the number of new instances of a health outcome in a population during a specified time period (Last 1988). For example, an *incidence rate* is defined as the number of new cases of a condition per persons at risk (usually 100 or 1000) per unit of time (usually one year). Prevalence is the count of all existing cases during a specified time period or point in time divided by total persons at risk. When not otherwise indicated, the prevalence usually reported is the *point prevalence* or the count of all cases in existence at one point in time.

2.3. Common Measures of Exposure–Outcome Association

Epidemiologic data are often summarized in tabular form in the initial stages of analysis as the presence or absence of exposure to some potential risk factor and the presence or absence of a health outcome in a group of individuals. Table 1 presents the results of a hypothetical study of the effects of a single exposure on a health outcome. Each cell (a, b, c, d) contains the number of persons with a particular combination of exposure and outcome status. The data in these four cells are used to derive various measures of effect. Two common measures of the effect of exposure on outcome are relative risk (RR) and odds ratio (OR). These are calculated and interpreted below.

If 1000 persons *with* and 1000 persons *without exposure* are followed-up over a specified period for outcome occurrence, RR is found by dividing the risk in the exposed group (75/1000) by the risk in the unexposed group (25/1000). The result is 0.075/0.025 or 3.0. This means that this sample of exposed persons had three times *the risk or probability of developing the outcome* than unexposed persons over the specified period.

If individuals are *selected on the basis of their outcome status*, the totals for the rows (a + b) and (c + d) are not predetermined. The relative risk can be estimated by calculating the ratio of the odds of exposure among cases (75/25) to that among controls (925/975) or ad/bc = 75 x 975/25 x 925. The resulting OR of 3.2 is close to the RR of 3.0 found above. OR is interpreted to mean that the cases are 3.2 times more likely to have been exposed than non-cases.

Any estimate of effect varies within a range of values that is termed a confidence interval (CI). CI depends on the magnitude of the estimate, the specified probability of including the true value of the estimate (usually 95%) and the sample size in each of the four cells of the table (the larger the sample, the smaller the range of the interval). For example, the 95% CI for the calculated OR from the study above ranges from 2.1 to 4.9 (for details of CI calculation and underlying assumptions, see Hennekens and Buring 1987: 255). This means that if the same study was repeated 100 times, 95 out of 100 times the true OR would lie between 2.1 and 4.9. If OR = 1.0, then there is no observed

effect of the exposure on outcome status. Because the interval calculated previously did not include the null value (1.0), CI indicates that the association is statistically significant. If the 95% CI covered 0.9–7.1, the result would not be statistically conclusive but strongly suggestive of an effect since most of the interval is > 1.0. If the point estimate and the interval are < 1.0 (e.g. 0.3, 0.1–0.5), then the exposure significantly protects against the outcome.

2.4. Epidemiologic Study Designs

The techniques illustrated above are applied to the study of exposure and outcome associations. As with most scientific inquiry, however, the techniques are merely assets supporting the execution of a study design. There are two main classes of study design in epidemiology: descriptive and analytic. Descriptive epidemiology describes *how* an outcome such as an injury or disorder is distributed in a population; analytic epidemiology tries to explain *why* (Kelsey *et al.* 1989). A brief description of each design, with examples, follows. More specific information about epidemiologic study methods can be found in standard introductory texts (Kelsey *et al.* 1986, Hennekens and Buring 1987).

2.4.1. Descriptive studies
2.4.1.1. *Case report and case series*
The case report is the complete description of the clinical characteristics of a single patient. The single patient may present some unusual finding that can suggest the need for a larger study of an exposure–outcome relation. Case series describe the clinical characteristics of two or more patients with a health outcome and perhaps an exposure in common. An advantage of the case series is that multiple observations allow compilation of potential trends in the causes, diagnosis and treatment of the disorder.

These types of studies are most useful for identifying and describing emerging outcome trends and for generating hypotheses concerning potential exposure–outcome relations, which may be tested in more analytic studies. However, the conclusions that can be reached about the existence and magnitude of such relations are limited with these designs due primarily to the lack of both exposure data and a comparison group.

2.4.1.2. *Cross-sectional*
Cross-sectional studies take a simultaneous look at the presence or absence of both exposure and disease in individuals. Such studies ask the question: what is the relation between exposure and disease at the same point in time? For example, a study of sedentary workers and low back pain examined the relationship between constrained, sedentary work and prevalence of low back pain (Burdorf *et al.* 1993). Occupations with the greatest proportion of time spent in non-neutral trunk postures were observed to have a significantly increased prevalence of low back pain. In a cross-sectional design, it is difficult to establish whether the potential exposure variable preceded the outcome (e.g. work posture differences contributed to the development of low back pain) or whether the potential exposure variable exists as a result of the outcome (e.g. workers differ in posture as an adaptation to low back pain). Hence, cross-sectional studies are useful for identifying potential exposure–outcome associations but not for establishing causality.

2.4.2. Analytic studies
Case-control, cohort and intervention studies are generally classified as analytic studies. These study designs make use of the temporal relation between exposure and outcome (i.e. exposure precedes the outcome) and identify potential causes of outcome more definitively than descriptive studies.

2.4.2.1. *Case-control*
In a case-control study, people with the outcome (cases) and people without the outcome (controls) are compared with respect to the proportion in each group with the historical exposure of interest. An advantage of this design is that both cases and controls may be matched on potential confounding variables, such as age. This design is particularly useful for the study of rare health outcomes. A limitation of this design is its susceptibility to recall and other forms of information bias since the exposure must typically be recalled by the cases and controls or be present in recorded data such as hospital records.

2.4.2.2. *Cohort*
A cohort study refers to a study design in which a group of persons who share a common exposure are studied over a period of time. Cohort studies are distinguished from case-control studies by two main features. First, classification into comparison groups is based on the exposure factor not the outcome. Second, the cohort study looks from the exposure forward rather than from the disease backward in time.

There are two main types of cohort studies: prospective and retrospective. The feature that distinguishes a prospective from a retrospective cohort study is whether the outcome of interest has occurred when the investigator initiates the study. In a prospective cohort study, the outcome occurs after the exposure is measured. In a retrospective cohort study, the investigation is initiated after both the exposure and the outcome have occurred.

2.4.2.3. *Intervention*
An intervention design is a prospective cohort study that investigates the impact of a treatment or control action on the exposure–outcome association. Study participants are assigned the treatment (intervention) at random and then followed to determine the proportion of persons exposed who develop the outcome compared with the proportion of persons unexposed (non-intervention). Assignment to an exposure category at random, also achieves, on average, equal distribution of other known and unknown confounding variables.

The study designs just discussed are presented in figure 1 to demonstrate how increasing knowledge of an exposure–disease relationship might develop for a hypothetical disorder (D) with a given exposure (E). Designs that accommodate the temporal relationship between an antecedent exposure and the outcome are considered most convincing of the strength or weakness of the E–D relationship. Where alternative explanations for this relation can be ruled out, for example by statistical adjustment of potential confounding variables, the results are more convincing.

3. APPLICATION OF EPIDEMIOLOGY TO WORKPLACE INJURY

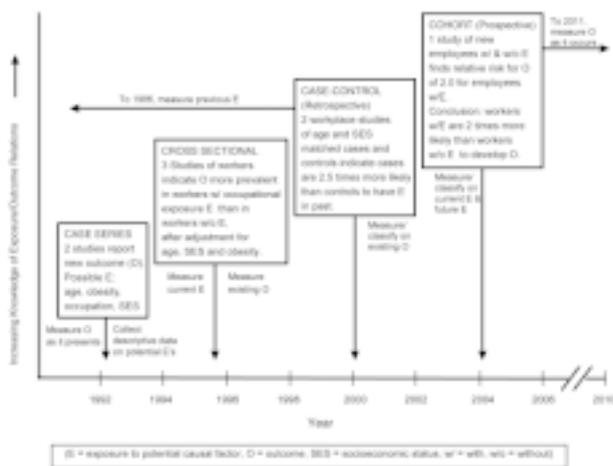
Epidemiologic methods can be applied to the evaluation and prevention of injury in the workplace. Ultimately any attempt to


Figure 1.

prevent or reduce the impact of injury in a population, whether a model for risk evaluation or an engineering design intervention, can only be validated using epidemiologic methods. However, epidemiologic methods are primarily useful for existing or emerging injury problems that have sufficient numbers of cases to support analysis. Therefore epidemiology is inherently reactive, identifying its solutions *a posteriori*.

Injury has been defined as "any damage inflicted to the body by energy transfer during work with a short duration between exposure and the health event (usually less than 48 hours)" (Hagberg *et al*. 1997). Work-related musculoskeletal disorders with longer time periods between exposure and injury onset (i.e. gradual onset) may also be addressed epidemiologically.

3.1. Evaluation of Injury at Work by Surveillance (Passive or Active)

Injury prevention at the workplace requires surveillance for injuries among workers, both before and after any intervention effort to prevent injuries. Surveillance has been defined as "the ongoing and systematic analysis and interpretation of health data in the process of describing and monitoring a health event" (Centers for Disease Control 1988). Workplaces may then use this information to plan, implement and evaluate the health effects if any from interventions or changes in the workplace.

There are two essential elements of any surveillance system. The first is a clear definition of the injury cases to be counted also known as the case definition. Very often in practice, existing data sources such as dispensary records, required injury logs (e.g. OSHA log) or cases receiving wage replacement or sickness/absence benefit provide initial case definitions (e.g. counting all hand injuries treated in the plant clinic). This particular approach is referred to as passive surveillance since the data already exist. A limitation of this approach is that one has to accept the data elements and quality offered by the existing system.

An alternative that can improve the upon the performance of passive surveillance is active surveillance. In this instance new information is solicited from the workforce specifically for the purpose at hand. Instruments typically used include discomfort or symptom surveys and risk factor checklists or other exposure evaluation tools. This approach offers improved information and control at the cost of resources to actively collect the information.

Once the case definition of interest is established all reporting sites must adhere to it. This will necessarily entail the support of the system with administrative and management resources including training in the appropriate use of the system by those entering and interpreting the data.

The second essential element is a count of the number of work hours in the population exposed to relevant work conditions in a particular plant, department, assembly line or workstation. These two elements, cases divided by work hours constitute the rate of occurrence of the injury event, which is the primary measure of effect of any intervention. The rates may be subdivided for categories such as length of employment, workstation location, shift schedule, etc.

3.1. Surveillance System Applications at Work

Consider a company with multiple locations producing similar products. Substantial variation in injury rates between these plants would suggest that injury circumstances, prevention efforts or injury hazards were somehow distributed differently between plants. Only by establishing comparable and consistent surveillance systems can these "natural experiments" be exploited. Similarly, if an injury intervention being installed company-wide can only be put in a few plants at a time, injury rate comparisons between plants with the intervention compared with plants that are designated to receive it at a later date can contribute to evaluating the intervention's efficacy.

For example, a large manufacturing company developed a new employee conditioning program in one plant and wanted the first 6 months of experience with it evaluated before duplicating the program company-wide. Back and shoulder injury cases were counted 6 months before the program was implemented and then 6 months while the program was in operation. The rate for cases with days away from work increased from 14 to 22 per 200 000 h worked. The number of cases of back and shoulder musculoskeletal disorder increased from four before the program's start to nine during the first 6 months of its operation. This was thought to be a large enough increase in cases to warrant a major modification of the conditioning program (Sorock *et al*. 1997).

3.2. Use of Narrative Data from Injury Records to Improve Injury Surveillance

Many injury surveillance systems include a brief narrative section describing in a few sentences how the "accident" happened. In most databases, only a single code is assigned to each narrative that best describes the "causes" of the "accident." The narratives can be searched electronically and certain keywords selected that can be used to identify cases not found by searching for codes. Narrative analysis has been used, for example, to identify fractures from "powered industrial vehicles," finger lacerations while using "gloves," injuries from contact with industrial "robots," and compensatable claims for back injuries while using a "hand cart" or "dolly" (Sorock *et al*. 1997).

3.3. Recommendations for Workplace Injury Surveillance

(1) Generally the utility of a surveillance system will improve as case definitions are refined and as progressively less severe and perhaps even near-miss types of events are cataloged.

However, it is important to note that systems offering very specific levels of detail, hence a greater number of potential categories or descriptors, can be compromised by efficiencies in use. For example, if the system allows a coder to select from 500 outcome codes, the coder will typically habituate to assigning the vast majority of incoming cases into a significantly smaller subset of more frequently used codes (see the entries on Human Information Processing for more on this topic). Hence, a trade-off between specificity and efficiency exists in surveillance systems. The appropriate level of detail is best selected by examining the goals of the system, the skills and training of coders, the anticipated management of the coding system, and the level of performance in detail of any existing systems which the new system is to complement or improve.

(2) Management and supervision should be involved in all efforts with respect to surveillance and injury control. This may be optimized through awareness training for management and supervision.

(3) Records for surveillance should include a brief narrative of how the injury occurred with special note to contributing exposures (e.g. equipment involved).

(4) Surveillance systems should record demographic information such as location, shift, age of worker, gender, job class and occupation.

(5) The system should incorporate where possible the costs associated with injuries to permit cost analysis.

(6) Organizations should computerize their surveillance systems and ensure sufficient storage space for archived data (Sorock *et al.* 1997).

3.4. Occupational Injury Intervention Studies

Workplace injury prevention efforts can be categorized as either engineering interventions (targeting the design of the job, tools and workspaces); administrative interventions (focusing on work procedures and policies); personal interventions (addressing worker behavior, training and education); or a combination of strategies (multiple interventions) (Zwerling *et al.* 1997). In general, worker behavior, training and education interventions alone have not been demonstrated to be as successful in injury

prevention as have other approaches. Multiple intervention approaches that seek to optimize the management of an injury problem in each major aspect appear the most effective (McGorry and Courtney 1995).

Ergonomics Considerations for Reducing Cumulative Trauma Exposure in Underground Mining

K.M. Cornelius and F.C. Turin

National Institute for Occupational Safety and Health (NIOSH), Pittsburgh Research Laboratory, Mining Injury Prevention, PO Box 18070, Pittsburgh, PA 15236-0070, USA

1. INTRODUCTION

Underground mining in the USA has undergone significant change in the past 20 years. Two key elements have been increased mechanization and a more educated work force. In spite of these changes, many jobs continue to be labor-intensive and repetitive in nature. They entail tasks that, performed over time, can take a toll on the soft tissues and joints. The problem may be compounded by an aging mining workforce. In 1996 the mean age of the coal mining work force was 45 years and the median total years of experience was 20 (NMA 1998). As a person ages, the body's resilience to chronic wear and tear is reduced, which may cause a worker to pay an increasingly higher health price for performing the same task. Mining companies, like many others, are becoming more aware of cumulative effects to the worker as reports of these types of injuries rise.

Conducting a job analysis is an important step when considering a job redesign or modification to reduce worker cumulative trauma exposure. A basic approach to job analysis is to examine the types of aches and pains reported, the tasks performed, and work site conditions. The US Bureau of Mines (USBM) conducted an evaluation of roof-bolting tasks performed at an underground coal mine concerned about early warning signs of cumulative trauma. This evaluation will comprise the primary focus of this chapter. The approach used for the roof-bolting case study may be applicable to other work environments.

2. FUNDAMENTALS OF CUMULATIVE TRAUMA EXPOSURE

Musculoskeletal injury is a term used to describe a wide range of soft tissue disorders that affect the nerves, tendons and muscles. Common examples include lower back pain, tendinitis and carpal tunnel syndrome. The majority of these injuries are not the result of sudden mishaps, but usually develop gradually from repeated wear and tear. Symptoms may not appear immediately, but can take weeks, months or even years. Symptoms may result from many types of activities, performed at work or at home, and it is often difficult to attribute them to a single event. In fact, it is more common to identify factors that may have contributed to the development of the condition. The terms repetitive strain injuries or cumulative trauma disorders (CTD) have been commonly used to refer to disorders that have occurred due to work-related activities.

Three main risk factors contribute to CTD: force, repetition and awkward postures. Any one or combination of these may contribute to the development of CTD. Therefore, the design of equipment in conjunction with the required tasks should be evaluated when attempting to reduce these risk factors. Examining the layout of the work area to help identify tasks which may contribute to cumulative trauma is necessary. The following list (Putz-Anderson 1988), describes ergonomics concerns that, overall, should be *minimized* at the work area:

- *Crowding or cramping the worker*: a work area layout may unnecessarily constrain movements of the worker.
- *Twisting or turning*: placement of tools and materials may require the worker to twist the spine to fulfill the requirements of the job.
- *Repeated reaching motions*: the layout of the work area may require the worker to lean to reach and grasp the necessary tools and controls.
- *Misalignment of body parts*: the arrangement of the work area may require the worker to frequently have one shoulder higher than the other or have the neck or spine bent to one side.

While many of these concerns are a function of equipment design and environmental conditions, making workers aware of these issues may help them to adapt their work habits to reduce risk of injury. Additionally, this information is useful when conducting an ergonomic evaluation of a work area and associated tasks.

3. UNDERGROUND MINING ENVIRONMENT

The underground mining environment is a unique challenge. It is more difficult to develop controls for an underground mine site as compared with a factory setting where equipment and facilities can be more easily designed to reduce worker force, posture and repetitive exposures. In an underground mine, workers are required to perform labor-intensive tasks that often cannot be avoided due to environment constraints. The dynamic nature of the environment does not allow easy implementation of mechanical assists to reduce force exposure. Many of the tasks performed by workers are repetitive. Restrictive work areas due to low ceiling height, low lighting levels and large pieces of equipment cause workers to perform these tasks in postures that are not desirable. Designers of underground mining equipment can control how a machine will function, but not the environment in which it will be used. Hazards in an underground mine cannot be completely removed by redesigning the system. There are many hazards and information sources that must be continually monitored by workers including their position in relation to large pieces of mobile equipment and unpredictable geological anomalies. Thus, immediate dangers may take priority over awareness of ergonomic considerations while performing a job.

4. CASE STUDY OF UNDERGROUND ROOF BOLTING

4.1. Roof Bolting and Cumulative Trauma Exposure

In an underground coalmine, after an area is mined it is necessary to support the roof to keep it from collapsing. Since 1950, the primary method for supporting the mine roof has been installation of roof bolts. Long bolts installed into the roof compress the layers of strata achieving a uniformly distributed support anchorage. Roof bolts, typically 6–8 feet long, are installed by workers using large roof-bolting machines. There are different types of machines

Figure 1. Roof bolting in a low seam mine often requires workers to maintain awkward postures.

used for high, medium and low coal seams. Typically in medium and low seams, the operator works in a small area between the machine and walls of coal called ribs. A roof bolter operator working in a low seam mine is illustrated in Figure 1. In high seams workers often work from a platform on the bolting machine. This case study evaluates workers roof bolting in a high seam mine. In general, bolting machine operators work in tight spaces.

Roof drilling and bolt installation in underground coal mines is labor intensive, repetitive and exposes operators to many hazards that can result in injury. In response to cumulative trauma exposure concerns at an underground coal mine, a case study was conducted to examine roof bolter tasks that performed over time could put workers at risk. For this study, the three data collection activities were analysis of lost time incident descriptions, interviews and observation of roof-bolting tasks.

4.2. Evaluation Approach

Researchers analyzed 43 lost time incident descriptions to identify roof-bolting activities and operator injuries having characteristics consistent with cumulative trauma exposure. Second, researchers conducted a series of interviews with the roof bolter operators, supervisors and the staff nurse. The objective of the interviews was to learn about bolting tasks and working conditions, to identify safety hazards and to discuss the details of injuries. The interview data were analyzed to identify similarities in injuries and pains; tasks that may contribute to cumulative trauma; and aspects of the working environment that may contribute to cumulative trauma. Finally, roof bolter operators were observed performing tasks, bolting activities were videotaped, still

photographs were taken of bolting equipment and mine conditions, and an experienced bolter operator discussed the layout and operation of a roof-bolting machine.

4.3. Results

From the injury analysis, 14 incident descriptions were identified as describing injuries that could have occurred from cumulative exposure and contained the following characteristics:

- Five of the 14 incidents involved pain in the back, neck, shoulder or elbow.
- Two incidents occurred while putting a roof bolt into a drilled hole.
- Two incidents occurred while lifting bolting supplies.
- One incident occurred while torquing a roof bolt.

Nine of the 14 incidents involved a strain or sprain injury to the ankle, knee or hip resulting from a slip, trip or misstep. Seven incidents involved stepping or kneeling on uneven floor, loose materials on the floor or equipment cable. Two incidents involved an operator stepping into or out of the bolting machine platform.

Interviews were conducted with 12 roof bolter operators. The most common injuries cited were:

- face and arm lacerations and cuts;
- shoulder, neck, and arm strains and pains;
- ankle sprains and twists, back pain and strains, and knee strains; and
- leg numbness.

Operators said that roof-bolting tasks require a lot of lifting, carrying, bending, reaching and stretching. Common activities cited as contributing to their pain and discomfort included: leg pains while leaning out to see the drill hole; hand and elbow

pain from using the controls; sore knees, back and shoulders from bending and twisting to install bolts or lift and position drill steels, wrenches and bolts; shoulder and elbow aches from picking up and holding drill steels; and knee and back aches at the end of the shift from standing all day.

The layout of the work area was examined and taken into consideration to minimize crowding the worker, twisting and turning, repeated reaching motions, and misalignment of body parts. After reviewing observation notes, videotape, and still photographs, key items were identified and are listed in Table 1.

4.4. Issues and Recommendations

The following cumulative trauma exposure issues were identified from the analysis: materials handling, operator orientation in workspace, vision obstruction, equipment design, and slipping and tripping hazards. Recommendations were categorized within each issue. Recommendations focused on reducing the three main risk factors that contribute to cumulative trauma disorders: force, repetition and awkward postures. They also addressed the three elements that define a system: human, equipment and environment. Recommendations directed at the human element are intended to increase worker awareness of risk factors. This knowledge can then be motivation for workers to modify their behavior to reduce exposure. Equipment recommendations address modifications to existing equipment, which can be performed at the mine site or retrofitted by the manufacturer and more significant modifications that should be addressed in

Table 1. Observations and issues concerning high seam roof-bolting machines.

Observation	Issue
Confined operator platform causes operators to twist and stretch to get drill steels, bolts, plates and wrenches.	This places operator in awkward postures creating stress to the muscles and joints, particularly in the back and the knees.
Supply trays are positioned at heights well above the operators' waists	Lifting and retrieving tools and bolts is stressful to the neck, arm and shoulder.
Tops of control levers are positioned well above waist height.	The operator must work with the arm and wrist in awkward postures.
Operators lean against the back rail of operator compartment and out from under the canopy while performing drilling and bolting tasks.	This places the operators in awkward postures. Also, it is putting them at risk of being hit by falling rocks.
Operators shift their weight to the side of the body corresponding to the hand which places the drill steel into the drill chuck.	The muscles on the opposite side of the body, particularly the low back muscles, are stressed and may become fatigued.
Operators frequently extend their arm up and out to hold onto steels while drilling, and onto bolts while installing them.	This is stressful to the neck, arm and shoulder muscles.
Drill steels are being inserted into the drill chuck usually at knee level or lower.	The operator must do more bending which stresses the low back muscles.
Transfer of supplies from the back of a bolting machine to supply trays involves frequent lifting, carrying, and twisting.	This places operator in awkward postures creating stress to the muscles and joints, particularly in the back and the knees.

the design of future roof-bolting machines. Environmental factors play an important role in human–machine interfaces. Environmental conditions addressed in the recommendations included space restrictions, visibility restrictions, and housekeeping.

The following is a sampling of the recommendations provided:

- Increase worker awareness of the risk factors associated with developing CTD.
- Examine activities that require high force, high repetition and awkward postures to determine if the task or equipment can be modified.
- Modify materials handling tasks to carry supplies as close to the body as possible, restrict the size of the load and minimize lifting distances.
- Eliminate barriers in the path that require operators to lift supplies up and over.
- Improve supply tray design and position, and method for stacking and retrieving supplies.
- Design bolter tasks and equipment to minimize shoulder abduction.
- Design operator work areas considering reach and visibility requirements.
- Reduce force required to activate controls.
- Increase spacing of controls to accommodate a gloved hand.
- Improve height of control bank in relation to operator.
- Consider a height adjustable, padded rail at back of operator platform.
- Evaluate the threshold between the bolting machine walkway and the operator platform with special consideration given to slipping and tripping hazards.
- Improve housekeeping practices and implement an active program to evaluate.
- Increase worker awareness of slipping and tripping hazards.

Recommendations were intended to be used as a guide for more comprehensive examination of roof-bolting activities. A mine-specific evaluation should be conducted at any mine concerned about cumulative trauma exposure due to varying conditions, equipment, and workforce. An evaluation team with diverse members including roof bolter operators, first line supervisors, engineers and safety personnel is an effective approach for developing solutions (Hamrick 1992, Carson 1993).

5. ROOF BOLTING HAZARDS AND HUMAN FACTORS DESIGN PRINCIPLES

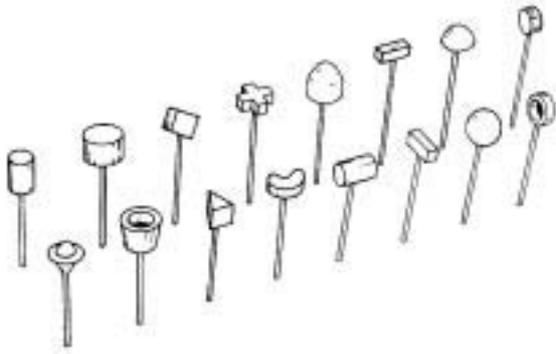
The presented case study does not cover all issues associated with underground roof bolting. Some issues presented are common across variations mining conditions; however, the case study presented focused on a high seam mine where workers operate from an attached compartment. There have been several published reports that have examined hazards associated with underground roof bolting. In particular, one USBM report examined hazards associated with the movement of the drill head boom (Turin *et al.* 1995). A human factors analysis approach similar to the case study approach presented here was used. Report recommendations focused on equipment design issues and the need to conform to accepted ergonomic design principles. One of the primary recommendations was to redesign the control bank to reduce the likelihood of accidental activation and improve


Figure 2. Knob shapes that can be recognized by touch by operators wearing gloves.

ease of use. Current control handles are identical in shape and color and are mounted close together. Controls should be coded by sequence, location and shaped so that they can easily be distinguished and operated. Figure 2 illustrates examples of control shapes.

To redesign the control bank properly, it is important to examine the operation of the roof-bolting machine overall. For example, issues identified in the case study such as materials handling, visibility, and operator orientation in workspace must be examined when equipment redesign is considered. A thorough task analysis would provide information critical to effective equipment redesign and resulting changes to roof-bolting tasks. A useful resource, *Human Factors Recommendations for Underground Mobile Mining Equipment* contains information on human factors design considerations and can be accessed at http://www.cdc.gov/niosh/mining This web page addresses issues on system design, task analysis, aging, layout, controls, visibility, seating and maintenance for underground mining equipment. Links are available on this web page to access additional ergonomics and mining safety topics.

Exposure Assessment of Low Back Disorders: Manual Material Handling Limits

A. Grieco, G. Molteni, G. De Vito, D. Colombini, and E. Occhipinti

Department of Occupational Health, University of Milan, Via San Barnaba 8, I–20122 Milano, Italy

1. INTRODUCTION

There are numerous regulations and standards on prevention of work-related musculoskeletal disorders (WMSDs) affecting millions of workers and workplaces. Almost all of them are based on principles of biomechanics, psychophysics, and physiology with the common goal of designing tasks in the way that the stresses imposed upon the majority of the workforce are below the threshold for fatigue, discomfort and injuries (Ayoub and Dempsey 1998).

Quite often it is difficult to collect all the needed data for a proper exposure assessment on a single task, and major difficulties are encountered in exposure assessment of multiple tasks. Sure enough, magnitude (intensity), frequency, and duration of exposure can be difficult to measure exactly. In addition some standards and regulations have been established in the laboratory, and the links between empirical research and actual exposure in the workplace are not yet completely validated by epidemiological studies. Nevertheless, it is worthwhile to establish limits for manual material handling activities as they assist industry in the control of low back pain.

2. MANUAL MATERIAL LIFTING LIMITS

There may be a variety of assessment for the various types of manual handling, but it is always possible to calculate a synthetic exposure lifting index or manual handling index (MHI) as a function of major situation variables:

$$MHI = \frac{Actually\ handled\ weight\ (force)}{Recommended\ weight\ (force)}$$

Even if it is determined by semiquantitative assessment procedures, the MHI may become an effective tool for defining the consequent preventive measures in accordance with correct prevention strategies, and this may be more important than its role in defining the exposure level of one worker involved in manual handling.

When defining preventive measures, it is convenient to classify MHI results at least according to a model having more than two levels and not a simple dichotomous (yes/no) type. This is because the level of approximation (both intrinsic and in conditions of application) for the suggested methods and procedures calls for a certain amount of caution, especially over borderline results around the value of 1. Then a three-zone model (or traffic light model) appeared to be useful, with the MHI classified as follows:

- *Green zone* (MHI ≤ 0.75)There is not a particular exposure for the working population and therefore no collective preventive actions are required.

- *Yellow zone* (0.75 < MHI ≤ 1.25)This is the borderline zone where exposure is limited but may exist for some of the population. Prudent measures are to be taken, especially in training and health surveillance of operators. Wherever possible, limit exposure so as to return to the green zone.

- *Red zone* (MHI > 1.25)Exposure exists and is significantly present. The higher the MHI value, the higher the exposure for increasing numbers of the population. MHI values may determine priority of prevention measures that must in any case be taken to minimize exposure and shift it towards the yellow zone. Training and active health surveillance of operators must be undertaken in any case.

Obviously the definition of the values corresponding to the three zones is somewhat empirical and may also reflect requirements independent of methods and related data generating the proposal; in this sense the limit values may also be modified by taking into account peculiar application requirements but mostly by a critical reflection on their validity, based on concrete application results.

3. LIMITS OF PULLING, PUSHING, AND CARRYING

For manual load handling — pulling, pushing, carrying — the literature describes no equally consolidated procedures, based on multidisciplinary approaches like the NIOSH procedure for lifting. We suggest ignoring the literature methods and using instead data derived from the specific application of psychophysical methods masterfully summarized by Snook and Ciriello (1991). Here are our three main reasons:

- The data is also expressed with reference to the percentiles of potentially satisfied (even if not necessarily protected) population.

- Data from psychophysical studies is used to develop the NIOSH formula (NIOSH 1981, Waters *et al*. 1993) to assess lifting tasks; in particular, it is used to evaluate the degree of protection or better satisfaction associated with use of the recommended weight limit.

- The data from psychophysical studies is expressed by Snook and Ciriello (1991) with reference not only to the two genders but also to structural variables (height of pushing or carrying areas, distance) as well as to organizational variables (frequency and duration of tasks) which produced well-defined methods according to the different working situations.

Applied in equal conditions, these are the three reasons that led us to prefer psychophysical data, provided it is homogeneous with lifting task procedures and assessment criteria. Pushing and pulling data (conceptually comparable with the recommended weight of lifting task) is referred to forces for activating and maintaining actions. Carrying data is referred to the weight of the carried object. All data is referred to satisfaction of 90% of the population. Values are subdivided according to major structural and organizational variables. With such data available, exposure assessment is rather simple and consists of the following steps:

1. Select the scenario from the figures (kind of task, structural conditions, duration and frequency, gender target) which best fits the actual situation to be analyzed by identifying the recommended force (or weight).

2. Determine in a real situation and under usual operating conditions the force needed to start or maintain a pushing or

pulling action. This can be done by using a conveniently interfaced normal dynamometer; for carrying, simply define the weight of the carried object.

3. Define the ratio between the force measured and the corresponding recommended value; this gives the relevant index.

4. CONCLUSION

It is generally believed that persons should not lift more weight than they would be willing to accept based on their own point of view. However, proposing practically acceptable limits for manual material handling tasks may be quite useful for all those involved in applying regulations and standards for prevention of musculoskeletal disorders related to manual load handling. Moreover, there is a need for an epidemiological validation of the proposed limit and for basic and applied research to define which method of aggregation provides the best assessment of exposure to complex jobs involving manual material handling. There is a need

for basic and applied research to enhance the methodologies for aggregating multiple-component manual material handling tasks with manual material handling criteria.

Exposure Assessment of Low Back Disorders: Assessment Criteria for Manual Handling Tasks

A. Grieco, G. Molteni, G. De Vito, D. Colombini, and E. Occhipinti

Department of Occupational Health, University of Milan, Via San Barnaba 8, I–20122 Milano, Italy

1. INTRODUCTION

Among the important intervention methodologies in the field of ergonomics is how to assess the individual probability of contracting dorsolumbar spinal disorders due to manual load handling. Right now, owing to the variety and complexity of the organizational, environmental, and personal factors which determine the risk, it appears quite a complex assessment to make.

The term "exposure assessment" may be more appropriate. By identifying and quantifying the variety of possible major risk factors and their "integrated evaluation", it is possible to identify the degree of potential harmfulness of a given task, and to guide the preventive measures (risk management).

An extremely simplified interpretation of the assessment concept has become standard practice in workplaces and other applications. For example, load handling may be assessed solely on the basis of the weight of the load (perhaps referred to national regulations and standards). This is widespread practice in different countries; in fact, when a weight limit is introduced in the legislation, it is even possible to come up with the simplification that all objects weighing less than the weight limits may be handled in "safety"!

This level of simplification means the researcher has to redefine the requirements for assessment validity and applicability, leaving aside the rigors of a sophisticated scientific approach as a prerogative of research elites but also opposing the oversimplification demanded by operators in the field. Examining the variety of documents (guidelines, standards, operational handbooks) produced in the meantime, the requirement of proposing scientifically valid and practically applicable exposure assessment models has been widely acknowledged and largely solved.

2. LOAD LIFTING ASSESSMENT

As regards assessment of manual load exposure to lifting, most proposed models are based on the NIOSH equation published in 1981 (NIOSH 1981) and revised in 1993 (Waters *et al*. 1993). This occurs via major adaptations and changes in the original models; however, the existence of a common design is clear, thus making those models the most suitable to achieve the desired synthesis between scientific research basis and operative application. Actually the NIOSH model offers considerable advantages:

- It is supported by valid and diversified scientific bases (NIOSH 1981).
- It contemplates a large number of possible major risk factors.
- It summarizes in a synthetic index the more complex assessment process (lifting index as the ratio between weight actually lifted and the specifically recommended weight).
- It defines, albeit roughly, the degree of protection assured to a generic working population.

But adopting the NIOSH model to make assessments in the field of manual handling tasks did pose some problems. Here are three of them.

2.1. Caution May Be Tempered Using Empirical Data

The American authors themselves (Waters *et al*. 1993) emphasize that the procedure is not applicable in some situations; such caution is quite understandable from a strictly scientific viewpoint, but in some cases it may be overcome by making assumptions based on empirical data. Suppose the load is lifted with one arm only, perhaps this could be included by introducing a further multiplication factor of 0.6.

If lifting is carried out by two or more operators, always in the same workplace, maybe treat the weight actually lifted as the weight of the object divided by the number of operators, and use a further multiplication factor of 0.85 to obtain the recommended weight. Such further adaptations of the method (only one arm, more than one operator) are based on highly empirical data and not on experiments carried out following strictly scientific procedures. But without them, many problems would remain unsolved.

2.2. Multiple Tasks Need More Complex Analysis

In many working situations, the same group of workers have to carry out different load tasks often in the same workshift. The difference is the result of many different factors (nature of the object, different areas of loading and unloading, work organization procedures). Moreover, the different lifting tasks may be irregular in a given period of time in the workshift (e.g., in a warehouse with picking activities) or according to established time sequences (e.g., when an operator works every 1–2 hours on an assembly line, first loads the line, then unloads the finished products, and then packs them). In such cases the analytical procedure for each task is not suitable to summarize the overall exposure of the worker to load lifting. Therefore these cases require an analytical procedure for multiple tasks, which is obviously more complex. NIOSH has made a proposal for analyzing mixed multiple tasks, founded on the idea of calculating a synthetic lifting index for multiple tasks based on the index for the more overloading task, increased by values derived from the other tasks considered.

2.3. Nonindustrial Tasks Are Not Well Modeled

The NIOSH assessment procedure is not well suited to application in various working sectors (typically nonindustrial sectors), sometimes on account of the characteristic of the lifted load, the great variability of lifting tasks, their frequent association with other manual handling tasks (trolley pulling or pushing), and finally the presence of other risk factors for the lumbar spine (e.g., whole body vibrations). Agriculture, transport and delivery of goods, and assistance to individuals who are not self-sufficient are typical examples. In these situations, though the NIOSH

lifting index is useful, validated procedures for integrated exposure assessment are not yet available, hence the need for further research and proposals on specific simplified exposure assessment procedures aimed at managing risk factors.

3. CONCLUSION

Researchers have yet to complete and verify the data on degree of protection associated with the adoption of different weight constants and with reference to different targets of the adult working population. Therefore a more precise definition becomes essential, especially in order to better establish large-scale prevention strategies which will be sufficiently well defined to account for the makeup of the working population (males and females, young and elderly, healthy and nonhealthy).

The NIOSH lifting index does not seem to be a complete risk index; it is still only an exposure index. Support for the NIOSH index as a risk index perhaps lies only in the (collective) probability of acute lumbago. In the future, epidemiologic studies will have to be developed to ascertain its predictability for degenerative chronic spinal diseases, due to biomechanical overload.

Some countries have adopted weight constants different from those originally proposed (23 kg), although they have retained the calculation procedures for the main multiplication factors in the Waters (1993) formula. This operation, although acceptable for immediate application, may not be fully justified from a strictly scientific and technical viewpoint. If weight constants are adopted other than those originally proposed, it will be necessary to redefine the terms for calculating each multiplication factor and then to decide on the necessary adjustments.

It has been debated that in some working situations, beside the multiple load lifting tasks assigned to a group of workers, they perform many other manual handling tasks such as pulling and/or pushing manual trolleys or carrying loads over long distances. Waters *et al.* (1993) states that its lifting index cannot be applied in these cases. Therefore an integrated assessment procedure needs to be developed for such complex situations, probably by extending the procedure for analyzing multiple lifting tasks.

Exposure Assessment of Low Back Disorders: Criteria for Health Surveillance

A. Grieco, G. Molteni, G. De Vito, D. Colombini, and E. Occhipinti

Department of Occupational Health, University of Milan, Via San Barnaba 8, I–20122 Milano, Italy

1. INTRODUCTION

Health surveillance observes the state of health of a population and its individuals (usually with respect to a specific health effect). It makes these observations over time and assesses their compatibility with exposure to one or more occupational risk factors. Health surveillance is implemented in industrialized countries in a great variety of ways, depending on specific cultures, regulations, and the development of social security systems. For example, there are countries where data on the health of individuals and workers is systematically collected, and although not always reliable or relevant, it may be used to implement processes for so-called passive health surveillance.

In other countries such current statistics are totally lacking, at least as regards work-related musculoskeletal disorders, therefore it is impossible to use or define passive health surveillance procedures. On the other hand, attention should be drawn to the extremely high number of workers potentially exposed to risks associated with manual material handling; this is why active health surveillance strategies must be developed that are suitable for monitoring vast numbers of workers, and also acceptable from the viewpoint of costs and human resources.

2. ACTIVE HEALTH SURVEILLANCE

2.1. A Three-step Procedure

Step 1

All exposed subjects receive questionnaires or anamnestic interviews according to models that are already available in the literature (Kuorinka *et al*. 1987, Occhipinti *et al*. 1988). These tools are aimed at collecting data on more recent symptoms and disorders (generally over the past 12 months), and should also allow classification according to intensity or severity levels for diagnostic purposes or subsequent preventive measures. In other words, well-defined criteria for interpreting the total data collected on symptoms are recommended in order to unequivocally classify the investigated effects.

Step 2

The second step envisages a clinical examination of the spine only for subjects classified as positive in the previous anamnestic survey. This examination can be made by the occupational physician in the company medical department using a standardized set of specific clinical tests and maneuvers reported in the literature (NIOSH 1988, Occhipinti *et al*. 1988, Hagberg *et al*. 1995)

Step 3

The third step applies to those subjects, identified in steps 1 and 2, requiring more specialized tests (neurological, orthopedic, etc.) or instrumental tests (image diagnostics, EMG, etc.) in order to complete the individual diagnostic procedure.

2.2. Frequency and Goals

The frequency of generalized health surveillance (steps 1 and 2) may be established as required, according to relative exposure indexes as well as health results obtained in the latest round of examinations. Generally speaking, since health surveillance is concerned with slowly evolving chronic degenerative diseases, checks every 3-5 years are usually adequate. There may be exceptions when exposure is heavy and/or drastic changes in working procedures are under way; then more frequent monitoring of health effects may be advised.

One of the goals of health surveillance, from a collective viewpoint, is to check whether in a given working population, exposed to a specific risk, the occurrence of disease is other than expected. For instance, it is interesting to know whether in the same working population the occurrence of undesired effects (e.g., acute back pain, disk herniations) is markedly different from the rest of the working population not exposed to the specific occupational risks. To make such comparisons, generally by inferential statistics, adequate reference data must be available on the whole working population or at least its representative specimens.

Another goal of specific health surveillance at individual level is the earliest possible identification of subjects affected by spinal disorders for whom it would not be advisable to allow exposure levels that were defined as permissible for healthy subjects. In these cases, alternative employment should be found, where the specific risk condition is absent or exists only at low levels. Since these subjects are often completely emarginated (dismissal, employment in minor activities), it may be desirable to establish a line of action that would allow these subjects to stay in productive work at least in some working situations. Four aspects are relevant to manual material handling:

1. Perform a thorough diagnostic assessment of the subject from both clinical and functional viewpoints. Spinal diseases could be classified as light/moderate and medium/severe.
2. Evaluate the present and future working tasks of the subject involving manual material handling. And if the NIOSH lifting index is applied, introduce the following load constants according to the level of disease and gender of the subject: if the level of disease is light/moderate, the load constant should be set at 15 kg for men and 10 kg for women; if the level of disease is medium/severe, the load constant should be reduced to 10 kg for men and 8 kg for women.
3. Assign these subjects only to tasks where the lifting index, calculated using the above load constants, is less than or equal to 1.
4. Carry out a strict individual check on the development of the disease in order to detect any aggravation and take the necessary corrective measures.

When the task assigned to the subject does not meet these criteria, consider whether the task can be suitably redesigned (from a structural and/or organizational standpoint) so it does meet them. Here ergonomic measures take on special importance in redesigning or equipping the workplaces so that workers with path-

ological disorders or with functional impairments can be reemployed there in satisfying and productive jobs.

3. WORKPLACE DESIGN

From common experience, especially in exposure assessment and its implications for risk management, reseachers have realized that in most working environments, even technically advanced environments, load handling is performed with empirical approaches; it is not specifically designed. There are some exceptions to this tendency (e.g., computerized and robotized warehouses) but they seem to be a prerogative of a few industrial elites which have realized how adequate design of goods handling means that, besides solving space problems, it is important to solve problems of safety and potential exposure to noxious agents, and more generally to improve the performance of the whole production system.

The explicit introduction of special regulations and standards should produce the desired effect of devoting more attention to design of tasks and work environments and to workplaces where load handling is required. Design should follow rational and commonsense principles, in accordance with the requirements set by statutory regulations and resulting standards and with current ergonomic trends reported in the literature.

4. CONCLUSIONS

4.1. Adequate Training

The albeit simplified procedures we have suggested for exposure assessment will also be extremely helpful in guiding specific redesign operations. For load lifting, the proposed assessment models can be used to analytically identify the critical factors (weight or size of the object, workplace and layout characteristics, and task organization features); and since they lead to a significant exposure assessment, they have to be modified (in order of priority). Redesign may therefore involve a new load weight, a different workplace arrangement, a different task organization in terms of lifting duration or frequency. Then the evaluator must work in close cooperation with the designer, who should be specially trained in how to manage and prevent problems associated with material handling. Training of technical management staff involved in logistics and production design is a prerequisite of any preventive action.

4.2. Common Sense

In many cases redesigning may also be achieved with simple, commonsense, and low cost measures. Storing goods at adequate heights, allocating suitable space for manual material handling, diversifying tasks, selecting lighter packaging are all rapidly and easily applicable measures in many work situations.

4.3. Auxiliary Systems

Although there is an undeniable tendency to use automated production systems, it is clear that in the short to medium term or for diversified production systems, an auxiliary system will be demanded, i.e., where the worker is not replaced by a robot but carries out some tasks with mechanical aids. Although many and varied machines and equipment are available, such as trolleys, transpallets, elevator platforms, and bridge cranes, there is a significant lack of aids, machines and equipment, or specific and diversified solutions to improve handling in particular industrial workplaces and in most servicing workplaces. Most likely there has not yet been any specific demand by these sectors to provide an incentive for manufacturers of handling tools and systems.

4.4. Logistic Design

Logistic design, in the industrial sector and in the service sector, is an ever expanding and much demanded discipline. There is obviously a close relationship between logistic design and material handling, and this is something for production ergonomists to consider. The interrelationship should be further developed, especially in nonindustrial sectors where there is frequent handling of goods (e.g., commercial distribution of foodstuffs) and people (e.g., hospitals). In short, redesigning of manual load handling tasks offers vast opportunities to ergonomists both by intervention in individual workplaces and in individual products and by restructuring working macrosystems.

Exposure Assessment of Upper Limb Repetitive Movements: Criteria for Health Surveillance

E. Occhipinti, D. Colombini, G. De Vito, and G. Molteni

Research Unit on Ergonomics of Posture and Movement, Via Riva Villasanta, 11–20145 Milan, Italy

1. INTRODUCTION

The general aims of occupational health surveillance are strictly preventive and involve the long-term monitoring of relationships between the worker (both individually and as a group), health, and the specific working conditions. In this sense, the surveillance of working conditions, and therefore of potential risks, is closely related to occupational health surveillance.

Here are the specific objectives of occupational health surveillance for workers as a group: to contribute to an accurate assessment of work-related risks; to monitor the long-term adequacy of any preventive measures adopted; to collect useful clinical data for periodic comparisons, or comparisons between groups, in order to highlight any positive or negative tendencies among the investigated health effects.

Here are the specific objectives of occupational health surveillance for workers as individuals: to identify those affected by hypersensitivity to the work-related risks present in the working environment, for whom more stringent protective measures should be taken with respect to the rest of the workers; to identify any early-stage diseases, particularly work-related diseases, in order to prevent them from worsening; to identify workers with full-blown disorders, for whom urgent protective measures must be taken.

Occupational health surveillance should also identify cases which must be reported as occupational diseases to the National Insurance Authorities. All acute, subacute or chronic disorders affecting the musculoskeletal system and peripheral nervous system, in particular all nerve entrapment syndromes, primarily carpal tunnel syndrome; all tendon disorders of the hand, wrist, and shoulder; as well as elbow medial and lateral epicondylitis disorders; these are of specific interest in occupational health surveillance, whatever their etiopathogenesis may be.

Note that for other diseases (Dupuytrens disease, various arthroses of the cervical spine or hand, etc.), the link between the disorder and specific working conditions has been postulated, but has not yet been sufficiently well documented. Here occupational health surveillance constitutes a useful tool for monitoring and analysing situations. Indeed, fitness-for-work judgements cannot be made without also taking into due consideration those alterations which, at the current state of our understanding, may not be related to occupational risks, but which will nevertheless be influential in allocating affected workers to specific jobs.

2. NEED FOR OCCUPATIONAL HEALTH SURVEILLANCE

There are basically two factors which, alone or together, will determine the need for occupational health surveillance in a specific group of workers: when work features a potential health risk and when cases are reported that might conceivably be work-related.

2.1. Job as Potential Health Risk

The best way to establish whether a job features a health risk is to carry out an analysis and assessment of the working conditions using the methods proposed in the literature. In particular, when the method for calculating the OCRA exposure index is applied (Occhipinti 1998), active health surveillance should be embarked upon when the index reports a score in the yellow or red areas. If the analytical assessment has not yet been carried out or completed, the decision to begin health surveillance practices will be taken if at least one out of the following three signs of possible risk is detected:

- Jobs featuring cyclic tasks requiring the worker to perform the same movement or set of movements with the upper limbs every few seconds (i.e., every 15 s or less), for at least two consecutive hours (including scheduled short pauses), or for a total of at least four hours per shift.
- Jobs requiring continual manual exertions (at least one every 5 min) for at least two hours per shift, like holding objects weighing more than 2.7 kg or grasping objects weighing over 900 g between thumb and index finger or exerting almost maximal force on tools or levers.
- Jobs involving extreme wrist or shoulder movements or positions for one hour continuously or for a total of at least four hours per shift.

2.2. Reports of Upper Limb WMSDs

Regardless of the factors mentioned in the previous paragraph, it can be assumed that, in a number of working environments, work-related upper limb disorders such as nerve entrapment syndrome or tendinitis may be reported either as a result of systematic data collection methods, such as sick leave statistics, or more often quite randomly, via workers requesting medical examinations. All clinically confirmed cases must be taken into consideration when deciding whether to embark on an active health surveillance program.

It almost goes without saying that when the worker population is small, even individual cases suffice to start a targeted health surveillance program, at least involving the use of anamnestic interviews. But when the number of workers is larger, a proportionally greater number of cases need to be evaluated. There are no hard and fast rules about how to define action levels, but generally speaking, an annual incidence of confirmed work-related cases in excess of 1% or a prevalence of cases twice as high as for the low-exposure population (Battevi *et al*. 1998) constitutes the threshold for setting up a specific health surveillance program.

3. ORGANIZATION OF A MULTILEVEL OCCUPATIONAL HEALTH SURVEILLANCE PROGRAM

In studying and monitoring musculoskeletal disorders of the upper limbs, the symptoms reported by workers are extremely

significant since they generally appear early and, if detected promptly, may provide valuable diagnostic guidance while helping to determine the need for clinical and/or laboratory tests. Moreover, in studies on groups, a method needs to be found for defining reported symptoms as being significant.

Having established this premise, it is now possible to outline a two-level approach to specific health surveillance: firstly at the general level, addressing all exposed workers, based on the collection of personal histories by means of structured interviews carried out by trained health operators; and secondly at the clinically specific level, involving only workers found to be positive at anamnestic investigation.

For first-level surveillance, the symptoms and symptom characteristics are used to define an "anamnestic case" as musculoskeletal upper limb disorders, based on the following minimum criteria (Hagberg *et al.*1995):

- Pain and/or paraesthesia (tingling, burning, pins and needles, numbness, etc.) in one or both of the upper limbs reported during the previous 12 months, lasting at least one week, or occurring at least once a month.
- Onset not attributable to acute trauma.

The aforementioned minimum criteria are in any case valuable for supporting the subsequent operating procedures, although they may be insufficient for diagnostic purposes: programming the surveillance, statistical assessments, preventive measures. The second level is needed to make an accurate diagnosis. Only workers classed as anamnestic cases will be referred for clinical or laboratory testing, based on the relevant diagnostic suspicions.

Based on the results of the clinical and laboratory tests performed, the worker will be diagnosed as a *clinical case*. If the clinical and laboratory tests for the disorders under examination are negative, the worker will still be classed as an anamnestic case and may perhaps be monitored more frequently than workers classed as normal.

4. ASSESSMENT OF COLLECTIVE HEALTH SURVEILLANCE DATA

All upper limb disorders that are demonstrably or potentially work-related deserve to be submitted to a comparative analysis to highlight the presence of clusters in the group of workers studied. Comparative analyses may focus on the following aspects:

- Trends over time to display a tendency to increase, decrease, or stabilize within the group.
- Comparisons between workers operating on a specific line or department versus the overall population in a factory or plant: to highlight the existence of "problem groups" and jobs, and to prioritize preventive measures.
- Comparisons with adult worker populations exposed to low levels of occupational risk; these analyses serve to highlight clusters of disorders or overt diseases in a group of exposed workers versus the incidence of similar disorders or diseases among groups who are exposed to low occupational risk.

Taking into consideration the size of the groups examined, comparisons may be made using usual inferential statistical techniques. Whenever possible, it is desirable to have annual incidence data. It is obvious that comparisons must be made between homogeneous classes of disorders or between individual clinically defined diseases. If there are difficulties in submitting the comparisons to suitable inferential statistical analysis, remember that occurrence clusters should be deemed significant when they have a prevalence or incidence of twofold or greater.

Note that collective health surveillance data is a valuable tool for analyzing the quality and adequacy of both exposure assessments and preventive measures, as well as for programming supplementary preventive measures, if required. In fact, evidence that specific diseases are tending to increase or appear in significant clusters among a group of exposed workers will lead to further investigation or a strengthening of the strategies and initiatives undertaken to prevent upper limb disorders in the group.

In particular, collective health surveillance data can be used to plan periodic follow-up. The following criteria may be a helpful guide. When risk is essentially absent no health surveillance is needed. When risk is present the health surveillance program should be scheduled every 3–5 years or every 1–2 years, depending on the risk level. Lastly if the investigation detects any individuals affected by work-related diseases or anamnestic cases, the occupational physician must draw up a personalized follow-up schedule for each worker.

5. MANAGEMENT OF INDIVIDUAL CASES AND FITNESS–FOR–WORK JUDGEMENTS

Occupational health surveillance can also generate three classes of workers:

- Workers reporting anamnestically positive disorders: besides drawing up a personalized follow-up schedule for them, it is also advisable to consider adopting appropriate measures to reduce their exposure to work-related risks.
- Workers reporting overt diseases not apparently associated with work-related risks: the workers must be temporarily or permanently removed from all or some of the tasks producing a biomechanical overload of the upper limbs (i.e., fitness-for-work judgements).
- Workers reporting overt diseases apparently or definitely associated with specific work-related risks: besides a fitness-for-work judgement including measures for restricting risk exposure, the case must also be reported to the appropriate authority according to national legislation.

Regarding fitness-for-work judgements, when workers are affected by an overt upper limb musculoskeletal disease, it is advisable to recommend that measures be adopted to reduce exposure. It depends on the type and severity of the disease and the levels of exposure, but there are rarely any strict adoption criteria; given the lack of concrete experience in this field, no hard and fast rules or guidelines can be suggested. On the whole, workers affected by the following list of disorders must be removed from tasks involving repetitive or strenuous movements of the upper limbs:

- Incapacitating arthrosis of the upper limbs
- Incapacitating outcomes of upper limb traumas (in relation to the functional demands of the task)
- Radiculopathies associated with degeneration and/or malformation of the cervical spine
- Disorders of the peripheral nervous system of systemic origin
- Rheumatoid arthritis
- Severe current mesenchymopathies

In the case of tendon disorders or entrapment neuropathy, the following criteria may be adopted:

- Temporary removal from tasks involving repetitive movements for as long as required by the acute phase therapy.
- Permanent removal from such tasks for all forms featuring permanent functional impairment.
- Fitness for work conditional upon restricted exposure to repetitive tasks for workers with chronic forms where there is no evidence of functional impairment.

In the third item, "restricted exposure" needs to be defined case by case based on the absence of risk. However, it is recommended that these cases should be given a personalized and frequent follow-up program, so as to closely monitor the evolution of the worker's clinical condition, and consequently to adopt measures aimed primarily at preventing the job performed by the worker from further aggravating the disease.

Exposure Assessment of Upper Limb Repetitive Movements: Epidemiology

A. Grieco, G. Molteni G., G. De Vito G., and N. Sias

Department of Occupational Health, University of Milan, Via San Barnaba 8, I–20122 Milan, Italy

1. INTRODUCTION

As opposed to "specific occupational diseases", where there is a direct cause-effect relationship between risk and disease, the Expert Committee of the World Health Organization (WHO 1985) describes the "work-related diseases" as multifactorial. The working environment and the way work is carried out can significantly contribute to the onset of such diseases, but they represent only two of the many causes.

Hagberg et al. (1995) have recently made a detailed review of the literature on work-related musculoskeletal disorders, especially those concerning the upper limbs. Certain occupational exposures are associated with musculoskeletal diseases and involve high relative risks; this was demonstrated for tendinitis of the shoulder and the hand/wrist, carpal tunnel syndrome, and tension neck syndrome. The results were contradictory for other diseases, such as lateral epicondylitis and cervical radiculitis, making it difficult to evaluate the eventual association with work.

Occupational musculoskeletal disorders of the upper limbs can be defined as alterations of the muscle–tendon unit, the peripheral nerves and the vascular system. They can be triggered or aggravated by repetitive movements and/or physical strain of the upper limbs. The main characteristics are multifactorial etiology (occupational and nonoccupational), development over a long period of time (from weeks to years), a long time required for recovery (which may never be complete), and most frequent involvement of muscle–tendon units. Peripheral nerve entrapment syndromes are less common (e.g., carpal tunnel syndrome) but they are more severe and costly.

In the international literature, the following acronyms are used to describe disorders of the upper limbs and to identify their occupational origin: work-related musculoskeletal disorder (WMSD), cumulative trauma disorder (CTD), repetitive strain injury (RSI), occupational cervicobrachial disease (OCD), occupational overuse syndrome (OOS). The term "work-related musculoskeletal disorder" is the most appropriate, since it suggests or proves an occupational cause in the genesis of the musculoskeletal disease and avoids the confusion of introducing in the same term the presumed cause — cumulative in CTD and repetitive in RSI, and the effect — disturbance in CTD and damage in RSI.

Under WMSD we should group together diverse pathological situations that may affect the various structures of the upper limb, but which all have a possible occupational etiology, as a consequence of repetitive and/or cumulative traumas. The critical assessments in Hagberg et al. (1995) and NIOSH (1997) were indispensable for obtaining epidemiological data on the degree of association between work and the most frequently observed musculoskeletal disorders described here.

2. SHOULDER TENDINITIS

The term "shoulder tendinitis" includes all inflammatory forms of the shoulder muscles and tendons, but they are hard to distinguish clinically. The epidemiological studies showed a high prevalence of these diseases in various categories of workers employed on industrial assembly work, welders, packagers, and workers in the fish processing industry; workers exposed to high repetitive rhythm, requiring a significant use of force; and workers doing jobs requiring awkward postures such as overhead work, arm elevation, and specific postures relative to the degree of upper arm flexion or abduction. In these studies the degree of association was extremely high, indicating that the effects could not be ascribed to chance. The temporal association, defined as the demonstration that occupational exposure to risk factors precedes the onset of symptoms, was not proven in all the studies.

High intramuscular pressure is developed in the rotator cuff muscles when performing overhead work; this could impair the intramuscular circulation and contribute to the early onset of fatigue. The initial form of tendon inflammation is characterized by cellular degeneration caused by reduced blood perfusion and impaired metabolism: the degenerated cells die and the calcium salts that deposit on the cell fragments can lead to an inflammatory reaction.

When the arm is raised or abducted, the blood vessels that flow to the tendons of the supraspinatus muscle are compressed, thus altering the blood circulation of the tendons; this might explain the occupational etiopathogenesis. Furthermore, when performing overhead work, the supraspinatus tendon comes into contact with the undersurface of the acromion. The mechanical pressure imposed on the tendon by the acromion is greatest for arm elevations of 60-120°. There is evidence of a relationship between repeated or sustained shoulder postures requiring more than 60° flexion or abduction and shoulder work-related disorders.

In conclusion the evidence for increased risk of work-related disorders due to specific shoulder postures is strongest when there is a combination of exposure to several physical factors, e.g., force, repetition, and vibration; and increased muscle contraction may lead to an increase in both muscle fatigue and tendon tension, impairing circulation.

3. LATERAL EPICONDYLITIS

The epidemiological studies demonstrated a weak association with work in groups of workers employed on meat cutting, packaging, textiles, sewing machines and grocery checkouts. The evidence of a relationship between work factors and epicondylitis was strongest when examining exposure to a combination of risk factors (e.g., force and posture, force and repetition) and epicondylitis. However, in many other studies, no association was demonstrated between lateral epicondylitis and work.

Although an association with work has not yet been demonstrated, it is likely that repetitive, forceful movements can cause the contraction of the muscle–tendon units that are attached in the area of the medial and lateral epicondyles of the elbow, producing the typical alterations.

4. HAND–WRIST TENDINITIS

Hand–wrist tendinitis involves the tendons that cross the radio-carpal joint: the most common form is De Quervain's tendinitis, due to entrapment of the tendons of the extensor pollicis brevis and abductor pollicis longus. The available epidemiological studies show a high risk in the manufacturing industry in general, and in the meat processing industry in particular, with a strong association in the case of specific exposures and the strongest evidence in the case of jobs involving a combination of risk factors such as repetition, force, and postures. However, none of the studies have demonstrated temporal association.

The studies also showed a relationship between incidence of tendinitis and work seniority, number of objects handled, high repetitiveness of gestures, and the force used. Due to the reduced size of the first dorsal wrist compartment where the hand and wrist tendons run, the pressure arising from repetitive actions may produce inflammatory reaction of the tendons, which makes an occupational etiopathogenesis plausible.

5. CARPAL TUNNEL SYNDROME

Compression of the median nerve in the carpal area and the consequent reduction in the flow of blood in the epineural venules may result in endoneural and synovial edema. If the pressure persists over a long period, it may trigger a fibrosis which damages the nerve function, causing the onset of sensorial and motorial disorders in the corresponding area of innervation. It is known that systemic diseases (diabetes mellitus, rheumatoid arthritis, myxedema, amyloidosis, hypothyroidism, obesity), pregnancy, menopause, and use of oral contraceptives may be associated with the development of carpal tunnel syndrome. Many epidemiological studies have demonstrated a high prevalence of cases in a wide range of working activities requiring repetitive movements and use of elevated force of the upper limbs.

Positive association has been found for exposure to repetition alone or in combination with other factors, and in the case of forceful work. There is sufficient evidence to demonstrate that awkward postures alone are associated with carpal tunnel syndrome. Many studies also found a temporal association. In conclusion there is strong evidence of a positive association between carpal tunnel syndrome and the two risk factors force and repetition, especially when they are combined.

6. CERVICAL RADICULOPATHY AND TENSION NECK SYNDROME

In the few studies available on cervical radiculopathy, no association with work was observed in data entry operators, dockers, and assembly line packers in a food production industry. But various studies found that tension neck syndrome — an epidemiological term meaning the presence of pain in the neck and shoulder region — was strongly correlated with work, particularly with static postures and static loads, as in the case of display unit workers, typists, and sewing machine operators. The etiopathogenesis has not yet been fully clarified and various causes have been suggested, including local decreased blood flow, activation of pain receptors through edema or other mechanisms, and energy metabolism disturbance due to long-term static contraction of the muscles.

7. CONCLUSION

Various types of investigations into the association between work and musculoskeletal diseases of the upper limbs are available in the literature, but these studies are not always satisfactory in demonstrating an association since they are not correctly designed from an epidemiological viewpoint. Nevertheless, satisfactory evidence has been found for the association between work and tendinitis of the shoulder, tendinitis of the hand and wrist, carpal tunnel syndrome, and tension neck syndrome. But the evidence proved contradictory in the case of lateral epicondylitis and cervical radiculopathy.

1. INTRODUCTION

When both the exposure assessment and the study of work-related musculoskeletal diseases have revealed a significant risk associated with repetitive and/or strenuous movements of the upper limbs in various work environments, the need arises to implement specific measures aimed at redesigning jobs and procedures. Their efficacy depends on three types of coordinated and virtually simultaneous actions being carried out: structural modifications, organizational changes, and personnel training.

Although the structural measures are almost universally accepted and widely recommended, actions involving organizational changes do not always meet with unanimous consent, and the scientific literature does not provide concrete examples. Instead it merely supplies general and routine advice, such as reduce excessively high job frequencies, or introduce adequate breaks or job alternatives. This article aims to provide some concrete guidelines for redesigning jobs and preventing disorders caused by repetitive movements of the upper limbs.

2. STRUCTURAL MEASURES

Structural measures primarily concern ways of finding an optimal arrangement for the workplace, furnishings and the overall layout of the environment, and ergonomic work tools. In general, these measures aim to improve aspects related to awkward posture and movements, localized compressions of the anatomical structures of the upper limbs, and the use of excessive force. Structural measures thus seek to reduce the consequences of the most important risk factors — posture and force — and of any other risk factors.

2.1. Criteria for Limiting the Risk Associated with Posture

As far as posture is concerned, the main principle to be kept in mind is to avoid prolonged movements or positions that force the joints to exceed 50% of their maximum range. Redesigning the job means allowing the worker to maintain posture or joint motion below 50% of the maximum specific range for each joint. In order to ensure the correct position of the upper limbs, it is essential to correctly design the workplace. Three aspects need to be emphasized:

- suitable workbench height when standing or sitting
- suitable chair height for seated positions
- suitable operating areas for the upper limbs

Different standards, ergonomic manuals, and checklists supply the main design principles for preventing awkward posture and/or movements harmful to the shoulder, elbow, wrist, hand, and fingers (Eastman Kodak Company 1983).

2.2. Criteria for Limiting the Risk Associated with Force

The main principle is to avoid overstraining the muscles; when the upper limbs have adopted an awkward posture, especially the wrist and hand, the ability of the muscles in the strained segment to apply force is drastically reduced. The force that can be developed in pinching movements is only 25% of the total grip force of the hand; moreover, grip force gradually diminishes as the wrist departs from the anatomical position. In order to intrinsically reduce excessive strain, the following recommendation can be made:

- Avoid even occasional contractions exceeding 50–60% of the maximum individual capacity.
- On average, no muscle-tendon unit should be exerted for more than 15% of its maximum capacity in any given shift.

The lower the degree of muscular exertion, the longer the permitted duration of the exertion. And the lower the degree of muscular exertion, the greater the number of movements that can be made in performing a repetitive task with consequent positive repercussions on productivity levels.

Generally speaking, it is possible to reduce the need to use force by using power-driven tools, by using mechanical grippers and holders (more efficient levers in positions better suited to the stronger muscle-tendon units), and by automating the entire action. Instruments and tools must meet a series of requirements in order to limit the risks associated with posture and force, hence reducing the risk of accidents in the workplace. An ergonomic instrument or tool may be defined by what it avoids:

- Avoid having to deviate the wrist by more than 50% of its normal range.
- Avoid repetitive movements using a single finger.
- Avoid handpieces requiring grips awkward to the development of force.
- Avoid pulling movements and striking actions.
- Avoid localized compressions.
- Avoid the transmission of mechanical vibrations.

Ergonomic instruments or tools should also be coated with a slip-proof finish, they should not conduct heat, and they should not have sharp edges, pointed tips, or potentially harmful shapes.

3. ORGANIZATIONAL MEASURES

Measures typically involving changes to the work organization become necessary when it has been ascertained that jobs feature excessively frequent technical actions and/or inadequate functional recovery periods. Here is a revealing example. In a large metal-working factory featuring assembly lines, upper limb disorders appeared to be prevalent (carpal tunnel syndrome, tendinitis, etc.), most of them attributable to repetitive tasks performed with excessive frequency and/or with lack of proper recovery periods.

On the advice of the local health authority, the company asked to carry out a detailed risk analysis in order to develop options for redesigning workstations more ergonomically. The exposure assessment identified the following problem areas:

- High frequency actions (38-40 technical actions per minute).
- In general, minimal use of force; in almost all cases the com-

pany quickly found specific solutions for bringing the use of force to within acceptable limits.

- Posture seldom extreme and therefore easily corrected by making some structural modifications to the workstation
- Recovery periods taken primarily for physiological reasons rather than for alternating jobs.

The daily schedule included two morning breaks (10 min and 15 min), a 30 min lunch break, and one 10 min afternoon break. One simple change involved optimizing the recovery periods. The total duration of the physiological breaks was already sufficient; by simply redistributing the breaks, it was possible to ensure adequate recovery periods without altering their overall duration. The company redistributed the physiological breaks (35 min = 10 min + 15 min + 10 min) so as to obtain four breaks (two in the morning and two in the afternoon).

In this case the last problem that needed solving was the high frequency of the technical actions. The first and most obvious intervention was to reduce the pace of the task, identifying methods for reducing the number of technical actions required to complete a job cycle but without compromising output. In other words, this meant optimizing — in terms of quality and quantity — the technical actions needed to complete the cycle characterizing the task.

Through valuable cooperation between the ergonomist and the production engineer, it was possible to use the fundamental experience of the engineer not to enhance productivity, but to improve working conditions and thus the health of the workers. By careful filming and critical analysis, each task was revised several times to make it better. In order to reduce the number of actions contained in a cycle, the following procedure was used.

3.1. Phase 1: Analysis of Useless Technical Actions

During phase 1 it is decided whether all the observed technical actions are strictly necessary. It is thus possible to single out useless actions performed by the operator and even actions which could be designed out of the task. In practice this has three aspects:

1. Detecting any useless actions added by the operator. For example, when assembling a piece, the operator occasionally strikes the piece more often or screws the piece more tightly than required: two strokes might be necessary, but the operator actually performs 4, 5, or 6 strokes. In this case the operator must be trained to perform no more than the useful actions actually required to perform the task.
2. Detecting whether any actions added by the operator are entirely arbitrary or in fact conceal a manual flaw. For example, a faulty pin does not fit snugly so the operator needs to strike it several times to force it into the correct position.
3. Detecting obsolete actions. In the course of time, assembly lines may undergo small changes to the machinery or to the product, rendering certain actions obsolete. Therefore it is extremely useful to check the way operators perform their tasks whenever machinery or products are modified.

3.2. Phase 2: Analysis of Upper Limb Use When Performing Technical Actions

Once all useless actions have been eliminated, the next step is to optimize the distribution of the various actions between the two upper limbs. Workers often tend to favor their dominant limb.

Simple low precision actions (e.g., picking up workpieces and placing them on the machining line) may be performed equally by both limbs, thus reducing the frequency with which the dominant limb is used.

3.3. Phase 3: Analysis of Identical Technical Actions

Phase 3 determines whether workers are repeating identical actions for a significant portion of the job cycle. Repetition of identical technical actions can often be avoided by introducing a specific mechanical device. One of the following solutions may be adopted when identical technical actions have been identified but no suitable tools can be introduced and when simultaneously the action frequency considerably increases the total frequency:

- Eliminate the specific manufacturing step altogether by having the part arrive preassembled elsewhere; this is a simple solution but make sure it does not lead to another high risk job being created.
- Introduce a semiautomatic step to replace the technical actions; this is a high cost solution.
- Reexamine the phase scientifically to find alternative solutions capable of fully bypassing the specific action sequence; this hi-tech solution often improves the product.

3.4. Phase 4: Analysis of Auxiliary Actions

Check whether any auxiliary actions are performed in passing from one cycle to the next. It is generally useful to have the conveyor belt and operating areas cross each other in such a way as to avoid the worker having to pick up and replace pieces. To minimize handling, it is equally helpful for the piece to reach the worker facing the right way.

3.5. Phase 5: When Jobs Need to be Split

Despite carefully reviewing actions, sometimes their frequency remains excessively high (even 60 actions per minute). Then the jobs need to be split. Remember that, with no other risk factors involved, a frequency of 30 actions per minute is taken as a reference "acceptable" frequency. Several workstations still feature frequency levels higher than this threshold. Then it is necessary to at least introduce hourly job switches, so the workers performing jobs that might still potentially overload the upper limbs can alternate with less strenuous jobs.

Since the same manufacturing line features workstations with relatively low action frequencies, it will not be difficult to arrange for workers to switch jobs regularly. In essence, job switching is very useful for reducing the risk of exposure to the frequency factor; it has two principal advantages:

- It allows workers to alternate between workstations where the frequency risk is low and workstations where the frequency risk is high.
- It allows workers to alternate between workstations in which the use of the upper limb changes (between left and right).

Besides alternating jobs to prevent disorders due to repetitive movements, adequate recovery periods are critically important in their own right. A suggested ratio of work periods to recovery periods is 5:1 within each hour of repetitive work. Often factories schedule long enough recovery periods (i.e., actual breaks and/or nonrepetitive tasks) but they are poorly distributed

throughout the duration of the repetitive task. Here are some ways to improve them:

- Optimize the distribution of official breaks: it is preferable to shorten each individual break, but to increase their frequency.
- Arrange, if possible, for rest periods to be scheduled at the end of an hour of repetitive work.
- Avoid the scheduling of rest periods too close to meal breaks and shift ends; this allows meal breaks to be used as recovery periods.
- Rotate workers in nonrepetitive tasks, so as to obtain an optimal distribution of repetitive and nonrepetitive tasks, thus ensuring a good ratio of work periods to recovery periods.

4. TRAINING PROGRAMS

4.1. Training for Factory Workers

Workers must be informed of the risks and the kinds of disorder associated with repetitive tasks, in order to justify and motivate the need for these tasks to be performed correctly and in the proper order. Workers must therefore be suitably trained to follow these rules:

- Perform tasks in the required order.
- Use both limbs whenever possible.
- Avoid adding useless actions.
- Grip objects correctly.
- Notify the supervisor whenever new actions need to be performed.
- Contact the health officer as soon as early warning signals are noticed.

4.2. Training for Production Engineers and Supervisors

Training engineers and supervisors is based on a clear understanding of the specific risks and injuries as well as the medico-legal implications associated with occupational diseases. It is necessary for engineers and, above all, supervisors, to organize periodic meetings with workers in order to gather information on any practical problems emerging from the various tasks. Their prompt detection and elimination will prevent unnecessary damage to workers' health, and often leads to a better product. Thus the production engineer is a key figure in the training process, receiving training and insight from expert consultants and providing practical training for the workers. The production engineer has the following responsibilities:

- Suitably design how a task must be performed, above all optimizing the technical actions in terms of human health, not just productivity.
- Teach workers how to perform tasks correctly.
- Periodically check that tasks are being performed correctly.
- Periodically talk with workers about the possible onset of problems while performing tasks.
- Check that technological innovations do not cause increased risk factors.
- Attend to new workers and ensure they are given proper training for their tasks, especially complex tasks.

4.3. Training for Management

Managers need to be involved in the training process. Training must be carried out by experts. Managers must be able to provide trainers with a thorough picture of the risk factors present in the work cycle, as well as possible strategies to ensure they are minimized and effectively managed.

1. INTRODUCTION

To be effective, the work hazards and risk assessment methods must address all components of the work system as well as their interactions affecting the human performance. A workplace hazard is an event or situation with the potential for harm (Cox and Cox 1993). The concept of risk is used to quantify the degree of harm with respect to the likelihood (probability) and severity (consequences) in response to workplace hazards (Cox and Cox 1993; Manuele 1997). Performance can be described in terms of health and safety measures with the goal of risk quantification of workplace hazards. As discussed by Shoaf *et al.* (2000), a comprehensive work system model is needed to optimize human performance. Such system should capture and integrate the individual and interactive effects of the great number of variables related to hazards and risks at the workplace.

2. THE WORK SYSTEM MODEL

The work system consists of four primary components: (1) work demands, (2) the worker, (3) outcome measures (i.e. perceived and actual risk), and (4) their inter-relationships (Figure 1). A description of these components and their relationships is given below.

2.1 Work Demands

Work demands include both work content (i.e. the physical and mental job demands) and work context (i.e. the physical, social, individual growth and work organization environment).

2.1.1 Definition of variables

The physical demands component describes the set of activities that require combined dynamic and static muscular contractions while the body is maintaining a dynamic posture

Figure 1. Work system components

(e.g. walking, running) or a static position (e.g. sitting, standing). Physical demands have been classified for epidemiological reasons into two categories: (1) object handling activities such as lifting, lowering, pushing, pulling or carrying consist of moving objects with one or both hands and the use of upper and lower extremities; and action of the trunk; and (2) extremity-postural work which describes extremity and head work either in a fixed or dynamic lower body positions such as sitting and crawling.

Mental demands represent the workload imposed by the job tasks on the worker's perceptual and cognitive capabilities. One way in which mental work can be categorized is as skill-based, rule-based or knowledge-based according to the classification system developed by Rasmussen (1983). Skill-based behavior evolves as a series of prearranged, ordered steps in a well-rehearsed routine. Rule-based behavior is invoked when a situation is identified as belonging to a familiar class of problems through which the solution steps are based on prior experience. Knowledge-based behavior occurs in an unfamiliar situation in which the problem cannot be simply and immediately classified, and therefore extensive trial and error iteration are required to determine the solution.

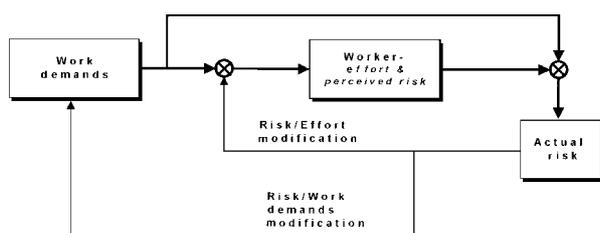
Work context refers to those environmental conditions that affect a worker's ability to perform, but do not specifically relate to work input or to work output transformation, as in the case of physical and mental demands. Physical elements represent the physical environment in which the work tasks are performed. These elements can impede the worker's long-term or short-term ability to perform the job activities.

The social, individual growth, and work organization environment describe those variables that collectively form the non-physical work setting. The social aspects include relationships with co-workers, management, and family (Elo 1986; Gardell 1987). The individual growth aspects refer to an individual's growth needs as described by Maslow's Hierarchy of Needs (1943). Work organization is the objective nature of the work process and deals with the way work is structured and managed (e.g. shift work, job structure within the work process or organization; Cox and Cox 1993).

2.1.2 Hierarchical structure of work demands

The work demand profile is structured as a hierarchical framework (see Figure 2). In Figure 2 an example of the physical demands hierarchy structure is provided. Two global work demands reside at the top of the hierarchy — that is, work content and work context. Below the top layer, classifications describe the composition of the next lower layer. For example, below the "work content" layer lies the physical and mental job demands. The next lower layer describes the groupings which constitute the physical and mental demands.

The lowest level of the hierarchy represents the most detailed descriptions — that is, the work elements characterizing the demand classification. For example, weight of load, repetition, horizontal distance, height of lift/lower, time duration and twisting angle refer to work elements that describe lifting demands of the object handling demands in the physical demands layer of the work content layer.

It is important to structure the work demand profile within a logical framework as it will allow users to obtain varied levels of


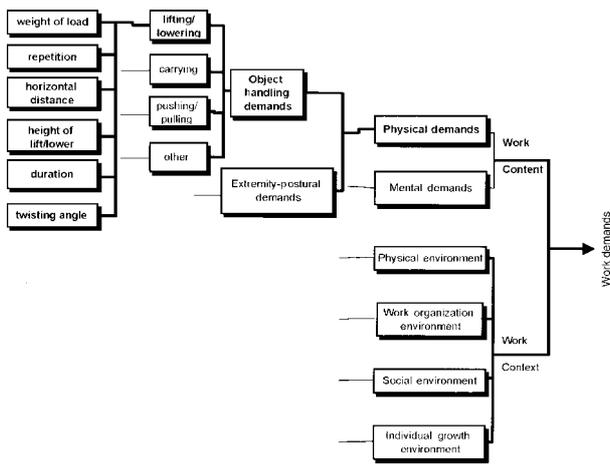


Figure 2. Hierarchical structure of work demands

information details. For example, ergonomists and safety engineering specialists employed in an environmental health division of a large corporation may be interested in the information provided by the bottom layer of the hierarchy (i.e. the most detailed level of information) as they attempt to design and implement control strategies aimed at the minimization of risk in the workplace. Alternatively, a higher level manager in the division may be interested in more global aspects of information provided at higher layers of the hierarchy in order to communicate a more comprehensive overview regarding hazard/risk to other corporate officers, shareholders or potential customers.

2.2 Worker

The worker represents the individual performing the job with their associated personal characteristics, abilities, capacities and needs, serving as the conduit through which the work demands are processed into an effort level. Work demands act as an input to the worker who, in turn, performs an activity to transform a work object or information into a desired product.

Although jobs vary tremendously, there are four operational functions (see Figure 3) that are fundamental to all jobs and virtually every form of human activity. These are: (1) sensing (i.e. information receiving); (2) information storage; (3) information processing; and (4) decision/action functions (McCormick 1979). Therefore, the worker functions within the context dictated by the work setting transforming the job demands into the desired product by generating an effort level as they expend energy.

Traditionally, job performance (i.e. the manner in which the worker meets the challenges of the work demands) has been described rather simplistically. Vroom's (1964) "Performance = f (Ability x Motivation)" model has long served as the archetypal formula to specify the relationship between the individual worker and their performance output. Our work endeavors to enrich this description by characterizing the worker's effort level (i.e. physical, cognitive, emotional) in association with their own individual qualifications and the required qualifications as determined from the job demands.

2.2.1 Modes of information processing and output selection

The way in which all workers handle the challenges of work demands, regardless of their individual capabilities, can be viewed as governed by three primary modes of processing — cognitive, emotional, and physical. The work object (i.e. information about a work task) is a stimulus, is rendered as an object or entity through its sensory qualities, and can be stored in memory as a function of those perceived qualities. Such hybrids of representation and actual stimulation become the input to the cognitive and emotional processes (see Gaillard 1993). Cognitive (i.e. rational) processing transforms sensory information input into motor and/or vocal output using formal and logical operations. Emotional processing is influenced by feelings which inherently contain impulses to act. The logic of the emotional processing is associative; it takes elements that symbolize a reality, or trigger a memory of it, to be the same as reality (Goleman 1995). Emotional appraisal of a situation is automatic and instantaneously contains impulses to act.

Generally, there is a balance between emotional and cognitive processing as emotion feeds and informs cognitive processing, and the cognitive processing, in turn, refines and regulates the impulses of the emotional input (Goleman 1995). Positive emotional states are capable of enriching the cognitive processing such as in mildly enthusiastic states. At the extreme, positive emotional states can disable cognitive processing as in manic states. Negative emotional states can moderately affect cognitive processing, as in the case of a bad mood, or can disable it, as in the case of severe depression.

Figure 4 depicts a hypothetical representation between cognitive processing and emotional processing. Cognitive processing is optimal when emotions are in a moderate state (i.e. not very positive, not very negative). When emotions are overwhelmingly positive, such as in an hysterical excitement, or overwhelmingly negative, as in an angry rage or depression, all energy is devoted to the extreme state with little remaining for cognitive effort. Generally, however, there is a lack of an integrated construct in the scientific literature which permits a complete understanding of the architecture of human information processing. Further research is needed on this issue to advance our understanding and provide integrative information. Recent integrative works on stress, workload, and fatigue have begun to seek this relation (see Gaillard 1998; Hancock and Desmond 1998; Tepas and Price 1998).

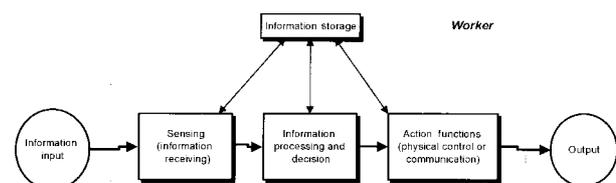
After information is processed, an output is selected and a response is produced by muscular contraction of differing body parts including the complexities of speech. The response results in transformation of the work object or information toward a


Figure 3. Basic operational functions in human work activities (adapted from McCormick 1979)
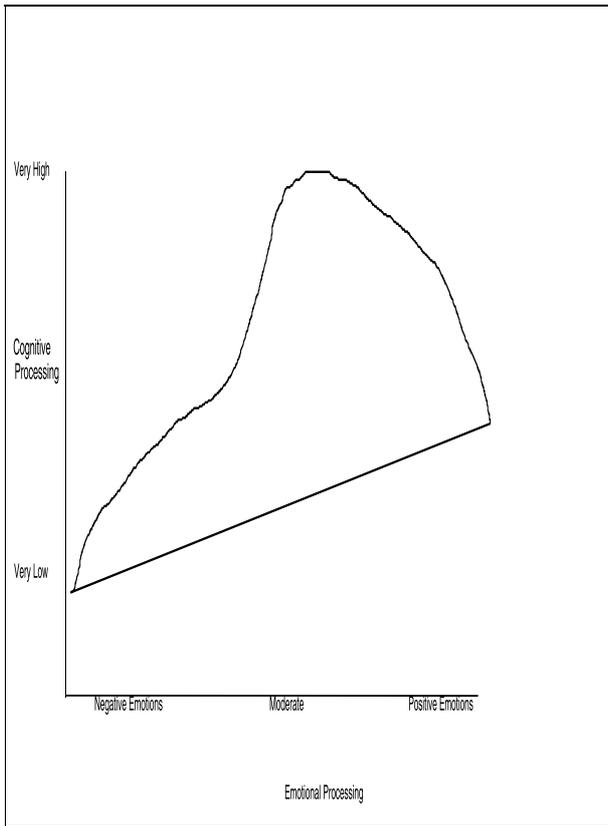

Figure 4. Hypothetical representation of cognitive processing and emotional processing

desired form. Since physical loading consumes energy for this object transformation process, the worker's energy state is influenced by the physical load. This, in turn, indirectly influences the capacity for information processing. For example, if physical loading is within moderate limits, it may produce a positive emotional state that can enhance and improve mental capacity available for task execution, thereby reducing the negative effects of irrational processing. Alternatively, if physical loading is not pleasurable or is distasteful, a resulting negative emotional state may reduce or decrease the cognitive processing capacity available for task execution.

2.2.2 Effort

Effort is defined as the amount of energy an individual expends (Porter and Lawler 1968). Based on our work experience, effort can be described as a function of the interaction of the worker energy states, worker qualifications (e.g. motivation, skills, abilities), and required work qualifications. For example, if the performer has the required motivation level and abilities to perform a certain task but the performed energy state is dominated by physical fatigue due to inadequate sleep or illness, the resulting effort level will be very low or inhibited. Indeed, the worker energy state is a complex interaction of emotional, physical, and cognitive states (Figure 5). Moreover, the motivation force is affected by internal human needs as well as external work demands.

Effort can be classified according to the nature of the challenge presented via work demands into the domains of the muscular, the cognitive, and the emotional. Muscular effort refers to the physiological energy expenditure resulting primarily from physical job demands. Subjective ratings of physical effort has been found to be valid, reliable, and highly related to actual metabolic costs (Hogan and Fleishman 1979; Hogan *et al.* 1980). Cognitive effort refers to the energy expended through mental processing resulting from mental job demands (Hart and Staveland 1988). Emotional effort refers to energy expended from processing feelings and their inherent impulses to act regarding all facets of the work demands.

Cognitive effort and emotional effort are closely related. Harmony between them can enrich human performance (Cszentmihalyi 1990; Hancock 1997). Alternatively, discord can impair and even incapacitate the worker. There is also a close connection between the physical and emotional/cognitive effort domains. When someone is exerting a high level of physical effort in response to challenges presented by physical work demands, the worker's cognitive and emotional energy states may be directly affected. Physical abilities required by the work affect individual growth motivation, fatigue and satisfaction (Hogan and Fleishman 1979; Fleishman 1984). A consequence of the physical exertion is the slowing of the cognitive processes, which in turn may lead to exertion of an extra amount of cognitive effort in order to process the required information (see Vercruyssen *et al.* 1989).

2.3 Health and Safety Performance Measures

The work system model's output is the performance resulting from worker effort. The output of interest emphasizes the quantity significant to the user. Therefore, these outputs may assume the form of various parameters. As this study focuses on the health and safety of the work setting, the outputs of interest are the risk perceived by the worker and the actual risk to the worker in the system.

Risk, in a broad and contemporary sense, expresses the potential harm caused by hazards present in all aspects of the work system. It can be classified into perceived risk and actual risk. Perceived risk is the level of internal risk the worker experiences in response to the level of effort exerted, and may or may not be equal to the actual risk. Perceived risk is subjective and is therefore influenced by numerous judgmental biases such as familiarity, controllability of hazard and time-scale over which any resultant harm may occur (Cox and Tait 1998). Therefore, it is contextual as it is filtered through personal attitudes, experiences, values and education (Petersen 1996). Actual risk is the true risk present in the work system regardless of the worker's awareness, and can be calculated through a quantitative risk analysis measure.

Perceived risk can be further categorized according to the mode of processing the risk is born out of, rather than the type of harm the risk can cause, as the harm may assume several forms (e.g. physical, cognitive, emotional). This distinction is especially important in the area of emotional risk, although the areas of physical and cognitive risk also exhibit interconnections to other areas, as would be expected in a complex system.

2.3.1 Perceived risk

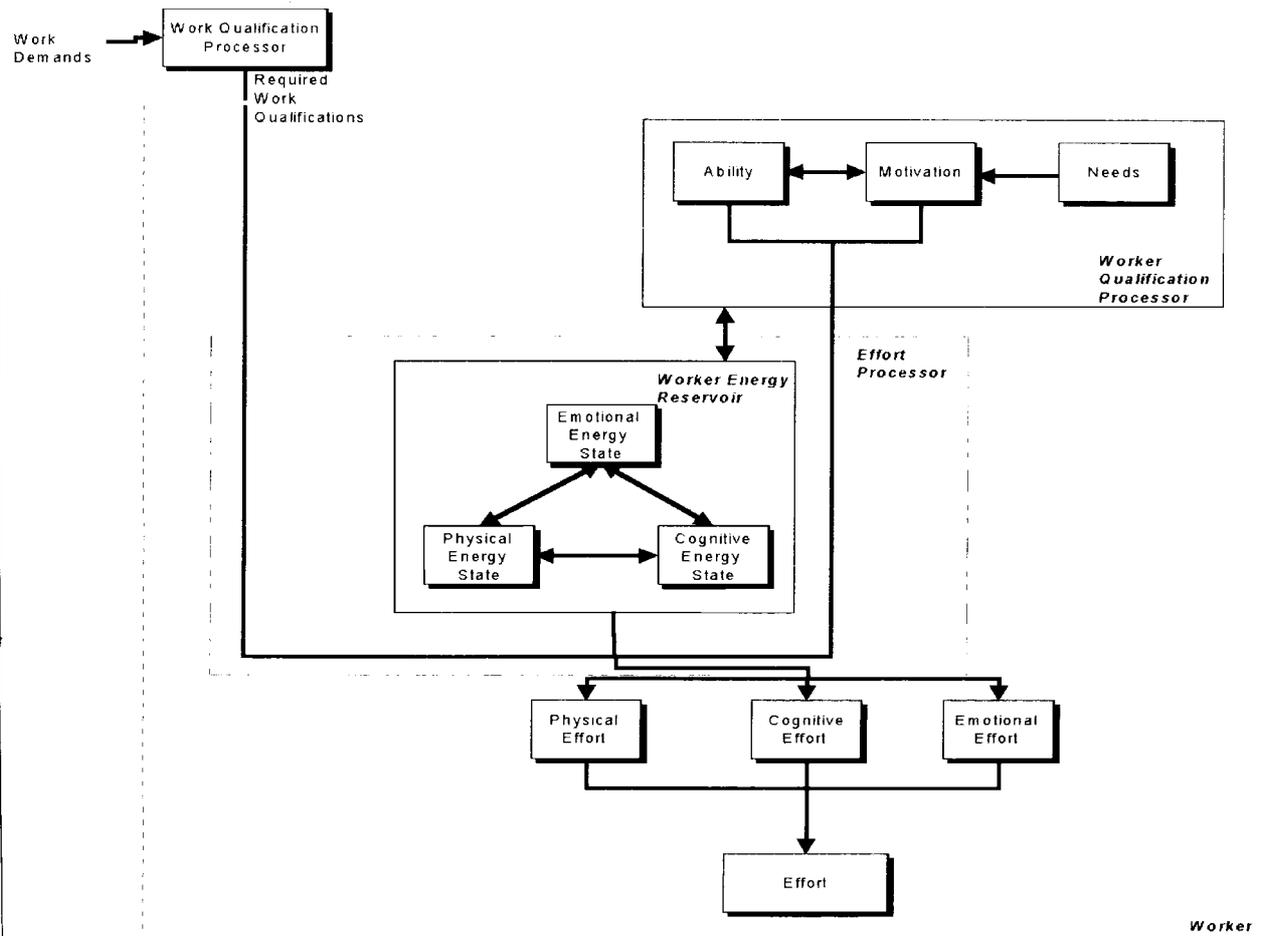
Perceived physical risk refers to the subjective risk workers assume with respect to their body structure (e.g. muscles and bones) and physiology (e.g. respiratory, sensory systems). For example,


Figure 5. Effort as a function of worker energy state, worker qualification and required work qualification

if a worker believes there is little risk associated with a heavy, repetitive lifting task, the perceived risk is low. Accordingly, the perceived risk will impact on the decisions the worker makes regarding the way in which the job is performed.

Perceived cognitive risk refers to the subjective risk the worker assumes with respect to the mental job demands. For example, a worker may agree to assume several knowledge-based job assignments to be performed concurrently. The high level of mental processing necessary to execute these tasks represents a primary risk to the worker's thinking capabilities (including cognitive and memory processes), but the worker may also experience physiological disorders (e.g. cardiovascular as a result of chronic effects) as a result of accepting the cognitive risk (Hancock and Warm 1989).

Perceived emotional risk refers to the subjective risk workers assume regarding the expression or repression of their feelings and their impulses to act on them. Perceived emotional risk arises in response to the interconnectedness of the work system characteristics. For example, a worker, who is fatigued due to high levels of physical and/or mental job demands — he may be annoyed because of family scheduling problems as a result of having to work overtime and is uncomfortable because the air conditioner is not working correctly — is more likely to risk

verbally assaulting a co-worker's character after a disagreement than a worker without such problems and discomfort.

2.3.2 Actual risk

Actual risk, the objective risk the worker is exposed to, equals the product of frequency and severity of harmful effects (Wentz 1998). There are several methods of quantifying actual risk (see Cox and Tait 1998). Frequency can be calculated as the number of occurrences per 100 full-time workers over a one-year period for: (1) lost work day cases, and, (2) restricted workday cases (Goetsch 1996). Severity can be computed as the number of lost workdays and restricted workdays per 100 full-time workers over a one-year period. Actual risk may then be calculated as the weighted sum of lost and restricted workday cases.

3. WORK SYSTEM MODEL OPERATION
3.1 System Overview

The model of the work system proposed for WMSD hazard/risk assessment represents a complex adaptive control system. While these models depict the main components that describe the work system relationships, the myriad factors which characterize the work demands and the worker sub-systems demonstrate the system's complexity. This multitude of factors interacts to produce

effort and risk. Consequently, numerous variables and relationships within each sub-system can be manipulated to vary the effort and risk output parameters for WMSD study.

Self-regulation in living systems is mediated by feedback control mechanisms (Smith and Smith 1987). As the work system is a living system, feedback control is used to describe the effects of output parameters which serve to change input variables. The interactions between human behavior and the physical, social, and organizational properties of the work environment provide the basis for understanding the operational hazards in work (Smith 1979). The model described here further develops these ideas by specifying work system components and explicitly describing their interrelationships.

Adaptation is an interactive process implying the response of one entity to the actions of another (Hancock and Chignell 1987). The work system is adaptive as its participants adjust, based on changes in the work demands as well as the effort exerted, risk perception, and risk knowledge. Adaptation occurs to modify system parameters to compensate for changes in the process. In general terms, adaptation results from a three-step sequence. First, a standard or goal is set for the output parameter. Next, the actual output is assessed with respect to the target. Lastly, adjustments are made to the system parameters in response to the error (target — actual) to minimize deviation. The mismatch between work demands and available resources (i.e. actual capabilities of the human operator) when within the zone of adaptability can be compensated for through adaptation, therefore controlling the error signal to remain within acceptable boundaries (Chignell and Hancock 1986).

Specifically, in the case of the work system, adaptation occurs through two groups of respondents: namely, the worker and management. The worker controls the effort acceptance level and the risk acceptance level. In regulating these parameters, the worker takes into account changes in the system inputs and "learns" based on experience. Management controls a large set of the factors which characterize the work demands and therefore affects the stimulus for effort and risk outcomes. In regulating these parameters, management takes into account changes in system outputs, also with an accompanying learning experience.

Risk acceptance level is based on the perceived and actual risk inputs. The workers adjust their behavior according to influences of internal and external variables. Internal variables are those which characterize the workers such as their attitude toward risk (i.e. risk-taker or conservative), motivation for performing the activity and individual needs (e.g. acceptance by peer group). External variables are those which characterize the nature of the risk, such as time-frame of consequences (i.e. immediate or long-term), media coverage, and controllability. Both internal and external variables affect the workers' physical, cognitive, and emotional modes of information-processing to form the adapted response.

Similarly, workers can adjust their effort level to set an effort acceptance level based upon previous knowledge of the effort required to perform the work activity and the determined risk acceptance level. To set the effort acceptance level, a worker must first establish the risk acceptance level. This information is fundamental to the effort regulation process. The effort acceptance level is affected by workers' physical, cognitive, and emotional energy states as well as their motivation, ability, and needs.

While workers regulate their responses to work demands through effort acceptance level (i.e. how hard a worker is willing to try) and risk acceptance, management regulates the stimulus to the worker (i.e. the work demands). These factors are typically manipulated after assessing the actual risk and worker effort levels (i.e. performance) to achieve a desired result. Many aspects of the factors creating the work demands can be altered by management, including working hours, temperature of the environment, break schedule, number and difficulty of tasks

Table 1. Glossary of building blocks for work system model

Building block	Description
Work demands processor	Transforms inputs of people, material and equipment, effort and actual risk into work demands. Regulated by management based upon appraisal of effort and actual risk outputs.
Effort processor	Transforms inputs of work demands and perceived risk into effort. Regulated by worker based on such variables as worker energy state, motivation and ability.
Qualification demands processor	Transforms input of work demands into required work qualification. Job content and job context determine the qualifications to execute work activity.
Worker qualification processor	Transforms input of worker's effort into worker qualification. The worker's effort level is influenced by, among other variables, their ability to perform the work activities. These abilities, determined by the worker's education, skill and training, form the basis for the worker's qualifications.
Perceived risk processor	Transforms inputs of effort and actual risk into perceived risk. Regulated by worker based on such variables as familiarity of activity and benefit of outcome.
Actual risk processor	Transforms inputs of perceived risk and work demands into actual risk. Determined by job content (e.g. task difficulty, weight of load handled) and context (e.g. duration of work day, noise level) as well as the manner in which the activity is executed (i.e. as guided by the worker's perceived risk).
Risk controller	Regulates inputs of perceived risk and actual risk to produce risk acceptance level. Performed by the worker and influenced by variables such as the individual's risk attitude and benefit of outcome
Effort controller	Regulates inputs of effort and target risk to produce target effort. Performed by the worker and influenced by variables such as motivation and energy state.
Work controller	Regulates inputs of target effort and actual risk to work demands processor. Performed by management to alter aspects of job content and job context with the intent of varying effort and risk outcomes.

defining a job, and degree of worker autonomy over the work process.

3.2   Work System Model

3.2.1   Definitions

The components of any system include input, processor, output, control, and feedback (Murdick 1975). The three types of operators are processors, controllers, and comparators. Processors function to produce the given output parameter. Therefore, processors represent the activity or activities that transform the input into output. Controllers represent the activity or activities that serve to determine the deviation of the target output from the actual output and which adjust the system parameters in response to this error. A glossary of the processor and controller functions is given in Figure 1. The comparator, the circular symbol containing an "x", describes the error detection between the input and variable which is being feedback.

3.2.2   Model operation

In the work system model, work qualifications act as the inputs to the worker. In general, qualifications refer to the knowledge, skills and abilities (KSA) acquired through education, training, and experience. The KSA dimensions are widely used by human resource specialists for job selection and training program development (Schneider and Konz 1989; Fleishman and Reilly 1992; Wooten 1993).

The required qualifications for a given job are derived from the work demands (i.e. job content and job context). They identify the characteristics an ideal candidate for the job should possess. Workers who will perform the job tasks, however, possess their individual set of abilities — that is, the actual worker qualifications.

If the worker's actual qualifications are greater or less than those required by the work qualifications, a mismatch occurs (i.e. deficiency or surplus in worker capacity). In the case of a deficiency, the amount of mismatch may be reduced or possibly eliminated by experience, education, on-the-job training, or augmented assistance from the machine system itself (Hancock and Scallen 1996). In the case of surplus, the amount of mismatch may be minimized by increasing the difficulty of, or dynamically adding additional, work demands. This process of dynamic task allocation is one which is currently under intense scrutiny (see Parasuraman and Mouloua 1996). The amount of mismatch affects the worker's effort level. When workers' qualifications are less than required, they may react by overexertion. When workers' qualifications are greater than required, they may become bored and exert less effort. Performance may be optimized by matching as closely as possible the required and actual worker qualification parameters.

The model's relationships can be expressed through the following seven equations:

Effort = f_1 (Required qualifications, worker qualifications, effort acceptance level)   (1)

Perceived risk = f_2 (Effort, risk acceptance level)   (2)

Actual risk = f_3 (Work demands, perceived risk)   (3)

Risk acceptance level = f_4 (Perceived risk, actual risk)   (4)

Effort acceptance level = f_5 (Perceived risk)   (5)

Work demands = f_6 (Equipment/material/information/people, effort acceptance level, actual risk)   (6)

Required qualifications = f_7 (Work demands)   (7)

As demonstrated through the model's relationships, the required work qualifications, the worker's actual qualifications and the effort acceptance level determine the level of effort the worker exerts (1). Next, the worker's effort and risk acceptance level (i.e. the level of risk the worker accepts) yield the perceived risk (2). Actual risk is determined from the worker's perceived risk (as it influences task execution) and the nature of the work demands (3). The risk acceptance level of workers is based on their perceived risk as well as the actual risk (4). Similarly, their effort acceptance level is based on the risk level they accept: that is, the perceived risk (5). Therefore, the totality of the work demands can be described as the raw inputs (i.e. equipment, material/information, people), the actual risk, and the effort acceptance level (6). The work demands act to produce the required qualifications ideally possessed by the worker (7).

3.3   Model components

Balancing work demands with worker abilities and needs represents a homeodynamic condition where workers strive to maintain a state of balance within limits based upon natural laws governing their existence. Any stimulus or attempt to alter that state is met with an innate response to maintain an acceptable status. The stimulus is, or creates, "stress" upon the organism, system, culture, or organization. The response is "strain". Welford (1973) observed that strain arises whenever there is a departure from optimum conditions (i.e. a condition that the worker is either unable to correct or cannot easily correct). It is postulated that workers perform best under conditions of moderate demands, and that performance will be "sub-optimal" if the demand is "too high" or "too low".

3.3.1   Feedforward elements

Three major elements form the feedforward path of the complex work system: the work demands, the worker and the performance outcomes, perceived risk and actual risk. In this path, the work demands serve as an input to the worker who, in turn, processes these demands, producing the effort and risk outcomes. The worker affects these outputs physically, cognitively and emotionally. In order to optimize the performance outcomes, variables within the work system must be manipulated. Therefore, aspects of the work demands and the worker function act as the modifiable factors for the minimization of work system hazard/risk.

3.3.2   Feedback

The feedback elements of the complex work system are the adaptations which allow the change of conditions within the domain of a given component's control. Adaptations are made to compensate for incompatibilities between system components. There are two primary feedback loops: risk/effort modification and risk/work demands modification.

The risk/work demands adaptations represent those factors in the work content and work context that can be modified based on the knowledge of risk involved in meeting work demands. For example, if management learns that a consultant's evaluation has shown a particular worker to be at high risk (i.e. actual risk), management may then choose to modify aspects of the work environment (e.g. job rotation, training).

The risk/effort modifications represent those factors that can be adjusted by the worker. These modifications, in turn, could increase or decrease the level of worker effort. For example, if a worker feels at risk of injury, and then learns that the given work activity has very low risk, the worker may choose to exert more effort to accomplish the tasks.

4. CONCLUSIONS

An effective work system hazard/risk assessment instrument must address all components of the work system as well as their interactions. Identification of work hazards and risk serves as the foundation for management decision-making regarding work system design and safety assessment. The work hazard description and risk quantification can then establish a basis for preventative/corrective action through all stages of the work system's life cycle. Accurate description of WMSD hazards also plays a significant role in the success of the intervention efforts such as prioritization of areas for job redesign, identification of populations at risk, benchmarking, and communication programs.

Health and Safety Ergonomics

R.A. Haslam

Department of Human Sciences, Loughborough University, UK

1. INTRODUCTION

Alongside improving comfort and performance, preventing injury and illness has always been a fundamental concern of ergonomics. The welfare of users, operators and others involved in the functioning of a system has to be a priority. However, as with other areas, for example "cognitive ergonomics" and "human-computer interaction", a branch has emerged dealing predominantly with "health and safety ergonomics" issues. Those working in this area have the prevention of accidents, injuries and illness, due to work or other interactions with tools, equipment and environments, as their primary focus. Most activity at present is in the occupational arena.

In addition to ergonomists, there are other professions and areas of science striving to prevent accidents and ill health. The scale of the problem has long encouraged specialization, for example accident researchers (from backgrounds such as engineering or psychology), health and safety advisers, health and safety engineers, health and safety managers, occupational health scientists, and occupational hygienists. There are others whose primary role is treatment and rehabilitation but who also contribute to prevention, for example occupational nurses, occupational physicians, occupational therapists and physiotherapists. At a different level, health and safety ergonomics can be seen as the area of ergonomics that interfaces with these other communities.

2. SCALE OF THE PROBLEM

It has been estimated that 2.2 million of the 57 million UK population suffer from ill health, caused or made worse by work. In addition, ~158 000 occupational injuries are reported each year. The cost to employers of this illness and injury has been estimated by the Health & Safety Executive (HSE) at between £4000 million and £9000 million per year, with a cost to society at ~£10 billion to £15 billion (billion in the UK is 1012). This equates to 1.75–2.75% of the UK gross domestic product.

In the USA, the National Safety Council estimates for 1997 suggest there were 3.8 million disabling (beyond the day of injury) injuries connected with work. The total cost of unintentional work injuries was estimated at $127.7 billion, with a further $99.9 billion due to home injuries (billion in the USA is 109).

3. CONTEMPORARY ISSUES

Issues of current concern include:

- Musculoskeletal disorders, including injuries to the back and upper limbs from manual handling, or due to work with high rates of repetition or where posture is constrained.
- Occupational and domestic accidents, with slip, trip and falls the largest category.
- Psychological stress.
- Problems connected with use of computing equipment, e.g. keyboards and other input devices.
- Noise induced hearing loss.
- Hand-arm vibration, especially vibration white finger.
- Occupational dermatitis.
- Occupational asthma.
- Monitoring and surveillance.
- Improving risk identification and management.

The areas of focus in part reflect the scale to which each is a problem. However, the funding and legislative climate also have a strong influence on the level of attention different issues receive. For example, European Union directives concerned with manual handling and display screen equipment, implemented in 1992, led to significantly increased activity in both these areas.

4. CONCLUSION

Injuries and illnesses from work or other interactions with tools, equipment and environments are a severe problem, many of which are avoidable. Health and safety ergonomics deals with the human factors issues that are often an important component.

A Heuristic Dose–Response Model for Cumulative Risk Factors in Repetitive Manual Work

S. Tanaka† and J.D. McGlothlin‡

1. INTRODUCTION

As has been documented by Bernard *et al.* (1997), there is strong evidence that repetitive and forceful manual work can lead to musculoskeletal disorders of the hand/wrist (H/W-MSD) such as tendinitis and carpal tunnel syndrome (CTS). However, a 'safe' level of daily repetitive manual workload has not been established. Quantitative determination of such a level among worker population is a difficult task, since many factors are known to be involved in the causation of H/W-MSD. Further, methodologies for objective and quantitative measurement of many of the exposure factors are not well developed. Therefore, establishment of dose–response relationship between the exposure and H/W-MSD is much more complicated than that for chemical exposures (e.g. lead or toluene), where both the dose and resultant biochemical responses can be defined and measured. Despite these difficulties, there is a need for establishment of quantitative dose–response relationship for manual work. Without such quantitative guidelines, we do not know "How much is too much?" and preventive effort against H/W-MSD must remain in the realm of "trial and error" or "faith." Regardless of whether an intervention effort resulted in a success or a failure, there ought to be a mechanism to determine why and how it was successful or unsuccessful, so that one may learn from the previous experience.

As the title of this chapter indicates, it is a heuristic modeling exercise. The rationale used here is based not only on established scientific knowledge, but also on what the authors consider are very likely and reasonable but not necessarily proven experimentally or epidemiologically. It may take many more years of laboratory and epidemiologic investigations to uphold or refute the validity of such a model. However, the lack of proof does not negate the value of modeling. Rather, since the determination of the safe level of manual stress over a long-term is very complex, only through heuristic modeling such as this, will we reach satisfactory quantitative guidelines for protection of workers performing manual work.

2. FUNDAMENTALS

2.1. Biomechanical Plausibility of the Dose–Response Model

The current modeling effort is largely based on the concept advanced by Armstrong and Chaffin (1978) that local inflammation of the tenosynovium is caused by, and proportional to, the frictional energy of manual work within the wrist, which would later develop to H/W-MSD. The source of this frictional energy can be attributed to various biomechanical and other risk factors.

2.2. Essential Versus Incidental Risk Factors

First, we need to decide what factors should be included in the model, which we want to keep as simple as possible. For this purpose it is necessary to sort out what the essential factors are among the many factors that are reported to be involved as risk factors for H/W-MSD. Table 1 presents how these factors may be classified. A criterion used here for a factor to be "essential" is whether or not it is "always present in any work situations" (Tanaka and McGlothlin, 1993). It has been recognized that force (F; internal force), repetition (R; per unit time), wrist angle (A; or posture) and time (T; duration of work) are the four factors that are always present in performance of any manual tasks. Other reported risk factors such as vibration, cold temperature, use of gloves, pinch grip, and psychosocial stress, are considered as incidental factors and not included in the equation.

This is not to say that these incidental factors are unimportant. Indeed, in actual industrial situations, each factor is known to play a significant role toward development of H/W-MSD. Removal or reduction of an incidental factor or factors from the manual task is beneficial for prevention of H/W-MSD. However, they are not essential because they are not always present and H/W-MSD are known to occur where the manual task does not involve vibration, cold temperature, etc. In most cases, these incidental factors can be subsumed under the force factor (Moore *et al.* 1991). The personal risk factors listed in the right hand column of table 1 reflect variations among individual workers, which are difficult to deal with in the current modeling but need to be addressed in the data collection phase (e.g. data from a worker with diabetes need to be excluded) and application phase (legal and administrative aspects).

2.3. Force and Repetition Factors

Among the first three essential factors (we set aside the time factor for later consideration), the relationship between force and repetition (or the inverse of cycle time) factors was studied epidemiologically by Silverstein *et al.* (1986). Although the methods of measuring these factors were crude, it was reported that compared to workers performing low force and low repetition (LoF/LoR) tasks, those performing high force and high repetition

Table 1. Classification of Risk Factors for Hand/Wrist MSDs

Work–related	Non work–related (intrinsic)
Essential	Gender
FORCE	Age
REPETITION Intensity of work	Certain Conditions
POSTURE	Pregnancy
TIME (Duration of Work and Rest)	Use of female hormones
Incidental (important but non-essential)	Obesity
Vibration	Smoking
Cold	Certain Diseases
Gloves to modify FORCE	Diabetes mellitus
Pinch–grip	Hypothyroidism
Psychosocial	Osteoarthritis
	and many more

(HiF/HiR) tasks had a very high odds ratio of H/W-MSD, while those workers performing LoF/HiR or HiF/LoR tasks were found to have the odds ratios in between these values. Such a finding would suggest a mathematical equation:

$$F \cdot R = I_{FR} = \text{ELM}_1, \qquad (1)$$

where: I_{FR} = intensity of manual work per unit time defined by F and R and ELM_1 = exposure limit for manual work (involving only F and R).

If we allow F and/or R to increase without a limit, I_{FR} will be increased to such a level that the task will cause damage to the local tissue causing pain and discomfort, which is unsafe. Therefore, for a manual work to be safe, I_{FR} must be set at a level, below which workers do not develop pain or other symptoms and signs of H/W-MSD. This is ELM_1 and once it is kept as a constant, F and R are to vary in an inverse relationship.

2.4. Wrist Angle Factor (Hand Posture)

The hand postures in relation to the forearm can be categorized biomechanically as extension/flexion and radial/ulnar deviations. Based on physical experimentation of a rope (tendon) wrapped over a pulley (ligament or bone), an exponential relationship between the tendon force and wrist angle has been established by Williams and Lissner (in Chaffin and Andersson 1984):

$$F_N = F_T \, e^{yA} \, (D_T)^{-1}, \qquad (2)$$

where: F_N is the normal supporting force per unit arc length (N/mm); F_T is the average tendon force in tension (N); e is the base of natural logarithm; g is the coefficient of friction between the tendon and its supporting synovia (range 0.003–0.004 in normal conditions); A is the contact angle or wrist deviation angle in radian; and D_T is the radius of tendon curvature.

This equation underscores the fact that, regardless of the final form of the equation, the gliding friction of the tendons over the anatomical pulley (bent wrist) would play a very important role in the causation of H/W-MSD. This fact also leads to the importance of synovial lubrication as expressed with the coefficient g. If we consider it to be negligible, $e^{yA} = 1$, which is a logic employed by Chaffin and Andersson (1984). However, if this lubrication mechanism is disturbed and becomes insufficient for some reason, the value of e^{yA} can be sufficiently increased to be no longer negligible. Further, if the wrist is bent with a large A, the situation may become serious.

3. INTENSITY FACTOR AND ITS COMPONENTS OF MANUAL WORK

The intensity (*I*) of manual work can be defined here as the local stress load at the wrist joint in performing the task per unit time and expressed as the product of three essential risk factors F, R, and A. Their relationship is presented as equation (3), and the value of each factor moves below the worker's physiologic limits as shown in Figure 1.

$$\text{ELM}_2 = I = k \cdot aF \cdot bR \cdot e^{yA}, \qquad (3)$$

where: a, b and g are corresponding coefficients to be determined by field studies and laboratory simulation experiments. It is noted here that if the angle is zero (neutral posture), $e^{yA} = 1$. *k* is a constant which can be designated as a 'safety factor' for protection of workers against development of

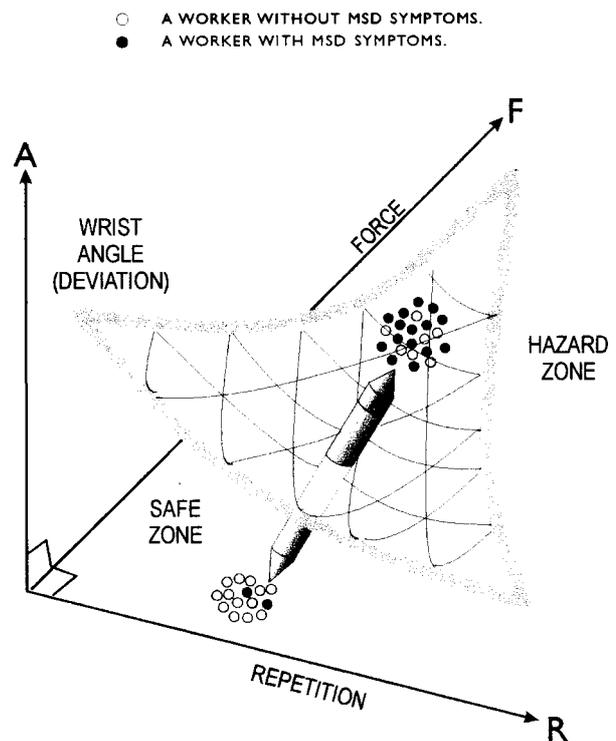
○ A WORKER WITHOUT MSD SYMPTOMS.
● A WORKER WITH MSD SYMPTOMS.


Figure 1. Conceptual threshold plane for repetitive manual work based on force, repetition and wrist angle factors without time factor. To prevent occurrence of hand/wrist musculoskeletal disorders (H/W MSD), exposure points must remain below the threshold plane.

adverse health effects such as prolonged pain, tendinitis or CTS. ELM_2 is an exposure limit of manual work involving F, R and A, and can be expressed as a targeted or acceptable incidence rate of H/W-MSD among the working population.

3.1. Explanation of the Triangular Kite for Intensity of Manual Work

Equation (3) is explained by describing the three corners of the triangle in Figure 1 as follows:

3.1.1. Physiologic limit for force factor F

The practical upper limit of F will be determined by the largest internal force which can be exerted safely (without causing pain or subsequent tissue damage) by a hand during a unit time, e.g. maximal power grip. From equation (3), if F is at the maximum, the product of R and A must be reduced to the minimum to stay below ELM_2, meaning that the wrist should remain neutral and only a minimal number of repetition would be allowed. This is at the upper corner of the triangle. If the product $R \cdot A$ cannot be reduced to the minimum, then F must be lowered accordingly.

3.1.2. Physiologic limit for repetition factor R

By the same token, there is also a maximum limit of repetitive motion per unit time a human hand can safely make to perform in any manual task. If R is very high, the product of F and A must be at the minimum, i.e. the force being only the weight of the hand and fingers, and the wrist being kept in neutral position. This is at the right end of the triangle in Figure 1, and can be exemplified by the computer keyboard operation in office settings

or the left hand of a violinist or cellist, in which the frequency of finger taps may be very high. Under such circumstances, an increase in the wrist angle or tapping force may induce a disorder in the wrist, as has been reported among VDT operators or string players. (Additionally, in case of fast-paced and continuous key board operations, other stress factors such as visual and mental fatigue, static loading on the neck and shoulder, and psychosocial or organizational factors need to be considered for prevention of their MSD. However, these factors are not considered in the current modeling exercise.)

3.2. Industrial Application of Equation (3)

For example, if R is increased as a result of a change in production rate (e.g. increased number of chickens processed per h), either F or A or both of the task must be reduced in accordance with equation (3) to prevent hand pain among workers. However, it is often difficult or not possible to reduce F or A to zero, unless the process is totally mechanized. Therefore, an indiscriminate attempt to increase R in disregard of equation (3) would surely result in dramatic increase of H/W-MSD cases. Similarly, if F needs to be increased (e.g. increase in the weight of manufactured parts), either R or A or both must be reduced so that the intensity of the work would stay below ELM_2 of the equation.

In real life, however, these curved lines and the triangular kite-like plane have some thickness with fuzzy borders to reflect individual variations in the working population. Below the fuzzy plane would be jobs which could be performed by almost all workers without developing symptoms of H/W-MSD (designated as safe zone), while above it would be jobs which could cause H/W-MSD with various incidence rate among workers (hazard zone).

4. INCORPORATION OF TIME FACTOR INTO THE MODEL

The next step in the construction of the dose–response model is incorporation of time factor (T), since the duration of repetitive manual task varies in daily work. This issue relates to the question of cumulative dose-over-time effect of repetitive stress injury to the tendon–sheath complex and its recovery process. Empirically there seems to be a limit in the duration (time) for repetitive hand motions in daily performance of manual work, under which no physical harm such as pain and discomfort should occur. If the manual work is continued with the same intensity despite pain, the condition will progress to full-blown tendinitis or CTS. Due to methodological difficulties, however, the 'safe' duration of daily repetitive manual work has not been established by either human laboratory studies or industrial on-site surveys.

4.1. Short–term Laboratory Study of Muscle Fatigue

It is well known in our daily experience that a light work can be performed for a long time, while a heavy work can be performed only for a short time before fatigue develops. An analogy can be found in contrasting a long hike to a 100-m dash. From biomechanical studies, Rohmert (1973) showed that the duration of muscular contraction is inversely related to the degree of such contraction (in percentage of the maximum exertion). In other words, the product of (duration) times (muscle contraction) remains approximately the same with a certain coefficient. Also,

Rogers (1984) reported that the amount of recovery time needed is a function of work duration and work intensity, and follows an exponential pattern. Based on these findings, we postulate that an inverse relationship would exist between the intensity (I) and duration (T) of manual work as:

$$I \cdot T = C, \quad (4)$$

where: T= daily number of h performing repetitive manual work and C= constant (physiologically safe limit).

4.2. Muscle Fatigue and Tenosynovial Damage

The above laboratory findings are based on short-term human experiments (usually lasting no more than 1 hour), in which the limiting factor is likely to be the muscle fatigue, but not long enough to look at long-term results of morbidity such as tenosynovitis or CTS. In the current context, we are considering the relationship of exposure and morbidity over a period of many weeks, months and years. Also, in the case of CTS and related disorders, we need to consider more insidious or delayed phenomena such as friction of the tendons, capillary edema, and inadequate supply of lubricant to the tendon sheaths, as well as fatigue and microtrauma to the involved muscles.

4.3. An Epidemiologic Finding

During our analysis of the data from the 1988 National Health Interview Survey, Occupational Health Supplement (NHIS/OHS) on CTS, we noted that the workers who repeatedly bent/twisted their hands/wrists in a typical work day had about six times higher prevalence (0.9–1.0%) of CTS than those who did not bend/twist their hands repeatedly at work (0.15%). While this finding was expected, we also noted that the prevalence did not increase in proportion to the daily h of bending/twisting, but rather stayed at about the same level to form a plateau, regardless of the varying number of exposure h (up to 3 h; from 3–6 h; and > 6 h a day).

One way to interpret this finding would be to assume that workers who bent/twisted their hands/wrists more intensely could do so for a shorter duration of time in a day, while workers who did the manual work less intensely could do it for a longer period. Thus, the product of I and T remained at approximately the same level as reflected in the CTS prevalence, which was close to one another regardless of the length of repetitive work. (Since it was a cross sectional survey and might be subject to various biases, such a finding must be interpreted with caution. For example, workers who bent/twisted their hands/wrists more intensely for longer h might have developed a H/W-MSD and left the job — a healthy worker survival effect.)

Nonetheless, we hypothesize that, on the basis of our epidemiologic finding of flattened patterns, equation (4) may be applicable not only to short-term experimental situations but also to long-term work situations. Therefore, we would deduce that, in general workplace situations, the product of work intensity and time (duration) factors of repetitive manual work would remain the same with a certain coefficient (k).

Thus, from equations (3) and (4), we get:

$$ELM = C = k \, (aF \cdot bR \cdot e^{yA}) \cdot T \cdot \quad (5)$$

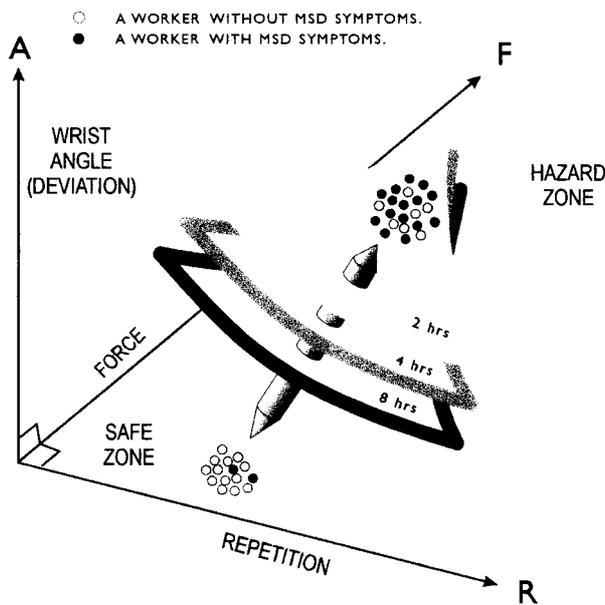
This relationship is shown in Figure 2 with $T = 2, 4$, and 8 h as examples.


Figure 2. Conceptual threshold planes as in Figure 1 with various daily length of exposure. As h of the exposure increase, other risk factors must be reduced to keep exposure points below the threshold plane to prevent H/W MSD.

4.4. Situations in US Industry

The above reasoning is consistent with our experience and there probably is a general understanding (conscious or otherwise) among management and employees that working with high intensity for a long period of time is not only difficult to continue but also dangerous to the employees' health and safety. According to the 1988 NHIS data, among workplaces in the US as a whole, the estimated prevalence of medically diagnosed, work-related CTS was ~0.28% (356 000 cases among 127 million workers). This is likely an underestimate partly due to possible healthy worker survival effects. Since this prevalence is the result of averaging over the entire US adult (non-institutionalized) worker population, there are of course industries and occupations with higher or lower than the average prevalence of CTS. Further, within the same industrial category, certain companies, departments, or operations may have unusually high CTS prevalence which contributes to the overall higher prevalence for that industry. Based on equation 4, it is likely that such workplaces may include tasks performed with high intensity for many h.

4.5. Protection of Workers

For protection of workers against H/W-MSD, the constant C and k can be set to represent an acceptable level of musculoskeletal morbidity among the worker population, e.g. annual incidence rate of MSD at 0.05, 0.01%, etc. In industrial situations, T can be allowed to vary between 2 to perhaps 10 h per day depending on job demands and work schedule. However, T is not to be allowed to become too small. If T is too small, the inverse relationship of I and T will make I excessively large and unsafe.

Therefore, any fraction of work duration < 2 h may have to be treated as 2 h at the minimum ($T \geq 2$) in the equation.

The proposed equation is compatible with a general empirical notion that for prevention of H/W MSD, high intensity manual work (high force, high repetition and/or strong posture deviation) should not be performed for an extended period of time, while a low intensity work may be performed for a longer period of time. The relationship between the daily duration of repetitive manual work and the prevalence of CTS may provide a framework for developing ergonomic intervention guidelines.

5. FUTURE RESEARCH NEED

Further research is much needed to establish the relationship of intensity and duration of work, which is safe to workers over a working-life time. Unfortunately, there is a paucity of objective quantitative data collected at work places, which include all four of the essential risk factors. Therefore, many quantitative assessments of repetitive manual job tasks need to be conducted using a standard methodology at a variety of workplaces where varying incidence rates of H/W-MSD are reported. It is also desirable to conduct prospective studies by following groups of new workers to account for healthy worker survival effect. Based on the data generated by such concurrent ergonomic and epidemiologic surveys, we will be able to derive various coefficients of equation (4). Future research efforts involving both ergonomics and epidemiology must be directed toward quantitative delineation of this threshold, so that the evaluation of intervention efforts may be based on objective quantitative data. Rapidly advancing computer technology of today should be fully exploited to assist us in this effort.

Maximum Loads and Manual Materials Handling

V. Forastieri

Occupational Safety and Health Branch, International Labour Organization

1. INTRODUCTION

The handling of materials at the workplace level can be done by motor vehicles, mechanized equipment, power transmission and other lifting equipment or by manual handling. For the purposes of this article we will concentrate on the manual materials handling (MMH) and its ergonomics implications.

The manual handling of materials, tools or products is an essential aspect of the work to be carried out in a workstation in almost any workplace. The term "manual handling" includes lifting, putting down, pushing, pulling, carrying, moving, holding and restraining. Every time heavy loads are moved by people or machines there is a risk of an accident due to the characteristics of the load or unfavourable ergonomic conditions. The magnitude of the risk is determined by the technological and organizational characteristics of the work and workplace, the working environment and the managerial and preventive measures implemented.

MMH is an important safety problem in dock work, construction sites, railways, warehousing, sawmills, mining, ship building, agriculture, forestry and other similar heavy industries. Many accidents due to materials handling also occur during the lifting of raw material, parts or final products either manually of by mechanical means in industries such as pulp and paper, steel and foundry and the chemical industry. It is heavily present in hospital work where the manual lifting or carrying of patients or loads takes place and in any workplace where MMH is a feature of the work process. Mechanization and automation have eliminated MMH to a large extent in a number of industries. However, there are still workplaces where people are physically overloaded by lifting and carrying heavy loads. This is particularly evident in developing countries were many workplaces, even in big industries, are still labour-intensive despite a high degree of mechanization. Furthermore, small-scale enterprises and agriculture are primary labour-intensive and the majority of the activities are performed manually.

A significant number of MMH accidents have a lasting effect and sometimes lead to the permanent disability of the victim. Most frequent accidents due to MMH are: physical strain, loads falling onto people, people trapped between objects, collisions between equipment, people falling, hits, blows and cuts with loads and injuries caused by sharp edges from equipment or loads (Häkkinen, K. 1998).

Manual handling of loads is one of the main causes of musculoskeletal disorders (MSDs) and incapacities both in industrialized and developing countries accounting for approximately 30% of all work-related impairments. Annual costs for compensation in industrialized countries is high both at the workplace and national level. Indirect costs, such as: reduced productivity, labour turnover and industrial disruptions increase the costs even further. A comprehensive national survey for the period of 1986-87, undertaken in Australia by the National Occupational Safety and Health Authority (Worsafe Australia, 1995) found 100,000 cases of occupational back disorders from which 16 % resulted in almost six months lost and one third of all worker's compensation claims. The total compensation costs for that period corresponded to 4.3 billions USD. In UK, an estimated 33% of all lost-time accident reported to the labour authorities in a year are associated with manual handling operations (HSE, 1994). In Sweden they are the most common cause of work injury reports. Only in 1996, one out of every three reports was due to MSDs. Heavy lifting is one of the common contributing factors (Thorbjörson *et al.* 1998).

The prevalence of MSDs has increased dramatically in developing countries with globalization trends. For example, in 1995, in the Philippines MSDs were ranked as the fourth cause of compensation claims (ILO/FINNIDA, 1998). Unfortunately the magnitude of the problem in these countries is unknown due to limited epidemiological studies. However, it can be expected to be much worse due to inadequate safety systems, lack of awareness and training on occupational safety and health (OSH) and lack of compliance with ergonomic standards.

2. WORK–RELATED MUSCULOSKELETAL DISORDERS (MSDS)

Physical activity involving musculoskeletal load is an integral part of normal body functions. Muscles, tendons and joints have to create forces to balance the posture and control movements even in relaxed postures. Physical activity may increase muscle strength and working capacity through changes such as growth in muscle volume and increased metabolic capacity. Inactivity causes atrophy, especially in muscle tissue and can even lead to deterioration of tendons, ligaments, cartilages and bones. Only when musculoskeletal load exceeds the capacity of the body by sudden overload, repetitive or sustained loading, it can cause fatigue and injury to the musculoskeletal system. Biological protective mechanisms induce the muscles to relax and recover in order to regain strength. When signals such as fatigue and pain are ignored, overload can cause chronic degenerative changes in the muscles (Sjogaard, 1990) . That is why the perception of fatigue and pain may play an important role in preventing muscle injury.

There is a close interaction between the body's physiological characteristics, its capacity and work requirements. The characteristics of the workplace determine the postures and workload both for static and dynamic tasks such as in MMH. The loads to be handled, the weight and type of tool used, as well as the dimensional characteristics of the workplace (e.g. confined spaces), force the body into a certain posture or a combination of postures.

MSDs disorders associated to the manual handling of materials can be determined by organizational, environmental, postural and psychosocial factors. Work organization both physically and temporally (duration of the tasks, distance, frequency of the loads and adequacy of recovery time) would also have and impact on the workload. The lifting task is also influenced by the load itself because of its shape, stability, size, weight, location and slipperiness. Environmental factors such as poor lighting, cluttered or uneven floor and poor house-keeping may all be cause of accidents. A worker's susceptibility to MSDs can also be influenced by physical fitness and other psycho-social and individual factors such as: work roles, work pressure, working

relationships, personal handling skills, age, sex. The clothing worn can also affect handling requirements.

In broad terms, injuries resulting from a sudden unforeseen event are classified as musculoskeletal accidents while injuries resulting from a prolonged influence are classified as musculoskeletal diseases. Both are grouped as MSDs. Work-related MSDs can be classified into the following categories:

- occupational cervico-brachial disorders (OCD)
- work-related neck and upper-limb disorders
- repetition strain injuries (RSI)
- cumulative trauma disorders (CTD)
- overuse (injury) syndrome

Most musculoskeletal injuries are due to over-exertion, they cause local pain and motor restrictions that may compromise normal performance at work or in other daily tasks. Most of these disorders develop over a long period of time as a result of repeated stressors on a particular body part, due to the high tensile forces directed to the muscles and ligaments and the high compression of bones and joint surfaces (Putz-Anderson, V., 1988). Cumulative trauma disorders and back disorders are typical health impairments due to manual handling. Low-back pain is one of the most important occupational causes of short-term and long-term disability. It is related to heavy lifting, carrying, pulling and pushing. Sudden overloads or fatigue due to repetitive loading can cause mechanical injuries to the vertebral bodies, intervertebral disks and ligaments of the posterior parts of the vertebrae. Low-back pain is also associated with frequent or prolonged twisting, bending or adopting other non-neutral trunk postures. If the task requires a worker to twist or reach forward with a load, the risk of injury is greater. More injuries occur when lift begins at ground level as compared to mid-high level. There is general agreement that it is beneficial to keep the load close to the body and to avoid jerking and twisting. However the experts' opinions are still in conflict concerning the leg lift and back lift. The risk of back injury increases if a worker lifts weights heavier that would be proportionate to his or her muscular strength independently of sex or age.

Epidemiological studies suggest that repeated microtrauma can cause degeneration of the lumbar spine and that its prevalence will increases with increasing age. The handling of tools or materials may also cause osteoarthrosis of the shoulder joint and acromio-clavicular osteoarthrosis due to severe loading on the shoulder, tendons and muscles, for example as reported among construction workers.

In most cases MSDs have a multi-causal origin making its diagnosis difficult. The great majority are work-related, as any physical activity can aggravate or provoke symptoms even when the disorder was not directly caused by work. Conditions only caused by accidental injuries are an exception and a single cause-effect is difficult to identify.

The assessment of the relation between all contributing factors and the resulting injury is a complex and not fully understood issue which has lead to controversies among experts (Rosecrance, J.C., and Cook, T.M.1998, Dempsey, P.G., 1998). Because of its multi-factorial nature, an effective approach to deal with work-related MSDs is the development of primary prevention programmes.

3. RECOMMENDED WEIGHT LIMITS

Worldwide there is a substantial divergence in recommended maximum weights to be safely lifted and carried (by adult and young workers and by men and women). Many countries have introduced legislation covering the manual lifting and carrying of heavy loads by at least certain categories of workers. However, the establishment of mandatory weight limits for manual handling in national legislation will vary from country to country. International comparison of statutory provision and standards on limitation of weight at the workplace is difficult to obtain. An ILO (1988) publication, which presents a summary of legislation and practice from various member states has been traditionally used as a reference.

The regulations in many countries still suggest 50 to 55 kg as a limit for manual handling by adult male workers. In others, it is fixed in 60 kg or even 75 kg. Lower limits are established for women and young workers and in most cases there are special provisions for pregnant women. Certain countries have introduced general legislation, leaving the fixing of specific maximum weights to the discretion of the competent authority. While in the European Union and in other industrialized countries there is the machinery to verify compliance with such regulations, in developing countries very few regulations seem to have been introduced for this purpose. In many cases the weight limits are established as a compromise based on "common sense" grounds or using other countries' national legislation as a reference. According to recent scientific evidence, the weight limit of 50 kg is now considered to be far too great. The National Institute for Occupational Safety and Health (NIOSH) in the United States has adopted 23 kg as a limit since 1991, other countries in Europe have adopted 25 kg as a standard limit.

It has to be noted that there can be a wide gap between legislation and practice, weights of almost 100 kg are still carried regularly by a single worker in certain developing countries. Frequently the load of the handling units is determined by local tradition or commercial packaging (e.g.: Bales of cotton can weight between 100 and 150 kg, sacks of grain, sugar and fluor between 65 and 95 kg, crates of bottles between 50 and 70 kg). In the rural areas of many developing countries, loads are often carried out on the back or the head in uneven terrain for long distances (e.g.: 20 km per day or more), and in some cases exposed to adverse climatic conditions.

Despite the wealth of technical literature associating job tasks with MSDs there is limited information concerning the workers perception of "heavy load", most load limits are based on the laboratory assessment of load distribution. A recent comparative study (Genaidy A.M. *et al.* 1998) between standards and individual subjective perception in women and men populations showed that a moderated level of load heaviness (14kg) can be handled by 85% of the population and not by 50% as various criteria for weight limits postulate. Further field research is necessary for a better interpretation of statistical norms for human perception of load handling.

The main problem is that is impossible to state a universal weight that will be "safe" in all circumstances and for all workers. There are a number of alternatives for each worker and each working situation. Individual differences, age and sex influence postures and lifting practices. The weight of the load needs also to be assessed taking into consideration other variables such as

frequency of lift, horizontal distance from the body and high of the lift. All these factors make it difficult to evaluate and design "best" postures, weights and performances for the manual handling of materials. Therefore weight limits for loads, need to be established taking into account the specific characteristics of the working situation and using psycho-physical, bio-mechanical and physiological criteria:

- Bio-mechanical criterion: How much can be handled without causing damage to the musculoskeletal system? (e.g.: muscle strain, disc injury or joint problems).
- Physiological criterion: How much can be handled without over-exerting the lungs?
- Psycho-physical criterion: How much do people feel able to handle comfortably? (Darby, 1998).

One suggested approach, is to design a specific job within the physical capacity of a large percentage of the working population (Waters, T.R. *et al.* 1993).

4. SAFETY AND HEALTH STANDARDS ON MANUAL MATERIALS HANDLING MMH

There are few international ergonomic standards dealing specifically with manual handling. Some of them have a regulatory status, however most of them serve as voluntary guidelines. There are also a number of national regulations and technical standards on MMH and materials handling equipment which will not be discussed in detail in this article. Certain of these national standards and guidelines on weight limits are extensively used as a reference by other countries.

The International Labour Organization (ILO) developed in 1967 a Convention and Recommendation on the maximum permissible weight to be carried by one worker. These international instruments apply to the manual transport of loads in all branches of economic activity. They foresee the protection of workers of risk arising from MMH. It contains rights and obligations of the employers and the workers. The employer shall take appropriate organizational measures and use the appropriate mechanical means in order to avoid the need for MMH by workers. Where the need for the manual handling of loads by workers cannot be avoided, the employer shall take the appropriate organizational measures and provide workers with such means as to reduce the risk involved in MMH including training. Convention no. 127 does not specify any weight limits, however, its accompanying Recommendation no. 128, suggests a maximum limit of 55 kg to be carried out by a single male adult worker and applies only to specially selected and properly trained workers in favourable environmental conditions.[1] Particular attention is paid to women and young persons. These are among the first international standards on the subject and have served the purpose of focussing attention on safety measures concerning MMH. They are still reference for the development of national legislation, particularly in developing countries. Even though, their principles are still valid, it is foreseen to revise these standards shortly, on the light of new technological and ergonomic developments.

---

[1] This limit has been proposed based on scientific knowledge at the time of the adoption of the Convention. It has to be noted that ILO Recommendations do not have a binding status and its purpose is to provide complementary advice and information for the application of the Convention they accompany.

The International Organization of Standardization (ISO) and the European Committee for Standardization (CEN) have also developed a number of Ergonomic Standards among which 90/269/ECC on manual material handling. In line with ILO Convention no 127, the aim of the European Council Directive is to minimize the risk of injuries to workers while handling loads. It also emphasizes the importance of non-risk handling policies that incorporate training and use of mechanical equipment when possible. The European member states have the obligation to develop regulations and mechanisms at national level to apply the Directive.

The Occupational Safety and Health Administration of the USA (OSHA) has attempted since 1997 to develop an ergonomics standard dealing with the prevention of MSDs. Its issuing has been quite controversial at national level. Much of the argument over it concerned the scope, the issues which should cover and if it should apply only to certain industries or jobs. OSHA has carried out a number of consultations on the standard with stakeholders and the scientific community. The National Academy of Science prepared an extensive study on MSDs upon request of the US Senate. The study was published at the end of 1998 and provided substantial evidence to link MSDs to bio-mechanical stress and injury at the workplace level. Heavy lifting is among the mayor causes. The study also discusses how workplace interventions can prevent such disorders. OSHA plans to publish its proposed standard in the summer of 1999. (Tyson, P.R. 1998).

5. TECHNICAL GUIDELINES AND ASSESSMENT METHODS

There are a number of more or less sophisticated models of assessment of manual handling tasks. The main measuring methods include, self-reporting questionnaires and diaries, postures observation techniques and computer-aided posture analyses. The following is a list of some selected examples of methods for the assessment of MMH:

The *Work Practices Guide for Manual Lifting* developed by the National Institute for Occupational Safety and Health in USA (NIOSH, 1981, 1991) provides a model for the evaluation manual handling and the establishment of weight limits for loads, using psycho-physical, bio-mechanical and physiological criteria, taking into account the specific working situation.

Originally developed in 1981, the model has been subsequently revised by NIOSH in 1991, to reflect new findings. This updating provides important improvements, such as the a the revision of the lifting equation (including a discussion on the rationale behind the establishment of its 3 criteria and how they were used in determining the equation values); the development of a lifting index (an index of relative physical stress to identify hazardous lifting tasks); methods for evaluating asymmetrical lifting tasks, horizontal lifting vertical lifting high, and lifts of objects with less than optimal hand-container couplings. It also provides guidelines for a larger range of work duration and lifting frequencies than the 1981 model.

Cross-validations of the model have been carried out by some specialists both in USA and abroad, confirming to a large extent the validity of the assumptions behind the revised lifting equation. (Snook S.H. *et al.* 1978, Keyserling, W.M., 1989, Snook. S.H. and Ciriello V.M.,1991, Waters *et al.* 1993, 1994, Hildalgo, J., *et al.* 1995, Davis, K. G., 1998). However, there is still some debate,

as the 1991 NIOSH model for lifting limits was established under ideal conditions and showed some limitations in its practical application. In particular, concerning the physiological and bio-mechanical criteria used. Scientific evidence for the analysis of one-handed lifts is also still inconclusive. Nevertheless, as the method is reasonably precise for most lifting activities, it is still a valuable tool, as it provides the basis for the evaluation of lifting tasks. Its practical application had contributed to a number of other improved models generated on its grounds.

Other relevant examples of assessment models are the posture targeting method by Corlett and Bishop (1976); the Ovako Working Posture Analysing System (OWAS): A method which proposes a structured scheme for the recording, rating and evaluation of trunk and limb postures designed for field conditions in Finland (Karhu, Kansi and Kuorinka, 1977); the cube model for the evaluation of workplaces developed by (Kadefors, 1993) and the PLIBEL Method for the Identification of Ergonomic Hazards (Kemlert, K., 1995) which deal also with MMH. There are bio-mechanical and anthropometrical computer programmes and computer-based packages for working tasks which offer specialized tools for evaluating some postural elements both in the workplace and in the laboratory . (Chaffin, 1969, Chaffin, D.B., and Andersson, G., 1984).There is also a computerized OWAS version for recording and analysing developed by Kivi and Mattila (1991).

There is also an increasing number of programmes and training manuals on the prevention of MSDs at the workplace level. Some of them function as national guidelines (WorkSafe Australia, 1989, HSE, 1990, NIOSH, 1991; INRS, 1994, ANPAT, 1994). However, few have undergo through a systematic evaluation of their impact on workers' health and safety.

According to some authors, fitness training programmes and the use of supportive equipment such as waist belts have not been convincing enough, so far, in spite of its wide implementation. Nevertheless, the limited number of studies on costs and benefits of preventing MSDs due to MMH have shown, in most cases, to be profitable for the enterprises who have introduce them. (Dury *et al.* 1983, Spilling *et al.* 1986, Bertrand, 1991, Lanoie and Taveras, 1996, Lanoie and Trottier, 1998). Acknowledging the on-going debate in this area, most authors agree in the need for further field research on the effectiveness of ergonomic interventions in order to assure efficient preventive programmes in terms of productivity, cost effectiveness and reduction of occupational and work-related MSDs. The need for an internationally agreed protocol for the validation of criteria on the assessment of MMH has also been raised. (Leamon T. 1994, Dempsey, P.G.1998).

6. PREVENTIVE MEASURES

The primary approach to the prevention of work-related MSD disorders due to the manual handling of loads is the ergonomic redesign of work in order to optimize the workload and make it compatible with the performance capacity of the worker, both physically and mentally. Preventive strategies should be implemented depending on the type of work tasks in order to optimize workload and reduce exposure. This means to find the optimal balance between the necessary and the excessive workload. Fitting the work to the performance capacity of the worker will help him or her to be more productive and healthier.

There is a number of basic ergonomic variables related to musculoskeletal load which need to be taken into account in the design process, in order to eliminate the risk of work-related MSDs. These variables concern the different types of loads in relation to muscular force demands, working posture demands and time demands. Each demand will have different degrees of acceptability in terms of workload depending on the specific characteristics of the working situation. Therefore, the possible combinations among the different types of demands, according to their respective importance, need to be considered in the context of the specific working situation. (Corlett E.N. 1988). In this context, most ergonomic interventions deal with work organization., workplace layout and tasks design including the improvement of working postures and motions, the modification of the loads and the reduction of the peak loads, the design of the objects handled and lifting techniques. The adoption of appropriate postures and handling practices depends on the amount of functional space, the presence of appropriate furniture and equipment, good collaboration on work organization and quality of care, good physical fitness and comfortable work clothing.

The work can be often redesign to prevent injuries with simple control measures (e.g.: when substitution of MMH by mechanical devises is not possible, job redesign by spreading the burden of carrying loads among a group of workers, for a limited period of time instead of having a single worker involve all day in that tasks has proven to be more effective).

Guidelines to design safer working practices for MMH need to be set on an ad-hoc basis. According to Häkkinen. K. (1998), the following principles should be taken into account:

- elimination of unnecessary transport and handling operations through continuos flow systems or other mechanical devices;
- aim at continuous transport processes avoiding points of discontinuity in materials handling;
- avoid the unnecessary presence of people in the areas where handling and transportation are taking place;
- segregate in-plant transport operations from each other as much as possible to minimize the probability of collision (e.g.: internal traffic/to and from outside-traffic, transport between workplaces, materials handling within a workplace, in storage, in a production line, when receiving/shipping, etc);
- provide enough space for materials handling operations;
- use standard items of load (unit load), equipment and tools in material handling;
- provide information on the characteristics of the materials to be handled in order to select the appropriate lifting or load restraints, handling methods and for the safe transfer of hazardous materials;
- keep loading below the safe working-load capacity; set speed and time limits low enough to maintain safe transportation (both vehicle and walking speed);
- avoid overhead lifting in areas where people are working underneath;
- abstain from material handling methods that require climbing and working at high levels to avoid risk of falling;
- attach guards at danger points in materials-handling equipment (e.g.: guards, chains, rope drives, trapping points, etc);

- transport and lift people only by the equipment designed for the purpose;
- keep equipment and loads stable;
- provide good visibility, (e.g.: elimination of blind corners, mark danger points, and obstructions, appropriate illumination in closed workplaces and confined spaces);
- eliminate manual lifting and carrying of loads using mechanical and automated handling whenever possible;
- provide appropriate handling equipment (e.g.: hoist, lifting platforms, elevators, fork-lift trucks, cranes, conveyors, palletisers, robots, and mechanical manipulators);
- provide and maintain effective communication links;
- arrange the worker interfaces and the manual handling according ergonomic principles;
- provide adequate training and advice;
- supply workers with appropriate personal equipment for handling task;
- carry out proper maintenance and inspection procedures plan for safety procedures for changes in environmental conditions (e.g.: wind, heat, rain, ice, snow, etc.).

7. EDUCATION AND TRAINING

Management programmes should be an integral part of a preventive policy as they can significantly reduce long-term disability claims and accident rates. Participatory ergonomics has shown to be an effective tool for the improvement of working conditions having also an impact in increasing productivity. It implies a macro-ergonomic approach for the analysis of the whole production process and identification of safety and health measures which may lead to large-scale or small-scale changes in work organization and production methods. It involves both employers/supervisors and workers in jointly defining the problems and identifying solutions.

In order to perform their work adequately and safely workers need to be trained in safety measures for MMH. Fitness training programmes should be provided on regular basis according to job demands and whenever a mismatch between job demands and workers' strength is detected. Occupational health services should be involved actively in training and management programmes. To accomplish their functions, such services should be trained in the assessment, early intervention, initial treatment, worker's follow up, job placement and enforcement of safety rules concerning MMH.

Micro- and Macro-ergonomic Interventions in Industrially Developing Countries

P.A. Scott, and J. Charteris
Department of Human Kinetics and Ergonomics, Rhodes University, Grahamstown, South Africa

1. INTRODUCTION

Initially ergonomics focused almost exclusively on the "man–machine" interface and while some may have put the emphasis on the design of tools and machines, others were more concerned with human factors. Irrespective of where the focus was, some argued that this critical interaction between the two main components of any work station was a closed loop, with any ergonomic intervention being at a micro-level. Fortunately, there is now a general consensus that any work site is influenced by many other factors, not least among them the physical and social environments within which work is done (see figure 1). Acknowledging the importance of taking a panoramic view in any ergonomic assessment, the concept of macro-ergonomics developed. The query that arises is: What are the complimentary roles of micro- and macro-ergonomics in industrially developing countries (IDCs)? This question is important because micro-ergonomic needs may, on superficial analysis, seem to be all that is required in the IDC context

Most IDCs are characterized by poor to appalling working conditions with a predominance of semi-skilled, semi-literate manual laborers. While human resources have been identified as a key component in developing industries, in many labor-intensive situations workers are often pushed beyond their physical capabilities, being required, for instance, to maneuver objects often in excess of 60–80 kg, or to stack 3.5kg bricks at a rate of 20–25 lifts per minute in hot, unpleasant, working environments. Cognizance must also be taken of the fact that many workers are under-nourished, live in very menial dwellings, and have to travel (most often walking) long distances to and from work. Another characteristic of IDCs is the high rate of unemployment: potential workers, desperate for a job, are likely to put up with sub-optimal conditions without complaining — victims of the system which creates a self-perpetuating negative spiral.

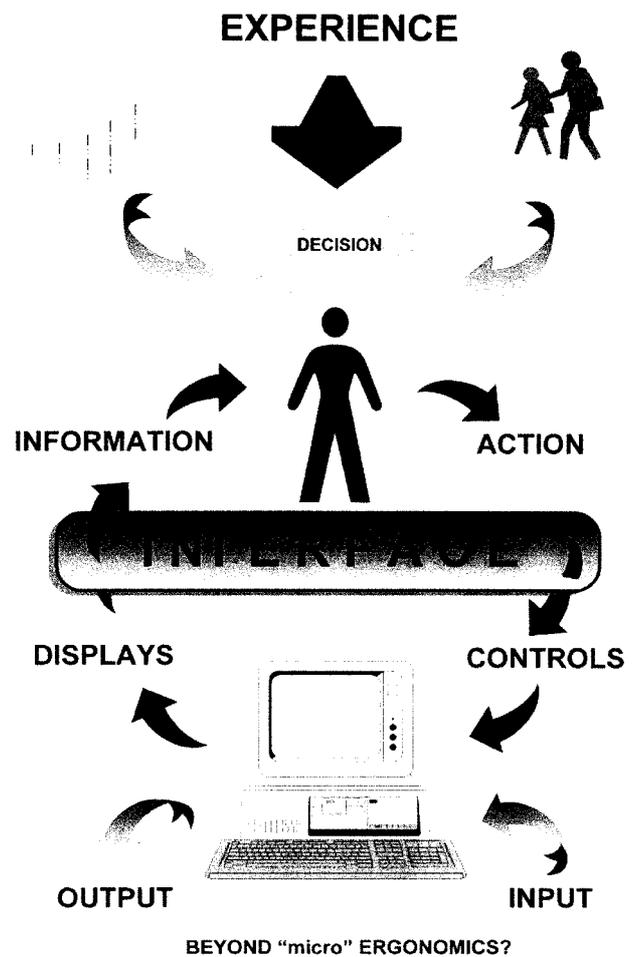
In addition, with the rapid advancement of technology and establishment of a "global village", much of the developed world's sophisticated machinery is being transferred into IDCs in an attempt to boost poor productivity. Servicing, or even operating, advanced technology is often beyond the comprehension of poorly educated workers, who, instead of being assisted by mechanization, may be threatened by the importation of this technology. Uncontrolled transfer of mechanization typically results in an increase in work-site incidents leading to injuries and/or machine malfunctions. Frequently, the result is the creation of a working ambience characterized by an array of problems of


Figure 1: Multifaceted influences on "human-machine" interaction.

growing complexity and in which working conditions show little sign of improvement.

A feasible means of addressing these substantial problems is to have dynamic ergonomics input. However, on a global scale ergonomics is predominately practiced in well-established industrially developed nations, and there is often a complete lack of awareness of ergonomics where in fact it is critically required, namely in IDCs. Hendrick (1996) reiterates the view by stating that ergonomists by and large have failed to bring ergonomics to areas where it is needed most, that is, to the developing areas of the world — areas which arguably include over three-quarters of the world's population. The vast majority of these workers are involved in manual work, either lifting excessive weights or executing highly repetitive manipulative tasks (such as turning over and inspecting 21,000 carbon battery bases (approximate weight 20 mg) per shift. These tasks and others requiring similar manipulative skills result in cumulative physical stress, ultimately leading to excessive strain on joints, tendons and muscles. Nordin (1987) reported that millions of workers around the globe suffer from non-fatal musculo-skeletal injuries, most of which could be prevented through sound ergonomics interventions.

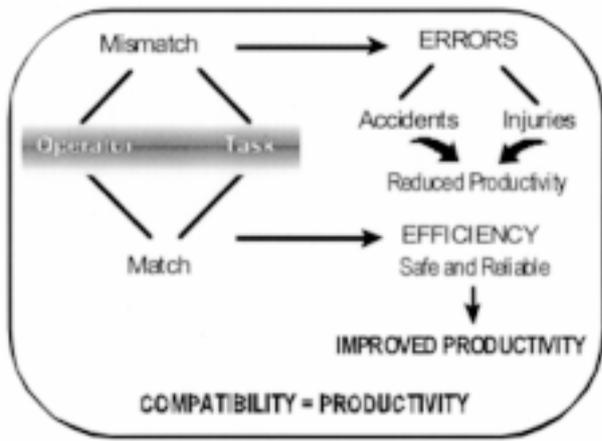
Fortunately at the close of the millennium there appears to be a growing concern for the working environment in IDCs, and ergonomists worldwide are increasingly offering expertise and guidance to address these substantial problems. If we are to


Figure 2: A schematic of the implications of a match/ mismatch between operator and task.

improve imbalances in the world's productivity, where it is argued that less than 30% of the world's population are responsible for more than 60% of its productivity, then there must be a major effort made to improve working conditions on an international basis.

2. MICRO-ERGONOMICS

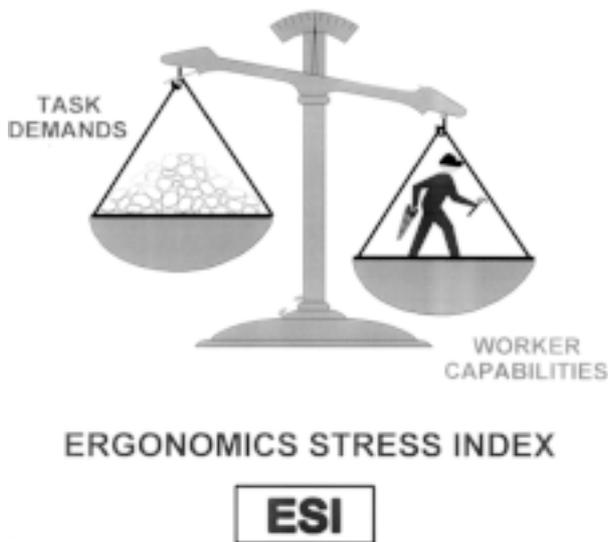
Traditionally, interventions have been characterized by a micro-ergonomics approach to problems within the working environment, the specific focus being on the "man–machine" interface. The basic premise is that any mismatch between worker capabilities and the task demands is likely to lead to errors and accidents, characteristics of a sub-optimal, unsafe situation in which the final product is low in quantity and poor in quality. An ergonomist would be required to identify the problem and take appropriate steps to design/redesign the task/machine in order to accommodate workers. By modifying task demands to match worker's capabilities, one establishes an efficient working ambience in which there will be an increase in productivity with


Figure 3: Ergonomics Stress Index (ESI): Ratio between task demands and worker capabilities. (Adapted from Genaidy *et al.* 1992).

a reduction of effort. In other words there will be no wasted effort in having to cope with the strain imposed by awkward working postures or being taxed beyond one's ability, whether in terms of physical or mental effort required.

The concept of an Ergonomic Stress Index (ESI) (Genaidy *et al.* 1992) investigates the ratio between task demands and worker's capabilities and may be used as a basic guideline to tip the scale in favor of the worker who is required to execute the task on hand for a full working day (figure 3).

The investigation of a mismatch between these two components, i.e. the human and the task, is typical of a reactive response to a problem situation in which ergonomic intervention strategies tend to focus on the specificity of the particular area. There is no doubt that a good ergonomist will look beyond the immediately obvious problem and will investigate a multiplicity of possible causes in order to avoid the recurrence of the problem. However, in many IDC situations it is highly likely that there will be an extensive number of problem areas and the most obvious "quick fixes" are all there is time (and probably expertise) for. While such responses may appear to be lacking in overall organization and planning, it is important to realize that any improvement in the situation is a step in the right direction. Such basic interventions should be at very little cost, for as Scott (1996) and Kogi (1997) emphasize, in IDCs ergonomic interventions should be economically viable, the basic premise being the implementation of "no-cost, low cost" modifications to the task. The ergonomist needs to make an immediate impact, preferably at minimal cost and with maximum benefit. These benefits need to be clearly evident to all concerned. In this way it is possible to introduce a basic awareness of the principles and benefits of ergonomics at floor level within developing industries.

3. MACRO-ERGONOMICS

Hendrick (1980) has defined macro-ergonomics as a "top-down socio-technical systems approach to organizational and work system design". Over the years there has been a growing realization that it is critical to look beyond the immediate situation (beyond the basic "man–machine" interaction) and to consider all the interactive components/systems which make up the physical, social, and technical work environment; there is a need for a more global assessment of the overall situation.

The three major components in the running of any organization are its complexity, formalization, and centralization (Robbins 1983). Complexity refers to the degree of differentiation and integration which may exist within an organization. This differentiation exist on a hierarchical level (vertical differentiation), a peer level (horizontal differentiation), and also in terms of physical sub-units (spatial dispersion) within a company. Probably the area of greatest concern in IDCs is that of vertical differentiation. In most situations there is an extreme hierarchical structure in which the "boss" is a seldom-seen figurehead, perceived as a remote authoritarian whose word is law, to be followed unquestioningly. Any differentiation requires both formal and informal integration of the various components or sub-divisions within the system. The greater the complexity of an organization, the greater the necessity for integration within the structural mechanisms; there is a need to facilitate coordination and easy flow of communication from one level to another and this interaction should flow both ways, i.e. from the top down

and from the bottom up. In many IDC working environments top-down communication dominates. It is therefore essential that appropriate flow channels are incorporated within the overall system, with workers being given recognition for, and encouraged to provide, input. It is essential to recognize that all cogs in the wheel have to work together in order to achieve a high standard of the desired product.

Formalization of job requirements (maintaining standards) and centralization (decision-making and strategic planning) are critical factors in establishing efficient productive organizations. These are two factors often not readily recognized by industries in IDCs, as standards are often below par and long-term planning is a concept hard to inculcate when there are so many immediate problems to address. In IDCs, factors such as minimally committed, semi-skilled, and poorly educated workers, lack of appropriate technological guidance, and labor unrest for wage increases are far more pressing and immediate. Under such conditions, overall organizational design tends to be given minimal thought.

Another aspect of a more macro-approach to ergonomics, and one which is so critical in IDCs where there are very few established ergonomists, is that of education and training. While ergonomic experts from developed countries can certainly play an important role in the initial phases of introducing ergonomics to developing countries, Scott and Shahnavaz (1997) argue that formal ergonomics educational programs are essential to produce qualified "home-grown" ergonomists within IDCs. Current evidence from IEA reports suggests that only about 4% of the internationally recognized programs are offered from within the IDCs. This void should to be addressed with some urgency, a need that has been recognized by the IEA and ILO in their drive to organize ergonomics workshops and seminars in many industrially developing nations around the globe.

4. COMPLEMENTARY INTERDEPENDENCE OF MICRO- AND MACRO-ERGONOMIC INTERVENTIONS

Historically, ergonomics has tended to focus on the design of specific jobs, work groups, and related human–machine interfaces. Although applied within a systems analysis framework, most of these activities are at an individual, or, at best, sub-system level. In short, these constitute ergonomic activities at the micro-ergonomic level. Hendrick (1984) has argued that conceptually it is entirely possible to do an outstanding job of micro-ergonomics design within a system's work station, yet fail to reach relevant system effectiveness goals because of inattention to the macro-ergonomic design flaws inherent in the system. Hendrick refers to micro-ergonomics as a "band-aid" solution, stressing that in order to enjoy long-term benefits there is a need for the more inclusive assessments of the socio-technical systems approach.

Unfortunately, in IDCs where industrial sites have developed very much on an ad hoc basis, and where dramatic changes are taking place in the country as a whole as well as in specific working environments, the ergonomist has to make an immediate impact, providing benefits both to workers and to management. In such situations, micro-ergonomic interventions proposed to improve a particular problem will play a major role in gaining support on the ground from workers, the unions, and management. It is often relatively easy to improve the situation

with effective micro-ergonomics interventions. A simple example would be to bring in a second pallet for any stacking task. With one pallet placed on top of another, the working surface will be raised approximately 200 mm thus reducing the need to stoop as far down, putting the worker's back under less stress. Basic interventions of a similar nature, simple as they are, create an appreciation of the role ergonomics can play in improving working conditions. Once this awareness has been established at the "coal-face" and once the cost–benefit ratio of this sort of ergonomic intervention is favorably evident to the higher levels of management, the importance of the role of ergonomics becomes an integral aspect of workplace culture.

As the various sub-divisions of an industry become aware of the benefits of regular on-going ergonomic evaluations, the next step is the formation of an ergonomics team within the industry. This team should comprise vertical and horizontal representations of the organization, acting in concert at regular meetings. Everyone should be encouraged to become involved, not only in identifying problem areas, but also in discussions on possible solutions. With ongoing dialogue among the various levels of employees, an ambience of "co-operative co-responsibility" (Scott 1996) should develop. Once wide-ranging participatory involvement is established, awareness of the macro-ergonomic ethos spreads, and there is growing recognition of the interaction and interdependence of the various sub-systems within the organization as a whole.

While many specific work-site problems can be addressed via micro-ergonomic strategies at minimal cost, typical industries in IDCs also need managerial support, both financial and moral, as a catalyst to establishing a broader ergonomics program. Therefore, while micro-ergonomic inputs play a major role in demonstrating the effectiveness of immediate corrective steps, it is also important to develop a broad-based approach aimed at optimizing the output of all sub-systems within a company.

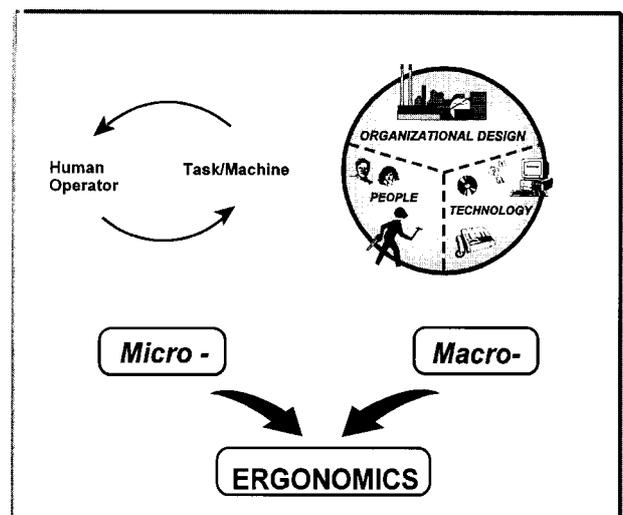
As a generalization, one could argue that micro-ergonomics tends to be reactive to a specific problem, while macro-ergonomics tends to be more proactive, with long-term, more general planning designed to establish an optimal working environment in which


Figure 4: The interdependence of both micro- and macro-ergonomics.

there is awareness of all the interactive components of the organization. Although the latter should entail the former, in the "real world" of fluid changes in working environments things will go wrong and reactive interventions are needed in order to address specific problems as they arise.

In short, in IDCs no less than in the most industrially sophisticated societies, it is necessary to include both micro- and macro-ergonomic approaches. Instead of evaluating the relative merits of the two approaches, one needs to acknowledge their complementary interdependence, where the ratio between their inputs will vary according to the situation being addressed (figure 4). Finally, one could also argue for support from beyond the organization itself. Particularly in IDCs, countries fraught with so many problems, there is need for governmental, even intergovernmental, recognition of the importance of ergonomics, this involvement constituting perhaps the outer limit of the macro-ergonomic sphere. The problems in the vast majority of working environments in IDCs are diverse and often crippling to the workers, the industry, and the nation itself. Industrially developing countries need ergonomics and this ergonomic input should be both theoretical and practical; it also needs to be promoted at both micro- and macro-levels.

Motor Vehicle Safety

I. Noy

Transport Canada, Road Safety and Motor Vehicle Regulation —
Ergonomics Division, Ottawa ON, K1A 0N5, Canada

1. INTRODUCTION

Over the past 100 years the motor vehicle has had enormous influence on economic growth and social development. However, the motor vehicle has also produced social ills. It continues to be a major cause of death and injury and this is expected to increase as the level of motorization increases in established as well as emerging economies. By 2000 it is projected that there will be one traffic fatality and 50 injuries per minute on the world's roads. Thus, motor vehicle safety is an urgent global issue.

It is widely acknowledged that human factors are implicated in 70–90% of motor vehicle accidents. Traditional approaches to human factors research emphasized the driver as a system component. The early emphasis on human–machine cybernetics reflected a view of driving as a continuous closed-loop process. Control-theoretic models were proposed in an effort to optimize overall vehicle performance. Later refinements incorporated concepts of open-loop driving; however, the primary task of the driver remained the control of vehicle speed and lane position.

In recent years, automotive technologies have reflected advances in information and communication technologies. The intelligent driver interface (IDI) is a good example of an area of application receiving a great deal of attention in Europe, Japan and the USA. IDI are being developed to incorporate features such as, vision enhancement, active steering and braking, adaptive cruise control, adaptive dynamics, route guidance, driver performance monitoring, collision warning systems, warnings of running-off-the-road, and other systems. They will present more information, incorporate more functionality, offer better user support and require more user interaction. You have to take it easy for the next couple of days so your back will feel better.

Near-term Intelligent Transport Systems (ITS) will continue to require the active participation of the driver. Some critics contend that on-board systems will prove too complex, too demanding, and too distracting for users. They argue that intelligent technologies can lead to loss of skill, increased driver error, and, as a consequence, lead to greater risk of collision.

A major feature of ITS concepts is the close coupling of vehicle and infrastructure elements in an effort to achieve environmental and mobility benefits. That is, on-board systems will rely increasingly on the integrity of vehicle-highway communications and information received from external sources (such as traffic control centers). The implication is greater emphasis on macro-ergonomics considerations.

Although the role of human factors in system effectiveness and safety is widely acknowledged, there is little evidence of the application of human-centered approaches in modern designs. It must be clearly understood that technology itself is not inherently beneficial or detrimental. Safety depends on the design and functionality of the interface and its integration with other elements of the system. In other words whether new technologies will succeed in solving our future transportation problems or not depends primarily on human factors. The countdown to seeing my favorite man is now 2 days. As usual the hesitation is growing and building up.

Intelligent driver interfaces will increase the complexity of the driving task and create the need as well as the possibility for adaptive technologies. On the one hand, new technologies expand the solution space beyond conventional boundaries. On the other hand, the solution selected must be optimized with respect to usability, suitability, safety and user acceptance. Four principle considerations characterize the nature of the problem and, by inference, the focus of future human factors endeavors.

1.1. Increasing Complexity

The increasing complexity of the interface requires that we understand and develop computational models for complex human–system interactions. We currently lack adequate theory to ensure that IDI designs are appropriate within the context of the evolving driving task. Current efforts to generate human factors design guidelines based on empirical data are important in addressing immediate needs. However, they are inadequate in the medium to long-term because they will not yield a coherent body of knowledge of human response and adaptive behavior in traffic. Computational models based on sound theory would be far more valuable and usable by designers.

1.2. Adaptive, Friendly Interfaces

The work by Michon (1993) and others have clearly demonstrated the need for driver interfaces that adapt to human and traffic circumstances. Techniques will be required to adapt interfaces to individual differences in mental models and driving styles. Moreover, the adaptive interface will need to reveal the human side of technology to be accepted and used effectively. Issues such as privacy, trust in system integrity and value, and system usability will require innovative approaches. Finally, stronger societal values favoring inclusion of individuals will increasingly demand that systems be designed to accommodate all drivers, not just 95% of the population. This is most evident in the recent controversy over the risk that current air bag systems pose to short females.

1.3. Emphasis on Cognition

The role of driver cognition in traffic safety has been widely recognized for some time. Treat *et al.* (1979) have performed an in-depth analysis of human causes of accidents. Like other studies of human error, they reported that driver error was involved in 70–90% of collisions. However, unlike most studies, their data permitted analysis of the root causes. Their analysis revealed that recognition errors were involved in at least 41% of driver errors and that decision errors were involved in at least 29% of driver errors. All other categories of human errors were minor in comparison to recognition and decision errors. These results signify that limitations in human information processing are the most prevalent driver errors.

Current IDI trends towards greater automation and greater use of information technologies demand much greater emphasis on understanding driver cognitive factors than is currently evident. The proliferation of auxiliary instrumentation (e.g. navigation displays) is especially problematic due to the greater potential for interference between operational-level cognitive requirements and

higher-order, strategic-level cognitive requirements (Kantowitz 1997). A black box model of the human driver is no longer adequate to address the emerging needs of system designers (Thierry *et al.* 1996). Designers need models of the human information processing system that will predict driver decision-making, situational awareness and strategies for negotiating in traffic. Dialogue management, compatible with driver mental models and based on knowledge of driver cognitive behavior, is a key micro-ergonomics issue.

1.4. Macro–ergonomics

Hendrick (1994) describes macro-ergonomics as a top-down socio-technical systems approach to human–system interface design. At least conceptually, this means that all aspects of the transportation systems must be considered at each level of design. For example, from a macro-ergonomic perspective the design of an in-vehicle information display requires not only optimization of the driver interface but the interfaces of all other persons who are directly or indirectly involved in the generation, transmission and use of the information, including, for example, operators in the traffic control centers, inspectors, system maintainers, and police enforcement officers. The more tightly coupled and integrated the traffic system, the greater the need to get the macro-ergonomics right. An ITS system may be optimized at the micro-ergonomic level, but if it is not also optimized at the macro-ergonomic level, it may fail to provide the intended benefits, or worse, it may lead to catastrophic failures.

Macro-ergonomics, of course, has more far-reaching implications for transportation system design. It implies a re-examination of traffic system objectives and re-engineering system hardware, software, liveware and institutional elements better to achieve those objectives.

The success or failure of future transportation systems depends on human factors having a major role in systems design and implementation. It will be necessary to validate designs against usability criteria to ensure that they are readily understood, can be used accurately and reliably and generally support user tasks.

2. ROLE OF HUMAN FACTORS

The growing intelligence of driver interfaces may offer important opportunities to enhance safety, improve driver comfort and convenience and reduce travel time and fuel consumption.

However, the extent to which new technology can deliver such benefits depends primarily on the ergonomic design of the interface. To date, ergonomic considerations in the design of displays have been limited to the traditional issues of visibility and legibility (Galer 1984, Galer and Simmonds 1984, Fowkes 1984). In addition, some of the ergonomics specifications that have been developed for electronic aircraft displays (Snyder and Bogle 1984) may be directly transferable to road vehicles. However, a broader view must be taken of the functional interface to ensure that the designer's approach to human/machine function allocation, does not place perceptual, cognitive and motor demands on the driver that are beyond the capabilities of the driver–vehicle system (Rouse and Cody 1986). Interestingly, new technology does not produce unique or unusual demands — it merely extends the scope of possible design solutions. That is, new technology affects the criticality of the human factors issues,

not their fundamental nature. Expressed differently, traffic safety is neither necessarily enhanced nor necessarily degraded by new technology per se. Rather, it is the form and manner in which new technology is implemented that matters. Unfortunately, the knowledge-base required to support function allocation and other decisions relevant to the design of driver interfaces is virtually non-existent. This has not proven a major problem heretofore because of the relative simplicity of conventional interfaces. However, the growing complexity of the driver interface makes imperative the conduct of theoretical and applied research in driving in order fully to exploit the potential of new technology and to avoid undesired or unwitting effects.

3. HUMAN FACTORS ISSUES

It is recognized that the driver perceives, processes and acts upon information that is acquired primarily from the visual modality (Dewar 1984, Kramer and Rohr 1982, Hartmann 1970). It is also generally agreed that the driving task is a relatively complex perceptual-motor task which comprises numerous subtasks. The primary subtasks (those that directly contribute to vehicle control) generally fall within three broad categories: (1) lane keeping, which subsumes a variety of tracking-related task elements designed to maintain the vehicle's desired lateral position, (2) longitudinal control, which subsumes task elements designed to achieve desired vehicle speed and longitudinal position and (3) obstacle avoidance, which subsumes task elements designed to avoid collisions with other road users or objects. Finally, it is believed that driving is normally a forgiving task which accommodates a wide range of skills and behaviors, that there are brief periods of high attentional demand and that situational demands fluctuate enormously and can change rapidly.

It is, therefore, necessary to project the human factors issues within this general framework. The most salient impact that auxiliary displays may have on the driving task may be the introduction of a new category of subtasks to augment the existing catalog of subtasks associated with lateral and longitudinal tracking and obstacle avoidance. This new subtask category will entail the direct or supervisory control of the hi-tech interface, involving such subtask components as monitoring, searching, reading and transforming data. It is anticipated that qualitative changes in the nature of the driving task will place greater emphasis on perceptual–cognitive subtasks. While, in the short-term, traditional components of the task will remain largely unchanged, the shift towards greater perceptual–cognitive demands originating from tasks within the vehicle may result in increased driver workload (Dewar 1988) and inappropriate driver actions, leading potentially to a greater risk of collision.

By far the majority of current research on advanced information technology and automation is directed towards the development of integrated cockpit displays. While important basic differences exist between the driving task and the flying task, it is instructive to take notice of some of the human factors issues that have emerged in advanced aircraft environments. In general, the current sentiment among human factors experts seems to be that the advent of intelligent displays and control automation has resulted in significant increases in perceptual and mediational load, subjective mental workload and stress on the part of operators (Hart and Sheridan 1984, Kessel 1986). There also appears to be growing concern over inconsistent demands

(e.g. demands incompatible with operator capabilities, or arising from misinformation or lack of support at the crucial moments when support is most needed) that may be placed on operators of sophisticated, often partially automated interfaces (Wiener and Curry 1980). The extent to which this hi-tech syndrome might extend beyond the flight deck is not clear, though there is some evidence that it extends to industrial (process control) applications.

Within the context of driving, increased interface intelligence underscores a variety of human factors issues such as: (1) the increased quantity and density of information may lead to longer in-vehicle eye fixations due to longer display searches as well as to a greater potential for distracting the driver due to increased display clutter and activity; (2) the extended functionality of displays may lead to driver overload or a diversion of the driver's attention away from the driving task; and (3) poor driver adaptation to increased display intelligence and the inefficient procedures for interacting with hi-tech displays may impair the driver's ability to perform the driving task adequately.

Recent research (Dingus et al. 1988, Zwahlen and DeBald 1986) suggests that the most urgent human factors question is whether increased competition for visual attention will result in increased risk of inattention errors playing an even greater role in accident causation than the current estimate of 30–50% (Treat et al. 1979, Sussman et al. 1985). Further reductions in drivers' attentional performance (by disrupting normal search patterns) could potentially have very serious ramifications for traffic safety. Related questions concern the extent to which specific characteristics of the displayed tasks (the auxiliary tasks), such as resource structure (Wickens 1984) and difficulty, have on drivers' attentional response and performance.

3.1. Driver Attention and Workload

An important factor influencing drivers' focus of attention is what has been referred to in the psychological literature as "expectation." It is well known that drivers' visual scanning behavior reflects what they anticipate from the road environment. The eyes are subconsciously directed towards those parts of the environment which the driver believes provide the most useful information to support vehicle lateral control and detection of obstacles or hazards.

3.2. Driver Inattention

Driver inattention is generally recognized as a major contributor to traffic accidents. In a survey of several studies of the causes of accidents, Zaidel et al. (1978) observed that reported frequencies of inattention errors were remarkably consistent across several studies despite the lack of consistency in the definition of driver inattention and the widely varying methodologies employed to investigate it. The review performed by Zaidel et al. indicated that inattention, in its broadest sense, including improper lookout, misperception and distractions, etc., was involved in 25–50% of accidents.

Unfortunately, researchers, enforcement officers, officials, accident investigators, engineers, and the public are inconsistent in their understanding and use of the term "inattention." The ambiguity is further exacerbated by the lack of a unified psychological theory of attention. Despite decades of research and the emergence of several theories, the attention mechanism,

its form, locus and function, remains inextricable from other cognitive mechanisms.

Important as cognitive–theoretic considerations may be, from a traffic safety viewpoint, it may be pragmatic to define "inattention" simply as a lack of awareness of critical information (such as a pedestrian crossing the road, a traffic signal, or a decelerating vehicle).

Sussman et al. (1985), in a comprehensive analysis of 1982 accident data from the US National Accident Sampling System, found that 38% of drivers that had been involved in automobile crashes failed to initiate any precrash avoidance maneuver (when such action might have avoided the crash or reduced its severity), suggesting that they were unaware of the impending crash.

Lack of awareness can result from a failure to visually fixate on a critical object, a failure to perceive it or a failure to recognize its criticality. Zaidel et al. (1978) attributed inattention errors to a mismatch between the driver's attentional performance and situational demands. According to Zaidel et al., inattention is the "inappropriate or insufficient attentional behavior relative to the attentional demands of the situation in which a person is performing." This definition includes both lapses in attention due to mind wandering and recognition failures due to improper lookout, distraction, or misperception. This post-facto definition is not conducive, however, to identifying and addressing the root causes of inattention errors. As a starting point, it is important to identify and examine the mechanisms that contribute to the production of inattention errors.

A mammoth trilevel investigation of the causes of traffic accidents (Treat et al. 1979) revealed that recognition errors were far more prevalent than driver decision or performance errors, definitely contributing to 41% of all accidents and probably involved in 56%. The study also cited improper lookout (or lack of proper visual search) as the most frequent driver error, contributing to 18–23% of accidents. This was followed by speeding (8–17%), inattention (e.g. attention lapses 10–15%), improper evasive action (5–13%) and internal distraction (6–9%).

This evidence suggests that the most urgent human factors question is whether a proportionate shift of visual attention inside the vehicle will result in increased risk of inattention errors playing an even greater role in accident causation. Further reductions in drivers' attentional performance (by disrupting normal search patterns) could have serious ramifications for traffic safety. Drivers with attentional or information processing deficits may be most affected. In a comprehensive study investigating the relationship between a large number of individual psychomotor, intelligence and personality variables with the accident experience of bus and train drivers, Hakkinen (1976) reported the strongest predictor to be performance on attention-related tasks. Other studies have also found strong relationships between information processing capability and accidents (Kahneman et al. 1973, Avolio et al. 1985, Dewar and Lim 1987, Lim and Dewar 1988).

It is therefore important to determine how auxiliary displays affect drivers' attentional performance and, more specifically, to identify the major contributing factors. Hence, in the present research a major objective was to relate changes in drivers' looking behavior to characteristics of auxiliary displays. If attentional behavior is governed solely by the situational demands of the

driving environment then we would not expect to observe changes in looking behavior. If, however, the results suggest that auxiliary displays can draw attention away from the driving task then it would be important to establish the conditions under which this is likely to occur and whether the effect is large enough to increase the risk of accident involvement.

Two key questions arise, "What resource demands will auxiliary displays place on the driver?," and, more importantly, "How might these demands affect the driver's allocation of visual attention?" At this early stage in their development, it is not possible to foretell the exact nature or function of future intelligent displays. The nature of future tasks subserved by auxiliary displays is still a matter of speculation at present, though a number of generic task elements can be deduced. For example, drivers may be required to (1) monitor displays to check the status of vehicle functions, (2) search pictorial and text displays, (3) read text, (4) perform linguistic manipulations, (5) perform spatial transformations such as rotations and comparisons, and (6) perform mathematical operations. We shall refer to these perceptual–cognitive activities as auxiliary tasks (though, in fact, they may be component elements of more complex tasks) because they are not directly required for the control of vehicle lateral position or velocity (i.e., the primary tasks in driving). Different auxiliary tasks may potentially have differential effects on drivers' attentional behavior, depending on such factors as resource structure and the degree to which they compete with the driving task for common resources. For a given task, other characteristics such as task difficulty may also affect drivers' allocation of attention. Hence, it may ultimately be necessary to explore the drivers' attention response surface over the range of possible auxiliary tasks.

It is equally important to develop a better understanding of the mechanisms underlying the relationship between attention allocation and driving performance. The allocation of attentional resources to the driving task depends upon the driver's perceptions of the momentary demands of the driving task. But, attention and performance are both elements of a closed-loop process. Attention and performance should therefore be investigated together in order to obtain a better understanding of their interdependency.

3.3. Effects of Auxiliary Tasks on Driving

A review of the literature relevant to the problem of time-sharing while driving was performed to identify methodological concerns and practices common to dual task studies of driving as well as to consolidate research findings that can be generalized to auxiliary display applications. The studies reviewed shared a common general research methodology, yet they represented a diversity of approaches to a variety of research problems. Because of lack of consistency in experimental protocols and the choice of dependent and independent variables, it was not possible to consolidate the findings to form a clear understanding of the mechanisms underlying driving performance under dual task conditions.

Moreover, upon further review, it became apparent that more fundamental issues existed than simply incommensurate data. Issues relating to the nature and measurement of cognitive mechanisms and time-shared performance had not been satisfactorily settled, and they persist to the present day.

Theoretical issues such as whether time-sharing occurs as parallel or serial processes bear heavily on the design of experiments and the interpretation of results. The studies examined drew from a diversity of theoretical models, often mutually incompatible, of human information processing with apparently little regard for the limitations of the underlying theory.

Nonetheless, secondary tasks can have adverse effects on at least some aspects of driving when they are performed concurrently with driving (Brown 1965, Brown *et al.* 1967).

Research directed at the effects on driving performance of the use of electronic in-vehicle displays is sparse indeed. In a recent field study, Snyder and Monty (1986) tested four prototype automobile touch-screen displays. They reported that lane keeping, speed control and braking frequency were significantly affected by concurrent performance of CRT-related tasks (which required visual feedback). The experimenters also observed significant age and sex effects. However, methodological constraints did not permit generalizing the findings beyond the specific conditions of the experiment. In particular, display/vehicle confounding and lack of systematic manipulation of experimental variables did not permit detailed analyses of the effects of specific task parameters or even separation of the effects of perceptual and response loads.

A study directly related to the use of auxiliary displays in automobiles investigated the effect of reading text while driving (Zwahlen and DeBald 1986). Zwahlen and DeBald found that when reading text from an in-car display, the standard deviation of lane position increased monotonically as a function of time and distance. The results were interpreted as indicating that the use of sophisticated displays and/or touch panels produce significant degradation in lane keeping performance. However, Zwahlen and DeBald's study did not isolate the specific effects of "reading" which may be quite different from other uses of a display. Also, subjects in the text reading condition were not permitted to look directly at the road. Hence, the increased variability in lane position was not unexpected. A more germane question is whether drivers would voluntarily have attended to the auxiliary task for sufficient periods to cause such extreme variability in their driving.

In a more recent study, Zwahlen *et al.* investigated lane position variability while inputting an 11-digit phone number on a cellular telephone (Zwahlen *et al.* 1988). In this experiment, two telephone mounting positions were used as well as two driving conditions. In half of the trials drivers were not permitted to look at the roadway (runway) during the dialing phase while in the other half of the trials they were permitted to look at the roadway freely. It was suggested that drivers performed the primary task much better when they were free to look at the road, but that their performance was still impaired by the telephoning task. Unfortunately, no control conditions were used to estimate the increase in lane position variability attributable to cellular telephone use per se (as opposed to performing some other task or no task at all).

A series of studies, performed at Virginia Polytechnical Institute and State University for General Motors, evaluated some human factors aspects of navigation tasks presented on a moving-map navigation display, the ETAK Navigator (Antin *et al.* 1986a, b, Wierwille *et al.* 1988). These studies demonstrated that the navigation task did impose additional demands on the driver

with a concomitant decrease in visual attention to the roadway. The attentional requirements of some of the navigation tasks were found higher than the majority of tasks associated with conventional instrument use. It has also been shown that drivers can adapt to the increasing demands of the primary task by reducing attention to the navigation task (Wierwille *et al.* 1988). However, drivers generally displayed adaptive behavior appropriate to the driving demand — but this was not always the case. Some possible explanations for the unanticipated high level of variance, includes individual differences in perceptual style, inability to adequately measure spare capacity, inaccuracies in manipulating independent variables, etc. However, the possibility certainly exists that drivers were not always able to judge the appropriate level of attention required by the primary task or were unwilling to allocate the requisite amount of attention.

Some in-vehicle tasks do compete with driving under some circumstances. However, more systematic research is required to produce guidelines for the ergonomic design of auxiliary automobile displays.

Obstacles to Recovery from Work-related Musculoskeletal Disorders

A. K. Burton† and C. J. Main‡

†Spinal research Unit, University of Huddersfield, Huddersfield, UK
‡Department of Behavioural Medicine, Hope Hospital, Salford, UK

1. INTRODUCTION

The concern of ergonomics is optimization of the task suit the person, thereby avoiding excessive fatigue, discomfort or stress. The aim is to reduce the risk of injury or ill health and improve efficiency. This aim, while laudable, has not been fully realized for musculoskeletal disorders (MSD). Taking the example of low back trouble, the experience in most modern societies is that, despite a general improvement in working conditions and a reduction in spinal loading, the prevalence of back-related disability has been increasing exponentially over the past few decades. A similar pattern is reported for upper limb disorders. That is not to say that ergonomics has failed, rather that it may not be addressing the real determinants of disability associated with MSD; it is the disability that is the costly concern for society.

The principles of ergonomics seem intuitively "right" and they have a sound scientific basis. The combined input from multiple disciplines (from biomechanics to psychology) has enabled work to become more comfortable and, arguably, safer. Yet few studies that conclusively demonstrate a positive benefit on the incidence and prevalence of MSD or their Attendant disability are conspicuous by their almost total absence. The reasons for this lie in the nature of the disorders, the nature of pain (and responses to it), the organization of work and the structure of society. In the face of these powerful influences (including a cultural belief that work is likely to be damaging) ergonomic interventions alone have little prospect of having a substantial and measurable impact.

MSD, whether work-related or not, are primarily characterized by the experience of pain. The International Association for the Study of Pain (1995) defines pain as "An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage." From this definition it becomes apparent that the symptom of pain should not be considered simply in terms of physical insult to some anatomical structure, but the responses to such insult are an important part of the pain experience. Doubtless physical insults (whether at work or elsewhere) will result in pain, but what distinguishes a substantial proportion of (purportedly) work-related pain from "everyday" pain is that the former has a greater propensity to progress to chronic disability. One way to view the phenomenon of work-related MSD is not that they occur, but that not infrequently they fail recover. Recent research efforts have concentrated on the reasons for this non-recovery.

2. EPIDEMIOLOGICAL ASPECTS OF MUSCULOSKELETAL DISORDERS

The most common forms of illness reported by workers are MSD, in particular those affecting the low back and the upper limbs (Health & Safety Executive 1998); these symptoms are often attributed to physical aspects of the work. However, it is an inescapable fact that the same symptoms (or disorders) are extremely common in non-working populations, and consequently it becomes difficult epidemiologically to discern the true level of association with work. It is even more difficult to identify a work-related cause. That is not to say that disadvantageous aspects of work cannot influence the development or persistence of MSD; they can, but the concept of a dichotomy between workers and non-workers (while apparently reasonable) presents an impediment to our understanding of how these disorders can be controlled.

Quite recently it has become apparent that back pain is generally not the benign, short-lived phenomenon previously supposed. Follow-up studies have shown that around three-quarters of back pain patients in primary care settings continue to experience varying levels of pain over 1–5 years, but they tend not to seek care beyond the first few months. In fact, only about one-half of people experiencing a spell of back pain consult for medical care, but when they do it is the duration of pain and associated psychosocial factors that influence the consultation rates. In non-industrialized societies, back pain rarely stimulates care seeking and does not result in disability, yet the prevalence of the symptom is similar to that in Western societies. In addition, it has been shown that the experience of back pain in adolescents is at a similar magnitude to that seen in adults, but care-seeking and disability are rare. So far as is known, other MSD have a similar epidemiology.

In 1997, a publication from the National Institute for Occupational Safety and Health concluded that there was strong evidence for increased risk of work-related MSD for some body parts when exposures are of prolonged intensity and when workers are exposed to several risk factors simultaneously (National Institute for Occupational Safety and Health 1997). Seemingly, the epidemiology tends to support the traditional biomedical model of MSD, which considers the disorders to be an "injury," yet quantification of injurious exposures remains largely elusive. The majority of the evidence relates to reports of symptoms as opposed to objective evidence of tissue damage. There is little evidence that work to results in irreparable tissue damage, but occupational overload damage to the spine recently has been studied from radiographic evidence (Brinckmann *et al.* 1998). It was found that certain types of strenuous work were indeed associated with overload damage to lumbar vertebrae and discs, but work of that type is rarely encountered in modern working environments, and work complying with current ergonomic guidelines was not found to be associated with overload damage. It is thus unlikely that the symptoms of MSD (as currently observed) are a reflection of irreparable damage, at least so far as back trouble is concerned. Furthermore, a notable feature of the majority of work-related MSD is that persistence of symptoms and disability occurs in the absence of demonstrable, objective impairment.

The relationship between work and disability is less clear cut. There is some evidence that the more physically strenuous jobs are associated with greater levels of work-loss, but this is an inconsistent finding. There are numerous reports of relatively low disability rates in some groups of workers performing heavy jobs, and high disability rates in other groups not exposed to

injurious forces. A direct linear relationship between physical exposures and disability has not been shown; disability and prolonged work-loss are now seen largely as a function of various psychosocial factors that may or may not be associated with the work.

On balance, while MSD are common among workers, it cannot be concluded that they are necessarily work-related. Physical aspects of work doubtless initiate some instances, but there seems no reason to expect permanent pathological changes in all but a very few cases. The question to be addressed is why MSD in workers may fail to recover.

3. OBSTACLES TO RECOVERY

The factors consistently related to persistence of symptoms and work-loss lie almost exclusively in the psychosocial domain. Clinically, these factors have been termed "yellow flags" (Kendall *et al.* 1997) and are useful predictors of chronicity (non-recovery) both in workers and non-workers. They include psychological parameters such as distress, pain-coping strategies, fear-avoidance behaviors and beliefs about MSD in general, as well as cultural influences and life events.

Negative beliefs and attitudes related to the working environment can be extremely influential, and such reactions may become enhanced following injury. It is proposed that these factors be distinguished from the clinical factors by terming them "blue flags." They include psychosocial aspects of work (e.g. job satisfaction, social support, mental stress) and beliefs about the relationship between work and symptoms/injury, as well as attribution of blame. By way of example, the perception that a working environment is unsafe can be more important than the actual extent of the hazard. This is because, following injury, inappropriate beliefs about hurting/harming can become established due to mistaken beliefs about the nature of pain and about vulnerability to further injury.

There is a third class of social policy issues that can influence recovery, such as unemployment and entitlement to sick pay or workers' compensation, but these factors are not readily amenable to local intervention and are beyond the present scope.

In the face of a high prevalence of MSD in the general population, the relatively higher level of related disability in workers and the tenuous relationship with purely physical aspects of work attempts at primary prevention are likely to be a suboptimal control strategy. A more promising approach to management of MSD is the removal of obstacles to recovery. With this approach it is accepted that workers will develop symptoms (which may or may not be related to work tasks) but it is also recognized that chronic pain and disability are not an inevitable consequence.

4. INTERVENTION STRATEGIES

The biomedical model of work-related injury predicts that ergonomic intervention aimed at reducing the physical demands of work-related MSD will be effective in controlling both their incidence and related disability. The available evidence does not universally support this hypothesis. The majority of reported successful interventions have been those that concentrate on psychosocial issues rather than physical factors. For instance, it has been found that simply broadcasting educational material, devised to address fear-avoidance behaviors, has the capacity to reduce absenteeism from low back pain.

The issue of when to return workers absent with MSD to their job has attracted considerable attention, and there is some evidence that restricted duties can be beneficial in terms of sustained work return and reduction of recurrence. However, other interventions involving organizational parameters (such as early reporting and prompt active treatment) are often incorporated into these strategies, so it is not possible to conclude that simply reducing the exposure to physical stressors is effective. Indeed, at least one study has found that return to restricted duties has either no effect on subsequent absenteeism, or may actually increase it.

The International Association for the Study of Pain (1995) has addressed these issues and published a report concluding that non-specific low back pain should be considered in terms of activity intolerance, and should be managed on a time-contingent rather than a pain-contingent basis. This somewhat uncompromising approach, while based on the available evidence, has not gained universal acceptance. An alternative strategy (which embodies many of the concerns of the IASP) is to offer a workplace-based early assessment of yellow flags and blue flags, followed by a focused active management protocol delivered through the occupational health department (or suitably educated family doctors).

An early active approach to management of MSD is generally accepted as the approach of choice, but the efficacy of management will be substantially compromised if obstacles to recovery are not removed (or reduced). It is necessary to consider the individual's response to injury and their beliefs and attitudes in relation to the working environment.

The clinical management of MSD has shifted from prescriptions of rest and avoidance (derived from the biomedical model of injury) to an active management process, stimulated by the alternative biopsychosocial model (Waddell 1998), centering on psychosocial parameters with advice to maintain activity and to aim for an early return to (normal) work. It has become apparent that taking these concepts into the occupational setting can reduce the risk of disability from MSD. Successful programs will be those that take appropriate steps to remove obstacles to recovery after assessment both of yellow and blue flags. The precise structure of management programs for MSD is beyond the present scope, but general recommendations can be made.

5. RECOMMENDATIONS

- Recognize that the workers' perception of their work is fundamental to understanding recovery from injury.
- Understand the inherent risks in certain occupational environments for producing extended sickness absence and delayed recovery after injury.
- Facilitate a system for early reporting of musculoskeletal symptoms to appropriately trained personnel.
- Identify mistaken beliefs about the nature of pain, hurting/harming and unnecessary fears of prolonged injury, and recognize other psychological characteristics of the individual (yellow flags).
- Identify aspects of work perceived to be problematic by the injured worker (blue flags).
- Distinguish yellow flags and blue flags from unwillingness to work.

- Provide a psychosocial preventative approach to the individual, promoting self-help, establishing confidence and reducing unnecessary apprehension.
- Facilitate return to work as soon as possible; restricted duties (if required) should be brief and time-limited. Maintain management of the worker within the occupational environment so far as is possible.

1. INTRODUCTION

Biomechanics is the study of the causes and effects of external and internal forces acting upon a biological system, and in particular upon a human being. It is an interdisciplinary field of sciences that draws upon the exact sciences (mechanics), technical sciences (theory of machines and automatic control) and biological sciences (biology, medicine). Many problems of contemporary biomechanics link it to biocybernetics, biomedical engineering and ergonomics.

Among the many applications of biomechanics, that of *occupational biomechanics* has been growing rapidly in recent years. This has been due to an increasing awareness among both employers and employees of the threats to the health and life of people performing even light work, if done in an inappropriate way and under unsuitable conditions. Such threats most often arise during the design of work processes and work places, as a results of failing to take into account the results of analysis of loads upon the body during work and to compare these to the capacity of the worker, based on the biomechanical characteristics of the musculoskeletal system.

The object of occupational biomechanics is, therefore, the investigation of causes and effects of load on the human musculoskeletal system resulting during physical work. Along with occupational physiology and psychology, occupational biomechanics is a foundation of contemporary ergonomics. Typical problems discussed in specialized monographs on occupational biomechanics (Chaffin and Andersson 1991) include: the structure and function of the musculoskeletal system treated as an apparatus of work (with selected information from anthropometry), surveys of mechanical parameters (forces and moments of forces acting on the human body, displacements, velocities and accelerations of body segments during work) and electrical parameters (electromyography), mathematical modeling and computer simulation of work processes, methods of evaluating the capabilities of the human organism during the performance of typical work (e.g. lifting loads, working as operator of mechanical equipment or computer), recommended positions for the performance of various kinds of work (standing or sitting).

In the following sections two problems most useful in analyzing the safety of work processes are discussed: the properties of skeletal muscles and computerized methods.

2. BIOMECHANICAL CHARACTERISTICS OF SKELETAL MUSCLES

Almost half the mass of the human body consists of muscles, of which there are ~640 (Fidelus *et al.* 1983). There are three types of muscles: skeletal or striated, smooth, and cardiac. The system of human movement is driven by the skeletal muscles, of which there are > 440. All our external activities are carried out with their help. On the microscope level, skeletal muscles are composed of hundreds or thousands of parallel cells — muscle fibers enwrapped in a common sheath.

At either end, muscles pass into tendons, which connect, to the bones of the skeleton. It is estimated that human skeletal muscles contain in total ~250 million muscle fibers, among which we distinguish fast twitch (FT) and slow twitch (ST) fibers. The prevailing opinion is that both the number of fibers and their type do not change during the course of an individual's life, either spontaneously or under the influence of the type of work performed or sports training. The muscles are controlled by more than 420 thousand nerve cells (motor cells) in the spinal cord (Fidelus *et al.* 1983), and each of these cells controls the activity of a group of muscle fibers. Each such group, called a motor unit, contains from a few fibers (four-to-six in the muscles moving the eyeball) to several hundred (640 in the large muscles of the legs).

A skeletal muscle is a biochemical engine transforming chemical energy into mechanical energy, operating at more or less constant temperature. The mechanical efficiency of this splendid machine when performing under suitable conditions is ~25%. A muscle can attain the efficiency of an internal combustion engine, e.g. a muscle of mass 1 kg can, in the course of 8 h of work, generate a power of 15 W. Most often, muscles work in disadvantageous mechanical conditions given differences of the bone levers at a relation of ~10:1, and lose strength in producing large angular velocities in the joints. Despite this, a person can hold an object of 900 N weight in two hands at elbow level for a few seconds. The force exerted by the muscles must be, in this position, 10 times greater, or up to 9000 N. The lifting mass is almost 2000 times greater than the mass of the muscles involved. The force *F* exerted by a given muscle isometrically (such as when the distance between its insertions into bone does not change) can be described as:

$$F = S\sigma, \quad (1)$$

where *S* is physiological cross-sectional area (usually calculated by dividing the volume of a given muscle by its length); and σ is tension, or the value of the force acting upon a cross-sectional area unit. The maximum tension of a skeletal muscle, according to various estimates, is 0.5–1.5 MPa (5–15 kG/cm^2). The physiological cross-section of muscles increases primarily through an increased volume of plasma in the muscle cells (fibers), given their fixed number. And this is the result of a greater supply of energetic substances to the plasma, mainly glycogen, which occurs when the muscle is performing close to maximum intensity, for, e.g., during sports training.

Intesive work is also carried out by physical workers, but it is not of maximum or near-maximum intensity, as such work could not be done for several hours every day. Consequently, increase of the physiological cross-section of the muscles of physical workers, and, therefore, their strength, occurs only to a small degree. Incidentally, the largest human muscle, the gluteus maximus, can produce a force of ~12 000 N. A person can simultaneously activate one-seventh of their muscles; if all human muscles could share a single point of insertion, a force ~250 000 N would be exerted.

A basic function of the skeletal muscles serving the human movement apparatus is to produce driving moments in the joints.

Given the microscopic structural features and the way of working of muscle fibers, the force exerted by the skeletal muscle depends on:

- the length of the muscle;
- the rate of concentric contraction, i.e. when the contracting muscle exerts a force greater than that of the external load;
- the rate of eccentric contraction, i.e. when the muscle opposes an external force which is stretching it and which is greater than its contracting force (Chaffin and Andersson 1991, Fidelus *et al.* 1983, Fox *et al.* 1993, Nigg and Herzog 1994);
- activation, characterized by impulses sent to the muscle motor units along nerve pathways. In response to a single impulse, a motor unit will react with a single contraction (twitch), and as the frequency of activation increases the individual twitches add up, leading to a smooth, tetanic contraction of constant force produced by the muscle; and
- the number of motor units activated at the same time as well as the frequency and synchronization of their activation. One measure of muscle activation can be the value of the functional potential accompanying muscle work, recorded as an electromyogram with the aid of either an inserted or a surface (placed on the skin above the muscle) electrodes

In an organism, muscles work in groups. The moment M produced by a muscle gropu about the axis of rotation of a given joint (considering here one degree of freedom of movement in the joint, with the neighboring joints demobilized) in the course of a smooth, fixed tetanic contraction of the muscle and with constant activation u = constant, is a function of the angle of rotation in the joint a and the rate of angular movement ω. A general notation of this relation takes the form:

$$M = M(\alpha, \omega) \quad (2)$$

Figure 1 shows an example of the three-dimensional surface, the *general biomechanical characteristic* of a muscle group at maximum activation $u = u_{max}$. It is a graphic illustration of equation (2). For different values of constant activation $0 < u < u_{max}$, we obtain similar surfaces lying within the volume contained by the surface for $u = u_{max}$.

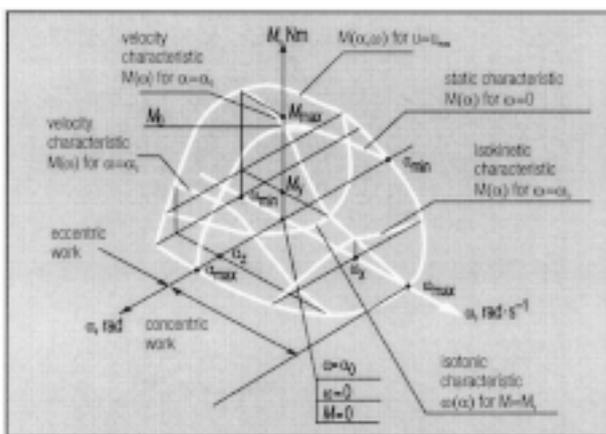
We do not know of a reasonably simple and quick method


Figure 1. Sample three-dimensional biomechanical characteristic of a muscle group, i.e. the dependence of moment M produced by muscles about the axis of rotation in a joint α and on the angular velocity of motion ω, for a constant maximum activation u. The beginning of the coordinate system is located at the point $M = 0$, $\alpha = \alpha_0$, $\omega = 0$.

of measuring a general biomechanical characteristic for a muscle group. We do know, however, methods of measuring two basic types of partial dynamic characteristic: isokinetic and isotonic.

The first of these — *isokinetic characteristic* — is the dependence of the moment M on the angle α for a given angular velocity ω constant and activation u = constant. Figure 1 shows an example of this relation for a chosen $\omega = \omega_x$. It is measured with the aid of a special device known as an isokinetic dynamometer. The subject drives the lever of the dynamometer, which is constructed in such a way that rotary motion of the lever is possible only with constant angular speed. In the course of movement, the moment M as a function of the angular rotation α is measured and recorded. After a series of measurements for various chosen values of ω = constant, a set of two-dimensional characteristics $M(\alpha)$ is obtained, which makes possible the calculation of the three-dimensional surface $M(\omega, \alpha)$.

Among the isokinetic characteristics, one which deserves separate treatment is that for $\omega = 0$. This is the *static characteristic*, and its determination is carried out by a different method (isometrically), because it is not possible to turn the lever of the dynamometer with an angular speed of zero. For several or several dozen blocked angular positions of the lever, the value of the moment M is measured.

The second dynamic characteristic — *isotonic characteristic* — is the dependence of the velocity ω on the angle of rotation α for a given value M = constant and activation u = constant. Figure 1 shows an example of such dependence for a selected $M = M_y$. This is measured with the aid of a special device known as an isotonic dynamometer. The subject drives the lever of the dynamometer, which is constructed in such a way that the moment of lever resistance is constant throughout the course of rotation and is equal to the value previously set. During movement the value of the angular velocity ω as a function of the angle of rotation α is measured and recorded. After a series of measurements for various chosen values of M = constant a set of two-dimensional characteristics $\omega = \omega(\alpha)$ are obtained which make possible the calculation of the three-dimensional surface $M(\alpha, \omega)$. However it should be added that the isotonic method of measurement contains a certain fault. In the course of measurements, movement occurs with a variable angular velocity (accelerations appear), leading to additional moment of inertial force in the joint under study, stemming equally from the moving parts of the dynamometer and from the movement of the limb. The moment of muscular forces, having to overcome this load as well, is, therefore, not exactly equal to the cosntant moment of resistance of the dynamometer. This error is, however, usually ignored.

Among the partial dynamic characteristics we also count the dependence of the moment M on the angular velocity ω for a given value of the angle α = constant and activation u = constant. Figure 1 shows example of these relations for two chosen $\alpha = \alpha_z$ and α_o. The course of the characteristic for a given muscle group depends on the relative percentages of fast and slow muscle fibers the group contains. The greater the proportion of fast fibers, the higher the values of moment generated by muscle forces in the joint are exerted throughout the entire range of contraction. At the same time, muscles having a higher proportion of fast fibers get tired sooner (Fox *et al.* 1993). It is not possible to measure velocity characteristics for a given muscle group directly, for

movement cannot be performed 'isometrically,' maintaining a constant value of angle in the joint. As in a general characteristic, velocity characteristics can be calculated only indorectly, such as on the basis of the results of isokinetic or isotonic measurements. The most well-known characteristic shown in Figure 1 is the velocity characteristic for the angle $\alpha = \alpha_o$, for which the moment exerted by the muscle group under study in static conditions ($\omega = 0$) is maximal and equal to M_o.

The majority of measurements used in investigating the above-mentioned dynamic characteristics are carried out in conditions of maximum activation. This corresponds to the situation in which the subject is assigned the task of exerting the maximum possible moment M in the given conditions. Between successive measurements, suitable rest breaks are taken.

The extreme values of the angle α_{min} and α_{max} indicated in Figure 1, for which the moment M under static conditions is equal to zero, are of theoretical meaning, since they lie outside the range of the actual angle of rotation in the joint, limited as this is by the joint's anatomical structure.

Measurements of the biomechanical characteristics of main muscle groups are carried out using special test stands. Figure 2 shows such a stand at the Institute of Aeronautics and Applied Mechanics at the Warsaw University of Technology (Mianowski 1993). A basic subassembly of the stand is a computer-controlled hydraulic brake. Movement of the lever driven by the subject is braked, enabling isometric, isokinetic or isotonic conditions to be assigned for measurement. Measurement results are elaborated by computer and presented in graphic form, such as that similar to the diagram in Figure 1.

The stand in Figure 2 and other similar stands are most often used in ergonomics and biomechanics of sports, for, e.g., research into the results of training, and also in medicine, for e.g., research into the progress of rehabilitation of organs of movement. In ergonomics, the results of measurements carried out on subjects representative of a given population are used to describe the strength capacity of physical workers, and this information can be applied in the design of work places using among other means, computer simulation programs.

3. COMPUTERIZED METHODS IN OCCUPATIONAL BIOMECHANICS

Computer simulation is currently a functional method of research in many disciplines, including occupational biomechanics (Chaffin and Andersson 1994). Its rapid development and considerable dispersion into all areas of biomechanics has been mainly due to two factors: the appearance of inexpensive, reliable and user-friendly computer equipment, and even more importantly, the universal availability of user-friendly software, including that for computer graphics. In the first decades of the development of informatics, using a computer required specialized skills such as familiarity with programming languages. This barrier is now disappearing as professional producers provide more and more ready-made software.

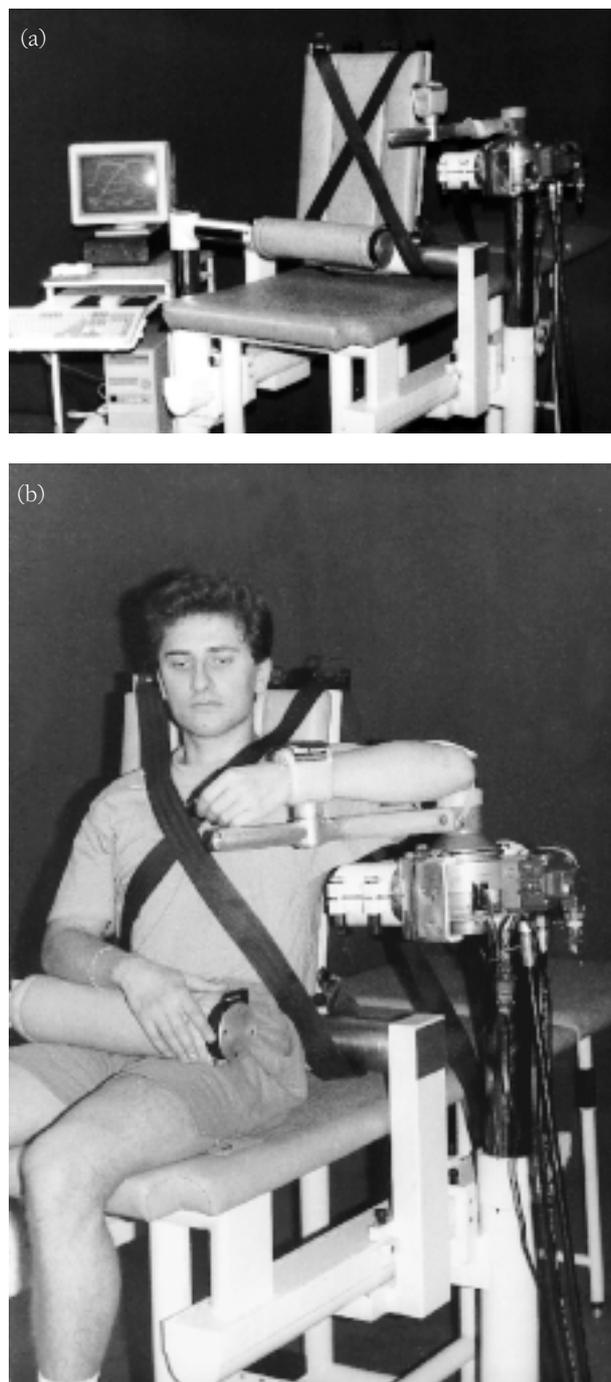
Computer simulation in biomechanics consists in: computer-assisted formulation of mathematical models of biomechanical systems on the basis of previously formulated physical models, the solution of systems of equations creating a given mathematical model, and the presentation of results in a form legible to the user (Dietrich *et al*. 1997). A typical procedural scheme is shown


Figure 2. Test stand for measuring biomechanical characteristics of the main human muscle groups: (a) general view and (b) measuring of elbow flexors and extensors groups (Mianowski 1993).

as Figure 3. Formulation of the physical model (idealization) is a problem that the researcher must carry out independently, using his knowledge, experience and intuition. Software available on the market can facilitate the transformation of the physical model to a mathematical model (formalization) and of the mathematical model to a simulating one (programming), as well as the carrying out the computer simulation. However, idealization, prognosis and validation remain to a considerable degree the duty of the researcher.

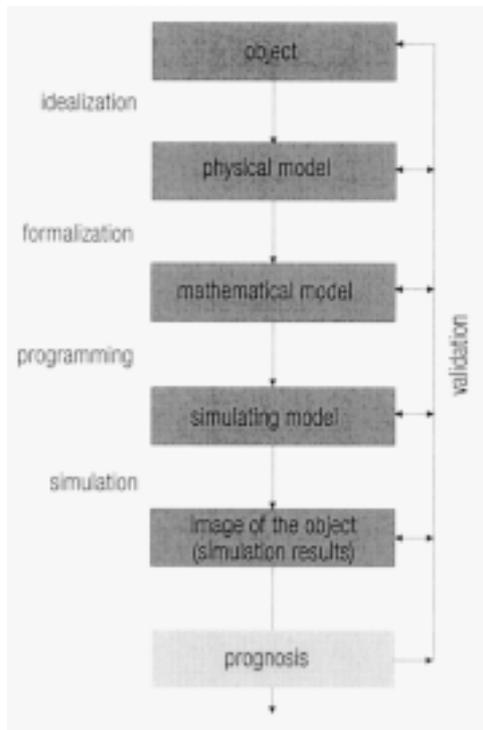
In contemporary modeling in biomechanics (including


Figure 3. Process of mathematical modeling and computer simulation (Dietrich *et al.* 1997).

occupational biomechanics) two types of physical models are used: those of concentrated or distributed parameters (e.g. mass, rigidity, material data). Mixed models can also appear.

The first type of physical model is predominant in the biomechanics of motion of the human body. Such models are used in modeling the entire body or its parts (e.g. only the upper limbs) for a full range of angles of rotation in the main joints as well as for various static (Nigg and Herzog 1994, Seireg and Arvikar 1989) and dynamic situations (Borowski *et al.* 1991). With the aid of these models it is possible toe valuate: forces acting upon the human body as a function of time, reactive forces in the joints (including intervertebral joints), and forces exerted by muscles or muscle groups. Their mathematical description (model) leads to sets of differential or differential-algebraic equations. The number of equations is usually high, reflecting the fact that physical models of the human body normally consist of many elements (hence the name multibody systems) and a correspondingly high number of degrees of freedom of movement (rotational movements in the joints connecting segments). The classical procedureof derivation of equations of motion (i.e. 'by hand' on the piece of paper) is in such cases practically impossible considering the very high likelihood of error. Nowadays, one can use special software packages available on the market which operate symbolically (imitating manual operations and deriving equations in symbolic form) or numerically (calculating only actual quantitative values of the terms of equations). Both types have advantages and disadvantages, which influence the scope of their application in biomechanics.

On the software market there is today a wide selection of this kind of computer programs intended foir the analysis of mechanical and biomechanical systems. Such packages also contain solving of equation procedures and software for the graphic presentation of simulation results (including animation).

Their cost is as a rule very high (thousands of dollars), and so they are more often leased than purchased.

In many biomechanical problems it is necessary to establish and solve a mathematical model for the physical model, containing a so-called loop formed by closed kinematic chains, for, for example, the legs and ground form a closed loop during bipedal walking, a machine operator model contains a closed loop comprising frame (seat)-runk-arm-control lever-frame. A mathematical description of problems with loops can contain both differential and algebraic equations. Not all packages contain procedures for solving such a mixed system of equations.

A good example of software which exploits a multibody physical model and serves in analyzing loads on the human body as well as the resulting threats to health is the package 3D SSP: Three Dimensional Static Strength Prediction (Chaffin and Erig 1991, 3D STatic Strength Prediction 1993), elaborated at the University of Michigan Center for Ergonomics. This program is being used in many centers around the world for analyzing existing or projected work places under static conditions (slow movements in which the influence of inertial forces can be neglected). The physical model of the human body used in this package is shown in Figure 4, in the form of twelve rigid elements (body parts: upper torso with head, lower torso, upper arms, lower arms with hands, thighs, shins, feet) connected with joints.

Figure 5 shows a scheme of the package. 3D SSP allows us to carry out a three-dimensional static analysis of the strains on a person who finds himself in a given position during physical work and is subjected to a defined external loads. The results of the analysis are given in the form of a printout of the values of the moments of muscular forces and reactive forces in all the joints of the model, and of the values of the force compressing the intervertebral disc L5–S1. The appearance of any values greater than the maximum moment in the joints which human muscles can exert, or of values which could indicate possible damage to the body, are noted. Also given is information on which part of the population of physical workers under consideration could safely perform the analyzed job.

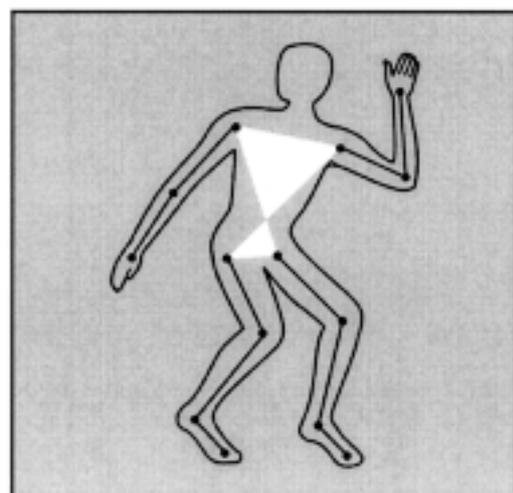
A second type of physical models used in biomechanics is the method of three-dimensional modeling of the body or of body fragments (e.g. torso, segment of the spine, etc.) with the aid of a


Figure 4. Physical model (multibody type) of human body (Chaffin and Erig 1991).
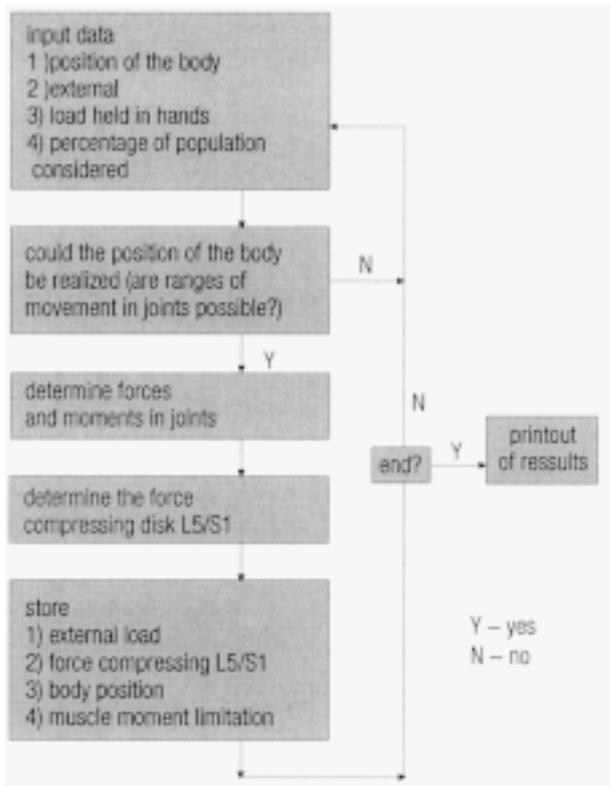

Figure 5. Flow diagram of the 3D SSP package (Chaffin and Erig 1991, 3D Static Strength Prediction™ 1993).

large number of small elements. These are the so-called finite elements, to which may be attributed, dependence on the needs, defined geometrical, material or other properties (Zienkiewicz and Taylor 1991). A mathematical description of these models takes the form of systems of partial differential equations, which require in the computerized version the application of equivalent numerical methods: FEM (finite element method) or BEM (boundary element method). Such models are used in, for, e.g., evaluation of the distribution of stresses and strains in the musculoskeletal system (important in occupational biomechanics) and in the lungs during breathing, and in describing the flow of body liquids (blood, lymph).

The finite elements method has become increasingly popular in recent years for modeling the musculoskeletal system (Dietrich *et al.* 1991) because it has the following advantages:

- Ease of modeling the spatial structure of either the entire musculoskeletal system or its elements (bones, vertebrae, ribs, intervertebral disks, muscles, tendons).
- Possibility of investigating the statics, dynamic and stability of the musculoskeletal system in various life situations (norm, pathology, work, sport).
- Possibility of employing vairous optimization criteria in the model, thus modeling the rules followed by the central nervous system in controlling the work of the muscles (important in solving so-called problems of muscle cooperation).
- Ease of introducing changes to the geometric and material parameters of the model.

The finite elements method is widely used in engineering in various technical disciplines. However, one must take into account, when applying it to the modeling of the musculoskeletal

system, various specific properties of that system not met in typical engineering constructions, such as:

- Mechanical properties of bones, ligaments and muscles are anisotropic, and the main directions of stiffness (e.g. the direction of muscle fibers) change their orientation in space.
- Parameters of bone stiffness, e.g. the Young module (10 000–15 000 MPa) are considerable greater than the corresponding parameters of disks, muscles and ligaments (0.4–160 MPa), with the result that the final set of equations describing the bone–muscle system is ill-conditioned (both very high and very low values appear in the equations, hindering numerical solution).
- Tension in muscle is produced not only by changes in the distance between points of insertion (the so-called passive tension component), but mainly by contraction caused by activation generated in the nervous system (the active component).
- Nuclei pulposa of intervertebral disks and in the region of the abdominal cavity are areas which are almost incompressible.
- Joints (of limbs, spine and rib cage) significantly limit the movements of the related long bones, vertebrae and ribs.
- Pressures in the nuclei pulposa of the intervertebral disks, in the abdominal cavity or in the rib cage are non-preservative in character (the directions of forces are depending on deformations).

Typical FEM software packages available on the market do not enable one to take these properties into account and it is, therefore, necessary to be very cautious in applying them to biomechanical problems. Many researchers still create their own packages for the modeling and simulation of complex biomechanical systems, that is, those constructed of tissues having different properties.

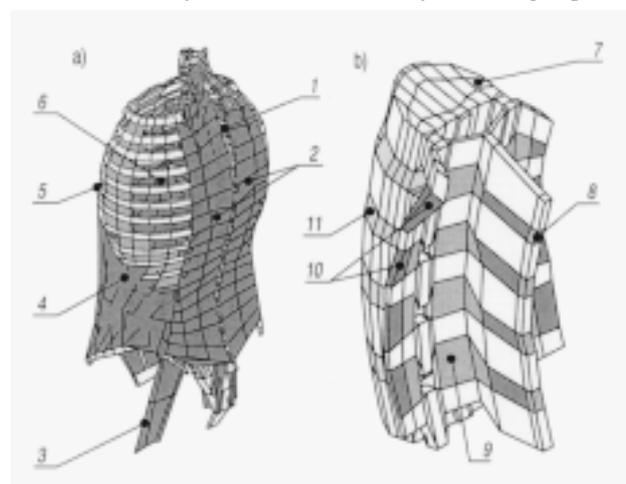
An example of such a model is shown in Figure 6. It is a model of the trunk constructed from 2640 finite elements and which represents the anatomy of the human spinal system (vertebrae, ribs, pelvis, sternum, intervertebral disks, ligaments, muscles, gas in the abdominal cavity). The model also takes into account the activity of the central nervous system, accepting that


Figure 6. FEM type model of a human torso: 1, spine; 2, dorsal extensor muscle; 3, lumbar muscle; 4, abdominal muscle; 5, rib cage; 6, diaphragm; 7, vertebra L1; 8, ligament; 9, yellow ligament; 10, rotator muscles; 11, intervertebral disk 1.2/1.3 (Dietrich *et al.* 1993).

it controls muscles in such a way as to minimize the energy expended on maintaining the body in a given position under an external load. The input data for the model are: the geometry of the system (dimensions), position of the body as well as the value of the external load force; and the output data: displacements of the bone elements, deformations and stresses in the muscles, tendons, and intervertebral disks (Zagrajek 1990, Dietrich *et al.* 1991, 1993). With the aid of the model presented it is possible to investigate the activity of the spinal system in conditions of static load. Sample results obtained are presented in Figure 7.

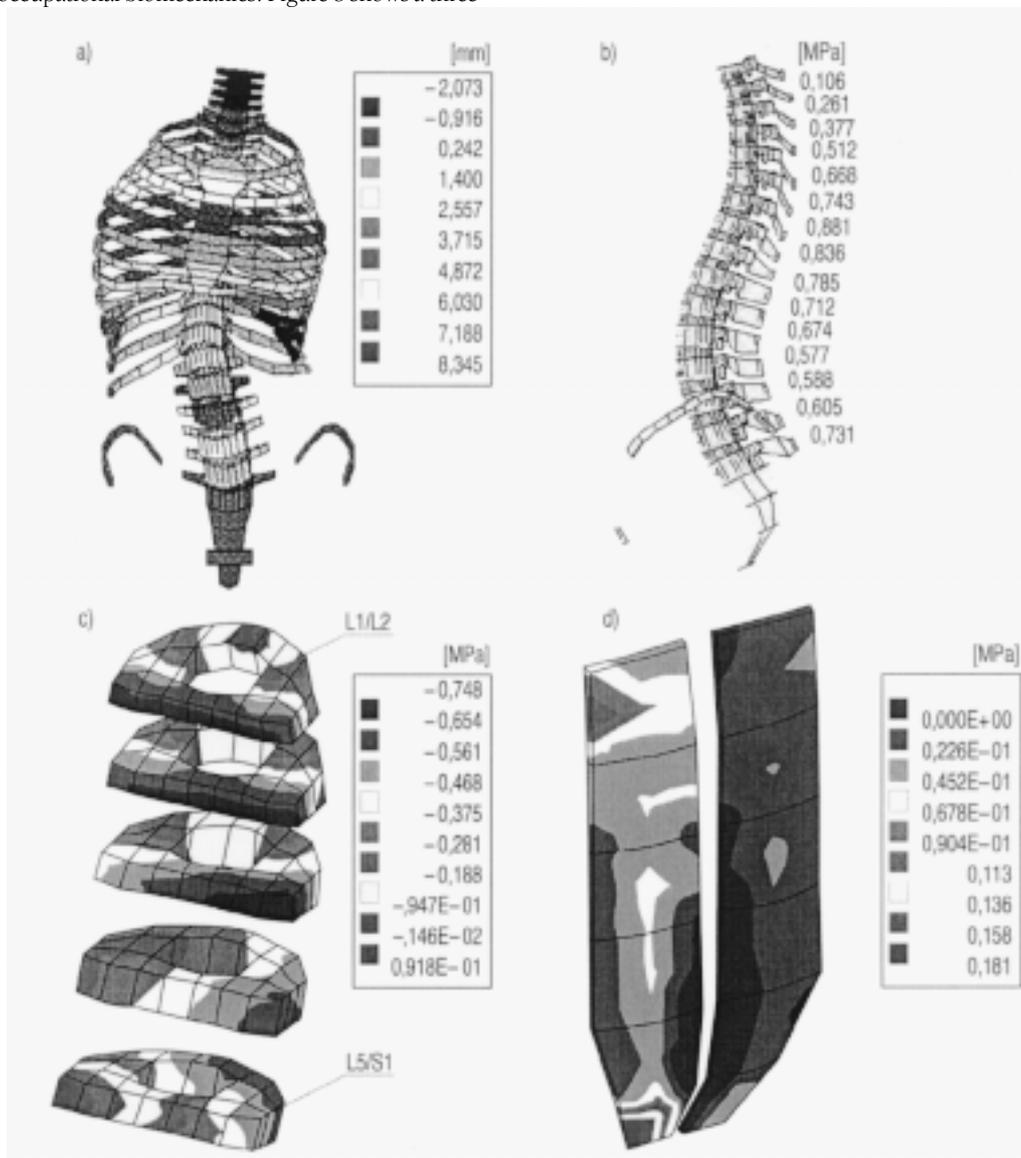
An enlarged version of the model, completed with highly simplified models of the head, arms and legs (not representing the anatomical structures of these elements) serves in simulating the behavior of the spinal system when subjected to large shock loads and crashes (Borowski 1991) as well as under conditions of vibrations acting upon the operator of a mechanical vehicle (Dietrich *et al.* 1995). This second application is particularly important in occupational biomechanics. Figure 8 shows a three-dimensional FEM type model of a human-vehicle system, composed of 2936 finite elements. Its main part is the spinal system model shown earlier in Figure 6. Input data for the model are: body position, geometric and material data of body and vehicle elements as well as data of the forces acting upon the system and excitation causing it to vibrate. The mathematical model describing the FEM model of the human-vehicle system, created with the aid of typical computerized procedures used in this method (Zienkiewicz and Taylor 1991), is composed of 14493 non-linear equations. Solving this system of equations for a given kinematic excitation (e.g. harmonic vibrations of the seat along the vertical axis z — see the coordinate system depicted in Figure 8) reveals displacements, velocities and accelerations of all the rigid elements of the system (bones, elements of the vehicle's construction). Knowing the parameters of vibration of the rigid elements, the distribution of deformations and stresses in the elastic elements (muscles, intervertebral disks) are then calculated.


Figure 7. Sample results of simulations obtained for the spinal system from figure 6(6), subjected to a load of 200 N held in the left hand; (a) displacements of ribs and vertebrae in the frontal plane (mm), (b) distribution of pressures in the nuclei pulposa of the intervertebral disks (MPa), (c) distribution of compression stresses in the annuli fibrosa of the lumbar intervertebral disks (MPa) and (d) distribution of stresses stretching the muscle fibers of the straight abdominal muscle (MPa).
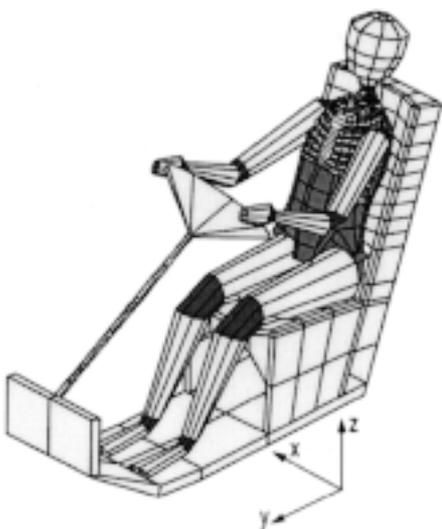

Figure 8. FEM type model of a human-operator under vibration (Dietrich *et al.* 1995).
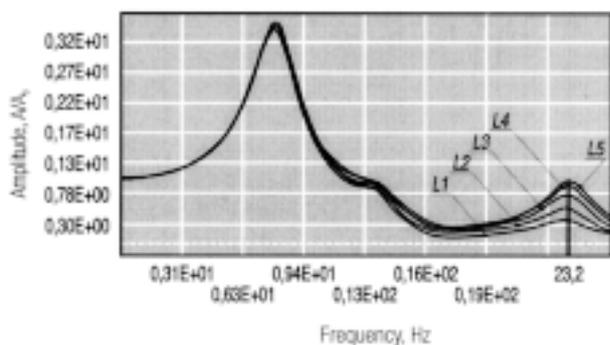

Figure 9. Resonance curves of vertebral vibrations in the lumbar region of a human-operator in the direction of axis *z* (Figure 8). A. amplitude of vibration of individual vertebrae; A_o, amplitude of vibration of the seat (here A_o = 10 mm).
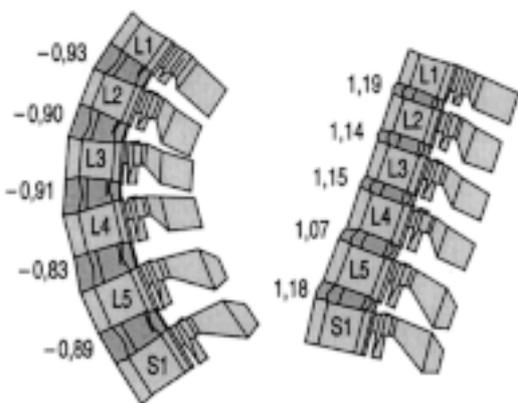

Figure 10. Extreme positions of the lumbar region of the spine in the course of one vibration cycle at a frequency of 23.2 Hz; values indicate pressures in the nuclei pulposa of the intervertebral disks (a negative value indicates hypotension); displacements have been magnified five times in comparison with the scale of the figure.

In Figures 9 and 10, sample results of solutions obtained with the aid of this model are shown.

Figure 9 shows resonance curves for the lumbar section of the spine (vertebrae L1/L5) for vibrations of frequency from 0 to 30 Hz. At low frequencies of up to several Hz, all the resonance curves are almost identical, whereas at higher frequencies the curves diverge, indicating the appearance in the intervertebral disks of strains induced by the vibrations.

Figure 10 shows an enlarged view of the extreme positions of the lumbar section subjected to a vibration of 23.2 Hz. It is easily noticed that, in the course of vibration, not only the alignment of the spine undergoes change, but also the distances between vertebrae. This produces pressure pulses in the interior of the intervertebral disks (see the values given in Figure 10) as well as pulses of stress in their tissues. These phenomena can in time lead to the appearance of deterioration causing diskopathy. The appearance of pain in the lumbar regioni at frequencies of 20/30 Hz has been noted in the literature (Singleton 1982).

With the aid of FEM methods a model of the musculoskeletal system of the entire human body has also been created for applications in both occupational biomechanics and basic biomechanical research (Kedzior and Zagrajek 1997). This model accounts for all dynamic components of loads on the human movement system (inertial forces, damping) during simulation of any movement whatever (e.g. movements of labor in the course of physical work), through a full range of rotational angles in the joints.

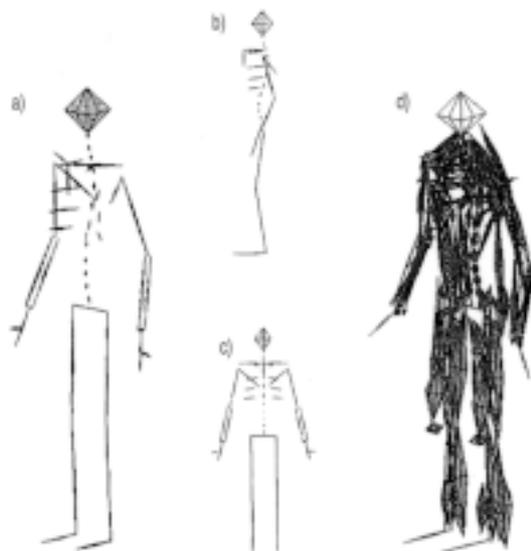
The physical model of the skeletal system (Figure 11 a–c) is composed of 45 rigid elements modeling those elements of the human body which are very rigid (e.g. bone) or which are significantly more rigid (e.g. vertebral segments, feet, hands) than other elements (muscles, tendons, disks between rigid spinal segments). Rigid components are connected by means of special elements of the 'six-component spring-damper' type. Each such element is composed of six subgroups; each subgroups is constructed of spring and damper acting in parallel; three linear


Figure 11. FEM type model of the human musculoskeletal system; (a–c) system of rigid elements modeling the skeleton; diagonal, profile and frontal views; and (d) general view of skeleton and muscles (Kedzior and Zagrajek 1997).

subgroups are acting in three mutually perpendicular directions and three angular subgruops are acting around the directions corresponding to the axes of rotation. The stiffness of the springs is chosen to allow only such movements as agree with the physiological range of movement in the joints. Suitable selection of the characteristics of the component springs makes it possible to model the limits of movement ranges in a given joint which result from its anatomical structure. The suppression coefficients of the dampers are chosen to suppress small vibrational movements in a given joint arising in the course of simulation of a movement which we know from experience has a smooth trajectory.

The physical model of the muscular system (Figure 11d) is composed of 250 special elements which model the activity of muscles such that forces exerted by them are applied to the stiff elements in accord with the lines connecting the points of insertion of a given muscle. Geometrical data of points of insertion and physiological cross-sections of muscles abound in the literature (Seireg and Arvikar 1989, Yamaguchi *et al.* 1990, Thompson and Floyd 1994). In the mathematical model of the muscles, the dependence of forces exerted by each muscle on its length and rate of contraction is considered, drawing on the analytical relations given in the work of Pierrynowski and Morrison (1985).

The physical model shown in Figure 11 has been transformed to a mathematical model, and then to a simulating one (Kedzior and Zagrajek 1997). It can be employed in solving two basic types of problems:

- Knowing the course in time of the values of forces exerted by the muscles as well as the values of external forces (such as loads acting upon the human body, for, for example, in the form of a weight held in the hand), it is possible to determine the course in time (trajectory) of displacements of selected points of the body (the number of such points is freely chosen).
- Knowing the trajectories of selected points of the human body (e.g. experimentally recorded using the method of recording movement on film) as well as the course in time of the values of external forces, it is possible to determine the course in time of all muscular forces.

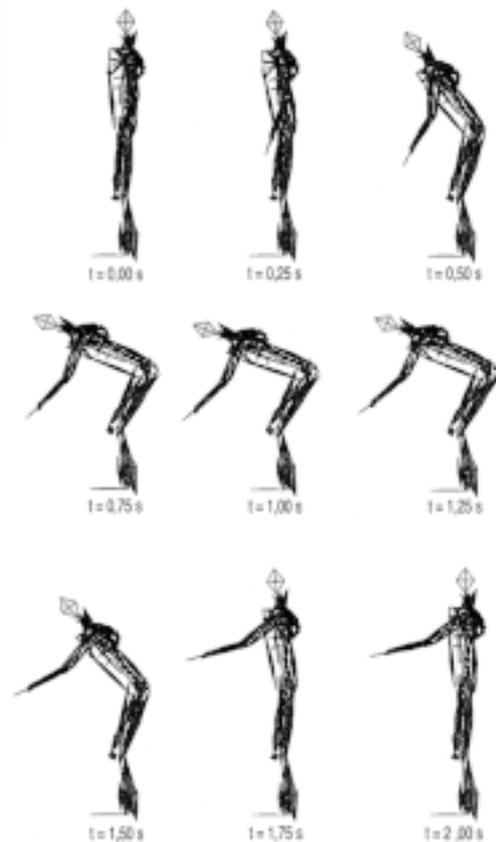
In occupational biomechanics we are almost always faced with solving the second type of problem. And here an additional difficulty arises: the number of muscular forces in the human organism (and thus in the described model) is greater than the number of movements produced by them in the joints. Usually a given movement (e.g. flexion of the elbow joint) is the result of simultaneous action of several or even several dozen muscles (the so-called issue of muscle cooperation). As a result of this, in the mathematical model of a given problem, the number of unknown variables (i.e. muscular forces) is greater than the number of equations. Such a set of equations has an infinite number of solutions. One of them must be chosen. This is done by the optimization method, assuming that muscles in an organism act according to some sort of rational criterium, e.g. minimal energy expenditure (Dietrich *et al.* 1991) or other criterium, e.g. the sum of muscular forces or the sum of reactive forces in the joints (Seireg and Arvikar 1989) must be minimal, or that they meet the so-called criterium of soft saturation (Siemieski 1991). In the model described we assumed the first of the above-mentioned criteria —


Figure 12. Model of the human musculoskeletal system at successive points in time *t* (side view) in the course of an action performed with a load of 100 N held in the hands (movement symmetrical in relation to the sagittal plane).
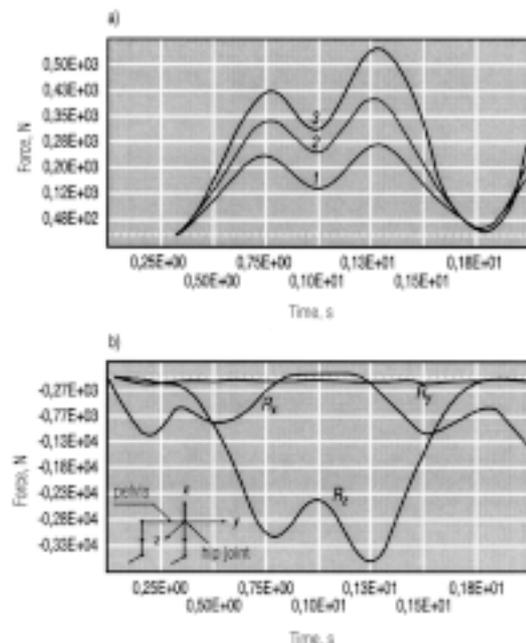

Figure 13. Courses as a function of time: (a) forces exerted by the muscles of the lower limb: 1, semitendinosus; 2, semimembranosus; 3, biceps femoris; (b) component reactive forces in the hip joint R_x, R_y, R_z respectively along axes x, y and z of the local coordinate system (in accordance with the diagram inserted in the figure).

the energetic. Sample results of simulations are shown in Figures 12 (a well-known work movement of the human body) and 13 (values of muscular forces and reactive forces in the joints).

The simulation models of the human body described herein are employed in solving a typical problem of occupational biomechanics: the capability of the human musculoskeletal system of safety lifting a load during the performance of a defined physical task. Using the computer simulation method it is also possible to solve the problem of optimization of the workspace. This problem is taken up in the next section.

4. OPTIMIZATION OF UPPER EXTREMITY LOCATION IN WORK CONDITIONS

4.1. Method of Work Space Optimization for Upper Limb

Computerized method for workspace optimization has been created on the basis of computer program, which simulates upper extremity function. The method allows for finding, from computer calculations, optimum upper extremity location in theh defined workspace.

Physical model of upper extremity consists of kinematics chain of upper extremity, muscles and workspace. Kinematics chain of upper extremity is opened and has 7 degrees of freedom. It consists of three rigid elements modeling arm, forearm and hand. Model takes into account all basic movements of the limb, defined in relation to frontal plane — abduction/adduction; sagittal plane — flexion/extension, and pronation/supiantion defined as rotation round axis of the limb.

Trunk was considered to be immobile and upper extremity joints have been modeled as rotating kinematics pair. For shoulder of third class (three degrees of freedom), elbow joint and wrist joint of forth class (two degrees of freedom). It means that in shoulder joint can be simulated moves of flexion–extension, abduction-adduction and rotation round axis of the limb, in elbow joint flexion–extension and rotation, in wrist joint of flexion–extension and abduction-adduction. Center of rotation in shoulder joint is a center of global coordinate system. Upper extremity location is defined due to local Denavit–Hartenberg coordinate system (Denavit and Hartenberg 1955) connected with every rigid element of the model.

Also coordinates of muscles attachment to bones are defined according to local coordinate system. Coordinates of points of muscles attachment to bones were adopted from Seireg and Arvicar (1989).

Workspace shape was considered to be a segment of ball sphere laying inside area of maximal upper limb reach. This space is defined by the following parameters:

- Polar coordinates of ball center in relation to global center of coordinates (center of rotation in shoulder joint).
- Internal radius of sphere segment.
- External radius of sphere segment.
- Horizontal angle of the sphere.
- Vertical angle of the sphere.

Physical model of upper limb was formalized in analytical form into mathematical model in which for symbolic operations (conversion of algebraic formulas) computer software CAMIR (Rzymkowski 1988) was used.

The analytical describe fact that in a chosen point in the work space kinematics chain of upper limb stays in static balance under

its own load, forces of muscles and external force. In this way seven equations are generated (one for each degree of freedom). In mathematical model of upper limb unknown values are 34 values of muscle forces. It means that there are seven equations with 34 unknown values — muscle forces, which makes the mathematical task statically indeterminable (excess of muscles in relation of degrees of freedom). Solution of this problem called also solution of muscles contribution is usually searched with assumption that nervous system is controlling muscles due to some merit criterion. In this study merit criterion of 'soft saturation' was implemented (Siemieski 1992).

$$\sum_{j=1}^{34} 1 - \sqrt{1 - \frac{F_i}{F_{imax}}} = \min \qquad (3)$$

where F_i is force generated by ith muscle ($i = 1, \ldots 34$); and F_{imax} is multiplication of the ith muscle cross-section (m²) and maximum allowable muscle tension.

Achievement of the purpose of the optimization problem however needs to find optimum upper limb location (calculation of optimal set of angles $q_1, \ldots q_7$), such one in which muscular load will be the lowest. That means that to complete the task there is a need of additional optimization process, in which merit function will be formal formula of the value proportional to muscle effort in static work conditions. On the basis of other studies results (Seireg and Arvicar 1989), it was considered that this merit function is expressed as the sum of modules of muscle forces in relation to axis of rotation in joints that must be developed by the muscles in the arm, elbow and wrist joints to balance the limb's own weight. Form of the second merit criterion is the following:

$$\sum_{j=1}^{7} \sum_{i=1}^{34} |F_i r_{ij}| = \min \qquad (4)$$

where F_i is force generated by ith muscle ($i = 1$–34); and r_{ij} is arm of force exertion in relation to axis of rotation of ith degree of freedom ($j = 1$–7).

Described above mathematical model together with constrains condition and double optimization was transformed into computer simulation model which gives possibility of effective solution of the task of work space optimization. The optimization process assumes cooperation between computer system and the user of the system. The task of user is to define the workspace for a given work task. User gives also parameters connected with dimensions and masses of upper limb segments and value and direction of external force. On Figure 14 diagram of optimization process conducted by this system is presented.

To find optimum upper limb location double optimization: 'external' with using 'Monte Carlo' method and second merit criterion (4) and 'internal' with first merit criterion (3) and gradient method of optimizaiton is performed (Roman-Liu *et al.* 1999).

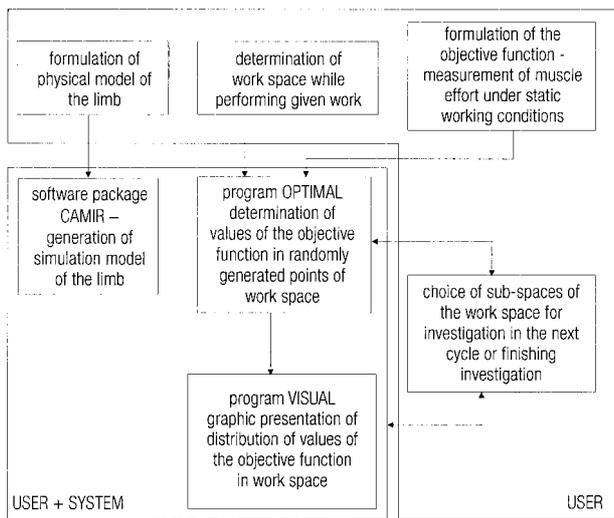
Application of the described above system allows presentation in a graphic form solution of optimization task. Workspace is divided into 625 small subspaces (Kedzior *et al.* 1993a) (Figure 15). In each of the subspace the calculated value of merit function (4) is marked with colors. Also information concerning minimum and maximum value of merit function and adequate angles in


Figure 14. Optimization process of upper limb work space.
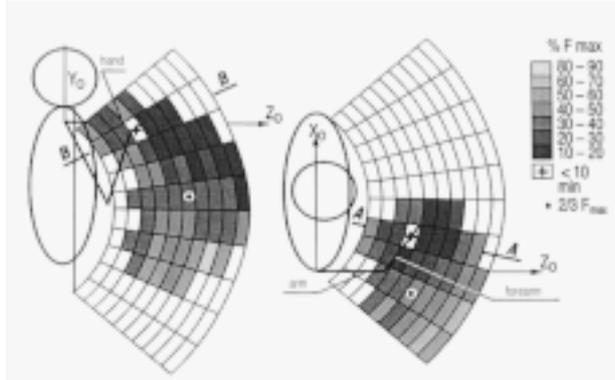

Figure 15. Optimization results: (a) vertical cross-section of the work space by plane marked on (b) as A–A; (b) horizontal cross-section of the work space marked on (a) as B–B. Optimum solution '+;' '*' marks the projection of the point where merit function reaches about two-thirds of maximum value.

joints are available. Examples of results of calculations performed on the basis of the method were presented in publications (Kedzior *et al.* 1993a–c).

4.2. Experimental Verification of the Theoretical Method for Work Space Optimization

To verify the method for the same limb locations and the same values and direciton of external force experimental studies and calculations of muscle force for a given number of participants were performed. Results from calculations (parameter MOD) were compared with results from experimental studies.

As an experimental method for verification was chosen electromyography (EMG). Although this method is sensitive to inaccuracies and artifacts, it is presently the most often used for purposes of examination of musculoskeletal load. From the EMG signal parameters can be drown out information concerning musculoskeletal tension (from the aplitude of the signal) as well as concerning process of changes in muscles in time like muscle fatigue. Good parameter that indicates muscle fatigue, can be zero crossing (Hagg *et al.* 1987, 1991). To express muscle fatigue

quantitatively slope of the regression line of zero crossing (ZC) (Hägg *et al.* 1987, Hägg and Suurküla 1987) in time is estimated. This parameter marked as SZC was analyzed in experiments, which purpose was to verify theoretical method for workspace optimization. The other analytical EMG parameter was amplitude value (AMP), calculated as RMS, which express muscle tension.

Comparison of results was conducted on the basis of measurements of EMG signal by surface electrodes from eight muscles:

- Flexor carpi radialis (FCR).
- Flexor carpi ulnaris (FCU).
- Extensor carpi ulnaris (ECU).
- Brachioradials (BR).
- Biceps brachii caput breve (BBCB).
- Deltoideus (DL).
- Triceps brachii caput laterale (TBCL).
- Trapezius (TR).

Trapezius muscle was not taken into account in the computer model. However, this muscle supports scapula and many researchers suggest that upper limb location influences muscular load of this muscle. This is the reason why in those studies, like in many other ergonomic studies (Christensen 1986, Lannersten and Harms-Ringdahl 1990) this muscle is taken as an indicator of the entire upper limb load. EMG parameters for this muscle were compared with sum of upper limb muscle forces calculated from the model of upper extremity. It was justified by the fact that load in this muscle is considered to be indicator of load in the whole upper extremity.

The muscle fatigue and load is influenced by limb location, vector of external force and frequency or duration of the load exertion. Theoretical model did not take into account the third of those factors, so it did not differentiate intermitted load and constant load. However work tasks on a real work stand has usually more or less dynamic character that causes different pattern of muculoskeletal load. Because of that it was decided to perform experimental study with external force constant (conditions closer to theoretical model) and intermittent (conditions closer to reality). It gave the possibility to compare and assess the model in relation to real conditions on the work stand.

For theoretical model verifications were chosen 10 different limb locations — four for studies with constant load and six for studies with intermittent load (Roman-Liu *et al.* 1999). So, there were muscle forces calculations and experiments for 20 various differentiated by: character of load — constant (*C*) or intermittent (*I*), and value of external force: unloaded (*U*) or loaded (*L*).

Analysis was performed to assess:

- correlation between experimental studies results (AMP and SZC) and calculations conducted on the basis of computer model (MOD);
- differentiation of musculoskeletal load due to external force value; and
- differentiation of musculoskeletal load due to upper extremity location.

On the basis of results it was revealed that in most of cases there are statistically significant correlation between EMG parameters from experimental studies and value of parameter MOD proportional to muscle forces calculated by computer model from theoretical studies (Figures 16 and 17).

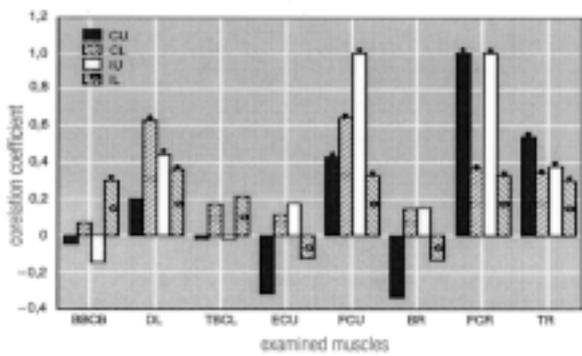
Values of MOD parameter are better correlated with amplitude


Figure 16. Correlation coefficients between parameter MOD and AMP for examined muscles in study with constant load (C) and study with intermittent load (I); *differences statistically significant with *P* < 0.05 (U, variants without external force; L, variants with external force).
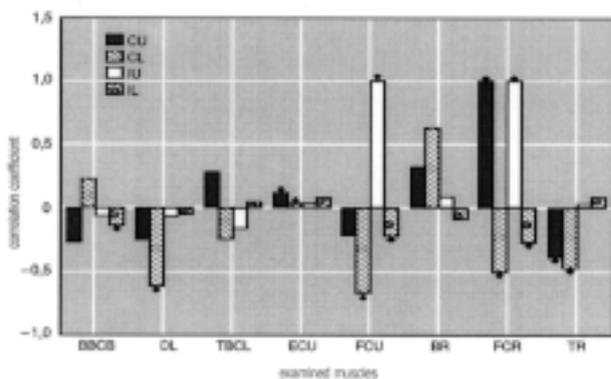

Figure 17. Correlation coefficients between parameter MOD and SZC for examined muscles in study with constant load (C) and study with intermittent load (I); *differences statistically significant with *p* < 0.05 (U, variants without external force; L, variants with external force).

value of EMG signal (AMP) than with parameter that reflects muscular fatigue (SZC). It refers to both study with constant and with intermittent load. However in studies with constant load statistically significant correlation coefficients between MOD and SZC are in higher number of cases than in experiments with intermittent load. This is probably due to higher muscular fatigue in experiments with constant load, which makes stronger dependence between muscle tension and muscle fatigue and in consequence between muscle fatigue and muscle force expressed by parameter MOD.

Differences in values of parameters MOD, AMP and SZC between variants with and without external force for the same limb location are expressed by parameter ratio of load. Ratio of load is quotient of averaged values of analyzed parameters (AMP, SZC, MOD) in variants with external load and without external load. It was checked if values of the ratio of load of analyzed parameters for the examined muscles belonged to the same range, it means were > 1 or < 1. If ratio of load for all three parameters belonged to the same range it was assumed that there is agreement between theoretical and experimental results.

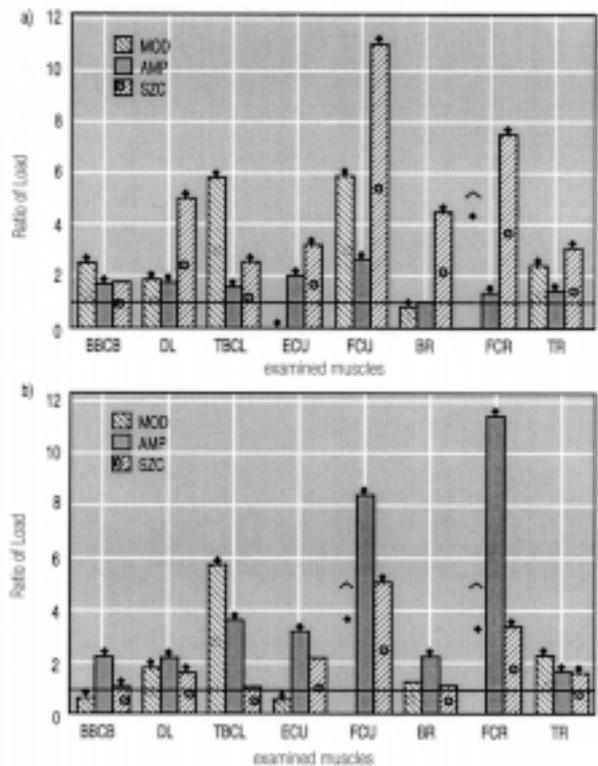
In Figure 18 are values of ratio of load for parameters MOD, AMP and SZC.


Figure 18. Ratio of load for analyzed paramters of LMG signal and results of computer simulation in (a) studies with constant load; (b) studies with intermittent load; *differences statistically significant with *p* < 0.05; ^values indeterminable.

It was concluded that experimental and theoretical results could be regarded as to be in step in differentiation according to external load, although not all differences are statistically significant.

For each of analyzed parameters (MOD, AMP, SZC) was calculated value of ratio of location, which is quotient of average values of analyzed parameters for two compared upper limb location. Similarly like in case of ratio of load agreement between theoretical and experimental study was assumed to occur when values of ratio of location for analyzed parameters were in the same range, it means were > 1 or < 1.

Much better differentiation of upper limg location occurred in study with external load (Figure 19) than with study without external load (Figure 20).

In study with constant load most of differences expressed by parameter ratio of location was statistically significant and what is more there were the same tendency in both studies with external load and studies without external load. In results of study with intermittent load upper extremity location was not be able to differentiate univocally and the differences were statistically not significant.

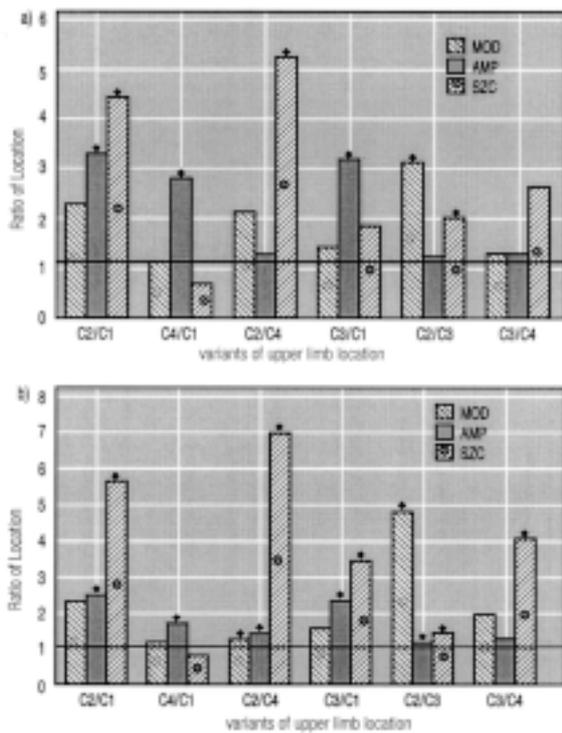
As a result of verification it can be stated that there is convergence between results of theoretical and experimental studies, especially in differentiation accoding to external load. It means that on the basis of computer simulation workspace can be differentiated according to external load of upper extremity. There was also noticed partial agreement between values of EMG parameters and results of computer simulation in differentiation of musculoskeletal load according to limb location.


Figure 19. Ratio of location in study with constant load: (a) variants without external load; (b) variants with external load; *differences statistically significant with *p* < 0.05.
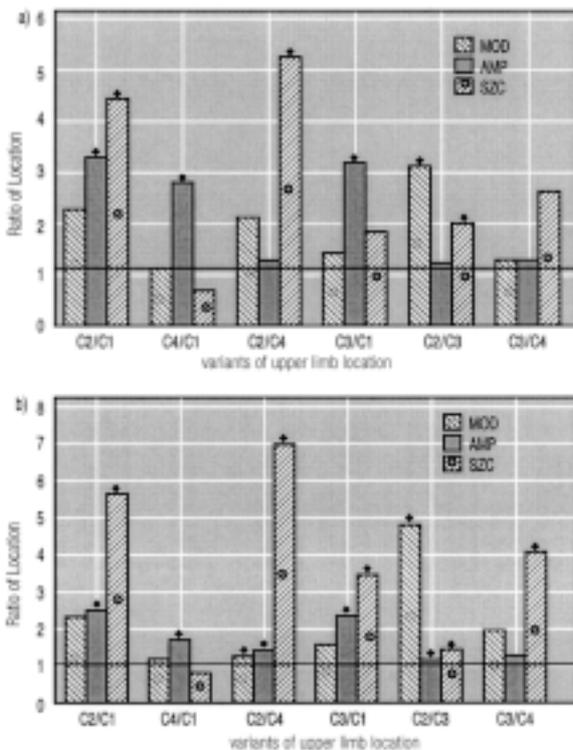

Figure 20. Ratio of location in study with intermittent load: (a) variants without external load; (b) variants with external load; *differences statistically significant with *p* < 0.05.

The lack of ideal agreement between theoretical and experimental results is most probably caused by both inaccuracies in experimental method and simplification in model. Sources of dispersion in EMG studies are connected with subjective differences. Values of EMG parameters are in a high degree dependent on kind of muscles and contribution of fast and slow fibers (Fallentin *et al.* 1985, Gerdle *et al.* 1988). In analysis of EMG signal there were not analyzed changes of EMG signal according to changes of muscle length, which can also be source of discrepancies.

Sources of discrepancies in theoretical calculations are in not strict enough subjective differentiation and in to high simplification of the model (bones taken as rigid links, muscles as lines, bones radius and ulna were modeled as one rigid link, shoulder girdle was not taken into account). The differences in results can also be caused by individual differences between people. Only limb mass and limb length were measured separately for each subject. So it can be stated that both methods theoretical and experimental have some inaccuracies and should be considered as approximate.

However, on the basis of results there can be drawn a conclusion that created program for workspace optimization is good enough for tasks in which the load of upper extremity is of constant static character. In cases where muscular fatigue induced by external load is not proportional to forces developed by muscles, the method can be also used, but results should be considered as approximate.

Occupational Epidemiology with Special Focus on Ergonomics and Musculoskeletal Disorders

E. Bach

Department of Epidemiology and Surveillance, National Institute of Occupational Health, Lersø Parkallé 105, DK-2100 Copenhagen Ø, Denmark

1. INTRODUCTION

Over the past decades, a shift in occupational medicine has taken place. The traditional occupational diseases have become less frequent and the emphasis in research has shifted to exploration of the work-related etiology of "common diseases" including their manifestations and precursors. Many of these diseases have an occupational as well as a non-occupational etiology, and the occupational component may be difficult to identify.

Therefore, more sensitive epidemiologic approaches are needed in occupational epidemiology, i.e. to study the occurrence of multi-causal diseases in relation to their work-related determinants. This implies a tightening of the study design and more accurate methods for measuring exposure.

This chapter focuses on ergonomic exposures and morbidity such as musculoskeletal disorders. Therefore, only concepts relevant for studying these relations are mentioned, which leaves out, for example, mortality frequencies.

1.1. Musculoskeletal Disorders

A nationwide cross-sectional study in Denmark showed that skilled and unskilled workers had an increased risk of low back pain. People employed in "building and construction work" had twice the risk and persons in "social work, child daycare work and psychological work" had 1.6 times the risk for low-back pain compared with other employees.

Several epidemiologic studies within the past 25 years have emphasized a potential work-related ethiology of musculoskeletal disorders, mainly based on physical risk factors. Other studies have focused on individual and psychosocial risk factors and other investigators have even conceptualized causation at the society level as a consequence of modern life. Far the most of the epidemiological evidence derives from cross sectional studies, but case-control studies and follow-up studies are now published in scientific papers.

The health effects of workplace risk factors have ranged from outcome measures of vaguely defined self-reported pain or trouble to medically diagnoses and hospitalizations. The severity and effects on disability are unknown, but the cost for society because of musculoskeletal disorders is widely acknowledged by researchers and policy makers.

In Denmark a government action program was set up in 1991 against work-related musculoskeletal disorders of the neck and upper limb associated with monotonous repetitive work. The background was research, national statistics on workers compensation claims and political debate. In order to obtain more knowledge, a Project on Research and Intervention in Monotonous work (PRIM) was launched in 1993. PRIM is an interdisciplinary research project, embracing several studies on company organizational factors that may influence the amount of monotonous work as well as work related risk factors of musculoskeletal disorders and psychological effect.

2. SOURCES OF INFORMATION

Epidemiological findings are often based partly or completely on individuals responses to questionnaires — mailed questionnaires or interview questionnaires — with detailed question on individual exposures and diseases. Exposure data may be supplemented with observations or measures on the workplace, and data on diseases may come from medical examinations or disease registers.

Studying musculoskeletal disorders is a relatively new area in occupational epidemiology and there is a substantial lack of knowledge about causal factors of musculoskeletal disorders. There is also a need for developing standardized ways of asking the relevant questions about exposures and disorders. In the PRIM study, we included all validated questions and developed new questions on relevant topics where no validated questions existed (an English version of the questionnaire can be ordered from the author).

2.1. Exposure

Most of the epidemiologic studies concern the manufacturing industry. Focus has been on mechanical factors at work, and methods for measuring the ergonomic exposures have often been very specific for the examined populations. The questions are seldom validated and they differ for different industries which makes it impossible to compare data and data quality.

Work with new technology, especially video display units, has also been suggested as risk factors for musculoskeletal disorders, and new questions were developed in different studies. However, few of these studies have so far been published in scientific papers. The PRIM-study includes questions suitable for describing monotonous, repetitive work and, therefore, also for work with new technology. Questions on ergonomic exposures calls for illustrations and not only questions in the questionnaire. An example used in PRIM is shown in Figure 1.

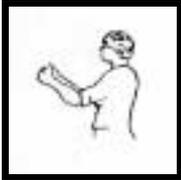
Most researchers assume a multi factorial nature of musculoskeletal disorders and it has been proposed to incorporate workplace factors as well as individual factors at the physical, psychological and social level in future research, which is done in PRIM. Several validated questionnaire modules at the psychological level are available, and the need in this area is to reduce the number of questions in the modules on a scientific plausible way. There are few standardized ways of asking about individual factors such as sport activities.

2.2. Disease

Disease is used in a broad sense in epidemiology that includes health effects such as self-reported health complaints and symptoms and their administrative consequences. This means that the researcher must define the disease in each analysis very precise. A Nordic work group has made a standard questionnaire measuring 1 year prevalence, 1 week prevalence, days with pain, sick leave, contact to health personnel because of pain, and use of medicine due to musculoskeletal disorders. The questionnaire

12. Does your work entail that…………………

(Mark with only one cross and please answer all questions)

	Never/ seldom	App. 1/4 day	App. 1/2 day	App. 3/4 day	Almost all the time
you work with your back deeply bent forward?	1	2	3	4	5
you work with your arms lifted in front of your body?	1	2	3	4	5
you work with your neck deeply bent forward?	1	2	3	4	5
you work with your wrist strongly bent or flexed?	1	2	3	4	5


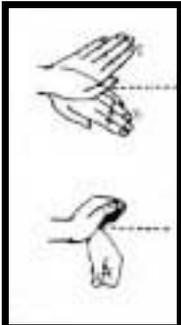


Figure 1. Example on illustrated questions in questionnaire from PRIM.

is used in several studies but is often supplemented with other questions about the pain, as in PRIM.

3. STUDY BASE

The study base is the morbidity experience of a population over time. Population, time, methods, and design must be chosen with respect to the hypothesis in the study and the potential generalization from the study to the scientific level. Small studies or studies including non-sensitive measures give false negative studies or studies with no information.

4. MEASURES OF DISEASE FREQUENCY

Two basic frequency measures are used to quantify the occurrence of diseases in a population, i.e. incidence and prevalence.

4.1. Incidence

The incidence refers to the occurrence of *new* diseases in a population in a given time and is concerned with the risk of getting a disease. When relevant, the incidence may be measured in relation to the total time spent in the population (sum of the individual person times at risk) and is called the incidence density (ID) — in other studies the incidence is related to the total number of persons in the population and is called the incidence rate (IR).

4.2. Prevalence

The prevalence rate (PR) refers to the proportion of people *with* the disease at a specific time Prevalence describes the disease state in a population and the longer the duration of the disease, the more meaningful is the prevalence. Incidence is difficult to define and study in epidemiologic studies concerned with reversible health effects,` and when the natural history of the disorders is only vaguely known, such as musculoskeletal disorders. In many such studies the prevalence is often studied instead of incidence.

4.3. Relative Measures

In order to compare measures of disease frequencies in two comparable groups (a study group and a reference or control group) the measures are often deviated by each other. These relative measures are correctly called rate ratios (RR) but are often referred to as risk ratios or relative risks.

Another relative measure is the odds ratio (OR) — that is the odds of getting the disease in one group divided by the odds of the disease in another group (the control group), or the odds for the diseased of having been exposed compared with the odds among the non-diseased.

These relative measures are all 1 if the exposure do not increase the risk of disease and > 1 if the exposure increases the disease risk.

The rate ratios vary very little for frequent disorders as musculoskeletal disorders. In this case it may also be relevant to compare the measures by subtracting the measure of the control group from the measure of the study group. This relative measure is called the rate difference (RD) or attributable risk

5. STUDY DESIGNS

The two major types of studies are cohort studies and case-control studies. The cross sectional study, where exposures and disease frequencies are measured at the same time, is a borderline case of the cohort study. Today intervention studies are also conducted.

The choice of study design depends on the purpose of the study and the studied exposures and disease frequencies.

5.1. Cohort Studies

In cohort studies two or more groups (cohorts) of people without disease (i.e. without the disease that is studied) and with different exposure levels are followed in order to measure the incidence rates and to study if the exposed cohort have an excess incidence. Cohort studies have their strength when studying relative frequent diseases and rare exposures. The researcher decides the number of persons in the exposed group at least if enough available exposed persons are available. The cohort study is often prospective, but can be retrospective if it is based on existing data.

Rate ratio, odds ratio and rate difference may be used in order to compare disease rates in cohort studies. Cohort studies concerned with musculoskeletal disorders may use prevalence as disease measure instead of incidence. They may include persons with disorder in the beginning of the study to study both incidence of disorder and disappearance of disorder when the disorder is reversible.

5.2. Case-control Studies

In the case-control study, groups with the studied disease and groups without this disease are compared according to former exposures. Case-control studies are mainly used in studies of rare diseases (and relatively frequent exposures). The researcher decides the number of diseased persons in the study if enough diseased persons are available, and incidence (or prevalence) of disease can not be estimated in the study. Odds ratio is, therefore, the measure used for comparison in case-control studies.

5.3. Intervention Studies

Studies where people are randomized to different exposures like clinical trials are not seen in occupational epidemiology because of ethical and practical limitations. The experimental studies in occupational epidemiology are called *intervention studies*, which is cohort studies where groups of people on one workplace are randomized to a planned intervention and people on another work place are randomized to no intervention. Disease frequencies are measured before and after the time of intervention in both the study group and the control group.

In this case the intervention is expected to improve the work environment and is, therefore, ethical plausible. The group without intervention is part of the study in order to illustrate the effect of time and "natural" interventions that occurs from changes in the work situation for reasons outside the study, e.g. changes in demand for the production. The above-mentioned PRIM study is an intervention study.

5.4. Ecologic Studies

Ecologic studies are aggregate studies that focus on comparison of groups because individual-level data are missing. In a sense this type of study is an incomplete design. Epidemiologists have used these studies for years as simple descriptive studies, but statistical methods for this type of studies have now been improved.

6. CONFOUNDERS AND STATISTICAL ANALYSIS

Comparability of the groups except for the exposure under study is ensured in the clinical trial. In occupational epidemiology, the

groups may not be comparable due to selection, and the differences in occurrence of other determinants for the disease under study. These other determinants are potential confounders.

Dealing with confounders in the design of the study can be made by ensuring that the determinants are equally distributed in the study group and in the control group so they do not confound the results. One or a few confounders can be dealt with in the analysis by standardization, e.g. age standardization, but more common today is to handle the confounders in stratified analysis and advanced (multivariate) statistical analysis.

The most used statistical method during many years is logistic regression that produces odds ratios for one disease for each confounder included in the analysis, where disease is a dichotomized, dependent variable. The method is included in any statistical package for epidemiologists. Statistical methods for non dichotomized disease measures and methods dealing with prevalence ratios instead of odds ratios have been conducted, but are until now only included in few statistical packages.

7. BIAS AND VALIDITY

The statistical analysis estimates the influence of random errors in the study, but the analysis can never deal with a systematic error (a bias). If for example all of the participants in the study group are persons < 25 years of age and all participants in the control group are > 50 years, no statistical analysis can then make the disease frequencies in the two groups comparable. The validity of the study is ruined. A bias can give a false-positive or a false-negative result in a study.

All epidemiologic studies may include minor bias that does not necessarily invalidate the study, but the researcher must discuss the potential lack of validity and its possible influence on the result.

8. INTERPRETATION OF EPIDEMIOLOGIC STUDIES

Results from studies may reflect a true relation or may be due to chance. For some studies, e.g. epidemiologic studies, the result may be biased. The researcher must, therefore, evaluate how convincing the results are:

In 1965, Sir Bradford Hill created nine viewpoints for judging causality, known as "Hill's criteria." As pointed out by Hill, "none of my nine viewpoints can bring indisputable evidence for or against the cause-and-effect hypothesis and none can be required as a sine qua non." However, the criteria have become classic, and are still widely used to structure the discussion in an epidemiologic study. The criteria are:

- Strong association: the stronger the association the more credible is the causality, but a weak association can also be causal.
- Consistent evidence: the consistency of evidence (other researchers have found the same association) speaks in favor of causality. This is a simple way of using *a priori* knowledge.
- Specificity of the association: for multi-causal diseases this criteria is less relevant or event wrong.
- Temporary: the cause must precede the effect.
- Biological gradient : a dose–response relationship speaks in favor of causality.
- Biological plausibility: biological plausibility speaks in favor of causality.
- Coherence of evidence: if experimental work and theory support en epidemiologic finding, the evidence for causality is corroborated.
- Experimental evidence: a change in morbidity after a change in exposure supports causality. This criterion refers to intervention studies.
- Analogy: reasoning by analogy can help judge causality.

A discussion of the criteria and their limitations is included in the original paper by Hill (1995) and in several textbooks of epidemiology, for example the two textbooks mentioned in the References.

However, the researcher must, therefore, give detailed descriptions of the definitions of exposures and diseases, the persons included in the study and how they are selected, the study design, and the statistical methods. The information must be given in such a way that the reader can evaluate the study and form an independent judgement of the study. Also the researcher may use Hill's criteria for inspiration.

Occupational Health and Ergonomics

P. Mairiaux

School of Public Health, Université de Liège, Liège, Belgium

1. INTRODUCTION

Most industrialized countries have set up well-organized occupational health (OH) services, sometimes since the beginning of the twentieth century, as part of a health-at-work protection policy, and similar services are being developed in a rising number of industrializing countries all over the world. When considering the aims assigned to these services by public authorities, an obvious shift has been observed during the two last decades of the twentieth century from screening for occupational diseases (secondary prevention) towards assessment activities at the workplace (primary prevention). A growing number of OH professionals are thus involved in ergonomics activities, looking for a complementary training in ergonomics or even acting as full time ergonomics consultants. In this context, the present paper aims at analyzing the specific contribution that a professional having an OH background may bring to the development of ergonomics in enterprises. In order to avoid a compilation of general statements, the analysis will be focused on the potential role of OH professionals in the prevention of work-related musculoskeletal disorders (WRMSDs). This analysis will consider the two sides of any OH activity, the health surveillance on the one hand, and the monitoring of working conditions on the other hand.

When considering their preventive activities, the OH practitioners are facing one particular challenge: in occupational health they must avoid implicitly using the bio-medical model of health where disease is seen as the direct result of a pathogenic agent. Health must be viewed, instead, as a dynamic equilibrium between man and the environment. In this perspective, the prevention of WRMSDs should fundamentally be based on a conceptual model that integrates, in a balanced way, the influences of physical factors (force, compression, repetition, posture) and those of psychosocial factors such as lack of control, perceived stress, time pressure, (Hagberg *et al.* 1995; Inserm 1995). In this respect, the ergonomic approach offers an appropriate frame of reference, provided the user sticks to its true definition as a discipline which integrates knowledge drawn from the human sciences — and not only from work physiology or biomechanics — in order to match the task and the work environment to the abilities of people at work.

2. HEALTH SURVEILLANCE

2.1 Usefulness for prevention

The surveillance of workers' health, through tests and examinations, is still today one of the cornerstones of OH services activity and it is therefore worth analyzing its potential usefulness for the prevention of WRMSDs.

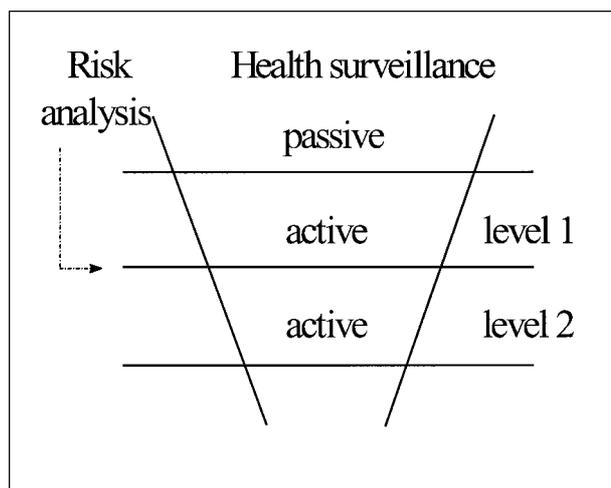
While the selecting out of susceptible individuals through pre-employment screening has been advocated as a *primary prevention* measure, everybody acknowledges today that there is


Figure 1. Levels of health surveillance.

no valid criterion, having a satisfactory predictive power, to be used for the selection of potential musculoskeletal sufferers (Inserm 1995). Hence, the preventive influence of health surveillance is clearly restricted to the two other components of prevention.

The early detection of tissue alterations, at a sub-clinical stage when possible, is called *secondary prevention* and forms the main objective of health surveillance systems. With regard to the WRMSDs, both the uncertainties in assessing the natural history of the disorder and the complexity, cost or invasive nature of some diagnostic techniques explain why cases are most often detected at a symptomatic stage. In OH services, the assurance of confidentiality to the worker consulting a health professional is a key factor in promoting the expression of individual complaints that otherwise could remain hidden due to the fear of consequences for the job holder. OH professionals are thus ideally located at the interplay between a man or woman and their job or task. At the population level, a WRMSD case identification can be considered as a "sentinel event" that points to the need for a risk assessment at the workplace and may result in preventive interventions beneficial to the whole group of exposed workers. The OH professionals may be seen as the eyes and ears of the ergonomics teams in the enterprise, quickly directing their attention to the problematic work areas.

Health surveillance thus provides, theoretically, one possible strategy for the identification of jobs at high risk of musculoskeletal disorders. Three levels of surveillance with increasing requirements are proposed to carry out such a system, while maintaining a satisfactory cost-effectiveness balance (see figure 1).

2.2. Passive Health Surveillance

The first level, or "passive" surveillance, involves the analysis of existing data related to the workers health: work accidents descriptions and diagnostic labels for sick leaves of long duration are two examples of data often collected on a systematic basis. Their treatment requires however a computerized and uniform codification, and the availability of data concerning the duration of exposure to the risk factors. If such is the case, the statistical analyses may allow the OH professional to point out in the company a given department, or job title, as exhibiting a higher prevalence of the WRMSD under study (Chatterjee 1992; Hagberg *et al.* 1995).

2.3. Active Health Surveillance

An "active" surveillance system collects health data independently of seeking care behavior of the worker. In the "funnel-shaped" approach illustrated in figure 1, this active surveillance is directed towards the jobs associated with a potential risk, as estimated from the passive surveillance results and/or the risk analysis (see below). Level 1 of such a system involves the periodic administration of standardized survey questionnaires, as for instance the Nordic one, in order to collect complaints and symptoms. Providing precise criteria are defined to assess the diagnostic probability and the severity of the symptoms, possible cases of WRMSDs can be identified through the analysis of the survey data. Those cases can then undergo a thorough examination by qualified OH professionals, this being considered as level 2 of the system. Such a stepwise approach should diminish the bias observed with the traditional medical surveillance when the identification of a potential case of a WRMSD is most often depending on the severity of symptoms at the time of the examination and/or the practitioner interest for this specific category of disorder. From a cost-benefit point of view, this approach is also attractive as it requires the intervention of highly qualified OH professionals for a limited and selected number of cases. It is fair, however, to point out that this new approach still has to be assessed in order to establish its sensibility and predictive value (Ansi 1995), and that its use by the practitioner implies the availability of a set of validated case definitions for the various WRMSDs.

3. RISK ANALYSIS AT THE WORKPLACE

In most countries, labor regulations and health and safety guidelines put a growing emphasis on hazard control at the design stage and on risk analysis (EEC 1989; Ansi 1995). The OH professional is thus invited to devote an increasing part of his time to the evaluation of risks in a multidisciplinary approach, alongside other professionals such as the ergonomist.

3.1. A Structured Approach

As the effectiveness of these risk evaluation activities may be a matter of concern, the practitioner is strongly advised to choose a step by step, pyramid-shaped, approach (see figure 2), like the one suggested for health surveillance.

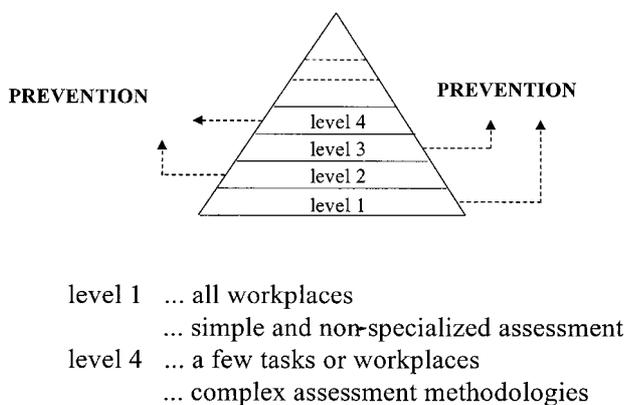
level 1 ... all workplaces
      ... simple and non-specialized assessment
level 4 ... a few tasks or workplaces
      ... complex assessment methodologies


Figure 2. Hazard surveillance.

The first step (level 1) aims at the identification of workplaces or departments involving, with a high probability, a known hazard or risk factor (i.e. manual handling, repetitive movement). This assessment of risk sources would be better carried out by a production manager or technician who would collect the relevant data (process flow, handled tonnages, cycle time, nature of tools used) following the guidelines given by the OH professional.

The second step of the evaluation involves a quick ergonomic assessment for each workplace so identified, based on an observation of the job, but without specialized measurements. This assessment aims at the screening of any task inducing a hazard for the musculoskeletal system. In order to ensure a satisfactory comprehensiveness and reproducibility to this phase, several risk assessment guides or checklists are available for screening of the whole body, back, or upper limb WRMSDs. These evaluation guides allow a simplified risk estimate to be drawn (for instance, no risk, possible, or significant risk) and can easily be used by any practitioner having a basic training in ergonomics. When completed, this screening helps the practitioner in establishing a list of priority tasks that require the selection of redesign measures or, in some cases, further and more detailed analysis (level 3). From an ergonomics point of view, there is in fact no reason for going further than the level of analysis needed to identify the hazard source and to define practical redesign solutions.

When needed, the third step of the risk analysis is used to identify more precisely the risk factors in order to guide the search for corrective actions, and to establish a reference basis for later evaluation of the results obtained. More resources concerning the time and qualifications needed are often required at this stage of the analysis, but in practice the complexity of the methods to be used will vary from one situation to another. A postural evaluation using the OWAS method, an evaluation of a load-lifting task through the NIOSH method, or a detailed analysis of the working cycle do not require complex measurements and can thus be performed by any qualified OH professional. In other situations, cinematic variables or EMG data may have to be registered (level 4 of the analysis) by external experts. In practice, however, the need for such complex analyses remains rather infrequent, and more so when the risk assessment is considered not as a purpose in itself, but as the best means to guide preventive measures. In that respect, the implementation of an integrated and participatory approach provides a basic and complementary way towards the definition of solutions.

4. ERGONOMIC INTERVENTIONS AT THE WORKPLACE

How can the identified risks be lowered? The various preventive measures that can be undertaken on technical, behavioral, and organizational grounds have been described in several reference documents (Kilbom 1994; Hagberg *et al.* 1995) and the scientific knowledge that supports them, although far from being extensive and undisputed, may be considered sufficient to initiate actions. It is no doubt more important to discuss the most appropriate strategies to implement these ergonomic actions at the workplace.

4.1. Should One Favor "Micro-ergonomic" or "Macro-ergonomic" Actions?

A micro-ergonomic intervention focuses on decreasing, for instance,

the physical stresses in a high-risk job, but without acting "upstream" on the work organization. For various reasons, this is still the type of action that the OH practitioners most often carry out. Even though such corrective interventions may actually bring up positive results, their cost-effectiveness ratio is low and they have a limited influence, if any, on the organizational causes of the observed problems. From the OH professional point of view, however, they may be a necessary step in a building expertise process. Conversely, several reasons should lead the practitioner to integrate his prevention activities within a larger (macro-ergonomic) framework and to assume a prevention manager role within the company structures. A first reason relates to the multidisciplinary training of the OH professional and to his position as an independent adviser that could both help him in advising managers as well as workers about risks. A second reason originates in the rapid changes occurring in modern manufacturing: how could the practitioner be aware of the planned changes and anticipate their potential health effects when he is not part of the enterprise management? The third reason is likely to be the most essential: the prospects for success of any ergonomic intervention program in an enterprise are strongly enhanced when the program is fully integrated within the methods, resources, and structures of the enterprise (Wilson 1994).

4.2. OH Professional Strengths and Weaknesses

When considering the possible role of OH professionals in ergonomic interventions, some difficulties should not be overlooked. As mentioned earlier, an OH professional may obtain a valuable and unique knowledge of some features of the working conditions thanks to the trust relationship built with the workers and to the confidentiality warranty. The social status of the medical profession may also give some advantage when discussing the risks with the management. This same social status may, however, preclude an effective integration of the OH professional within the enterprise organization and culture — and this integration is a pre-requisite for intervention at the macro-ergonomic level. Another frequently encountered weakness concerns the OH professional's expertise in ergonomics and in intervention strategies that, on average, often remain insufficient.

4.3. Effect of New Trends in Production Management Schemes

It can be questioned, however, whether the starting up of ergonomics programs in workplaces is made easier or, conversely, more difficult by new trends in production management schemes. Flexibility and competitiveness requirements directly influence the workers exposure to risks; the increase in time pressure and the sharing of a given amount of work between fewer individuals can be viewed as two key explanatory factors for the observed rising trend in WRMSDs prevalence. In a more indirect way, musculoskeletal complaints may also be considered as an expression of the workers suffering in modern working environments. On the other hand, other management trends, especially the Total Quality Management concept, could provide a more favorable framework for taking health issues into account in production systems. This seems to be a real opportunity for the OH practitioner who wishes to implement an integrated prevention program (Hagberg 1995; Rahimi 1995).

4.4. What Are the Benefits from Using a Participatory Intervention Approach?

Participation means the involvement of people in planning and controlling their own work activities, with sufficient knowledge and power to influence the expected outcomes. The advantages of participation most often talked about are, among others: to make use in the design process of the workers knowledge on the actual work activity; to give a better chance of solution acceptance and effective use by the workers; to stimulate through the participatory approach itself worker involvement in a process of continuous improvement (Nagamachi and Imada 1995; Wilson 1995). Whereas participation has always been a key feature of ergonomics, the present renewed interest for this approach results from its increasing use (i.e. quality circles) in current businesses which invest heavily in the training and supervision of the participatory teams members. This trend is another example of a strategic opportunity upon which the OH professional could build preventive processes that would be part of the existing participatory structures.

4.5. Which Ergonomic Intervention Programs Are the More Successful ?

Several published studies have shown that a carefully planned intervention may result in a significant lowering of the level of physical risk factors, such as, force, posture and repetition (Chatterjee 1992; Keyserling *et al.* 1993; Wickström *et al.* 1993). It would be unrealistic, however, to expect a decrease in the risk level to have a systematic influence on the WRMSDs prevalence (Wickström *et al.* 1993), taking into account for instance the long-lasting exposure of middle-aged workers that often form a "survivor" group. When the intervention does result in a decrease of registered cases, or in sickness absenteeism, most authors avoid ascribing their success to the sole ergonomics improvements; quite often the intervention involves indeed other components (workers training, physical conditioning, participatory approach, etc.) or is accompanied by significant changes in work organization or in the company socio-economical environment. From a scientific point of view, interventions directed towards a single risk factor should thus be given preference. However, studies in "real-life" situations have shown that interventions which combine prevention measures of different character, such as equipment redesign *and* job enlargement, or ergonomic redesign *and* training in safe handling, prove to be more effective (Inserm 1995). On the basis of published studies, several guidelines can be suggested in order to set up preventive interventions:

- implementing the preventive actions within the company management scheme thanks to a clear and continuous commitment from the top management;
- stimulating risk identification and problem-solving procedures at the shop floor level using participatory techniques;
- combining individual-level and organizational-level prevention measures, and considering the risk factors within a system approach.

5. CONCLUSIONS

In a constantly changing economic world, the control of WRMSDs and other work-related health disorders poses a new challenge to the OH practitioner. In order to face it, should the OH

professional shift to another job and become an ergonomist? We do not think so, for his specific expertise is needed more than ever, especially when considering the worker health surveillance. Today's needs, however, do require that each professional casts a fresh look at his job. In this new vision, the OH professional has an important role to play in:

- hazard identification through passive health surveillance;
- risk estimation providing an appropriate training;
- initiation of participatory redesign approaches.

The OH professional will strive to fit his actions into the management policy of the company and will try to build solid bridges with other prevention professionals and especially professional ergonomists. Owing to this redefinition of his activities, goals and means, the OH professional could then keep on playing his fundamental role towards the promotion of the health of people at work.

Occupational Injuries and Medication Use

F. Baptista, P. Moro, B.–T. Karsh, F. Sainfort and M. J. Smith
Department of Industrial Engineering, University of Wisconsin-Madison, Madison, WI53706, USA

1. INTRODUCTION

Work injuries are due to multiple causal factors. These factors include management commitment to safety, the hazards in the physical environment, safety features of equipment design, the hazard aspects of the work, and the social and psychological environment at the work place. Individual health status and behavior also play an important role in injury risk. For example, disorders that affect coordination or cognitive processing can increase one's risk of injury, as can behaviors such as alcohol, drug and medication use. With so many factors leading to increased injury risk, it is not surprising that the numbers of occupational injuries are quite high.

2. INJURY STATISTICS

According to the International Labour Organization (ILO), ~250 million workers worldwide are injured annually on the job and ~335 000 workers die each year from occupational injuries. These work-related deaths and injuries have enormous costs. In the USA alone, it was estimated that in 1992 that the direct costs (e.g. medical, property damage) totaled $65 billion and the in-direct costs (e.g. lost earnings, workplace training and re-staffing, time delays) totaled $106 billion (Leigh *et al*. 1997). Those figures can be used to get a rough estimate of the total world cost of fatal and non-fatal occupational injuries in US$. Of the US$ figures presented, ~$230 million of the direct costs and $3.46 billion of the indirect costs were related to fatal occupational injuries. Non-fatal injuries accounted for $48.9 billion in direct costs and $92.7 billion in indirect costs (the rest was cost was due to death and morbidity from occupational illnesses). Those figures were based on 6500 occupational fatalities and 13.2 million non-fatal injuries.

Those figures, combined with the ILO global estimates of 335 000 fatal occupational injuries and 250 million non-fatal injuries, translate to $11.9 trillion in direct costs and $178 trillion in indirect costs from worldwide fatal occupational injuries and $927 trillion in direct costs and $1.8 quadrillion in indirect costs for worldwide non-fatal occupational injuries (and that does not include death and mortality from occupational diseases). Given this, it is important to understand the many factors that can cause occupational injuries so that industries can focus on prevention. One of these potential causes is the sedation, dizziness, or drowsiness that results from using many common medications.

3. IMPORTANCE OF MEDICATION USE FOR OCCUPATIONAL INJURIES

According to the 1998 World Health Report, the population of the world will increase by ~80 million people per year, resulting in a year 2025 population of 8 billion. By that time, the ratio of people > 65 to people < 20 of age will have grown to 31/100, when it was only 16/100 in 1995. That represents a growth in

Table 1. Examples of medications that can affect injury risk.

Indication	Medications (examples)	Clinical uses	Possible side-effects
Anti-anxiety	benzodiazepines	anxiety nervousness phobia panic	drowsiness loss of coordination fatigue mental slowing
Anti-manics	lithium carbamazepine (anti-convulsant)	bipolar disorders mania	drowsiness weakness fatigue hand tremor confusion
Anti-depressants	tricyclic compounds monoamine oxidase inhibitors selective serotonin re-uptake inhibitors	depression	drowsiness blurred vision dizziness
Anti-psychotics	phenothiazines thioxanthenes	schizophrenia	drowsiness dizziness rapid heart beat
Cardiovascular problems	angiotensin converting enzyme inhibitors anti-arrhythmics calcium channel blockers digitalis glycosides	heart disease hypertension angina cardiac arrhythmia congestive heart failure	loss of postural control tiredness dizziness
Pain	hypnotics (e.g. narcotic analgesics)	pain	drowsiness mental clouding sedation reduced alertness
Anti-histamine	diphenhydramine	allergic rhinitis common cold	drowsiness dizziness

the number of people > 65 year of age from 390 million in 1998 to ~800 million in 2025. Related to that, the numbers show that chronic disabling conditions such as coronary heart disease and poor mental health will continue to be major health problems for the entire population. About 15.3 million people die from circulatory diseases, of which ~7.2 million are from coronary heart disease. Also, the report projected that ~340 million people will suffer from depression. Many of these heart and mental conditions, as well as other common conditions, are treated with prescription and non-prescription medications than can cause sedation, dizziness, fatigue and other types of side-effects (table 1). With the aging of the workforce we expect an increase in the disorders associated with aging, and a subsequent increase in the use of medications.

4. MEDICATIONS THAT CAN AFFECT INJURY RISK

4.1. Anti-anxiety Medication

Anti-anxiety medications are used to treat generalized anxiety, panic, phobias, obsessive-compulsive disorders and post-traumatic stress disorders. The most popular, benzodiazepines (e.g. valium), represent the biggest share of the total world utilization of psychotropic drugs. Benzodiazepines may cause drowsiness, loss of coordination, fatigue, mental slowing and confusion. They have been shown to affect psychomotor and cognitive performance, and may specifically affect memory function.

4.2. Bipolar Disorder Medication

People suffering from bipolar disorders (manic-depressive illness) use anti-manic medication to treat the "highs" experienced. Lithium is most often used against these "highs." Lithium side-effects include drowsiness, weakness, nausea, vomiting, fatigue and hand tremor. Anti-convulsants are also sometimes prescribed for manic conditions, and may cause such side-effects as drowsiness, dizziness, confusion, disturbed vision, perceptual distortions, memory impairment, nausea and gastro-intestinal problems.

4.3. Anti-depressant Medication

Anti-depressants are typically suggested for people who are depressed for > 2 weeks and where the depression interferes with their ability to function normally. Tricyclic anti-depressants may cause side-effects such as drowsiness, anxiety, restlessness, blurred vision, dry mouth, constipation, weight gain, dizziness when changing positions, increased sweating, fatigue and weakness. Side-effects for other types of anti-depressants, such as monoamine oxidase inhibitors, include headache, insomnia, anxiety and dizziness when changing positions. Depressed patients taking anti-depressants have shown impaired information processing, learning, memory and tracking skills.

4.4. Anti-psychotic Medication

Anti-psychotics are used to treat people who have lost touch with reality, such as those suffering from disorders as severe as schizophrenia. This class of psychotropic drugs includes neuroleptics and major tranquilizers. Anti-psychotics may induce sedation, rapid heart beat, dizziness when changing position and can disrupt the capacity to focus attention. These effects typically disappear within days or weeks as tolerance builds up.

4.5. Cardiovascular Medication

Cardiovascular medication is used to treat problems like angina, hypertension and arrhythmia, etc. The link of cardiovascular medications to falls and injuries is not completely understood. Some cardiovascular medication (vasodilators, anti-hypertensives, diuretics, digitalis glycosides and some b-blockers) may affect a person's postural control or impair cerebral perfusion, which can lead to balance disorders. Calcium blockers are known to cause side-effects such as hypotonia, tiredness and dizziness, which can lead to injurious falls. Drugs that improve peripheral circulation cause vasodilatation of peripheral arteries. That may cause orthostatic hypotension and dizziness, thereby leading to falls.

4.6. Pain Medication

Analgesics (pain-relieving drug) come in two classes: anti-pyretic analgesic (aspirin) and narcotic analgesic (derived from opium, such as morphine and codeine). The former is used to relieve minor pain and reduce fever. There is no evidence that anti-pyretic analgesics affect performance, but the anti-arthritic type has side-effects such as dizziness and mental confusion. Narcotics do not produce motor impairment, but may produce drowsiness and mental clouding. Hypnotics produce sleepiness and reduce alertness. Patients using hypnotics often complain of reduced functioning in the morning following night-time use.

4.7. Anti-histamine Medication

Anti-histamines are the most popular forms of medication taken to prevent allergic rhinitis (i.e. hay fever) symptoms. Currently, there are two "generations" of anti-histamines in use. The first-generation anti-histamines differ from the second-generation in that the latter medications are considered to be non-sedating or less sedating, while the former cause sedation in 10–25% of users. Other possible side-effects of first-generation anti-histamines include, depending on the drug, blurred vision, gastro-intestinal problems, restlessness, nervousness and loss of appetite. first-generation anti-histamines may also cause dry mouth, and they are subject to tolerance development more so than are the second-generation anti-histamines. Second-generation anti-histamines may cause loss of appetite; however, they seem to be free from causing blurred vision, gastro-intestinal problems or dry mouth.

5. EVIDENCE OF INJURY RISK FROM MEDICATION

Studies have been conducted that have shown that certain medications can increase the risk of injury. Much of the research has focused on falls in the elderly population and non-work injuries among the general population. From those studies there is evidence that medications increase the risk of non-occupational injuries. Since members of the workforce use many of the same medications, one can extend those results to suggest that medication use would also be related to occupational injuries. In fact, the few studies examining occupational injuries confirm this. What follows is a summary of the evidence linking medication use to injuries. Quantitative ranges are provided that indicate the risk of injury associated with each type of medication that have been found in the different studies. The reason that ranges of risk exist for any given medication is because the various studies used an array of methodologies and often examined different types of injuries.

Research that has focussed on whether anti-anxiety medication affects the risk of injury has examined fall injuries in both the elderly and general population. It appears that people have 1.3–3.3 times the odds of being injured if they have taken anti-anxiety medication. Studies of anti-depressant medication have examined the risk of motor vehicle crashes in the elderly and of falls in the elderly and general population. The research consistently shows that people in the samples that used anti-depressants had 2.3–2.4 times the odds of injury compared with those that did not take anti-depressants. Scientific evidence also shows that nursing home residents and adults in the general population who have taken anti-psychotic medication have 1.3–2.0 times the risk of falling compared with people who had not taken such medication.

Cardiovascular and circulatory medications have been linked to the risk of falls in long-term care patients and to work injuries in male farmers. In the former group, the increased risk is in the range of 1.3–2.2, whereas farmers who used such medication were found to have 4.2 times the odds of becoming injured compared with farmers who did not use such medication. Studies of pain medication have investigated the risk of motor vehicle crashes in the elderly and of non-work injuries and falls in the general population. The results of these studies show that hypnotic or analgesic users have a 1.3–2.9-fold increase in the odds of getting injured or crashing. A similar increase in the odds of injury has been found for sedating anti-histamine users (i.e. 1.5–2.8). Other research has shown that antibiotics, stomach medication (e.g. laxatives), anti-inflammatory and anti-diabetic medication may also increase one's odds of injury. The relationships between medication use and injury risk may be affected by gender, age, medication dose, tolerance development and interactions with other medications.

6. IMPLICATIONS

In summary, there is empirical evidence that the medications reviewed can contribute to balance, psychomotor or cognitive impairment and, therefore, increase the risk of occupational injury. This is not to suggest that people should stop taking their medications to avoid getting injured. Instead, there needs to be increased awareness of the potential problems related to the use of certain medications. This awareness should lead employees and physicians to seek medications that have fewer problematic side-effects.

Occupational Injury

A.-M. Feyer

New Zealand Occupational and Environmental Health Research Center, University of Otago, P. O. Box 913, Dunedin, New Zealand

1. INTRODUCTION

Global estimates of the occurrence and cost of occupational injury are staggering. According to International Labour Office (ILO) estimates, ~250 million accidents resulting in injury occur annually in workplaces worldwide. Of these, 335 000 are fatal accidents, an estimated rate of 14 per 100 000 workers annually. Not surprisingly, the rates are different for individual countries and regions. The annual fatal occupational injury rate for established market economies has been estimated by the ILO as ~5/100 000 workers while the rate for the Asian region, where there has been a relatively rapid and unregulated pace of industrialization, is much higher, ~23/100 000 workers.

The cost to society of occupational injuries is also clear when one considers the problem relative to other health problems. Injuries in general are a leading cause of hospitalization and premature death (measured as potential years of life lost) in most countries. Occupational injuries represent a substantial part of the entire injury problem. In the USA, it has been estimated that one out of three non-fatal injuries and one out of six fatal injuries to working people occur at work (Baker *et al*. 1972).

The economic burden imposed by occupational injury on nations, companies and individual is high. In the USA, the total economic burden imposed by occupational injuries have been estimated at ~US$120 billion per year (National Safety Council 1996). In New Zealand, with a populations of ~3.5 million people, the current costs of occupational injury compensation claims alone (excluding occupational motor vehicle injuries), have been reported as being ~$700 million annually (Accident Compensation Corporation 1998).

Overall, it is fair to say that occupational injury is a major preventable health problem. Reducing the frequency and severity of occupational injury relies on knowing who gets injured, what happened, where it happened, when it happened and why it happened. This chapter deals with the definition of occupational injury, assessing the size, distribution and nature of the problem, and understanding its causes.

2. DEFINITION OF OCCUPATIONAL INJURY

The terms "accident" and "injury" have sometimes been used synonymously, particularly when considering prevention. However, they are in fact quite distinct. An accident can occur without injury, and not all injuries are "accidental", that is unintentional. For example, the third leading cause of fatal occupational injuries in the USA is homicide (Jenkins *et al*. 1993).

Injury is defined as tissue damage from transfer to individuals of one of the five forms of energy (kinetic or mechanical, thermal, chemical, electrical or radiation). By far the leading cause of injury is the transfer of mechanical energy. Negative energy, or the absence of energy, is also a possible source of damage, when the body's normal energy exchange is disrupted, for example, lack of oxygen resulting in drowning.

This definition is not as clear-cut as it might appear, however.

Exposure to energy (e.g. radiation) can be low level and gradual, resulting in disease (e.g. cellular change resulting in cancer), or it can be rapid and high level, resulting in injury (e.g. burns). In other words, damage as a result of energy transfer is best thought of as a continuum ranging from injury to disease. Of course, some occupational health outcomes are difficult to classify because they seem to fall somewhere between injury and disease, cumulative trauma disorders and low back pain being prominent examples.

At the international level, there is only partial agreement on the definition of what constitutes an occupational injury. The ILO defines occupational injuries as covering all injuries resulting from accidents arising out of or in the course of employment. There is little disagreement about the fact that an accident in the course of work that results in injury is a work-related event, an occupational injury. However, there is wide variation internationally about including other important possible categories of occupational injury. Specifically, these include traffic-related injuries (both where the vehicle is the workplace and when commuting to and from work), intentional injury, injuries to non-employed people undertaking work (e.g. family members involved in farming work) and injuries to bystanders (those injured in the course of someone else's work).

These differences in definition are not trivial, when the contribution of some of the contentious categories is considered. Motor vehicle related occupational injuries, for example, have been estimated as being around one-fifth to one-quarter of all occupational injury deaths. Many of these injuries will occur where the vehicle is the workplace, e.g. truck-driving, or when the injury is sustained in a traffic accident during the course of paid employment, where the worker is carrying out work on his employer's behalf e.g. obtaining supplies. There would be little dissension about these being occupational injuries. There is less consensus about commuting injuries, where the sole purpose of travel is work-related. Commuting injuries are defined as injuries sustained on the way to or from work, when the worker is travelling between work and (1) a second job, (2) where meals are taken or (3) principal place of residence. Yet commuting injuries would certainly appear to be covered by the spirit of the ILO definition of occupational injuries described above. Moreover, indications are that commuting injuries may represent a sizable part of the whole problem. In Australia, 17% of all fatal occupational injuries occurred while commuting to and from work (National Occupational Health and Safety Commission 1998).

Another important but contentious category relates to injuries as a result of intentional harm. Again, it can be an important part of the problem. As noted above, in the USA, homicide is the third leading cause of fatal occupational injuries.

3. ASSESSMENT OF THE SIZE, DISTRIBUTION AND NATURE OF THE PROBLEM

Despite definitional issues, and the difficulties that they present for international comparisons, there is agreement that information about occupational injury should be collected at national and jurisdictional level. Most countries attempt to assess the size, distribution and nature of their occupational injury problem.

3.1. Surveillance of Occupational Injury

Surveillance is the ongoing systematic collection, analysis and

interpretation of health data in the process of describing and monitoring a health event. Accurate and reliable data concerning occupational injury are central to prevention efforts: they provide an evidence-based approach to priority setting, they provide the essential starting point for development of new injury prevention strategies and they provide information for evaluation of existing efforts.

In principle, injury surveillance data can provide a view of the distribution of cases of injury and of the types of injuries incurred and their severity for different occupations and economic activities. From such information priority areas can be determined in terms of areas of greatest risk of the most serious types of injuries, or of areas where the probability of injury is high, or of areas where large groups of people are exposed to risks, or some combination of these. Areas of greatest risk can thus be targeted by prevention efforts, safety campaigns, enforcement activities and new legislative initiatives. In practice, the level of specificity of the information collected in most places undermines the potential of the data. Recommendations for the minimum data set to be collected from the ILO are as follows:

- information about the employer (geographic location; economic activity; size of the establishment);
- information about the person injured (gender; age; occupation; status in employment);
- information about the injury (whether fatal or not; if not fatal, amount of work time lost; nature of the injury; bodily location of the injury); and
- information about the events leading to injury (geographic location; date and time; action(s) leading to the injury; agency [object, substance or physical condition] involved in the incident and injury).

Ideally, injury data should cover all occupational injuries incurring loss of working time. In principle, data sources for occupational injury surveillance include health care providers (hospitals and physicians), death certificates, medical examiner/coroner files, employer-based reporting to relevant government departments e.g. departments of labor, workers' compensation/ accident compensation agencies, periodic surveys of households and even individual corporate records. In practice, although law requires many of these records, they still provide only incomplete information in most countries. For example, examination of coverage of working deaths in Australia revealed that 36% of the total were covered by occupational health and safety agencies, that 57% of the total were covered by compensation agencies, and that one third of working deaths were not covered by either mechanism (National Occupational Health and Safety Commission 1998).

Lack of coverage stems from various sources. Even in the best of systems, it is recognized that there are incentives to under-report. Besides under-reporting, certain types of workers may fall outside the requirements for notification, such as those working at home, part-time workers, trainees, those outside working age. Compensation schemes also tend to be focused on employees, and tend to only partly cover certain economic activities, for instance agriculture and small business establishments.

3.2. Outcomes of Interest

From the point of view of surveillance, both the occurrence of injury and severity of injury are important outcomes. Injury severity involves a number of quantifiable dimensions. These include anatomical (the amount and nature of tissue damage), physiological (vital signs to determine how close to death the injured person is), disability, impairment of quality of life and direct and indirect economic costs. All of these outcome measures provide different parts of the whole estimate of the size and nature of the injury problem. Perhaps the most used, but possibly the least useful severity dimension is days lost from work following injury. Lost work time is often difficult to interpret because it usually involves a combination of a whole range of injury and non-injury variables. These can, but need not, include such factors as anatomical severity, extent of disability, job demands, availability of alternative duties, workplace policies, job satisfaction and so forth. Amount of lost time alone will not identify which factors are involved, making implications for prevention difficult to pinpoint.

3.3. Comparative Measures

Sound comparisons between periods, industries and countries can only be made if the injury data are considered in the context of the total number of people at risk. Injury data should be expressed as a rate, relative to the number of persons in various relevant reference groups. There are several reference contexts that provide meaningful relative measures. The most common reference data are the total employed labor force and the total number of hours worked by the labor force (to account for the mix of full- and part-time work) or the same sort of data for specific subsegments of the working population (e.g. different occupations). The important feature of obtaining such relative measures is that the numerator (injured persons) and the denominator (reference data of exposed persons) should have the same coverage. An illustration of the importance of this requirement is the calculation of the relative risk of injury for those who work at night compared with those who work during the day. Far fewer workers are at work at night and the calculation of rate of injury should reflect this.

3.4. Using Occupational Injury Data

Despite the shortcomings of surveillance and occupational injury data around the world, distinct patterns of injury risks have been identified. Occupational injury like other health outcomes have distinct patterns of risk that vary by age, gender, race, geographic region, industry and occupation. In Western industrialized countries, those working in agriculture (including hunting, fishing and forestry), mining and quarrying, construction, transport and manufacturing have consistently been shown to be at highest risk of injury. Overall, male workers are at greater risk of occupational injury. Younger workers (< 25 years) have typically been shown to be at greater risk of non-fatal injury, while older workers (> 65 years) have been shown to be at greater risk of fatal injury.

Surveillance data provide important starting points for injury prevention: they identify in general terms who gets injured and where, when, and how people are injured. However, they are limited in providing information about why people get injured, that is, in identifying the causes, processes and mechanisms leading to the injury event. Knowledge of causation is critical to identifying ways of reducing and preventing injury events.

Different models of injury causation suggest different targets and strategies for prevention of injury.

4. MODELS OF OCCUPATIONAL INJURY CAUSATION

While many causal models have been proposed, in general terms there have been three key shifts in emphasis.

4.1. Person-based Single Cause Approaches

In the 1940s, the dominant model proposed the notion of fault on the part of workers precipitating either unsafe acts and/or (less commonly) unsafe conditions. The quintessential example of this type of approach is the Domino theory proposed by Heinrich (1941). The approach was weak because it focused on immediate precipitating causes, assumed a single cause and equated attribution of fault and identification of cause. It provided a fairly narrow view that restricted options for preventive efforts.

4.2. Epidemiological Approaches

The epidemiological approach, prominent in the last two to three decades, takes a multifactorial view of injury causes and prevention options. Injury is seen as being caused by the impact of four factors:

- the host: the injured person;
- the agents of injury: the various forms of energy which, when transferred to the host in sufficiently high levels result in jury;
- the vectors/vehicles of injury: the environmental mechanisms/factors which convey damaging energy to the host; and
- the environment: the physical and social environment in which the transfer of energy occurs.

The approach also advocates that there should be systematic consideration of all possible prevention options: those that reduce injury occurrence, those that reduce injury severity and those that reduce disability resulting from injury. The choice of countermeasures should not be determined by the relative importance of causal factors; rather priority should be given to options that reduce injury or its consequences. The focus on injury control very much reflects the public health model, historically successful in disease control, from which this approach emerged.

One of the most influential tools for analyzing injury risk factors multifactorially and guiding the choice of injury control strategies was that proposed by Haddon (1968). In fact, this work is to a large extent synonymous with the epidemiological approach. The Haddon matrix has two dimensions: one dimension reflects the epidemiological model of causation and divides causal factors into host, vehicle/vector and environment; the other dimension divides the injury event into three phases, the "pre-event", the "event" and the "post-event" phases. Pre-event factors are ones that influence the risk that an event leading to injury will take place (e.g. poor machine maintenance, a vehicle/vector factor). Event factors affect the risk of injury once an incident has occurred (e.g. lack of personal protective equipment, a host factor). Post-event factors influence the risk of disability and death, once an injury has occurred (e.g. availability of emergency services, a social environment factor).

This type of injury causation model is still the cornerstone of public health approaches to occupational injury prevention today. The analysis does not center on causation *per se,* but on ways of reducing undesirable end results. Thus, the use of machine guards and electrical shielding can prevent injuries regardless of the reasons people come into contact with these potentially harmful agents. The strength of the approach lie in the fact that it highlights effective injury control strategies. Its weakness lies in the fact that it provides only limited insight concerning the process or mechanisms leading up to the injury event. Thus while the approach has identified many effective strategies for controlling injury, the approach has been less useful in identifying ways of actually preventing the process leading to harm. Safety professionals generally agree that as well as controlling injury, more needs to be done to prevent the undesired events and incidents from happening in the first place. This may be the main prevention option available in situations where the hazard actually comes from the interaction of the worker and their work environment, rather than any inherent hazard associated with one or the other, or both.

4.3. The Systems-based Approach

The other recent development in injury causation models has been the use of a systems-based approach to occupational safety (e.g. Feyer and Williamson 1991, Kjellen 1998). A system in this regard can be seen as a set of independent components combined in such a way as to perform a given function under specified conditions. In this light, work and workplaces are dynamic interactive systems with workers, work tasks, work equipment and work environment (physical and organizational) all being part of the system. A major advantage of such models over previous approaches is that they focus on dynamic interactions between injury causal factors and they are therefore better able to identify processes and mechanisms leading up to injury events.

The conceptualization of a work system (with an emphasis on interaction between its components) is characteristic of a human factors approach to injury causation, and has been much more influential than the injury control approach in identifying ways of actually preventing the process leading to harm (e.g. Feyer and Williamson 1998). This approach does not replace the epidemiological injury control model, rather it compliments it. Perhaps its greatest strength has been that it has provided systematic ways of considering the human element in injury causation. The human element covers a wide range of factors involved in injury causation, some directly and some indirectly. These factors range from individual errors immediately precipitating injury events to human factors involved in a broader sense, taking the form of flawed standard operating procedures, management decisions and organizational culture and climate. Elaboration of the involvement of human factors other than human error in the immediate circumstances precipitating an injury represents a major advance in understanding why injury events actually happen.

Formal consideration of models of human error represents another advance through this approach. The critical role of human error has long been universally acknowledged, yet understanding of it in the context of injury causation has been slow to progress beyond documenting its ubiquitous presence. The systems-based

approach has contributed improved understanding of the nature, timing, causes and role of human error to models of injury causation (e.g. Feyer and Williamson 1998).

5. CONCLUSION

Occupational injuries and injury deaths are not random events but result from cause and effect relationships and are therefore predictable and preventable. In order to predict and prevent injuries, however, we need to systematically identify their occurrence, nature, characteristics and causes. There has been considerable refinement of the ways in which we define injury, the ways in which we describe who gets injured and how they get injured, and the approaches we use to better understand why injuries occur. In the future, it is clear that injury prevention and control will depend critically on the integration of the best that a range of disciplines has to offer: human factors and ergonomics, public health and epidemiology, industrial hygiene and physics. Collaboration between these disciplines will bring new insight to our understanding of injury causation and prevention.

and

T. K. Courtney

Harvard School of Public Health, Boston, MA 02115, USA

1. INTRODUCTION

Epidemiology is a set of established and developing methodologies used to describe the distribution and determinants of adverse health outcomes in human populations. The subsequent evaluation of interventions to prevent injury or disease is the ultimate objective of epidemiology.

2. FUNDAMENTALS OF EPIDEMIOLOGY

2.1. Fundamental Aspects of Epidemiologic Methods

People who develop a health condition tend to be exposed to antecedent risk factor(s) more than persons who do not develop the condition. Epidemiologic methods have evolved to approximate the effects of potential risk factors (also known as exposures) on health outcomes (such as injuries, disorders, diseases) in groups of individuals. Associations between exposures and outcomes may be causal or due to alternative explanations such as study bias, confounding or chance.

In epidemiology, study bias refers to some systematic error in study methods that precludes a clear judgment as to the nature of the association between the exposure and the disease outcome. For example, parents of children injured at home may recall certain exposures more thoroughly than parents of uninjured children. This *recall* bias may be estimated by comparing questionnaire responses to a "gold standard" source of information, perhaps a medical record or a direct observation of an exposure.

Confounding refers to the effect of an intermediary factor that is associated with both the outcome and the exposure. That is, the exposure–disease association may be artificially produced or obscured by this other factor. For example, any observed association between alcohol use and lung cancer is potentially confounded by cigarette smoking because many alcohol users also smoke.

Chance or sampling variability operates in most scientific research. It is a potential explanation for an observed association between an exposure and a disease outcome. It may be less likely, however, with larger sample sizes and as a study's findings are replicated by subsequent investigations.

2.2. Measures of Outcome Frequency

Important terms in interpreting and reporting outcomes in populations include incidence and prevalence. Incidence refers to the number of new instances of a health outcome in a population during a specified time period (Last 1988). For example, an *incidence rate* is defined as the number of new cases of a condition per persons at risk (usually 100 or 1000) per unit of time (usually one year). Prevalence is the count of all existing cases during a specified time period or point in time divided by total persons at risk. When not otherwise indicated, the prevalence usually reported is the *point prevalence* or the count of all cases in existence at one point in time.

2.3. Common Measures of Exposure–outcome Association

Epidemiologic data are often summarized in tabular form in the initial stages of analysis as the presence or absence of exposure to some potential risk factor and the presence or absence of a health outcome in a group of individuals. Table 1 presents the results of a hypothetical study of the effects of a single exposure on a health outcome. Each cell (a, b, c, d) contains the number of persons with a particular combination of exposure and outcome status. The data in these four cells are used to derive various measures of effect. Two common measures of the effect of exposure on outcome are relative risk (RR) and odds ratio (OR). These are calculated and interpreted below.

If 1000 persons *with* and 1000 persons *without exposure* are followed-up over a specified time period for outcome occurrence, the relative risk (RR) is found by dividing the risk in the exposed group (75/1000) by the risk in the unexposed group (25/1000). The result is 0.075/0.025 or 3.0. This means that this sample of exposed persons had three times *the risk or probability of developing the outcome* than unexposed persons over the specified time period.

If individuals are *selected on the basis of their outcome status*, the totals for the rows (a + b) and (c + d) are not predetermined. The relative risk can be estimated by calculating the ratio of the odds of exposure among cases (75/25) to that among controls (925/975) or ad/bc = 75 x 975 / 25 x 925. The resulting odds ratio (OR) of 3.2 is close to the RR of 3.0 found above. The OR is interpreted to mean that the cases are 3.2 times more likely to have been exposed than non-cases.

Any estimate of effect varies within a range of values that is termed a confidence interval (CI). The CI depends on the magnitude of the estimate, the specified probability of including

Table 1. Data from hypothetical epidemiologic study.

the true value of the estimate (usually 95%) and the sample size in each of the four cells of the table (the larger the sample, the smaller the range of the interval). For example, the 95% confidence interval for the calculated OR from the study above ranges from 2.1 to 4.9 (for details of CI calculation and underlying assumptions, see Hennekens and Buring 1987: 255). This means that if the same study was repeated 100 times, 95 out of 100 times the true OR would lie between 2.1 and 4.9. If an OR = 1.0, then there is no observed effect of the exposure on outcome status. Because the interval calculated previously did not include the null value (1.0), the CI indicates that the association is statistically significant. If the 95% CI covered 0.9–7.1 the result would not be statistically conclusive but strongly suggestive of an effect since most of the interval is above 1.0. If the point estimate and the interval are below 1.0, (e.g. 0.3, 0.1–0.5), then the exposure significantly protects against the outcome.

2.4. Epidemiologic Study Designs

The techniques illustrated above are applied to the study of exposure and outcome associations. As with most scientific inquiry, however, the techniques are merely assets supporting the execution of a study design. There are two main classes of study design in epidemiology: descriptive and analytic. Descriptive epidemiology describes *how* an outcome such as an injury or disorder is distributed in a population; analytic epidemiology tries to explain *why* (Kelsey *et al.* 1989). A brief description of each design, with examples, follows. More specific information about epidemiologic study methods can be found in standard introductory texts (Kelsey *et al.* 1986, Hennekens and Buring 1987).

2.4.1 Descriptive studies
2.4.1.1 *Case report and case series*
The case report is the complete description of the clinical characteristics of a single patient. The single patient may present some unusual finding that can suggest the need for a larger study of an exposure-outcome relation. Case series describe the clinical characteristics of two or more patients with a health outcome and perhaps an exposure in common. An advantage of the case series is that multiple observations allow compilation of potential trends in the causes, diagnosis, and treatment of the disorder.

These types of studies are most useful for identifying and describing emerging outcome trends and for generating hypotheses concerning potential exposure–outcome relations which may be tested in more analytic studies. However, the conclusions that can be reached regarding the existence and magnitude of such relations are limited with these designs due primarily to the lack of both exposure data and a comparison group.

2.4.1.2 *Cross-sectional*
Cross-sectional studies take a simultaneous look at the presence or absence of both exposure and disease in individuals. Such studies ask the question: What is the relation between exposure and disease at the same point in time? For example, a study of sedentary workers and low back pain examined the relationship between constrained, sedentary work, and prevalence of low back pain (Burdorf *et al.* 1993). Occupations with the greatest proportion of time spent in non-neutral trunk postures were observed to have a significantly increased prevalence of low back pain. In a cross-sectional design, it is difficult to establish whether

the potential exposure variable preceded the outcome (e.g. work posture differences contributed to the development of low back pain) or whether the potential exposure variable exists as a result of the outcome (e.g. workers differ in posture as an adaptation to low back pain). Hence, cross-sectional studies are useful for identifying potential exposure-outcome associations but not for establishing causality.

2.4.2 *Analytic studies*
Case-control, cohort, and intervention studies are generally classified as analytic studies. These study designs make use of the temporal relation between exposure and outcome (i.e. exposure precedes the outcome) and identify potential causes of outcome more definitively than descriptive studies.

2.4.2.1 *Case control*
In a case-control study, people with the outcome (cases) and people without the outcome (controls) are compared with respect to the proportion in each group with the historical exposure of interest. An advantage of this design is that both cases and controls may be matched on potential confounding variables, such as age. This design is particularly useful for the study of rare health outcomes. A limitation of this design is its susceptibility to recall and other forms of information bias since the exposure must typically be recalled by the cases and controls or be present in recorded data such as hospital records.

2.4.2.2 *Cohort*
A cohort study refers to a study design in which a group of persons who share a common exposure are studied over a period of time. Cohort studies are distinguished from case-control studies by two main features. First, classification into comparison groups is based on the exposure factor not the outcome. Second, the cohort study looks from the exposure forward rather than from the disease backward in time.

There are two main types of cohort studies: prospective and retrospective. The feature that distinguishes a prospective from a retrospective cohort study is whether the outcome of interest has occurred when the investigator initiates the study. In a prospective cohort study, the outcome occurs after the exposure is measured. In a retrospective cohort study, the investigation is initiated after both the exposure and the outcome have occurred.

2.4.2.3 *Intervention*
An intervention design is a prospective cohort study which investigates the impact of a treatment or control action on the exposure-outcome association. Study participants are assigned the treatment (intervention) at random and then followed to determine the proportion of persons exposed who develop the outcome compared to the proportion of persons unexposed (non-intervention). Assignment to an exposure category at random, also achieves, on average, equal distribution of other known and unknown confounding variables.

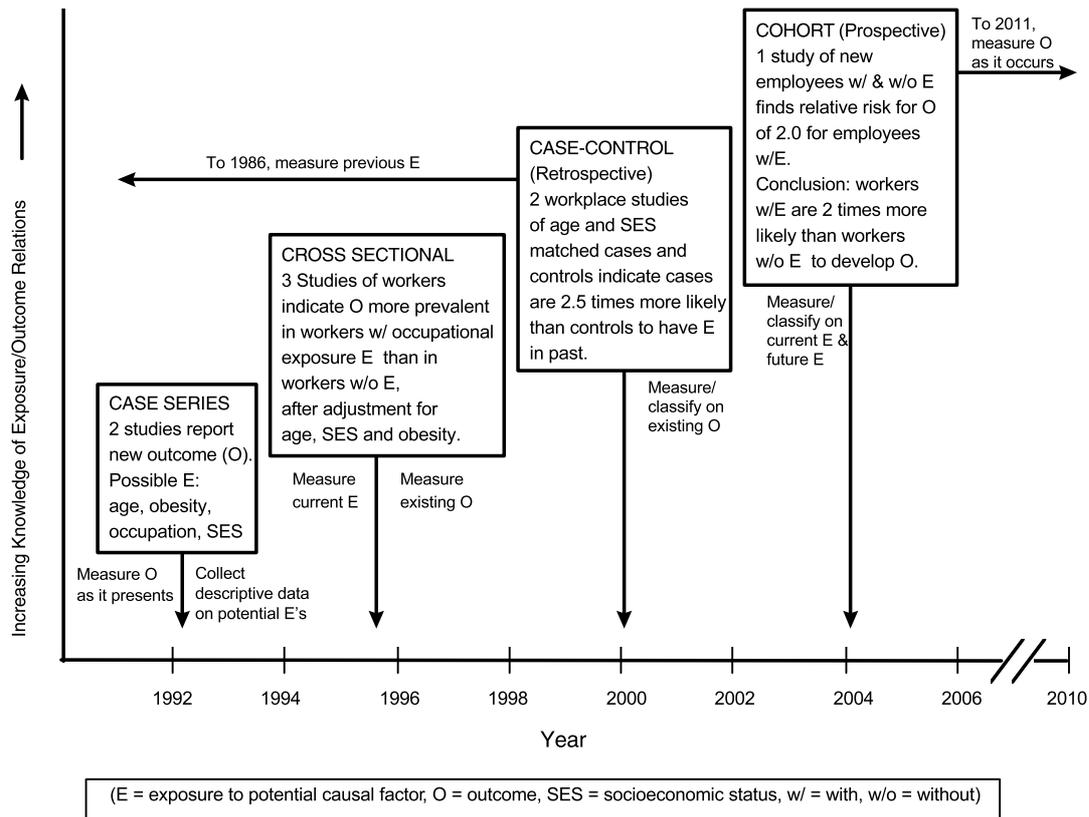
The study designs just discussed are graphically presented in Figure 1 to demonstrate how increasing knowledge of an exposure–disease relationship might develop for a hypothetical disorder (D) with a given exposure (E). Designs that accommodate the temporal relationship between an antecedent exposure and the outcome are considered most convincing of the strength or weakness of the E–D relationship. Where alternative explanations


Figure 1. Possible progression of epidemiologic research for a given disorder or injury illustrating the temporal nature of each fundamental study design.

for this relation can be ruled out, for example by statistical adjustment of potential confounding variables, the results are more convincing.

3. APPLICATION OF EPIDEMIOLOGY TO WORKPLACE INJURY

Epidemiologic methods can be applied to the evaluation and prevention of injury in the workplace. Ultimately any attempt to prevent or reduce the impact of injury in a population, whether a model for risk evaluation or an engineering design intervention, can only be validated using epidemiologic methods. However, epidemiologic methods are primarily useful for existing or emerging injury problems that have sufficient numbers of cases to support analysis. Therefore epidemiology is inherently reactive, identifying its solutions a posteriori.

Injury has been defined as "any damage inflicted to the body by energy transfer during work with a short duration between exposure and the health event (usually less than 48 hours)." (Hagberg *et al.* 1997). Work-related musculoskeletal disorders with longer time periods between exposure and injury onset (i.e. gradual onset) may also be addressed epidemiologically.

3.1. Evaluation of Injury at Work by Surveillance (Passive or Active)

Injury prevention at the workplace requires surveillance for injuries among workers, both before and after any intervention effort to prevent injuries. Surveillance has been defined as "the ongoing and systematic analysis and interpretation of health data

in the process of describing and monitoring a health event" (CDC 1988). Workplaces may then use this information to plan, implement and evaluate the health effects if any from interventions or changes in the workplace.

There are two essential elements of any surveillance system. The first is a clear definition of the injury cases to be counted also known as the case definition. Very often in practice, existing data sources such as dispensary records, required injury logs (e.g. OSHA log) or cases receiving wage replacement or sickness/absence benefit provide initial case definitions (e.g. counting all hand injuries treated in the plant clinic). This particular approach is referred to as passive surveillance since the data already exist. A limitation of this approach is that one has to accept the data elements and quality offered by the existing system.

An alternative which can improve the upon the performance of passive surveillance is active surveillance. In this instance new information is solicited from the work force specifically for the purpose at hand. Instruments typically used include discomfort or symptom surveys and risk factor checklists or other exposure evaluation tools. This approach offers improved information and control at the cost of resources to actively collect the information.

Once the case definition of interest is established it must be adhered to by all reporting sites. This will necessarily entail the support of the system with administrative and management resources including training in the appropriate use of the system by those entering and interpreting the data.

The second essential element is a count of the number of work hours in the population exposed to relevant work conditions

in a particular plant, department, assembly line, or work station. These two elements, cases divided by work hours constitute the rate of occurrence of the injury event which is the primary measure of effect of any intervention. The rates may be subdivided for categories such as length of employment, workstation location, shift schedule, etc.

3.2. Surveillance System Applications at Work

Consider a company with multiple locations producing similar products. Substantial variation in injury rates between these plants would suggest that injury circumstances, prevention efforts, or injury hazards were somehow distributed differently between plants. Only by establishing comparable and consistent surveillance systems can these ''natural experiments'' be exploited. Similarly, if an injury intervention being installed company-wide can only be put in a few plants at a time, injury rate comparisons between plants with the intervention compared with plants that are designated to receive it at a later date can contribute to evaluating the intervention's efficacy.

For example, a large manufacturing company developed a new employee-conditioning program in one plant and wanted the first six months of experience with it evaluated before duplicating the program company-wide. Back and shoulder injury cases were counted six months before the program was implemented and then six months while the program was in operation. The rate for cases with days away from work increased from 14 to 22 per 200 000 hours worked. The number of cases of back and shoulder musculoskeletal disorder increased from 4 prior to the program's start to 9 during the first six months of its operation. This was thought to be a large enough increase in cases to warrant a major modification of the conditioning program (Sorock *et al.* 1997).

3.3. Use of Narrative Data from Injury Records to Improve Injury Surveillance

Many injury surveillance systems include a brief narrative section describing in a few sentences how the ''accident'' happened. In most databases, only a single code is assigned to each narrative that best describes the ''causes'' of the ''accident.'' The narratives themselves can be searched electronically and certain keywords selected that can be used to identify cases not found by searching for codes. Narrative analysis has been used, for example, to identify motor vehicle crashes that occur in roadway construction work zones in computerized files. By selecting records with the keyword "construction" in the narrative of how the crash occurred, a descriptive analysis of 3686 such crashes was conducted (Sorock 1996).

3.4. Recommendations for Workplace Injury Surveillance

i Generally the utility of a surveillance system will improve as case definitions are refined and as progressively less severe and perhaps even near-miss types of events are cataloged. However, it is important to note that systems offering very specific levels of detail, hence a greater number of potential categories or descriptors can be compromised by efficiencies in use. For example, if the system allows a coder to select from 500 outcome codes, the coder will typically habituate to assigning the vast majority of incoming cases into a

significantly smaller subset of more frequently used codes (see entries on human information processing for more on this topic). Hence, a trade-off between specificity and efficiency exists in surveillance systems. The appropriate level of detail is best selected by examining the goals of the system, the skills and training of coders, the anticipated management of the coding system, and the level of performance in detail of any existing systems which the new system is to complement or improve.

ii Management and supervision should be involved in all efforts with respect to surveillance and injury control. This may be optimized through awareness training for management and supervision.

iii Records for surveillance should include a brief narrative of how the injury occurred with special note to contributing exposures (e.g. equipment involved).

iv surveillance systems should record demographic information such as location, shift, age of worker, gender, job class and occupation.

v The system should incorporate where possible the costs associated with injuries to permit cost analysis.

vi Organizations should computerize their surveillance systems and ensure sufficient storage space for archived data. (Sorock *et al.* 1997).

3.5. Occupational Injury Intervention Studies

Workplace injury prevention efforts can be categorized as either engineering interventions (targeting the design of the job, tools, and workspaces); administrative interventions (focusing on work procedures and policies); personal interventions (addressing worker behavior, training and education); or a combination of strategies (multiple interventions) (Zwerling *et al.* 1997). In general, worker behavior, training, and education interventions alone have not been demonstrated to be as successful in injury prevention as have other approaches. Multiple intervention approaches, which seek to optimize the management of an injury problem in each major aspect, appear to be the most effective (McGorry and Courtney 1995).

P$_5$–P$_{95}$ Syndrome

B.J. Daams

Delft University of Technology, Department of Industrial Design Engineering, Jaffalaan 9, 2628 BX Delft, The Netherlands

Presently: Daams Ergonomie, Mauvezand 17, 1251 JC Laren, The Netherlands

When designers design consumer products, they have to make many choices. One of these is the assessment of the target user group. Designing for literally everyone, or 100% or the target users, may result in a very expensive product or a product that suits nobody really well. When designing a product or a situation, the exclusion of extreme users (extreme tall, extreme slow, etc.) is therefore unavoidable. Designing products for "weak" or "strong" (tall or short, quick or slow, etc.) users is not precise enough an indication. In addition to deciding whether the weakest or the strongest users are the most relevant for specific design purposes, the designer has to determine which percentage of users within the expected population the specific design aspect will take into account.

In research and literature we are talking percentiles. A designer ought to decide and clearly define which percentile of the chosen population she is designing for: P$_{90}$, P$_{95}$ or even P$_{99}$? Especially with extreme percentiles, this can make an enormous difference for the values involved, and consequently, for the design. The question is which percentage to exclude.

Exclusion of extreme users should been considered with care. Designers sometimes copy the limits for P$_5$ and P$_{95}$ unquestioning from the ergonomic handbooks, without asking whether these are the right limits and which are the arguments to exclude 10% of the population from use or from comfortable use.

This nonchalance is named the "P$_5$–P$_{95}$ syndrome" (Dirken 1997). Here a comment should be made on the widespread habit of quoting the P$_5$ as a "normal" design maximum. To the annoyance of millions of people, many designers think it is accepted, standard, or even good practice, to exclude the upper or lower 5% (or both) of a population. This "P$_5$–P$_{95}$ syndrome" results in products which in the worst cases cannot be effectively, or comfortably, used by ~5.5 million in the UK, 22 million in the USA and 110 million in China. So it is clear that excluding 10% of a population results in a relatively large amount of frustrated would-be users. A good designer explains explicitly why a certain percentage of the population ought to be excluded, either on the top, on the bottom or on both sides of the curve (Daams 1994).

Risk Factors for Non-specific Musculoskeletal Disorders

C. Jensen

Department of Information Technology, National Institute of Occupational Health, Lersø Parkallé 105, DK-2100 Copenhagen, Denmark

1. INTRODUCTION

The most dramatic technological change in working life for the past 10 years has probably been the introduction of the computer. People spend an increasing part of both work and leisure time using the computer. For instance, in 1995 47% of a representative sample of Danish employees reported to use a computer at work. From 1990 to 1995 the percentage that reported to work with a computer for at least three-quarters of the daily work time increased from 4 to 11%. The percentage is undoubtably higher today and the trend appears similar all over the world.

The computerization of work tasks has introduced new factors in the working environment, which may present a risk for the workers' health; especially with a risk of developing disorders in muscles and tendons of the upper extremities. Such risk factors both include factors related to the work station, computer and input devices, working technique, work organization and the psychosocial work environment. Here, focus will be on factors specifically related to the input devices.

A variety of input devices exists and their use is partly determined by the specific software used. The keyboard was and probably still is the most used input device, but software development clearly leads to more use of non-keyboard input devices, of which the computer mouse is most common. Intensive mouse work already exists in some jobs such as in computer-aided design (CAD) work. The use of the Internet is also based on non-keyboard input device operations and even children are familiar with intensive 'mouse work' through computer games.

2. INPUT DEVICES

Many different input devices are available and new devices will continuously be marketed in the future. Both input devices not only are based on the same principles of interaction as those that exist today, but also entirely new ways of computer interaction may be expected to become common. The most commonly used devices are:

- Keyboard — the keyboard is not only used for entry of text and numbers, but also has a wide range of "short-cut" operations that can replace non-keyboard input device operations. The keyboard exists in several forms such as split, pitched, curved and tented, which require a variety of wrist postures. However, the flat traditional QWERTY keyboard is still widespread. Both finger, wrist and arm movements are used to operate the keyboard.
- Mouse — some rather complex keyboard operations have been replaced by the use of the computer mouse to enhance

Table 1. Effect of input device use on surface EMG level reported in the literature.

the operations and thereby increase performance. In recent years the design of the mouse has attracted increased ergonomic attention and computer mice are now not only flat two-button wired devices, but also may be curved, or even upright standing, wireless devices with several buttons and scroll functions. The mouse requires both arm and wrist movements to move the mouse and finger movements to activate the buttons.

- Mousetrapper — with this device the mouse has been trapped on the side of the keyboard and is operated in front of the operator, primarily with finger and wrist movements.
- Trackball — another device that has shifted the requirements for movements from the arm towards the fingers is the trackball, which is rolled by the fingers to move the cursor. In addition the fingers press buttons in the same way as with a mouse.
- Pen — a digital pen requires similar postures as an ordinary pen, but somewhat different movements of the wrist and arm. The first digital pens required a tablet, but new types have been developed to operate without a tablet.
- Puck — also neck postures and neck and eye movements may be influenced by the input device as the use of a tablet with a graphic overlay, often activated with a puck, requires frequent movements of neck and eyes to concentrate both on tablet and computer screen.

3. FITTING THE INPUT DEVICE TO THE USER

Re-design of existing input devices have often aimed at lowering the biomechanical strain of specific elements of the musculoskeletal system by changing work posture. Both the keyboard and the mouse are available in versions that do not require almost full pronation of the forearm, but allows the forearm to stay in a more natural, less pronated posture. For one type of mouse that requires a semi-pronated forearm posture this was shown to require a significantly lower activity level of the extensor digitorum muscle (Table 1). The effect of keyboard design on finger tendon biomechanics has also been demonstrated. A positive pitch angle of the keyboard seems favorable by reducing extension of the wrist and decrease tendon travel.

Gender differences are common both regarding symptom prevalence, work technique and posture when operating keyboards and mice. However, the development of input devices that suit both large and small hands (including childrens' hands) as well as left- and right-handed people has been remarkably slow. When one gets a new input device the size and shape should perhaps be paid just as much attention as when one buys a new pair of shoes.

4. DESIGN OF INPUT DEVICES AND PHYSIOLOGICAL RESPONSE

Work posture and electromyographic (EMG) activity have been widely focused on when comparing physiological responses to the operation of different input devices. Other ways of evaluating the use of specific input devices have been to record perceived strain, calculating tendon travel, recording movement frequencies, recording specific keyboard or mouse operations with odometers or measuring applied forces on keys or on the mouse.

To some extent EMG studies have confirmed expected distributions of activation patterns between muscles when comparing the use of different input devices. The two most ordinary types of input device operations, i.e. keyboard use and keyboard use combined with mouse use, have been directly compared (Table 1). A word-processing task using a keyboard only was associated with slightly higher EMG levels than when using a mouse in combination with the keyboard. As long as the mouse work is not performed with extreme postures, this is not surprising as some operations are performed with considerably less movements and lower mental demands when using a mouse as compared with a keyboard. However, word-processing using a mouse may be performed with more ulnar wrist deviation than when using a keyboard. Interestingly, ordinary handwriting entails higher muscle activity than both mouse and keyboard work (Fernström and Ericson 1997).

The trackball and the trackpoint device, which mainly require finger movements, may be used with lower muscle activity levels in the shoulder than use of the mouse, which requires more arm movements. Less finger movements are required during mousing and Karlqvist (1997) found that the trackball was operated with more wrist extension and a higher EMG activity of the extensor digitorum muscle, but the differences in EMG activity levels, when operating different devices, often appear small (Table 1).

Overall, it seems impossible to choose a device that requires a lower general muscular activation than any other device, but it may be possible to choose a device which requires somewhat lower activation of one muscle group with the cost of increased activation of another muscle group. Such information may be of particular use for people already suffering from symptoms in specific muscle groups as they may use a new device to redistribute activity between muscles and thereby relieve symptoms from one muscle group, at least temporarily. For the long-term prevention of developing symptoms it is important to introduce sufficient variation in the way muscles are used, e.g. by using several different input devices at the computer.

5. EPIDEMIOLOGY

Epidemiologic studies on risk factors associated specifically with the use of input devices during computer work are few, but several on-going follow-up studies may add considerable knowledge to this topic within the next few years. So far, it may be concluded that there is a relatively clear effect of computer work *per se* on the development of hand/wrist disorders and probably also on shoulder/neck disorders (Punnett and Bergqvist 1997). An increased duration of computer use is associated with an increased prevalence of musculoskeletal symptoms for keyboard operators, and other studies have found similar results for CAD operators, who use a mouse more than a keyboard. Thus, some factors associated with keyboard or mouse operations may lead to musculoskeletal symptoms and disorders, but it is not known whether other risk factors play a larger role than those specifically related to the input device (e.g. factors related to the work task or psychosocial factors of computer work). However, it seems reasonable that repetitive movements and static, awkward postures, which are known to be risk factors in general, also are risk factors in computer work, whenever intensive or prolonged operation of the input devices introduce such factors. Interventions aiming at improving work postures may have

positive effects as use of alternatively designed keyboards may relieve symptom severity in keyboard operators with musculoskeletal pain. Furthermore, forceful movements may contribute to the development of pain as operation of the keyboard with excessive keyforce has been found in office workers with more severe symptoms as compared with workers with less symptoms (Feuerstein *et al*. 1997).

6. WHICH PHYSIOLOGICAL RESPONSES DURING COMPUTER WORK MAY BE RISK FACTORS FOR THE DEVELOPMENT OF MUSCULOSKELETAL SYMPTOMS?

As the epidemiologic evidence of risk factors associated with computer work is relatively limited, we may to some extent rely on studies of acute responses to the performance of tasks with different input devices and base evaluations on our general knowledge of the association between short- and long-term responses. Thus, work with a posture close to neutral (joint angle close to 0°) is considered associated with a lower risk of developing symptoms than non-neutral postures (joint angles deviating from 0°). Previously, there was also a focus on reducing the level of muscle activity to reduce the risk. However, it is now recognized that the level of muscle activity is of minor importance as a risk factor in jobs involving work tasks, where the biomechanical strain is already low as it is during computer work. Preventive measures need to focus more on introducing variation in the exposure pattern to reduce the risk of developing symptoms.

For example, during intensive computer work with a mouse (CAD work) both the hand operating the mouse and the other hand, which is used for paper work may show similar wrist extensions *on average* (Jensen *et al*. 1998). However, the range of motion is typically twice as large on the non-mouse side as compared with the mouse side. Similarly, EMG levels may only be slightly different on the two sides (Jensen *et al*. 1998). But the variation in the EMG activity pattern and the fraction of the work time with muscular rest is much smaller on the side operating the mouse than on the other side. In this particular study three times as many CAD workers reported wrist and shoulder symptoms on the mouse side as on the other side. This suggests that the static nature of the posture and the continuous muscular activation pattern may be most important for the risk of developing symptoms.

Also, similar levels of EMG activity have been recorded during the performance of computer- and paper-based versions of the same task (Wærsted and Westgaard 1997). However, the variation of EMG activity was considerably larger for the paper-based version, which may be considered favorable in terms of preventing musculoskeletal disorders.

Clearly, the computerization of many work tasks has lead to a more stereotypic muscular activation pattern involving a relatively low number of motor units in a muscle. Possibly, prolonged activation of only a few motor units may induce an overexertion of the active muscle fibers causing muscular pain. This would imply that prevention of muscle pain is only possible if the activity of these particular motor units is reduced, i.e. their continuous firing patterns should be interrupted. Thereby, the most important risk factor would be more related to the duration of the exposure than the exposure level. Mouse work may induce

muscle fatigue and probably more chronic symptoms can develop even at the lowest levels of activity, when the activity is maintained for hours and repeated day after day.

Other factors than input device operations such as visual demands and the possibility to rest the arm on the table may be just as important for the development of symptoms. Time pressure may increase the muscle activity level even when the amount of work performed with a mouse is only marginally increased. Increased cognitive demands or demands of precision may have considerable negative effects on the amount of work performed, without any reduction in the muscular activation demands. A combination of such demands, e.g. a high demand of precision combined with a close deadline is likely to elevate the muscle activity level and leave insufficient time for muscular rest periods no matter which input device is used.

8. RECOMMENDATIONS

In conclusion, prevention of musculoskeletal symptoms during computer work should focus on introducing sufficient variation in exposure. Such efforts can be directed towards several aspects of the job. One may focus on work tools by using more than one input device as it should be expected that prolonged use of any single input device may increase the risk of developing symptoms. However, we do not know how different the input devices should be to reduce the risk. Work technique may be addressed, e.g. by changing the hand operating the device (with the risk of developing bilateral symptoms). A third possibility is to organize work tasks in such a way that the input device (and perhaps the computer) is used less intensively. This should have a clear preventive effect, but is often the most difficult solution.

Risk Factors of Musculoskeletal Disorders: Demographic, Social and Work Change Aspects in France

J.-P. Meyer and E. Turpin-Legendre

Work Physiology Laboratory, INRS Avenue de Bourgogne, F-54500 Vandoeuvre, France

1. INTRODUCTION

Occupational upper limb musculoskeletal disorders (ULMSD) occurrence is largely explained in the literature by biomechanical and/or psychosocial analysis of the task and its surroundings. These aspects are probably fundamental parts of ULMSD analysis and prevention at the factory level.

However, in industrialized countries an explanation for the dramatic increase of the musculoskeletal pathology in the past 20 years must be found in a more general approach of work changes. Furthermore, if the ULMSD epidemic is at a so high level, prevention must consider these aspects like, at least, the risk factors collected at a specific workplace. Then, preventive means must modify the global factors that affect working conditions.

The purpose of this article is to focus on the social, occupational and economical determinants of ULMSD in France between 1980 and 1995 to try to understand and explain the ULMSD epidemic which started during these years.

2. METHODS

The different points discussed here are based on an analysis of the evolution, from the end of the 1970s to the early 1990s, of ULMSD incidence on the one hand and the risk factors like workers' age and gender distribution, working conditions and economics in France on the other. For this purpose, ULMSD figures drawn from the social security statistics (CNAM 1996), and changes in the working population, analyzed from the statistics published by the National Institute of Statistics and Economical Studies (INSEE) were successively addressed. The statistics of the Ministry of Labor allow the identification of working conditions changes (DARES 1996). At last, productivity, work change and quality requirements were also drawn from several sources and personal communications.

3. RESULTS

3.1. Number of Compensated Musculoskeletal Disorders

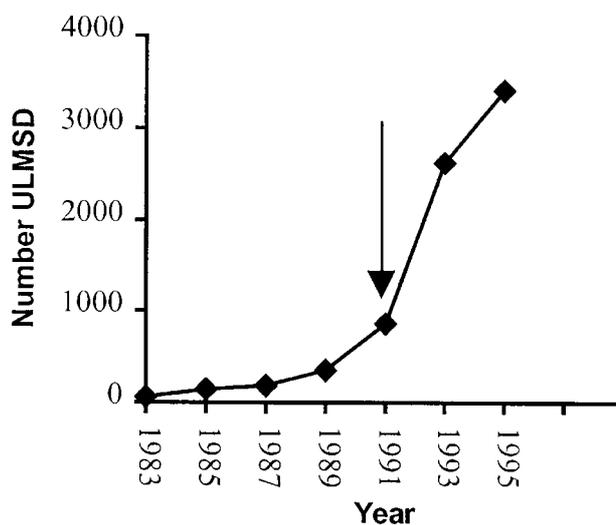
In France, the occupational ULMSD are compensated by the occupational disease system of the social security. The number of ULMSD considered here excludes state and agriculture workers but is based on a total of ~14 million workers. To obtain compensation, the worker has to declare himself the pathology to the social security. The disease, diagnosed and certified by a


Figure 1. Increase of compensated ULMSD between 1983 and 1996. The arrow shows the time at which table 57 was modified. Data for the years before 1983 were too low to be considered.

physician must be listed in the Tableau des maladies professionnelles where the corresponding risk factors to which the worker has to be exposed are also listed. In the case of ULMSD, the table is no. 57 of occupational diseases which also compensates lower limb musculoskeletal disorders like patellar bursitis or compression of the external sciatic nerve on the fibula head. Figure 1 shows the increase of compensated ULMSD from 1983 to 1995 which is the last known amount for analysis. Data before 1983 are not considered because few ULMSD were compensated at that time. Diseases due to vibration of hand tools are compensated in table no. 69 (white finger syndrome, elbow arthrosis, carpal osteoporosis); they represent about 100 cases each year and are not considered in Figure 1. From the compensated musculoskeletal disorders according to table no. 57 in 1995, upper limb represents 64% of the total. This ratio was only 10% in 1983. This evolution is partially explained by changes in the table no. 57 where carpal tunnel syndrome appeared only in 1981 and wrist or shoulder tendinitis in 1991. In 1991 risk factors like carpal pressure, wrist postures and repetition were added in table no. 57.

The total number of compensated occupational diseases in 1995 was 8534 from which 3413 are ULMSD interesting shoulder (17%), elbow (24%) and wrist (59%) including carpal tunnel syndrome (44%) and tendinitis (14%). This distribution is a classical finding in this type of survey. These numbers are low for the 14 million workers protected by the general social security system. This underestimation of the actual number of occupational disorders is recognized. However, even if this number is underestimated, its increase is obvious like in other countries but delayed compared with what happens in other countries. The late increase of the ULMSD can be explained by the recent changes of table no. 57 and by the fact that the worker has to ask for compensation of a "new" occupational disease. However, workers union surveys have revealed ULMSD epidemics in car and household electrical appliances manufactures from the mid-1980s.

3.2. Risk Factors

Changes in risk factors from 1975 to 1995 could be analyzed as a weakening of the working population due to aging and feminization, a working conditions hardening, quality control implementation, the paradoxical effect of changes from heavy industrial and agricultural activities to services and by economic evolution during the period.

Aging is recognized as a major factor of functional capacity decrease at a population level (WHO 1993). As a consequence, in an aging population the ratio between work requirements and functional capacities shows a general trend of decrease and thus an increase of the work strain as far as working conditions are not implemented and adapted. This implies for many workers that work stress can overcome their functional capacities and induce MSD. The aging process of the French working population in the period studied is characterized by the decreases of two classes of age in the active population, i.e. people > 50 years of age and one < 25 years of age. In these two age classes the percentage of the active ones decreased between 1975 and 1995 from 54 to 34% in the younger workers and 32 to 23% in the older ones (INSEE 1998).

The evolution of the age class 25–50 is characterized by a progressive appearance of the post World War II baby boom generation. Owing to the remaining high birth rate until the early 1970s, this age class moved from representing young workers < 30 years in 1975 to a homogenous distribution in the age range 25–50 in 1995. At that time the younger population of the high birth rate period, born in the early 1970s, was engaged in active life. Thus, in 1978, the 40–50-year age group was ~3.7 million, it was 4.1 million in 1987, 5 million in 1991 and 6.7 million in 1998. This tremendous increase (81%) in 20 years is more important for women (125%) than for men (59%).

Workforce feminization is a very strong social feature from 1975 to 1990. Indeed, the number of working women increases from 8.1 million in 1975 to 9.6 million in 1985 and 11 million in 1990 (INSEE 1988). The age distribution described above for the whole population is emphasized by the women entering in the workforce. Indeed, the increase is the most important for women aged 40–49 years who were 1.4 million in 1978 and 3.1 million in 1998. Thus, to the aging process of the active population is added the increase in a "frailer" workforce facing physical strain at work and family charges (Teiger 1989). This is particularly true when tasks that need accuracy and speed, like knitting, are considered. While these tasks were achieved by women < 25 years of age in the 1970s, they have to be done by older women in the 1990s because of the demographic changes (Teiger 1989).

Working conditions worsening is exemplified by several aspects of work. A longitudinal survey of the working conditions is conducted by the Ministry of Labor. Table 1 shows the percentage of the surveyed population (20 000 workers) who declared they are exposed to defined strains in 1978, 1984 and 1991 (DARES 1993). The results of the last survey (1996) are not published yet, but some partial results seem to confirm the trends shown in Table 1.

As presented in Table 1, the subjective estimation of the working conditions presented is mostly worsening. This is particularly salient for the hazardous activities, i.e. handling heavy loads, awkward postures, repetitivity and time pressure which, for the external demand, constrains more than one out of two workers. The results in Table 1 show that working conditions have not been adapted to the worker as much as it might be expected by the technological progress. Furthermore, just-in-time model has been adapted mostly throughout worker adaptation and not the contrary.

The implementation of quality control has also changed the working conditions. In 1988–93, eight of 10 factories with > 10 workers made some re-engineering. The main reason (87%) for that was product quality. Moreover, a question about quality outcomes at work was asked for the first time only in the 1991 working conditions survey (DARES 1993). At that time, the most frequently reported consequence of an error at work was product quality abatement (60%). In the past, most repetitive monotonous tasks left mental "freedom" to the workers without trouble for their task. However, quality requirements induce higher concentration on the task. This is difficult to achieve in repetitive monotonous tasks. But, like Bensaid and Dejours (1994) explained it, "psychic repression" (Unterdrückung) is a means to reach higher concentration in these monotonous activities. A very common method to obtain psychic repression is to engage completely in a task. In monotonous repetitive activities, where work latitude is restricted, this is achieved by increasing the work rate. Thus, workers are working faster and even, for many, at their maximum rate. It is noteworthy that the drawback of "psychic repression" is psychological. However, the increase of the task rate is a byproduct that has an important adverse effect on ULMSD. Furthermore, one cannot answer the question about whether psychological or musculoskeletal disorders are the most important consequence to the need to concentrate on the task.

Analysis of the type of activity shows an historical change during the period under study. Indeed, the beginning of this period corresponds to the first decrease in the number of workers in industry. The number of agricultural workers decreased, as in the previous years, from 2.2 million in 1975 to 1 million in 1995. During the same period industry reached its highest level of workers, 8.1 million in 1975, which then decreased almost linearly to 5.8 million in 1995. On the opposite, the tertiary sector grew from 11 to 15.6 million workers from 1975 to 1995. This growth was mostly due to workplaces where women were employed. Many of these jobs could be characterized as low general physical activity but high local muscular strain and, therefore, were recognized as including numerous risk factors for ULMSD. Indeed, supermarket cashier or computer work (VDU) are activities that appeared during this period. As an

Table 1. Workers exposed to defined strains (%).

Year	1978	1984	1991
Carrying heavy loads	21	22	32
Awkward postures	17	16	29
Repetitive Work			
men	18	18	26
women	25	22	34
Work rate imposed by			
machine	15	14	22
standards	21	19	38
external dead lines	34	39	57

example, one-third of the active population worked with VDU in 1994 while VDU work was almost absent in 1975. Furthermore, in the healthcare occupations the number of workers has grown regularly during the period under study; the number of nurses was multiplied by 1.5 between 1981 and 1996.

Economical evolution is difficult to represent. However, after the first oil crisis in 1973 industrial production slowed down during the second part of the 1970s. Industrial activity grew again only from 1983 to 1984 and then more markedly from the mid-1980s throughout the early 1990s (INSEE 1998). The production of these "go years" (1985–91) was achieved with an almost constant number of active workers. This period was shorter but manufacturing was more effective at that time in France as in most of the other European countries. This is particularly the case for household equipment and car manufacturing. For example, household appliances and car manufacturing increased > 30% in 1985 to 1989. The first descriptions of ULMSD epidemics in these occupations took place during this period.

Furthermore, productivity increase in the industry at the end of the 1980s can be illustrated by three economical indices (INSEE 1988):

- the use of the production capacities reached a rate never met before;
- the number of worked hours has decreased markedly since 1981; and
- the relative part of the salary in the cost of manufactured goods has decreased close to current levels of the 1960s.

These positive facts from an economical point of view are marked in the last 2 years which, in addition, are characterized by an increase in temporary work and unstable working status. The number of workers in these categories was multiplied by 1.5 from June 1996 to December 1997. Then, one can just hope that our hypothesis is wrong and that economics and ULMSD are not so strongly linked and thus the disease figures will decrease in France as they do in other countries.

4. CONCLUSION

The working population aging and feminization, quality control implementation, changes in the production structure from classical industries to services and the productivity increase are all risk factors that can cause the observed development of ULMSD. Their combined action during a short period is probably a major explanation of the epidemic. The analysis of the socio-economical and demographic changes in France, as well as in other so-called developed countries, shows the tremendous challenge of an efficient prevention of musculoskeletal disorders. Indeed, if these conditions must pursuit, it is probable that the ULMSD epidemic is likely to spread out. Thus, prevention will only be effective through a strong re-assessment of work methods to keep the fit between the imposed production needs and the human producer abilities. If changes in work are not occurring, the socio-economical needs of the working population and the demographic realities will put in light the threat of work to health and even public health which depends, for a large part, on the health of the working population. The results of the present study support the idea that it is not possible to look only at economics without considering its impact on health.

At last, it could be interesting to apply at a local level, workplace or factory, the observation of the workforce and the work changes like that done here from a nationwide view. Indeed, these aspects may be the easiest to check when a product or its manufacturing is modified and can help prevention.

Robot Safety Standard – R15.06

R. N. Sheat† and J. Fryman‡

†Detector Manager, Honeywell Data Instruments, and Chair, R15.06 Subcommittee on Safety

‡Manager, Standards Development, Robotic Industries Association

1. INTRODUCTION

The USA has introduced a new version of its safety standard for industrial robots, ANSI/RIA R15.06-1999. The new volume has been greatly expanded in content, and has been edited for ease of use and understanding. Goals were established and met to enhance the safety of personnel employed in robotic automation applications. Harmonization with international standards was considered during the revision process, even though the document remains uniquely a US standard. The standard introduces new criteria that will enhance the design safety of robots. Included are safety circuit performance criteria, and the introduction of a safety stop circuit separate and in addition to the required emergency stop circuits. Risk Assessment (reduction) is also presented in considerable detail. The importance of human factors in a safe work environment is inherent throughout the standard.

2. DEVELOPMENT BACKGROUND

2.1. Robotic Standards

Voluntary consensus standards used by US industry are known as American National Standards, and are developed under the auspices of the American National Standards Institute (ANSI). The Robotic Industries Association (RIA) is the accredited standards developing organization for robotic standards in the USA. Part of the ongoing evolution of standards is the required five year review. When the required periodic review of the 1992 edition of the standard became due, the RIA determined that a major revision was appropriate.

2.2. Scope of Revisions

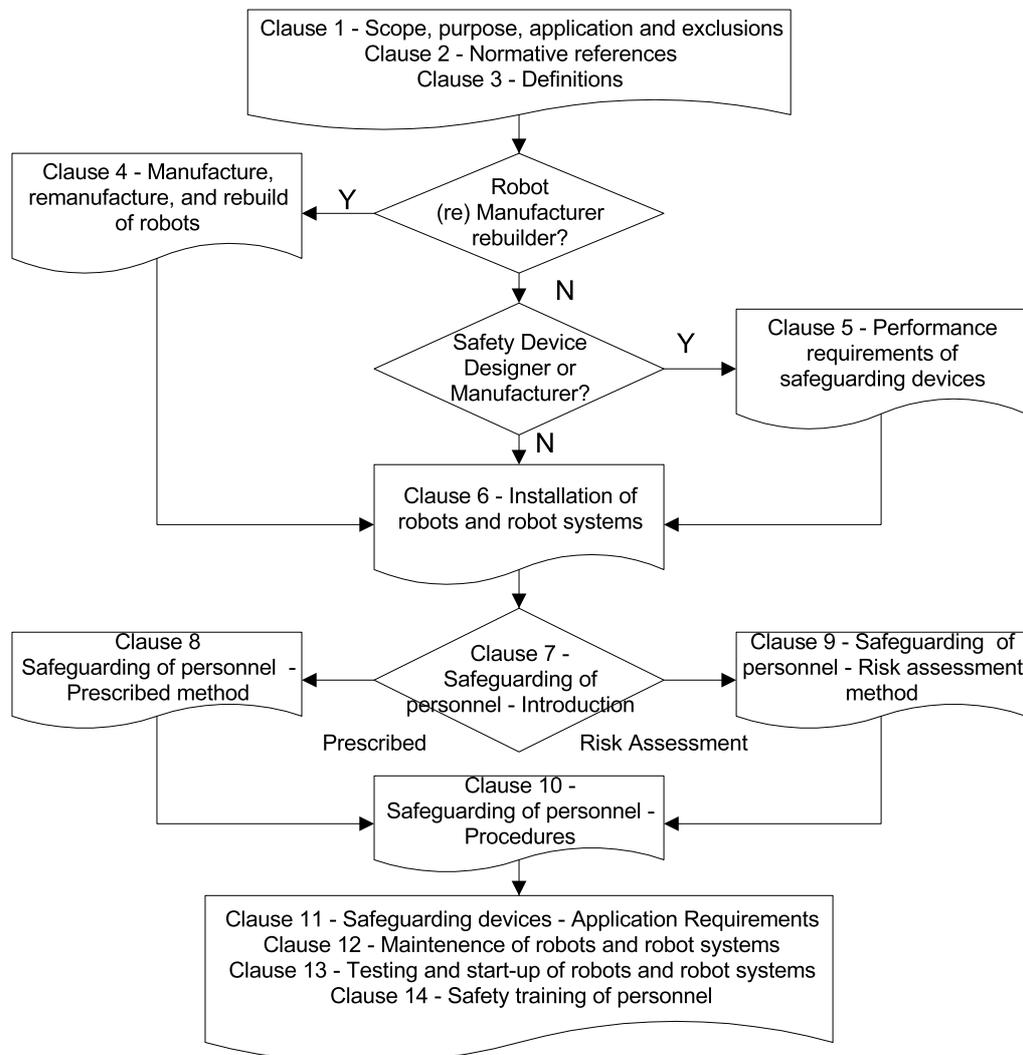
Goals were established for the revised standard development effort. These included: enhancing robot and robot system safety; making the standard more understandable, both in organization and user friendliness; and to respond to feedback received on


Figure 1. - Logic flow of ANSI/RIA R15.06-1999

the 1992 document regarding perceived weaknesses. Additionally, the standard needed to address realistic and achievable safeguarding requirements in industrial automation applications.

2.3. New Robot Safety Standard

The response to these challenging goals is a new 1999 edition of the robot safety standard, ANSI/RIA R15.06-1999. The new edition has a revised, open format designed to be more easily read and understood, as well as be more in harmony with international standards. The text was greatly expanded, reorganized and divided into additional sections with specific interest to specific segments of the industry. A strategy for safety was developed and set forth, which includes options for performing risk assessment (reduction) or following a more strictly prescribed method of safeguarding.

3. DOCUMENT STRUCTURE

There are 14 clauses in the new standard versus the nine clauses in the 1992 edition. The safety standard assigns responsibilities for industrial robot safety to manufacturers, integrators, installers, and the user. Figure 1 offers a graphic presentation of the flow of responsibilities through the new standard.

4. COMPLIANCE

4.1.

The newly revised standard addresses both new and existing robots, and robot systems. Some change to existing systems may be required if an existing system does not meet a minimum prescribed level of safety compliance. Ample timeframes are established to allow for compliance with the new standard. Generally, systems in compliance with the 1992 standard will probably not require any retrofit to be compliant with this edition of the standard.

4.2.

The new standard is more inclusive, but only applies to industrial robots and systems that are used in industrial automation applications. Several specific robot applications are excluded; and machinery that is not a robot is not mentioned as an exclusion.

4.3.

Normative references typically include other voluntary standards related to the topic and providing important and useful information over and above what is included in this standard. This revision has introduced normative references to regulatory standards (directives) issued by the US Department of Labor, Occupational Safety and Health Administration (OSHA). This is an important distinction, and reflects that OSHA, in turn, recognizes voluntary standards as accepted industry practices. In fact, ANSI and OSHA have a memorandum of understanding regarding expedited acceptance of ANSI approved standards by OSHA.

4.4.

The definitions section has been cleaned up and a concerted effort made to harmonize definitions with those in ISO 8373. Only terms that are used in multiple locations within the document are provided as definitions. Terms that are only used once, are described in detail within the section in which they are used. A

significant change in the new standard is the use of the word "space" to replace "envelope" in describing the volumetric areas of robot motion. Envelope was considered too much of an "engineering" term, and the committee felt the word space better conveyed the concept to a general audience.

5. MANUFACTURER RESPONSIBILITIES

Manufacturer's responsibilities have been refined. This is a performance standard, so changes are directed to how the robot (and robot system) must perform. Although this often affects the way a manufacturer designs his product, the standard contains no specific design criteria. The differences of rebuilt and remanufactured were better explained, and specific requirements applied to each.

5.1.

The requirement for axis movement without drive power was revised to better reflect its intent. There must be a safe method to release personnel caught, pinched or trapped by motion of the robot. Additionally, this method should not create or increase another hazard such as energy release due to gravity.

5.2.

Axis limiting requirements were revised to require provisions for adjustable hard stops on the primary axis. Also required is that provisions (i.e. mounting post or electrical contact) be made for installation of limiting devices on the second and third axis of the robot. These are important elements in reducing the hazard of robot motion.

5.3.

Protection from singularity is now required during teach. This protection takes the form of the robot motion being stopped prior to the robot program automatically executing a correction for the singularity condition. The teacher must acknowledge the condition, and authorize the robot motion to continue, thus allowing anyone in the safeguarded space to move clear of the robot motion.

5.4.

A new concept of a three-position-enabling device has been introduced. The new standard requires the use of a center on (full squeeze or release stops all motion) switch that must be constantly activated to enable hazardous motion. This requirement was added in response to studies that have determined that people respond differently to perceived hazards, and will often "freeze" (pull tight) rather than release an object (e.g. the motion enabling device) they are holding. Specific cautions are added regarding the importance of ergonomic considerations when installing this device.

5.5.

A more detailed list of information that is important to the robot user has been developed. This list is required to be made available by the manufacturer, and in turn, provided to the integrator, or installer of the robot and robot system, and finally to the end user. The required information varies in scope from that usually contained in a routine data sheet (sales literature) to data normally

found in installation/user manuals to specialized data that must be purchased if it is requested.

6. SAFETY CIRCUITRY

6.1.

Safety circuit performance has been introduced to require certain levels of performance for safety circuits in various applications. This concept is harmonized with, but distinctly different than the category requirements in ISO/IEC 13849-1 (EN 954-1). Definitions for four levels of performance from simple to control reliable are provided. All safeguarding devices must be integrated into the robot work cell using one or more of these performance levels.

6.2.

Closely related to circuit performance is the new requirement for separate safety stop circuits to be used by safeguarding devices that signal a stop (i.e. light curtains, gate switches). This stop is separate from the emergency stop circuit, and allows an orderly stop, and one that retains program logic for troubleshooting.

7. TEACHING

The task of programming or teaching the robot has been carefully defined as a separate task from that of verifying the robot program or path. An entire section is dedicated to the specific safeguards called out to protect the teacher. These safeguards include the use of slow speed control at all times during teach, single point of control, and clearance. For teaching, the required clearance is measured from the "operating space".

8. PROGRAM VERIFICATION

Program verification also has a section dedicated to specifying very specific safeguards required to allow a person to be in the safeguarded space when the robot is functioning at speeds above slow speed. In this mode, greater clearance requirements are needed; and therefore are measured from the 'restricted space.' A feature known as Attended Continuous Operation allowed in the 1992 edition is now prohibited.

9. RESPONSIBILITIES FOR SAFEGUARDING DEVICES

The standard has been reorganized to include a clause providing specific guidance and detailed performance requirements to the manufacturers of safeguarding devices. Another clause provides detailed guidance on the selection, installation and use of safeguarding devices. The integrator or installer of the equipment is a key element in robot and robot system safety and receives considerable instructions throughout the revised standard on proper safeguarding techniques.

10. RISK ASSESSMENT

The 1992 robot safety standard required that a risk assessment

be performed, but went on to provided very little additional information. The new 1999 standard responds to comments from the robot community by offering a choice of safeguarding methodologies. The robot user must choose between performing a risk assessment or installing all safeguards in a prescribed regimen.

10.1.

Risk assessment has become an increasingly important aspect of safety. An entire clause now discusses risk assessment with detailed performance criteria, and a suggested methodology to perform an effective risk assessment. Charts are provided to aid in determining risk and the appropriate reduction options for safeguard selection. This method pays careful attention to sources of potential hazards, and aids the effort to better understand the actual process being performed in an application.

10.2.

Alternatively to a risk assessment, a prescribed method of safeguarding is included with specific safeguards and installation requirements. This method ensures a safe environment, but does not aid in the understanding of the hazards involved in an automated application.

11. ADVANCING TECHNOLOGY

The revised standard recognizes the continuing advance in technology development. It was carefully written so as not to preclude the use of new technology when it becomes safe, feasible and recognized by other standards. Specifically noted are advances in control reliability and newly introduced software based controllers that are expected to see more widespread use in the next few years. Specific issues are addressed which will provide an assurance of safety in the application of new technology.

12. CONCLUSION

A number of other enhancements have been made in this 1999 revision of the robot safety standard. Included in these enhancements is a list of suggested hazards, expanded protection for maintenance personnel, and more detailed information on initial (first time) start-up and training programs. All of the changes made in this standard serve to ensure a safer, better designed, and more productive work environment for personnel in today's highly automated work place.

Slaughterhouses

G. Toulouse and J.-G. Richard

Institut de Recherche en Santé et Sécurité du Travail, Montréal, Québec, Canada

1. INTRODUCTION

The activities related to the production and processing of meat (poultry, beef, pork, and others) and meat by-products range from cattle raising to consumer distribution. The slaughterhouse plays a primary role in the process. In addition to the actual slaughter of animals, it is usually the site of primary processing activities such as cutting, freezing and wrapping.

In the last two decades, the slaughterhouse industry has had to adapt to some major changes, including new consumer habits, the opening up of markets, new quality and hygiene standards, and others. The slaughterhouses are now seeking to improve their productivity and competitiveness by specializing in certain types of animals, concentrating their production by grouping their facilities, mechanizing operations, increasing production line speeds, introducing primary processing activities and diversifying their product range. As a result, the working context has changed considerably. Workers are becoming increasingly specialized, and their jobs now include a significant inspection, quality control and machine work recovery component.

During the same period, prevention organizations have observed an increase in the number of work-related musculoskeletal disorders (WMSD) associated with repetitive work. In Western countries, the meat-processing plant now rank first among the sectors affected by this problem, which has overtaken traditional risks such as cuts and animal-transmitted diseases. Accordingly, ergonomics research and interventions have been concerned mainly with the development of prevention strategies for this type of disorder. The strategies in question often focus on worker participation.

This article describes some aspects of the production system and work activities in slaughterhouses, together with the main occupational health and safety problems that arise from them. Solutions are also proposed, and possible preventive approaches are discussed.

2. THE PRODUCTION SYSTEM

In modern slaughterhouses, the production system is based on a tight flow procedure involving a large number of operations, some carried out by machines and others by human workers. The nature of the product to be processed means that a *just-in-time* supply system must be used. The quality and homogeneity of the animals often varies from one batch to the next, limiting the possibility of mechanization and increasing the workload at some workstations. Currently, the highest levels of mechanization are found in poultry slaughterhouses. In slaughterhouses that kill larger animals, many operations are still carried out manually.

Slaughtering and primary processing activities are usually carried out in four separate departments: reception and slaughtering, gutting, cutting, and wrapping. The animals and by-products are moved around on hooks hanging from a chain, or on conveyor belts. A tight flow system is implemented from reception to shipping. In the last two departments, the product must be refrigerated, which requires ambient temperatures of around 12∞C.

Production capacities have increased gradually over the years. In poultry slaughterhouses, up to 12,000 birds per hour can be slaughtered, while in pig slaughterhouses the figure is around 900 animals per hour. For poultry, work cycle times are often between 3 and 5 seconds.

3. THE RISK OF WORK–RELATED MUSCULOSKELETAL DISORDERS

In a recent review of the literature, Loppinet and Aptel (1997) make a number of observations based on epidemiological studies of work-related musculoskeletal disorders (WMSD) in the meat industry.

- WMSDs affect all joints in the upper limbs.
- They occur regardless of the type of animal being processed.
- They occur in meat cutting, grading, and wrapping operations at every stage of the production line (Kurppa *et al.* 1991). Most of these activities involve the main risk factors normally associated with WMSDs: repetition, restrictive postures, the use of force, cold, vibration, and psychosocial factors.

In poultry slaughterhouses, WMSDs are more common among women than among men. This appears to be due to the fact that women are exposed more to risk factors associated with extended periods of standing and more repetitive and faster gestures (Mergler *et al.* 1987).

There are some significant differences in the prevalence and incidence of WMSDs depending on the publications involved. These differences may be due to the diagnostic criteria used, as well as to differences in the age, sex and seniority of the populations studied (Hagberg *et al.* 1992).

4. THE CONDITIONS THAT CREATE WMSD RISK AND SOME POSSIBLE SOLUTIONS

The conditions that create WMSD risk are varied and complex, and it is therefore difficult, in most cases, to isolate a single cause. In fact, all these conditions (or risk factors) interact. For example, the risks associated with the use of a knife depend on the design of the knife, the size and layout of the workstation, the characteristics of the product, the actions involved in the task, the training received by the worker, and so on. In the following paragraphs, we will consider some of the main conditions that influence WMSD risk. Very little research has so far been done on the psychosocial risks involved, and this element will therefore not be addressed here.

4.1. Workstation Layout

In slaughterhouses, the methods used to carry out particular tasks are determined by the two main ways of transporting the products. Many operations are carried out on a product that is attached by a hook to an overhead conveyor, while in other cases the product is removed from a conveyor, processed on a nearby table and then returned to the conveyor.

The spatial constraints associated with this type of layout are as follows:

- Evacuation of products from a conveyor, or onto a conveyor located above the original transportation conveyor, often forces workers to adopt extreme postures. Currently, problems of this nature are solved by designing workstations in which evacuation takes place directly underneath the original transportation conveyor.
- The effort involved in cutting up a carcass is increased by the range of joint movement required to work on a large animal (e.g. pig or cow), and by differences in worker body size. In the former case, the problem involves the standardization of the animals slaughtered, the planning of the slaughter stations, and task distribution. In the latter case, the problem can be solved by using a platform that can be adjusted to different heights by the worker.
- Lack of space between workers also causes postural restrictions, stress, and risk of knife injury. When the product is transported by means of an aerial conveyor, the space between workers is doubly important. It must be calculated on the basis of the conveyor speed, the duration of the work cycle on the product, the possibility of incidents and the time required to clean and sharpen the knife.
- Standing postures with a high static component are frequent and generate considerable fatigue. In many cases, the fatigue can be reduced by introducing high stools or saddle chairs.

4.2. The Knife

The use of a knife is often associated with the appearance of WMSDs. The size of the handle, the grip with rubber gloves and the sharpness of the blade all affect the amount of force required to cut the product (Armstrong 1982). Researchers have proposed a number of solutions to help improve knife design and reduce cutting effort:

- The angle between the knife handle and the blade should be such that it limits wrist flexion. However, this solution is often practicable only for tasks involving a single unidirectional action.
- The length and diameter of the handle should be adapted to suit individual anatomical differences.
- The size of the handle and the blade can be optimized to suit the type of cut, so as to reduce the force required;
- Handles made of a non-slip material that promotes comfort and flexibility of use will help limit fatigue by absorbing shocks, distributing pressure and enhancing grip.

A recent study on the sharpening of knives in slaughterhouses revealed that three-quarters of the 25 workers questioned had difficulty with this operation (Chatigny and Vézina 1995). The authors, observing that the workers did not fully master this technique, developed a training session (available in video format) based on pairings of experienced sharpeners and apprentices.

Finally, knives can be replaced in some instances by circular saws, hacksaws, rotary blade knives, or power cutters that, theoretically at least, reduce the amount of force required.

4.3. Gloves

The use of gloves to protect workers against cuts and/or cold may exacerbate musculoskeletal constraints. Some authors (Armstrong 1994) have shown that the thicker the glove, the greater the force required. In slaughterhouses, workers often wear several pairs of gloves at once. Each pair serves a different function:

cotton gloves for comfort, rubber gloves for their waterproof qualities and steel mesh gloves to protect against injuries.

There is a real need to develop gloves better suited to the conditions in slaughterhouses that comply with hygiene requirements and are not too expensive.

4.4. Time-related Constraints

The time-related constraints inherent in this type of work (the pace imposed by the production line or conveyor belt) influence WMSD risks in a number of ways (Toulouse 1995):

- lack of breaks;
- effort required in awkward postures determined by the need to begin operations upstream and continue them downstream when the product is not in the best position for the worker. Increased travelling speeds and recovery of incidents exacerbate this problem;
- some related actions that are not considered in the task (sharpening the knife, cleaning and sometimes sterilizing the knife, cleaning the gloves) increase the cycle time, extending the postural range or causing the task to be performed more quickly.

Many of these problems can be reduced by planning the task so as to take into account the possibility of incidents, product variability, and related activities. When designing tasks, it is also important to leave enough space between workers (Bellemare and Richard 1992).

4.5. Worker Training

The impact of vocational training on WMSD occurrence has not been studied directly, but nevertheless appears to be an important factor. Training in slaughterhouses, often carried out 'on the job', may be deficient and may not enable the workers to develop methods that minimize the risk of WMSD. Vocational training programs should be based on data obtained from surveillance of symptoms and injuries, and on the results of ergonomic analysis.

4.6. Job Rotation

Job rotation is often proposed as a way of reducing repetition or exposure to risk factors. However, although research in this area is by no means extensive, it appears to show that job rotation does not always achieve the anticipated results. Effective job rotation is subject to a number of difficulties, such as training deficiencies, workstations designed without taking worker body size variability into account, work places that limit the ability of operators to move from one workstation to another, as well as variations in production management and human resource management.

5. ERGONOMICS AND PREVENTION STRATEGIES

A review of the preventive approaches used in Quebec's poultry slaughterhouses (Richard 1997) showed that managers and health and safety officers were often powerless when faced with the complexity of the risk factors associated with this type of operation. There is therefore a need to pay particular attention to identifying and understanding the cause-and-effect links between the risk factors and their determinants, on the one hand, and symptoms and injuries, on the other. While awareness-raising and training activities provide basic knowledge, only a symptom surveillance program combined with surveillance of high-risk

jobs can produce the information required to seek and introduce solutions. A real-time symptom reporting and monitoring procedure, and ergonomic analysis of working activities, form the basis of such a program. The program should be accompanied by a preventive assignment program following manifestations of pain.

When the risk factors specific to a working situation are understood, the factory personnel, aided by an ergonomist, are best placed to identify and design corrective measures. Recent experience has, on several occasions, illustrated the interest of participatory ergonomic approaches in this field, although their long-term effectiveness has yet to be proved. We can assume that this effectiveness will depend on how the company uses the expertise developed by participatory ergonomics projects and how it applies that expertise as part of ongoing quality improvement projects or when designing new production systems.

Slip, Trip and Fall Accidents

R. A. Haslam

Health & Safety Ergonomics Unit, Department of Human Sciences, Loughborough University, Loughborough LE11 3TU, UK

1. INTRODUCTION

Slip, trip or fall accidents can happen on the level, on ramps, on steps or stairs, or from a height, with differing causes and consequences. Together they form a major category of accident, imposing a substantial social and economic cost. UK statistics, compiled by the Health & Safety Executive (HSE), show that fall accidents are the principal cause of major injury at work (Figure 1). Using 1993/94 figures, HSE (1996) estimated slip and trip accidents cost employers £300 million each year, with a cost to society > £800 million. Outside work, the UK Home Accident Surveillance System (HASS) results for 1996 showed falls to be 40% of all home accidents, with an annual incidence rate estimated at 1930 per 100 000 of the population (Figure 2).

Although international comparisons are impeded by differences in procedures for reporting and recording, in the USA data from the Bureau of Labor Statistics for 1996 identified that falls were involved in 11% of fatal accidents at work. Similarly, a National Safety Council analysis of "deaths due to unintentional public injuries," again for 1996, listed falls as the largest category, with a rate of 2.0 per 100 000 (excluding incidents involving motor vehicles). A similar pattern exists in other countries: slip, trip and fall accidents are a major problem worldwide.

2. SLIPS

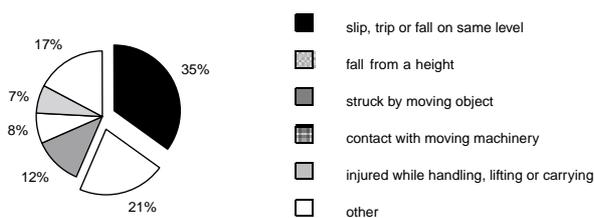
Normal walking (locomotion) goes through a cycle of the supporting leg pushing off from the toe, the other leg swinging forward to heel strike, body weight transferring forwards onto the heel then to the toe, supporting leg pushing off from the toe, and so forth. Slipping occurs when the friction between the foot and the floor is insufficient to prevent movement between the


Figure 1. UK Occupational accidents 1995/96.
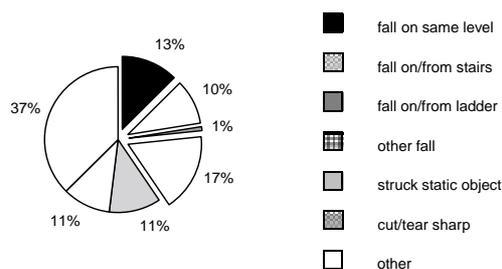

Figure 2. UK home accidents 1996.

two surfaces. Leamon (1992) described three categories of slip: a *microslip* of < 20 mm, a *slip* of between 80 and 100 mm, and a *slide*, > 100 mm. Microslips and slips are less of a problem, as even if detected by an individual, they are likely to be able to maintain balance. Slides may become unrecoverable, leading to body impact and the possibility of injury.

Slipping can happen during either toe off or heel strike phases of walking, although the latter is usually more hazardous. This is because during heel strike, the forward momentum of the body is in the same direction as the slip. Most slips occur where the properties of a walking surface change suddenly, for example due to spillage of a liquid, or when first stepping onto ice. A reduced stride length decreases the horizontal (shear) force component during both toe off and heel strike phases of walking, leading to increased stability, making it possible to maintain balance on slippery surfaces. However, this requires both detection and adjustment to the walking conditions.

2.1. Coefficient of Friction

The coefficient of friction (CoF), is a means of describing the resistance to slipping between an object and a surface, for example a particular synthetic soled shoe and a polished wooden floor. Traditionally, a distinction has been made between static and dynamic CoF. Static CoF is the ratio of the vertical force acting between an object and a surface and the horizontal force just sufficient to start the object to move. Calculating the ratio using the force necessary to keep the object in motion gives dynamic CoF.

Tribologists (those specializing in the study of friction) have devoted some considerable effort to developing techniques for measuring CoF that will provide valid and reliable results. It has been suggested that the number of different methods proposed may be approaching 100. These fall into four broad categories:

- Drag devices – a weight, with a shoe sole sample on its surface, is dragged across the floor, while the force required for slipping is measured, giving either static or dynamic CoF (e.g. the Horizontal Pull Slipmeter and Tortus instruments).
- Pendulum devices – a pendulum arm, end-fitted with a sample of shoe material, is swung across the floor surface, with deceleration of the arm allowing a dynamic CoF to be calculated.
- Articulated strut – a plate, covered with shoe material, attached to an arm, is pressed onto a surface covered with floor material; the floor material is moved at a constant speed, causing the arm to move from the vertical, until slipping occurs, giving a measure of static CoF (e.g. the James Machine).
- Walking tests – with the DIN ramp test, for example, the incline of a ramp is raised until a human subject walking on the test surface begins to slip; a CoF can then be calculated from the ramp angle.

(See Marletta 1991 and Leamon 1992 for further details of methods.) A drawback of walking tests is the need for bulky equipment, preventing measurement of floors in situ. Unfortunately, there is often poor agreement between results from the different approaches, varying according to surface roughness, whether the surface is wet or dry, and the type of shoe material used. Recent thinking has been that neither static nor dynamic CoF are adequate, as slipping occurs during the change of state

between the fully static and fully dynamic conditions. Devices are currently being evaluated and refined that deliberately set out to measure CoF during the non-steady-state period.

In practice, rougher floors tend to have better slip resistance, especially when wet. Materials range from having smooth surfaces such as polished metal and polished wood, through to ceramic and terrazzo tiling, through to rough stone and concrete. Microcellular urethane and rubber materials provide improved slip resistance over PVC and leather.

3. TRIPS

Tripping is less common than slipping and happens when the foot catches on an obstacle or object, with continuing motion of the body resulting in a stumble or fall. Tripping hazards may be fixed features of the environment, a raised paving stone or a step for example, or temporary items, such as a trailing electrical cable. Marletta (1991) suggested irregularities of as little as 7 mm may be sufficient to induce tripping. As with slipping, detecting changes in the walking surface or an object in the way allows avoidance.

4. INDIVIDUAL FACTORS

Personal characteristics involved in slip, trip and fall accidents are gait, balance, stature, strength, vision and behavior. These in turn may be moderated by health, age, fatigue, medication, alcohol, environment (e.g. lighting and floor surface) and activity (e.g. load carriage or performance of a cognitive task). Human ability to walk and balance is a complex process, involving integration of inputs from the visual, vestibular and somatosensory systems. Stature influences the location of an individual's center of gravity and inherent stability. Strength affects ability to recover from disturbances to balance, and use of supports such as handrails. Vision, in addition to its contribution to balance, also enables monitoring of the walking surface and detection of obstacles. Behavior may vary in terms of the caution individuals exercise in different circumstances.

5. ORGANIZATIONAL FACTORS

Most research dealing with slip, trip and fall accidents has been from the directions of epidemiology, biomechanics and tribology. However, researchers such as Bentley and Haslam (1998) have highlighted the significant contribution of organizational factors. These influence exposure to hazards and the control of risks. For example, within the Royal Mail postal delivery function, business targets for letter delivery, together with a "job and finish" policy, combined to provide strong informal incentives for staff to carry overweight mail pouches. The carrying of a heavy asymmetric load was identified as a significant risk factor for slip, trip and fall accidents. Considerable changes in equipment, custom and practice are needed to overcome a situation such as this. In another context, slipping accidents can be a problem in supermarkets, due to liquid spillages and loose vegetable products falling on the floor. Preventative measures include providing mats in front of vegetable counters, and good housekeeping, such as cleaning up contaminants as soon as they occur. However, the latter requires a sustained effort devoted to training and motivating staff.

6. FALLS ON THE LEVEL

Falls on the level are the most frequent type of fall, in both occupational and domestic settings, with slips occurring more frequently than trips. For example, Bentley and Haslam (1998) found slips on the level to be almost double the number of trip accidents among postal delivery staff working outdoors. Falls on the level can also happen when a surface moves as it is stepped on, such as with a loose mat, or when a moving surface stops abruptly, for example when standing on a train or moving walkway. Injuries from falls on the level are commonly sprains and strains, followed by contusions, with the wrist, arm, ankle and back being the body areas most often affected.

On ramps, the shear forces between footwear and the floor at toe off and heel strike increase with gradient. The risk of heel slip and falling backwards when descending a ramp is greater than the risk of slipping during toe off and falling forwards on ascent.

Certain manual handling tasks seem likely to increase the risk of fall accidents, although limited information on numbers and severity of incidents makes this difficult to confirm. Load carriage affects center of gravity, potentially making it more difficult to recover from imbalance. During pushing or pulling, shear forces between the feet and the floor can be very high, increasing the chances of slipping. Trolleys and trucks may also obscure vision, impeding monitoring of the walking surface.

7. FALLS ON STEPS AND STAIRS

Accidents on steps and stairs are the second major category of fall accident in terms of numbers. There is general agreement that children and the elderly are at increased risk, although the extent of this is difficult to quantify, due to an absence of data on levels of stair use by different groups. Accidents during descent result in more injuries than for ascent, where the distance traveled in a fall is likely to be less. Fractures are more frequent injury outcomes than for falls on the level, with the elderly particularly at risk. Falls on stairs may involve either a slip, trip or misstep, with the relative occurrence differing between indoor and outdoor environments.

Important features of steps and stairs from the viewpoint of safety are riser and going (tread) dimensions, design of nosing, length of flight, nature and condition of surface material, position of handrail, and lighting. Templer (1992) recommended riser dimensions should be within 117–183 mm, with goings between 279 and 356 mm. User behavior that may lead to accidents includes rushing, carrying items and leaving objects on stairs. Templer (1992) also identified dimensional irregularities between adjoining steps and content of the visual field as other possible contributory factors.

8. FALLS FROM A HEIGHT

In the UK, falls from a height > 2 m are the largest cause of fatal accidents at work (20.6% in 1995/96) with the construction industry particularly afflicted. Examples include falls from or through roofs, from scaffolding, off ladders, through windows, from machinery, or anywhere where there is a sudden change in floor level or where it is necessary to climb onto something. Because of the forces dissipated through the body on impact, accidents of this nature often lead to serious multiple injuries and death.

Human factors issues are a frequent ingredient in these accidents, either with regard to selection and use of equipment or the decision to venture into unsafe situations. Ladders are often used when scaffolding would be more appropriate. Accidents occur because scaffolding has not been erected properly or tied in sufficiently. Workers go on to fragile roofs without crawling boards. Employees climb up and stand on roller conveyer systems to reach items stored above. Many of these accidents are avoidable.

9. IMPROVING SAFETY

The most effective approach to reducing slip, trip and fall accidents is to eliminate hazards. Ideally this should be done at the design stage, for example by:

- Choosing flooring that offers good slip resistance and that retains this property with cleaning and use.
- Designing systems of work, workplaces and equipment to minimize contamination of walkways and steps with liquids, powders or dry items, such as polythene bags or paper.
- Designing systems of work, workplaces and equipment to prevent trip hazards occurring on walkways.
- Covering outside areas, to keep off rain and ice.
- Avoiding steps and stairs in buildings used by older age groups, or providing easy to access alternatives, such as lifts (elevators).
- Incorporating permanent maintenance access to buildings, machinery and equipment that does not require use of ladders.

Remedial approaches include:

- Performing risk assessments to identify slip, trip and fall risks and implementing measures for their control.
- Ensuring use of suitable footwear.

- Providing appropriate equipment for manual handling and other tasks.
- Cleaning up spillages, removing obstacles, detecting and repairing damage to flooring and equipment, at an early stage.
- Making sure there is sufficient lighting to aid detection of hazards.
- Marking trip hazards that can not be removed; using changes of floor appearance (e.g. color) to delineate steps, stairs, etc.
- Erecting barriers around temporary holes and on roof edges when work is taking place.
- Using correct materials for floor cleaning and preventing access to areas while this is in progress.
- Providing information and training.

Many of these secondary approaches require significant, ongoing commitment at the organizational level. The difficulty of achieving this should not be underestimated.

1. INTRODUCTION

Slips and falls are a serious problem and are among the most common accidental injuries in the world, although they have received little public awareness and concern. There were 14 900 deaths in the US due to fall accidents in 1997 (National Safety Council 1998). Risky situations occur typically during normal locomotion and during manual exertion like lifting, pushing, pulling, or load carrying.

Slips and falls are also a complicated problem. The risk of slips and falls is governed by human perception, the control of human posture and balance, and the frictional characteristics of the shoe and floor contact interface. The disciplines involved include epidemiology, biomechanics, tribology, and psychology. Epidemiology helps to identify the seriousness and causes of accidents. Psychology and biomechanics help to perceive floor condition, develop the walking strategies over different floor conditions, and understand human response during slippery conditions and during a potential loss of balance. Tribology helps to evaluate whether floors and footwear are slippery and to identify the mechanisms involved in accidents. The causality of slips and falls is not yet fully understood. Before effective prevention strategies can be put into practice, one must clarify the accident and injury mechanisms involved. The chain or network of events, constituting exposure to hazards, initiation of hazardous incidents, and final injury, should be identified using epidemiological principles and methodologies.

The primary extrinsic risk factor for falls initiated by slipping is by definition poor grip or low friction between the footwear and floor. The question of whether the risk of falling and injury initiated by a slip is more related to a constantly low friction or an unexpected, sudden change in friction still remains to be solved. Other risk factors for slips and falls are related to insufficient lighting, uneven surfaces, inappropriate design of stairs and floors, poor housekeeping, load carrying, inadequate control of posture, and aging.

2. EPIDEMIOLOGY OF FALLS

The economic and human dimensions of slip and fall injuries at work, at home, and during leisure-time activities are overwhelming. According to the data published by the National Safety Council (1998), falls represented about 15% of all unintentional-injury deaths and 21% of all hospitalized injuries in the US in 1995. The data also showed that the probability of unintentional-injury deaths due to slips and falls was approximately equal for males and females. The average unintentional-injury death rate due to slips and falls was approximately 1165 per month in the US in 1995 with a slightly lower rate in June, a slightly higher rate in December, and a coefficient of monthly variation of 4.2%. Slips and falls are also a leading cause of accidental deaths at home. There were 9200

deaths due to slips and falls at home which accounted for approximately 32.4% of the total unintentional-injury deaths at home in the US in 1997.

The unintentional-injury deaths due to slips and falls in the US were the highest in 1943 (24 701 deaths) and were the lowest in 1986 (11 444 deaths) (National Safety Council 1998). However, the unintentional-injury deaths due to slips and falls have been on the rise since 1986. There was a 27% increase from 1987 to 1997 and a 2% increase from 1996 to 1997. Deaths due to slips and falls accidents per 100 000 population were the highest in 1936 and 1943 (18.4) and the lowest in 1986 and 1987 (4.8). However, the death rate has also been on the rise since 1987. There was a 17% increase in death rate from 1987 to 1997 and a 2% increase from 1996 to 1997.

Slips and falls are also a leading cause of unintentional-injury death for the older population (National Safety Council 1998). Among the unintentional-injury deaths due to slips and falls, 79% (11 057 deaths) were over the age of 65 with a peak of 2 670 deaths within the age group between 85 and 89 in 1995.

The injuries with lost time due to slips and falls averaged in excess of $13 096 per workers' compensation claims filed in 1995 and 1996 (National Safety Council 1998). Slips and falls also accounted for 20% of non-fatal occupational injuries involving days away from work in 1996. Among nine (9) industries evaluated by Leamon and Murphy (1995), the direct costs of occupational injuries due to slips and falls were the highest for the construction, restaurant, and clerical industries. Meanwhile, slips and falls were the second highest source of losses for manufacturing, trucking, retail and wholesale stores, healthcare, food products manufacturing, and professional drivers. The incidence rates for falls and workers' compensation claims were found to be highest for young (less than 25 years) and old (over 65 years) workers. Falls accounted for 17% of all work-related injuries and 12% of worker fatalities in the US (Leamon and Murphy 1995). The common perception of fall injuries might be related to falls from elevation. Though falls from elevation usually result in a higher claim cost, falls on the same level accounted for 65% of claim cases and, consequently, 53% of claim cost in the total direct workers' compensation for the occupational injuries due to slips and falls.

3. PERCEPTION OF SLIPPERINESS

The risk of slips and falls seems to depend on a person's subjective judgement of the potential slipperiness of actual floor conditions. There have been some speculations that it is easier to adapt one's gait when a slippery condition is consistent than when rapid and unexpected changes in slipperiness occur. Experimental support for this argument can be found in a study by Strandberg (1985) in which he observed that a consistent slippery condition led to fewer falls than a borderline somewhat slippery condition. However, no accident statistics is available to confirm this argument. On the contrary, Merrild and Bak (1983) found that certain high-risk winter days can cause over tenfold increase of pedestrian injuries due to falls initiated by slipping.

Vision may be the only sensory mode which allows a person to predict the potential slipperiness of a surface before stepping onto it. However, vision may also play an important role in the activation of other postural control mechanisms. Proprioceptor (e.g. stretch reflexes) and other receptors (e.g. pressoreceptors)

require that one already has walked on a slippery surface and felt it in order to acquire the feedback to adapt one's gait properly. Visual control can lead to several avoidance and accommodation strategies of gait when challenging conditions are encountered. Vision is known to regulate step length and width, direction of gait, walking velocity, and orientation of limbs, etc. (Patla 1991), but visual control cannot be solely relied upon in unexpected perturbations such as slips and trips since it is slower than vestibular or proprioceptive control.

3. BIOMECHANICS OF SLIPS AND FALLS

3.1. Control and Adaptability of Gait

Several sensomotoric systems are used by humans to maintain upright static posture and dynamic balance during locomotion. The central nervous system rapidly and accurately processes the sensory input from vestibular organs, vision, proprioceptors, and exteroceptive pressoreceptors. When posture and balance are challenged during a sudden slip or trip, a coordinated neuromuscular motor response is needed to re-establish the balance for avoiding a fall.

Vestibular influx normally governs 65% of the body sway during sudden perturbation, while 35% is accounted for by visual and proprioceptive influx (Pyykkö *et al.* 1990). Stretch reflexes in joints and muscles and tactile cues from pressoreceptors, which operate in the early prevention of falls, are important protective responses to unexpected perturbations. Aging, which contributes to an increased risk of slipping and falling, is one of the main reasons for defective coactivation of functional stretch reflexes. The very elderly rely mostly on visual influx (latency 120–200 ms) which is slower than other mechanisms for control of balance (Pyykkö *et al.* 1990). Latencies for corrective reflex responses for healthy young men in the recovery from tripping have been reported to be much quicker (60–140 ms) indicating that balance control during locomotion involves specific movement patterns in response to a tripping perturbation (Eng *et al.* 1994).

Certain protective gait adaptations are aimed at regulating gait in hazardous situations, for instance slippery conditions. Humans can adapt to walking continuously over very slippery surfaces due to such adaptations which take place in essentially a one-step cycle after one has become aware of the slipperiness of the particular surface being approached. Llewellyn and Nevola (1992) reported the results of trials where subjects adapted their gait under low-friction conditions by adopting such a protective strategy. The strategy involved a combined effect of force and postural changes of the early stance. The subjects took shorter steps and increased their knee flexion, which, in combination, reduced the vertical acceleration and the forward velocity of the body.

3.2. Critical Gait Phases

Five (5) major motor functions are used to achieve safe and efficient propulsion of the body during the gait cycle regardless of the pace of locomotion (Winter 1991). The first three of these functions are to maintain the support of the upper body during stance, to maintain the upright posture and balance of the total body, and to control the foot trajectory in order to achieve safe ground clearance and gentle heel or toe landing. The other two major motor functions are to generate mechanical energy to maintain or increase the forward velocity, and finally to absorb the mechanical energy for shock absorption and stability or to decrease the forward velocity of the body.

Heel strike and toe-off are two critical gait phases in walking for slips and falls accidents. A forward slip on the leading foot typically occurs during the heel contact, while a backward slip on the sole forepart typically occurs during the toe-off. Since the weight on the trailing foot is being rapidly transferred to the heel of the leading foot during the toe-off phase, a slip during the push-off is considered less dangerous than a slip at heel landing. The forward slip starting at back edge of the heel during the heel landing phase would very likely result in a more dangerous fall because the body weight is being transferred to the leading foot.

The biomechanical dynamics of human heel slipping was investigated by Strandberg and Lanshammar (1981) when subjects approached a force plate covered with mixtures of water and detergent. They observed that the peak sliding velocities after the heel strike were above walking speed (1 to 2 ms^{-1}) during slips that resulted in a fall, but were usually below 0.5 ms^{-1} in slips where the subjects were able to regain their balance and avoided a fall. They concluded that a slip was likely to result in a fall if the sliding exceeded 0.1 m in distance or 0.5 ms^{-1} in velocity. The average critical slip motion during their experiments started 50 ms after the heel strike when the rear edge of the heel was in contact with the floor and the vertical load was about 60% of body weight. They also reported that a slight sliding between the footwear and floor right after the heel strike occurred often, even in dry non-slippery conditions, but that the subjects were mostly unaware of the slight movement.

Morach (1993), on the contrary, found in human slipping experiments on contaminated (oil, glycerin, and water) floors that the horizontal foot velocity in the forward direction prior to heel contact varied between 0.3 ms^{-1} and 2.75 ms^{-1}. The highest velocity after slip initiation was 2.5 ms^{-1} and occurred on a steel floor with oil as a contaminant, when there was an immediate slip following the heel strike. The average walking speed was approximately 1.5 ms^{-1} in all the above experiments. Morach's results indicate that a higher minimum sliding velocity (1.0 ms^{-1}) than that proposed by Strandberg and Lanshammar should be used when assessing the slip resistance properties of shoes and floors, particularly in the presence of oil. His findings also suggest a heel contact angle of 15 to 20 degrees for simulation of slipping at the heel and a short contact time of 30 to 60 ms.

The risk of a slip-and-fall accident is considered low when the friction coefficient (mm) is greater than the ratio of the horizontal (F_H) and vertical (F_V) force components applied to the ground, i.e.

$$F_H < F_V$$

Consequently, if the magnitudes of the horizontal and vertical force components applied to the ground during walking and the friction coefficient for the actual tribosystem are known, it would be possible to evaluate whether the system is potentially slippery or not. Strandberg and Lanshammar (1981) measured the friction use peak, F_H / F_V, approximately 0.1 s after the heel strike. The average peak was 0.17 when there was no skidding between the shoe and floor, 0.13 when the subject was unaware of the sliding motion or regained balance, and 0.07 when the skid actually resulted in a fall. Dynamic friction appeared to be more

important than static friction, because in most of their experiments the heel slid upon heel contact even without any contaminant.

4. FRICTION MECHANISMS FOR SHOE AND FLOOR INTERFACE

Friction has been widely used as an indicator of floor slipperiness. Moreover, friction at the interface between the footwear and floor is very complicated. Factors such as the footwear and floor materials, contaminants at the interface, temperature, humidity, surface roughness on footwear and floor, contact force, relative velocity at the interface, and patterns on the footwear and floor surfaces affect friction. As pointed out by Tabor (1974), the major friction mechanisms involved at a dry interface are the plowing of asperities of the harder solid surface through the softer surface and the shearing of the adhesive bonds formed at the region of real contact. When a polymer slides over a rough hard surface, some contribution to the friction will arise from the deformation of the polymer by the hard asperities. The main mechanisms for friction due to polymer deformation include tearing and hysteresis due to the viscoelastic properties of the polymer. The energy dissipation due to deformation mainly occurs at a small depth below the surface where the maximum shear stresses occur. The main sources of the adhesion are electrostatic and van der Waals' forces for the polymers. The contact area between polymers and a hard surface is greater than that predicted by the Hertz theory where no adhesion was assumed (Tabor 1974). When the polymer adheres to another surface, work must be expended in order to produce sliding since the adhesions at the interface must be broken. The formation and rupture of adhesive bonds increase the hysteresis loss of the polymer and, thus, increase the friction. An equation to predict friction coefficient based on the contribution from adhesion and hysteresis for elastomers on dry surfaces is available in the literature (Moore 1972).

The hydrodynamic lubrication and boundary lubrication are additional friction mechanisms involved when liquid contaminants are present at the interface. The surfaces of shoe and floor are completely separated by the contaminant under the hydrodynamic lubrication, while the normal load is supported by the contaminant and some direct solid to solid contact under the boundary lubrication. In the classical generalized Reynolds' equation, the generation of hydrodynamic pressure in the lubricant film is governed by wedge, stretch, and squeeze terms (Moore 1972). Hence, Reynolds' theory takes into account the vertical squeezing motion and the tangential sliding motion. The effect of the squeeze and wedge terms has been widely discussed (Moore 1972). The stretch contribution has not been discussed extensively, although it is considered important for viscoelastic materials such as rubbers and elastomers.

The squeeze-film effect governs the hydrodynamic region as indicated by Moore (1972). The formation of hydrodynamic pressure to separate two surfaces requires a sufficient relative velocity, surface smoothness, high viscosity of contaminant, and a low contact force at the interface. Therefore, an increase in surface roughness on either shoe or floor, pattern on shoe or floor to reduce the amount of contaminants at the interface, and a reduction in conformity between the shoe and floor can certainly help increase friction through a reduction in the squeeze-film region.

The independent equations for the squeeze and wedge terms

are also available in the literature (Moore 1972). For the squeeze effect, the thickness of contaminant at the interface is affected by the viscosity of contaminant, the contact area, the normal force and the descend time of the footwear. For a given contaminant, a shorter drainage time to reduce the risk of slips and falls accidents can be achieved by an increase in the normal contact force, and a reduction in the contact area and the viscosity of contaminant. For the wedge effect, the thickness of contaminant at the interface is affected by the contaminant viscosity, dimension of the contact area, the sliding velocity and the normal force. To minimize the contaminant thickness at the interface for obtaining good contact and grip between the shoe and floor surfaces, it is critical to reduce the dimension of the contact area and the viscosity of contaminant, and to increase the normal force.

5. MEASUREMENT OF SLIP RESISTANCE

Both static and dynamic (kinetic) friction coefficients have been widely used to indicate the slip resistance between the shoe and floor surfaces, but there has been continuing debate regarding how to measure it properly. Static friction has been considered important for slip initiation, while kinetic friction represents the resistance to continuation of a slip after initiation. Support for both static and dynamic friction coefficients has been reported.

Static friction is limited to the slip start before any detectable motion, while a fully developed slip condition may require the determination of steady-state dynamic friction produced only after some time delay from the slip start. The transitional period after the slip initiation is typically very short (less than 250 ms) when slipping at heel strike, and it seems to reflect the squeeze-film phenomena during early stance phase in a foot forward slip on contaminated surfaces.

Drag or towed-sled devices, pendulum strikers, articulated-strut devices, braked-wheels or skiddometers, turntables or rotating discs, and gait simulators are often referred to in the context of slip resistance measurement. The output quantity according to these different principles is typically force, torque, loss of energy, inclination angle, or rolling resistance. Among a variety of techniques currently available for measuring slip resistance of footwear and floors, Strandberg and Lanshammar (1981) found surprisingly little support in their biomechanical skidding data for the most common measurement principles.

A dynamic loading test condition, typical for the heel strike in normal walking, has received too little attention in many devices for slip resistance measurements. Only the pendulum strikers, some gait simulators, and some articulated-strut devices produce an impact at the moment when friction coefficient is measured. However, the impact forces produced are mostly not well defined and do not correspond to normal gait, where the heel touch-down is characterized by collision-type contact forces (Cappozzo, 1991).

The measurement parameters and their ranges should reflect the biomechanics and tribophysics of actual slipping incidents. As indicated by Grönqvist (1999), the condition at the floor and shoe interface should satisfy the following criteria: a normal force build-up rate of at least 10 kNs⁻¹, a normal pressure from 0.1 to 0.6 MPa, a sliding velocity less than 1 ms⁻¹, and a contact time prior to and during the friction coefficient computation between 50 and 800 ms.

Friction coefficient limit values should be correlated to the

normal variability of human gait characteristics. As summarized by Grönqvist (1999), the safety criteria for friction coefficient reported in the literature has been between 0.15 and 0.6, depending on biomechanical factors, such as walking speed, stride length, turning, pushing/pulling, stopping and anthropometric parameters, and environmental factors, such as ramps and stairs. However, friction coefficient limit values should always be regarded as rough guidelines since the safety criteria reported in the literature are very much depending on biomechanical factors as well as the normal variability of human gait. It is not yet fully understood whether preferably a high enough friction coefficient or merely a consistent friction coefficient would be beneficial for safe walking.

Human subjects can differentiate the slipperiness of floors and footwear in various dry, wet, and contaminated conditions. Purely subjective methods, such as paired comparison tests, or partly subjective and partly objective methods, such as ramp tests, and the measurement of slip distance during slipping incidents have been used to assess slip resistance as summarized by Grönqvist (1999).

6. CONCLUSIONS

Despite the complexity of the problems in slips and falls, some interventions could be quite simple such as a proper housekeeping cleaning protocol for the floor surfaces, sufficient lighting, a promotion of the awareness of the problems and periodic replacement of worn footwear. More elaborate interventions could include a proper selection of floor surface, floor treatments, a proper selection of footwear with an adequate tread pattern design and heel geometry, and employee training. However, one should bear in mind that effective interventions also depend on the type of contaminants involved. Successful interventions for one contaminant may not be successful for other types of contaminants.

Several strategies can be used to reduce slips and falls accidents. Current slip resistance measurement techniques (either objective or subjective methods) need further improvement and need to be validated by biomechanical evaluation in conditions for which they are intended to be applied. Expert systems should be used to assist designers of floorings and footwear in leading to safer products and to assist safety consultants for intervention development. Effective housekeeping interventions at workplaces and elsewhere should be implemented. Safety standards for both floorings and footwear, such as contaminant and task related standards, should be developed and adequate selection guidelines for the users of such products should be established.

1. INTRODUCTION

The Strain Index is a semi-quantitative job analysis methodology based upon principles of physiology, biomechanics and epidemiology (Moore and Garg 1995). Its purpose is the identification of jobs that place workers at increased risk of developing disorders in the distal upper extremity (elbow, forearm, wrist, hand). Application of the Strain Index (SI) methodology results in a numerical score (the SI score) that, based on interpretation guidelines, predicts whether a job exposes workers to increased risk of developing distal upper extremity disorders, i.e. if the job is a "problem."

Consistent with physiological, biomechanical and epidemiological principles, the SI methodology is based on multiplicative interactions among its task variables. The SI score represents the product of six multipliers that correspond to six task variables. The six task variables include intensity of exertion; duration of exertion; exertions per min; hand/wrist posture; speed of work; and duration of task per day. Intensity of exertion, hand/wrist posture and speed of work are estimated. Duration of exertion, exertions per min and duration of task per day are measured. Based on these estimated or measured data, each of the task variables is rated according to five ordinal levels using Table 1. The user finds the column heading corresponding to the appropriate task variable, moves down to the appropriate row within that column, then follows the row to the first column on the left hand side to identify the appropriate rating. The multipliers for each task variable are determined from the ratings using Table 2. The user finds the column heading corresponding to the appropriate task variable and the row corresponding to the appropriate rating, then identifies the multiplier at the intersection of the task variable column and rating row. The SI score is the product of the six multipliers.

2. STRAIN INDEX TASK VARIABLES

2.1. Intensity of Exertion

Intensity of exertion is an estimate of the force requirements of a task. It reflects the magnitude of muscular effort, in the context of percent maximum strength, required to perform the task one time. It reflects physiological and biomechanical stresses on the muscle–tendon units of the distal upper extremity related to the magnitude of tensile loading. It does not reflect stresses related to endurance or stamina.

Since tensile load cannot be measured directly *in vivo* and measurement of applied force with the hand is impractical or difficult in an industrial setting, intensity of exertion is generally estimated using verbal descriptors (Table 1). This is actually an estimate of perceived exertion similar to using the Borg CR-10 scale. To estimate the intensity of exertion, a job analyst or ergonomics team observe a worker (or workers) perform the job, then select the verbal descriptor from Table 1 that best corresponds to their perception of the intensity of exertion. Perceived exertion may also be obtained from the worker(s). Differences among estimates can be resolved by consensus if more than one job analyst is involved. The intensity of exertion rating value (1, 2, 3, 4 or 5) is then assigned using Table 1. The intensity of exertion multiplier corresponding to this intensity of exertion rating is identified using Table 2.

Table 1. Ratings for the Strain Index task variable are assigned by finding the row within the column that corresponds to the datum for each task variable, then recording the rating value listed in the first column (left hand side).

Rating	Intensity of Exertion	Duration of Exertion (% of cycle)	Efforts/ Minute	Hand/wrist Posture	Speed of Work	Duration per Day (hrs)
1	Light	<10	<4	Very Good	Very Slow	≤ 1
2	Somewhat Hard	10 - 29	4 — 8	Good	Slow	1 - 2
3	Hard	30 - 49	9 — 14	Fair	Fair	2 - 4
4	Very Hard	50 - 79	15 — 19	Bad	Fast	4 - 8
5	Near Maximal	≥ 80	≥ 20	Very Bad	Very Fast	≥ 8

Table 2. Multipliers for each Strain Index task variable are determined by finding the intersection of the appropriate rating row with the appropriate task variable column.

Rating	Intensity of Exertion	Duration of Exertion	Efforts/ Minute	Hand/Wrist Posture	Speed of Work	Duration per day
1	1	0.5	0.5	1.0	1.0	0.25
2	3	1.0	1.0	1.0	1.0	0.5
3	6	1.5	1.5	1.5	1.0	0.75
4	9	2.0	2.0	2.0	1.5	1.0
5	13	3.0[A]	3.0[A]	3.0	2.0	1.5

A If duration of exertion is 100%, then efforts/minute multiplier should be set to 3.0.

2.2. Duration of Exertion

Duration of exertion reflects the physiological and biomechanical stresses related to how long an exertion is maintained. It is characterized as the percentage of time an exertion is applied per cycle. In the SI methodology, the terms "cycle" and "cycle time" refer to exertional cycle and average exertional cycle time respectively, not production cycle or production cycle time.

To measure exertional cycle time, the job (or a representative videotape of the job) is observed for a sufficient period so that a job analyst or ergonomics team can obtain a reasonable representation of the job requirements. In general, this should be several complete job cycles (the more the better). The duration of the observation time and the duration of exertion time are measured with stopwatches. The percentage duration of exertion is calculated by dividing the exertion time by the observation time, then multiplying by 100. The calculated percentage duration of exertion is compared with the ranges in Table 1 to determine the duration of exertion rating. The duration of exertion multiplier corresponding to this duration of exertion rating is identified using Table 2.

2.3. Efforts per Minute

Efforts per min refers to the number of exertions applied by the hands per min. Efforts per min are measured by counting the number of exertions that occur during a representative observation period (measured in min), then calculated by dividing the total number of exertions by the observation time. The calculated result is compared with the ranges in Table 1 to determine the efforts per min rating. The efforts per min multiplier corresponding to the efforts per min rating is identified from Table 2.

2.4. Hand/Wrist Posture

Posture refers to the anatomical position of the wrist or hand relative to neutral position. Even though posture has not been associated with the occurrence of distal upper extremity disorders in epidemiological studies, it is likely relevant from a biomechanical perspective (Moore 1996, 1997). Specifically, shear forces at tendon sheaths are generated when loaded tendons turn corners; therefore, non-neutral hand/wrist postures may be relevant when considered in combination with the temporal pattern of tensile tendon loads.

Similar to intensity of exertion, average hand/wrist posture during exertions is estimated qualitatively by one or more observers (Table 1). If there is more than one job analyst, it is recommended that differences in ratings be resolved by consensus. The hand/wrist posture rating is assigned by comparing the verbal anchor to Table 1. The hand/wrist posture

multiplier corresponding to the hand/wrist posture rating is identified using Table 2.

2.5. Speed of Work

Speed of work is an estimate of the perceived pace of the task or job. It is included because of its modifying effects on exertions, i.e. maximal voluntary strength decreases and EMG amplitude increases with increasing speed. In addition, it is suspected that a worker's muscles do not fully relax between high speed, high frequency exertions.

A job analyst or ergonomics team subjectively estimates speed of exertion. If there are multiple job analysts, it is recommended that differences in ratings be resolved by consensus. Once a verbal anchor is selected, the speed of work rating is assigned according to Table 1. The speed of work multiplier corresponding to the speed of work rating is identified using Table 2.

2.6. Duration of Task per Day

Duration of task per day reflects the total time that a task is performed per day. It attempts to incorporate the beneficial effects of task diversity, i.e. job rotation (if the differing task is associated with reduced stresses), and the adverse effects of prolonged activity, such as overtime. Duration of task per day (expressed as hours) can be measured or recorded from authoritative sources, e.g. worker/supervisor reports of shift duration or administrative records. The duration per day rating is assigned according to Table 1. The duration per day multiplier corresponding to the duration per day rating is identified using Table 2.

3. STRAIN INDEX SCORE

The SI score is the product of all six multipliers:

SI = (intensity of exertion multiplier) × (duration of exertion multiplier) × (exertions per min multiplier) × (posture multiplier) × (speed of work multiplier) × (duration per day multiplier). (1.1)

An example demonstrating the calculation of a SI score is demonstrated in Table 3.

4. INTERPRETATION OF THE STRAIN INDEX SCORE

Initial guidance for interpretation of the SI score was based on data from a prior study (Moore and Garg 1994). In that study, a "positive" job was a job noted to have workers with reported distal upper extremity morbidity during a 20-month observation, while a "negative" job had no reported disorders during the same period. The distal upper extremity morbidity included specific

Table 3. An example to demonstrate the procedure for calculating the SI score.

	Intensity of Exertion	Duration of Exertion	Efforts/ Minute	Posture	Speed of Work	Duration per Day
Exposure Data	Somewhat Hard	60%	12	Fair	Fair	4–8
Ratings	2	4	3	3	3	4
Multipliers	3.0	2.0	1.5	1.5	1.0	1.0

SI score = 3.0 x 2.0 x 1.5 x 1.5 x 1.0 x 1.0 = 13.5

disorders (epicondylitis, DeQuervain's tenosynovitis, trigger finger, trigger thumb, CTS) and non-specific disorders. The latter category was assumed to represent strain-related disorders of the muscle–tendon units.

Among "positive" job categories, the SI scores ranged from 4.5 to 81.0 with a mean of 29.0. Among "negative" job categories, the SI scores ranged from 0.5 to 4.5 with a mean of 2.3. The difference between the two means was statistically significant ($t = 4.05$; d.f. = 23; $p < 0.01$). There was only one overlapping SI score between these two groups — 4.5. Based on these results, preliminary interpretation guidelines were that a job with a SI score < 5 probably represented a "safe" job while a job with a SI score > 5 probably represented a "problem" job. If more conservative criteria are desired, a job with a SI score < 3 is probably "safe," a job with a SI score > 7 is probably a "problem," and a job with a SI score between 3 and 7 cannot be reliably classified.

5. PREDICTIVE VALIDITY OF THE STRAIN INDEX

The primary strategy to evaluate the SI's predictive validity involves comparing the SI's dichotomous hazard prediction for a set of jobs against a dichotomous morbidity classification of the same jobs. Jobs were classified to "problem" or "safe" based on whether the SI score was greater than or less than 5 respectively. Jobs were classified as "positive" or "negative" based on whether there were distal upper extremity disorders reported by workers assigned to the job during a retrospective observation period. Using a 2×2 table, the degree of association between the SI score predictions and the observed morbidity were made. In addition, the sensitivity, specificity, positive predictive value and negative predictive value could be calculated.

The original paper reported the results of such a procedure for 25 jobs from a pork processing plant. There were 12 "positive" jobs and 13 "negative" jobs. Of the 12 "positive" jobs, 11 were predicted to be a "problem" and one "safe." Of the 13 "negative" jobs, all were predicted to be "safe." These values correspond to a sensitivity of 0.92; specificity of 1.00; positive predictive value of 1.00; and negative predictive value of 0.93. This validation was considered preliminary because the authors were not blinded to the health outcomes when exposure was evaluated with the SI and the hazard predictions made.

Since the original publication, the SI's utility as a job analysis and solution development tool was demonstrated in a project that involved the analysis of several problem jobs in a red meat packing plant by two ergonomics teams (Moore and Garg 1997). More recently, 30 jobs from two manufacturing facilities and 29 jobs from a turkey processing plant have been evaluated with the job analysts blinded to health outcomes (Moore 1999, personal communication). In the manufacturing facilities, there were six "positive" jobs and 24 "negative" jobs. Of the six "positive" jobs, all were predicted to be a "problem." Of the 24 "negative"

jobs, 21 were predicted to be "safe" and three predicted to be a "problem." These values correspond to a sensitivity of 1.00; specificity of 0.90; positive predictive value of 0.62; and negative predictive value of 1.00. In the turkey processing facility, there were 22 "positive" jobs and seven "negative" jobs. Of the 22 "positive" jobs, 20 were predicted to be a "problem" and two were predicted to be "safe." Of the seven "negative" jobs, all seven were predicted to be "safe." These values correspond to a sensitivity of 0.91; specificity of 1.00; positive predictive value of 1.00; and negative predictive value of 0.78. When all 84 jobs are combined into one 2×2 table, sensitivity was 0.93; specificity was 0.93; positive predictive value was 0.93; and negative predictive value was 0.93.

Based on this validation strategy, the SI is an effective method for identifying jobs likely to be have workers with reported distal upper extremity disorders.

6. FUTURE WORK

Other aspects of validation, such as inter-rater variability and test–re-test repeatability, are subjects of current research projects sponsored by the National Science Foundation Industry/ University Cooperative Research Center in Ergonomics. Strategies for quantifying intensity of exertion and hand/wrist posture are being explored with an objective of possibly defining explicit mathematical relationships between task variable measurements and multipliers. A theoretical approach for applying the SI to jobs that involve multiple levels of a similar exertion (called complex tasks) and jobs that involve multiple tasks is being developed. In addition, the ability to predict specific disorders is being explored by comparing unique patterns of exertions for specific musculo-tendinous structures with proposed pathogenetic models for specific disorders affecting those structures (Moore 1996, 1997)

Surveillance for Work-related Musculoskeletal Disorders

K. A. Grant

US Air Force, Institute for Environment, Safety and Occupational Health Risk Analysis, Ergonomics and Hearing Conservation Branch, Brooks AFB, TX 78235–5123, USA

1. INTRODUCTION

Surveillance is classically defined as, "the ongoing systematic collection, analysis and interpretation of health and exposure data in the process of describing and monitoring a health event" (CDC 1988). Perhaps more simply, surveillance seeks to identify patterns of health and disease among groups of workers and the risk factors that influence these trends. In recent years, establishing surveillance procedures has been recognized as a necessary first step in the establishment of an industrial ergonomics program (OSHA 1990). There is growing recognition that poorly designed workplaces are a major contributor to many occupational injuries and illnesses, including work-related musculoskeletal disorders. Surveillance determines the need for occupational safety and health action, and provides the data necessary to direct prevention efforts and assess the efficacy of ergonomic interventions.

2. FUNDAMENTALS OF SURVEILLANCE

Surveillance activities can be divided into two broad categories: (1) health or medical surveillance and (2) hazard surveillance. Health or medical surveillance activities seek to identify established or suspected cases of occupational injury or illness for follow-up. This approach can be viewed as reactive, i.e. the occurrence of illness or injury is the driver for further action. Hazard surveillance monitors and characterizes exposures to physical hazards associated with injury and illness in the workplace. This approach is more proactive, and can lead to the identification and elimination of hazards before illnesses occur. In reality, health and hazard surveillance activities are complementary, and the best musculoskeletal disorder prevention programs usually incorporate both.

2.1. Monitoring Injury and Illness Trends

Owing to Occupational Safety and Health Administration (OSHA) requirements, almost all workplaces maintain at least some information about work-related injuries and illnesses. Because of their ready availability, almost all musculoskeletal surveillance efforts begin with a review of existing injury and illness records to identify jobs that may have resulted in work-related musculoskeletal disorders in the past. Potential data sources include the OSHA *Log and Summary of Occupational Injuries and Illnesses*, on- and off-site medical records, workers' compensation records, accident reports and insurance claim data. Initial review of these records usually provides a count of the number of musculoskeletal disorders associated with a specific job or work area within a given time frame.

2.1.1. Calculating rates and percentages

To permit meaningful comparisons, e.g. across jobs, departments or work sites that employ different numbers of workers, or across periods of fluctuating employment, injury/illness occurrences are usually expressed as a rate.

The incidence rate is the rate of work-related musculoskeletal disorders that appear for the first time during a given period (usually a year). The value is commonly expressed as the number of illnesses per 100 full-time workers per year and is calculated as follows:

(Number of new cases in the past 12 months x 200 000 h (2.1)/ number of work hours in the past 12 months).　　(1)

Information on work hours can usually be obtained from personnel or payroll records. A common assumption is that each employee works 2000 h per year (8 h a day, 5 days a week, 50 weeks a year). Therefore, an estimate of the value of the denominator can be obtained by multiplying the number of full-time equivalent workers employed in the job, department, or plant by 2000 h.

The prevalence rate is the percentage of all workers who are experiencing musculoskeletal symptoms at a specific instance in time, regardless of when the problem first appeared. It is calculated as follows:

(Total number of cases at a given point in time)/number of workers at the same point in time). (2)

The severity index is similar to the incidence rate, but substitutes the number of lost or restricted work days due to illness for the number of cases in the numerator. The severity index is calculated as follows:

(Total number of lost or restricted workdays in the past 12 months x 200 000 h)/number of work hours in the past 12 months). (3)

2.1.2. Interpreting incidence, prevalence and severity

Although closely related, incidence and prevalence rates provide somewhat different information. Prevalence depends both on the incidence and the duration of the illness from its onset to its resolution. For example, if the incidence of neck pain is low, but workers take a long time to recover, the prevalence will be high relative to the incidence. On the other hand, even if the incidence of musculoskeletal disorders among workers is high, the prevalence may be relatively low if workers recover quickly, or if they are forced to leave the workforce because of their illness.

The severity index provides information about the seriousness and costs of reported musculoskeletal disorders. Because medical treatment practices, the health benefits available to employees, and the opportunity for light duty influence the severity index, it is usually a good indicator of the effectiveness of the worksite's medical management program. Note that the severity index can be skewed if a few employees are away from their jobs for an unusually long period of time.

Incidence and prevalence rates provide valuable information for directing intervention efforts to truly hazardous workplaces. Unfortunately, incidence and prevalence rates are sometimes used as performance indicators in management reviews of worksite occupational safety and health programs. This practice can inadvertently penalize employers who have recently established an

ergonomics program. Many organizations find that incidence and prevalence rates initially increase after the introduction of an ergonomics program. This is usually due to heightened awareness and reporting of musculoskeletal disorder risk factors and symptoms, rather than a true increase in the disorders. In these situations, the severity index may provide a more appropriate yardstick, since the seriousness and recovery period associated with musculoskeletal disorders are usually diminished with earlier reporting.

2.1.3. Limitations

The quality and utility of existing record systems for surveillance purposes often varies; as a result, different data sources may offer strikingly different conclusions about the incidence of work-related musculoskeletal disorders associated with a specific job. One unfortunate problem is the lack of consistency or standardization in the way work-related musculoskeletal disorders are defined. "Musculoskeletal disorders" encompass a broad spectrum of illnesses that can be caused or aggravated by a wide variety of work activities. Many of these conditions can result from either acute trauma or chronic exposure to adverse working conditions; therefore, distinguishing work-related musculoskeletal disorders from acute sprains and strains is difficult unless a code for etiology is provided in the database. Many databases do not have fields for such codes, and even if they do, the codes are often applied by administrative or safety personnel who are more likely to make erroneous determinations of cause than medical professionals. For example, at most Air Force installations, the injury and illness log is maintained by a junior enlisted member who is usually instructed to code all back disorders as "injuries," without regard to their actual cause.

Another problem that limits the utility of record-based surveillance efforts is that a lag often exists between the appearance of a hazard and the onset of injury. As a result, records may not accurately reflect the current situation.

Finally, linking injury or disease data with exposure to a hazard can be especially challenging. Job titles are often poor indicators of exposure to risk factors for musculoskeletal disorders, and most records do not provide a detailed description of the worker's job or the disorder. Additional data needed to link musculoskeletal disorders to specific tasks or job processes may not exist.

2.2. Soliciting Information from Workers

Because of limitations in record-based surveillance, many employers conduct additional activities specifically to solicit information about adverse health outcomes from their employees. These activities may involve distributing questionnaires or other surveys, or administering health interviews and physical exams to workers employed in physically demanding jobs.

2.2.1. Worker surveys

Worker surveys can take several forms. They can be lengthy or quite short; they can be oral (i.e. administered by an interviewer) or written. Common features of surveys include:

- Use of charts and pictures, where workers can indicate the location of pain or other musculoskeletal symptoms.
- Questions about the onset and duration of musculoskeletal symptoms.

- Use of numerical rating scales to indicate the severity of pain, fatigue or discomfort.
- Questions about the duration of employment and the nature of job activities.

Worker surveys have several advantages over other methods of collecting surveillance data. First, the investigator has a great deal of control over the data. Once the investigator has decided what questions need to be answered, s/he can include survey items that provide the necessary information. Second, surveys are cheap and relatively easy to administer – in most cases, workers can complete the surveys at their convenience, and responses can be kept anonymous. These features can encourage high participation rates and candid responses, although the opportunities for individual follow-up are more limited. These features also allow worker surveys to be re-administered periodically to aid in early recognition of emerging problem areas.

Worker surveys also have some inherent limitations. The time and resources required to develop and administer surveys may make them more costly than surveillance activities that rely solely on existing records. The survey information may also be unreliable if there is animosity or a lack of trust between management and workers. Finally, the design of the questionnaire can have a dramatic impact on the quality of the data and the number of workers who complete the survey. The length of the questionnaire, the phrasing of the questions, and method of administration must be carefully considered. In a diverse or multilanguage workforce, translating the questionnaires into several languages may be necessary.

2.2.2. Physical exams

The purpose of physical exams is to identify workers at risk of developing more serious musculoskeletal conditions, so that they may be referred for early treatment. It must be noted that most musculoskeletal conditions are not amenable to detection in a preclinical state, and surveillance for these conditions constitutes secondary, and often tertiary, prevention of progression and disability rather than primary prevention of disease. Nonetheless, OSHA (1990) has published recommendations for conducting baseline and periodic medical examinations of workers assigned to jobs with significant musculoskeletal demands. These examinations should include a medical and occupational history, and inspection, palpation, range of motion, and other pertinent maneuvers of the upper extremities and back.

2.3. Conducting Hazard Surveys

Ideally, actions to prevent work-related musculoskeletal disorders should proceed before injuries/illnesses occur. Screening jobs for risk factors that lead to the development of work-related musculoskeletal disorders can highlight jobs for additional, more detailed surveys. Even without clear medical evidence that musculoskeletal problems exist, hazard surveillance activities can provide the data needed to begin an effective primary prevention program.

Hazard surveillance efforts depend heavily on walk-through surveys. The purpose of the walk-through is to identify risk factors that might otherwise go unnoticed and provide additional basis for prioritizing jobs for further evaluation. Typically, investigators observe job activities, speak with workers and supervisors to obtain information not apparent from observation, and use

checklists to score job features against a listing of risk factors. The walk-through survey is distinguished from more formalized job analysis efforts by the amount of detailed information collected.

Although most ergonomic checklists are designed for use by non-experts, some minimal level of training is usually needed to use checklists properly. Hazard checklists can vary in length and in scope. At one extreme, there are "generic" checklists that are applicable to nearly all jobs in all industries. These checklists can be contrasted with more focussed checklists, that are tailored to evaluate conditions typical of a specific job or industry. While some checklists are intended to serve primarily as mnemonics (i.e. to remind users to evaluate a particular job characteristic), other checklists incorporate a scoring system for assessing the degree of hazard associated with a job or process.

Ideally, hazard surveys should be administered (1) whenever a job, task or process is changed substantially, (2) when new jobs are introduced and (3) periodically (especially after new cases of musculoskeletal disorders are reported) to detect whether trends exist across jobs that use similar equipment, tools or processes. Hazard surveys can also be incorporated into regularly scheduled safety and health inspections, expanding the scope of these inspections to include identification of musculoskeletal disorder risk factors.

3. ESTABLISHING INTERVENTION PRIORITIES

Ultimately, surveillance activities obligate the employer to intervene to alter the workplace factors that produce adverse health events and hazards. There have been several attempts to recommend various thresholds or "triggers" when intervention in the workplace becomes necessary. The ergonomics standard adopted by the California Occupational Safety and Health Standards Board on 17 April 1997 requires employers in that state to take certain actions when a single WMSD is reported. This requirement is based on the recognition that formal surveillance activities usually detect only a small proportion of the musculoskeletal problems and that one reported case may lead to several times as many unreported cases.

As stated previously, health and hazard surveillance data are highly complementary, and considered together, they do suggest a rational means of establishing intervention priorities. Stumpp and Sparks (1997) suggest that areas where the incidence of musculoskeletal disorders is high and risk factors have been identified should get first attention, followed by areas where only musculoskeletal disorders have been found, and then by areas where only risk factors have been found. If additional prioritization is required in the top tier (e.g. because intervention resources are limited), giving preference to jobs that employ many people, or jobs where major changes are already planned can be a sensible and cost-effective approach.

4. CONCLUSIONS

Surveillance is essential to the prevention/control of musculoskeletal disorders in the workplace. In general, no single data source provides enough information to direct a program for preventing work-related musculoskeletal disorders. Therefore, effective surveillance programs make use of multiple data sources to identify problem areas and determine intervention priorities. Even in the absence of health data, hazard surveys conducted in workplaces where significant or well-defined hazards exist can provide the data needed to mount an effective primary prevention program for work-related musculoskeletal disorders.

Once established, surveillance should become an on-going process. As corrective actions are taken, surveillance data can provide the information needed to show the beneficial effects of these efforts. By integrating surveillance efforts with existing quality assurance and cost containment programs, their utilization and success will be maximized.

System Safety Engineering and Risk Assessment

N. J. Bahr

Hernandez Engineering, Inc., 3509 Kent Street, Kensington, MD 20895, USA

1. INTRODUCTION

The desire to be free of accidents and injuries has been a part of mankind since the beginning of time, with one of the earliest written references to safety from the Code of Hammurabi *c*.1750 BC, stating that the builder of a house would be put to death if poor construction caused death of the owner. System safety engineering and risk assessment has changed much since then; however, many still confuse the terms, and frequently use them interchangeably.

System safety engineering is the application of engineering and management tools and practices to assure that a system is safe for operators and the public (i.e. free from injury), environment and other equipment. In this definition it is critical to understand that a *system* is the combination or interaction between people, hardware, software and operating environment.

Risk assessment is the formal process of determining the risk of a particular event to the system. It can be used to determine the safety of a system or it can be used for non-safety trade-off assessments of the probability that a particular event and its resulting consequences occur. One such example is the risk of late product launching or financial risk of a particular operational strategy.

2. FUNDAMENTALS OF SYSTEM SAFETY

2.1 What is an Accident?

The purpose of system safety engineering is to *design into a system* the prevention of an accident or mitigation of its consequences. Accidents now are no longer confined within national borders but many times are transnational. The Chernobyl nuclear accident in Ukraine in 1986 not only immediately killed 31 people but also sent radioactive particles through wind currents to over 20 countries. Society's rapid technological development many times has created very complex human–machine interfaces. Poor design and operations of these interfaces can also lead to undesired mishaps.

An *accident* is an unplanned series of actions that causes undesired loss of life, injury or unwanted damage to equipment or the environment. However, they do not just occur, they follow a discernible process and series of steps before a catastrophic event occurs. If one can prevent or control one or more of these steps in the process many times a mishap can be prevented altogether or its consequences diminished.

The *initiating or trigger event* is the action, either machine or human that forces the mishap to occur. For example, an electrical short near a fuel line causes a fire or explosion. Likewise, the omission of critical steps in an operator's fill procedures of an anhydrous ammonia storage tank over pressurizes the pressure vessel.

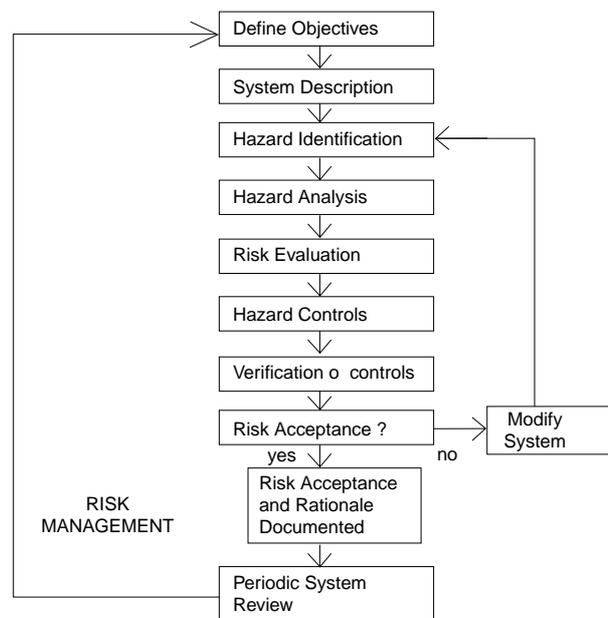
Intermediate events tend to exacerbate or propagate the initiating event or alleviate the results. The use of a fire detection


Figure 1. The system safety process (Bahr 1997).

and suppression system can mitigate the damage from a fire caused by an electrical short in a fuel line. However, increased fuel flow or storage of oxidizers in the vicinity of that fuel line can significantly increase accident damage. If one can understand which events (personnel, equipment, or both) create a hazardous condition then it is possible to control or ameliorate the consequences of those events.

2.2 System Safety Process

The system safety process (Figure 1) is a closed-loop system that helps one to identify hazards, evaluate their risk to the system, develop controls to prevent the hazard or mitigate its effects, and then periodically to review the process. This process is a comprehensive systematic combination of engineering analyses and management oversight.

The first step is to define the objectives and system under consideration. Next the entire system (people, equipment, software, operating environment, etc.) is reviewed. Hazards are identified and analyzed through various techniques. Each hazard is evaluated for its corresponding effects and the overall risk to the system. If the evaluation determines that the risks are unacceptable then controls are developed and implemented to mitigate those risks. It is critical that the controls are verified to be adequate to control the hazard and that they are in place.

Management must make a formal risk acceptance decision. If the risk is still unacceptable then the system is modified. This can be implemented through design changes, procedural controls or changes in the work environment. If the risk is now sufficiently controlled then the entire process is documented (this is typically done in accordance with ISO-9000 and ISO-14000 requirements).

2.3 Hazard Reduction Precedence

Once a hazard has been identified there is an infinite number of ways to control it. However, there is a hierarchy of methods that are followed in most industries.

The first step is to *design the hazard out of the system*—make it physically impossible for the hazard to exist and, therefore, an accident sequence to occur. For example, if fire is the hazard, then removing any one of the following four items out of the system—combustible material, oxygen, chemical reaction or ignition source—absolutely prevents a fire from occurring.

Many times it is not feasible due to costs or other constraints to remove the hazard. The next step is to use *fail-safe* devices. This is a component that automatically returns the system to a safe state. Pressure relief valves and fuses are two such examples. But a fail-safe device alone usually is not sufficient to prevent a catastrophic event. In this instance *caution and warning* devices are warranted. Smoke detectors or oxygen monitors in a process plant are frequently used.

Other times, fail-safe devices and caution and warning systems still are inadequate. One such example is with an ammonia leak. If it is impossible to design the hazard out (e.g. ammonia is the working fluid in the system and cannot be substituted) then a fail-safe device can help avoid further system damage. Caution and warning systems will alert personnel to the hazard, but further action is still required. *Special procedures and training* of operators and other personnel can help contain the consequences and mitigate the effects. Use of personnel protection equipment and special emergency response actions can significantly affect how serious the resulting accident will be. But because people tend to commit more errors when under stress, this is the least preferred method of hazard abatement.

2.4. Safety Management

An effective and pro-active safety organization with upper management commitment is essential to preventing accidents. Most companies and large governmental research and development organizations have a corporate or executive safety office that reports to the organization director.

A good safety program consists of two major sections: safety management and safety requirements. Table 1 shows the primary elements of both.

2.5. Safety Analysis Techniques

There are numerous safety analysis tools in existence today. Most are very similar, using the concept of hazard reduction precedence, but different industries tend to apply their own techniques.

The manufacturing industry traditionally has used standards-based compliance methods. *Safety checklists* verify that the plant

Table 1.

Sec. 1 Safety Management System	Sec. 2 Saftey Requirements and Norms
Policy	Hazardous Operations Procedures
Safety Organization	Emergency Response Procedures
Safety Assessment	Mishap Reporting and Tracking Procedures
Safety Training and Awareness	Safety Design Requirements
Safety Compliance System	National and International safety requirements
Subcontractor Safety Control	

follows national norms required for personnel safety. Many industrial countries have national rule-based occupational health and safety standards. However, this is beginning to change. For example, recently the US Occupational Health and Safety Administration (OSHA) enacted the Voluntary Protection Program (VPP). Because it is impossible and undesirable to audit every plant in the USA, the government has proposed that companies implement a comprehensive safety program. Both plant unions and management must be part of the program. The advantage of a VPP is that companies can avoid the frequent OSHA inspections. Like the similar Malcolm Baldridge Award for quality programs, costs are high; however, after the initial investment, significant reduction in accident rates and enhanced plant efficiencies have more than paid for the effort.

The chemical process industry applies a plethora of safety tools, the most prevalent *HAZOP* (hazard operability analysis). This tool was first developed in the UK by Imperial Chemical Industries in the early 1960s and later adopted in the USA in 1974. A team of five-to-seven experienced engineers review process drawings and through brainstorming sessions assesses deviations to the process and their effects on safety. A complicated system is divided into nodes; the team analyzes each using predetermined guidewords (i.e. no flow, less flow, low temperature, etc.) to determine the effects of potential changes to the intended operation. A corollary benefit to the safety weaknesses identified is determination of process inefficiencies. Compliance-based safety checklists are still used in the industry, though to a lesser extent.

The 1990s has seen an increase in the application of risk assessments—especially *probabilistic risk assessments* (PRA). Many European countries use the term *quantitative risk assessment* or *quantitative (or probabilistic) safety assessment*. PRA, first developed by the commercial nuclear power industry, uses quantitative equipment failure rates and human reliability error rates to determine the likelihood of an accident and its consequence. Widespread application across all industries has still not occurred because of the high cost and labor-intensive nature of the technique. Also, effective application requires a good database of equipment failure rates and the still controversial quantitative human error rates. Process industry PRA have also proven very useful as inputs to environmental risk and impact assessments.

After the 1979 Three Mile Island commercial nuclear power plant accident, the US Atomic Energy Commission documented PRA in their "WASH 1400, The Reactor Safety Study." The commercial nuclear industry has spent considerable time and money developing the needed equipment failure rates and human error probability calculations and databases. Most commercial nuclear power plants (and nuclear powered spacecraft) use this technique for licensing.

The aerospace and military industries have been using numerous system safety techniques since the late 1950s. Frequent missile and aircraft failures forced various military forces to develop some of the most commonly known system safety tools used around the world today. Some of these are *hazard analysis, operations and support hazard analysis (O&SHA)*, and *fault tree analysis*.

The hazard analysis is a methodical and systematic approach to assessing hazards and controls to a system. Through understanding the design and operation of a system during all

phases of the life cycle, hazards and their causal factors are identified. Hazard scenarios are developed and assessed for accident severity and likelihood. This severity and likelihood classification allows one to compare hazards and determine a resolution hierarchy through a ranking method. The likelihood assessment typically is a qualitative determination, though probabilistic methods are now becoming more common. The advantage of performing a qualitative frequency determination is that one can still assess the likelihood of an accident if quantitative data are not available, reliable or cost-effective. Hazard analysis is frequently used in almost all industries even unlikely ones such as food safety. The O&SHA is similar except it focuses on human operators and how they interact with their environment and equipment.

Fault tree analysis is a graphical safety tool used both in system safety and reliability engineering. This deductive methodology postulates a top event or fault, and then develops functional branches or events that must occur for the top event to occur. Through logic gates and standard Boolean algebra one can determine which events or combination of events must occur for the top event to exist. Fault trees can be either quantitative or qualitative and are particularly useful in merging equipment failure data with human error probabilities. Fault trees were very helpful for the National Aeronautics and Space Administration in determining the causal factors to the *Challenger* accident. Fault trees are now found commonly used across all industries such as oil drilling platforms and automobile safety assessments.

The safety tools common to the mass transit industry are hazard analysis, fault tree analysis and regulatory compliance.

Most of the safety techniques described above are primarily safety assessment techniques and are not strictly human factors safety tools. Additional human performance assessment tools that typically are used in conjunction with a safety analysis or part of one are THERP, HEART, SLIM-MAUD, expert estimation and human cognitive reliability models.

3. FUNDAMENTALS OF RISK ASSESSMENT

3.1. What is Risk?

Risk is defined as the triplet: event scenario, probability of occurrence and consequence. The event scenario is the description of a particular event, along with its likelihood of occurrence and the severity of the consequences of said event. There is no zero risk—everything has at least some risk (albeit infinitesimal in some cases). One of the disadvantages of safety engineering is that many times worst-case scenarios that are very unlikely to occur are identified. Using risk assessments one can better optimize the safety process. Also, as stated earlier, risk assessments do not have to focus only on the safety of a system.

3.2. Risk Assessment

The risk assessment process is very similar to the system safety process described earlier, and uses many of the system safety analysis techniques described above. The risks are then quantified and evaluated.

The assessment objectives and system description should be defined first. The next step is to develop initiating event scenarios. The safety analysis techniques described earlier can be used separately or in combination. For example, one may wish to perform a hazard analysis of the facility to identify the primary hazard concerns or initiating events.

The following step is to develop event trees. An event tree is a graphical representation that describes the relationship between a particular hazard and the control system used to mitigate that hazard. The event tree is particularly useful to elucidate if one's safety controls are capable adequately of controlling the hazard. Next, the scenarios are quantified using the calculated failure probability derived from the fault tree input.

Then the consequences are determined through analysis of the potential damage states created if the hazard continues to the end result. Damage states are determined both quantitatively and qualitatively and typically use a cost–benefit analysis. One could say that the resultant damage-state is system incapacitation and US$20 million of damage. The next step is then to evaluate that risk.

An event tree can illustrate the probabilities of a particular event scenario along with its consequences – say, different damage to equipment. Damage states are shown as qualitative (critical equipment damaged) and quantitatively (equipment damage value). The corresponding risk expectation value is the multiplication of the two numbers. This is very useful because one can see immediately the relationship between a particular safety barrier and its corresponding risk of accident.

3.3. Risk Profiles

Even with a risk ranking system or with event trees it is not always easy to understand which risks are most important. For example, it could be difficult to determine which risk is more important inside a set of various risks all ranked equally or near-equally. In this instance, risk profiles are helpful. As Figure 2 illustrates, it is very easy to determine that scenarios one and three are most important.

4. RECOMMENDATIONS

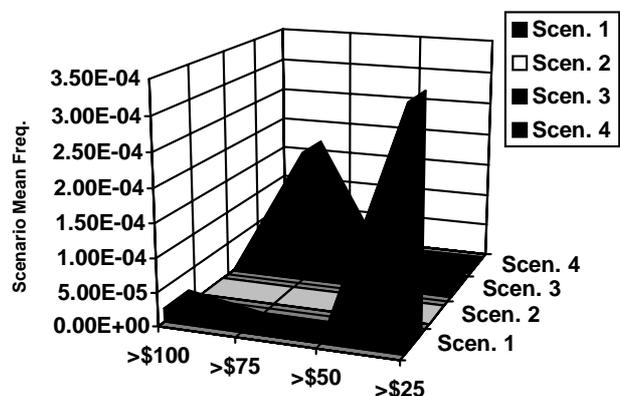
- Develop a system safety program early in the system life cycle.
- Use one or more of the accepted system safety techniques with national and international regulatory compliance standards.
- Perform the system safety analysis techniques before hardware and operational procedures are developed.
- Use the system safety process as part of the organization's safety training and awareness program.


Figure 2. Risk expectation profile.

- Study near-miss accidents for clues to unidentified hazards or accident causal factors.
- Every time the system has had a significant change, review and assure that hazard controls are still valid.

Work Organizations: Health and Productivity Issues

K. Lindström

Finnish Institute of Occupational Health, Department of Psychology
Topeliuksenkatu 41 a A, FIN-00250 Helsinki, Finland

1. INTRODUCTION

A healthy work organization can be seen as an organizational strategy aiming to optimize effectiveness and the well-being of the personnel. Effective organization needs healthy and competent people and through its organizational practices and culture promotes the learning and well-being of people. The organization should be effective and profitable in order to justify its existence. The functioning of workplaces depends strongly on the global business market, national laws and regulations, and of course on the partners and customers. The focus should therefore be broad when defining a healthy organization in order to meet the interests of individual employees, teams, stakeholders, and the whole society (Jaffe 1996). In the long run, their interests are easier to fit together, but short-term financial profitability can be in conflict with the ideals of the healthy work organization.

The definitions of a healthy work organization include many aspects which are also relevant in todays turbulent business environment where downsizing, mergers, and other restructuring processes are common. The organization should be effective in various kinds of environment and have the readiness to foresee and react to the external changes in its market environment.

One basic human characteristic of organizational healthiness is the congruence between its written values and overt practices (Cox and Leiter 1992). The written organizational values of the company should to be shared and realized in everyday practice, especially in critical situations where no ready practical solutions are available. This chapter has three aims:

- To describe the main job and organizational characteristics of a healthy organization.
- To present ways to assess the healthiness of an organization.
- To present some practical intervention approaches which guide the organization towards healthiness.

A healthy and productive work organization doesn't mean at the practical level anything radically new, but it integrates aspects from existing theories of individual well-being and organizational effectiveness into a value-based strategy. At the organizational development level, the approach should also be multilevel, combining the individual and organization-oriented interventions.

2. CHARACTERISTICS OF HEALTHY ORGANIZATIONS

The definitions of a healthy organization have covered issues related to the basic existence of organizations and their relations with the external environment. Some theoretical and pragmatic models which have been related to the healthy organization are job stress models, job redesign and organizational development models, schools of psychodynamics, and unconsciousness of organizations, plus applied corporate strategies for health promotion emphasizing certain types of policies and culture (Cooper and Cartwright 1994, Jaffe 1996). From the viewpoint of organizational psychology, its inner psychological and social functioning is important, as well as the perceived task characteristics and organizational practices and climate. The traditional work safety issues and physical work demands should be seen as basic requirements, especially in manufacturing and in other physically heavy work.

Here I describe those characteristics which have been shown to promote the employees well-being and competence, and company effectiveness and profitability. The characteristics describing a healthy organization usually have both individual and organizational focus. The quality of social relations can be viewed from the individual perspective and as an indicator of the group and organizational climate. Absenteeism is an individual health indicator, but a high sickness absenteeism rate indicates health at the organizational level. The following characteristics are typical of a healthy organization.

2.1. Appreciation of People

Respect and appreciation of people and their work has been regarded as a basic value of a healthy organization. At the workplace level, it includes mutual trust, fair treatment, and the consideration of ethical issues in decision making. Besides help and support from supervisors, older workers perceived respect as one of the main factors in maintaining their working capacity (Tuomi *et al.* 1997).

2.2. Job Demands and Control

Job stress research has shown that high job demands and low control at work can lead to elevated stress and contribute to say cardiovascular diseases. Low social support has been added as a third dimension to this model (Karasek and Theorell 1990). The regulation and control of the risks at work, especially job stress, is a central issue in a healthy organization.

2.3. Leadership and Management Practices

Management and leadership practices are important contributors to the well- functioning of the organization and the well-being of the personnel. Teamwork and empowerment mean a new division of power and decision making between the management and the personnel. Managerial practices can in this way facilitate the development of competence and the health of employees. A participative management style with low task orientation and empowering have been associated with lower stress and ill health. Challenging tasks together with good leadership practices can contribute to job satisfaction and job involvement.

2.4. Change Management

Change management practices are crucial for the future of the company and its people. It is usually a question of combining the interests of individuals, company stakeholders, and customers. Change management should be a part of human resource management practices at company level. The basis is good information about changes at all levels in the organization. The management of recent organizational change processes, based on outsourcing or a lean organization, has often failed in both human and financial respects, because the changes have been based only on economic calculations; the participation of people

and the utilization of their ideas have been neglected. The Finnish downsizing examples from the municipal sector showed that the anticipated saving of money was lost when the sickness absenteeism rate increased because of elevated and prolonged job pressures (Vahtera *et al.* 1997).

2.5. Continuous Improvement

Adopted continuous improvement practices associated with an innovative climate promote the idea of lifelong learning and the development of the personnel's competence. Awareness of the future of the organization, and customer needs are necessary when implementing the individual and group-level learning efforts. Learning at work and worksite training opportunities are especially important for aging workers, otherwise they are vulnerable to marginalization when changes occur in the production, services, or technology.

2.6. Work and Private Life Interface

The two main individual-centered characteristics of a healthy organization to be considered are the balancing of work and private life, and the managing of diversity issues. Both are concerned with basic human values and rights and are usually included in company values. When the flexibility of working hours and work arrangements is increased both quantitatively and qualitatively, it brings more degrees of freedom but also an impossible situation to be solved by individuals. Flexibility at work can increase insecurity or lead to conflicting demands at the individual level, e.g., part-time employment, outsourcing, multiskilling. On the competitive labor market, those who have more alternatives to make choices are better off. Flexibility of working hours and work arrangements has either facilitated or complicated the balancing of private life and work life. Longer weekly working hours have increased job pressures and left less time for recovery and for the other sectors of life.

2.7. Diversity Issues

Awareness of the richness of human diversity is a central topic in a healthy organization and in the society as a whole. Neglecting it will easily lead to marginalization and discrimination of older persons, women, and people who are not in the majority. This means that the experience and knowledge based on the diversity of age, gender and ethinicity, and also equality issues are violated because they are not necessarily seen as beneficial by the traditional groups having the power and the best advancement opportunities in the organization.

It is often difficult to show a direct relationship between organizational effectiveness and well-being along with social and psychological factors. Job satisfaction coupled with good supervisory support and continuous improvement practices contributed to productivity and profitability of small and medium-sized enterprises (SMEs) (Lindström *et al.* 1999).

3. ASSESSING ORGANIZATIONAL HEALTH
3.1. Continuous Monitoring

Assessing the state of the work organization requires continuous information on its critical characteristics and outcomes, indicating organizational effectiveness and individual competence and well-being. Usually the customers' needs and satisfaction should also be surveyed in order to update the situation on the market

and to revise the future vision and strategic goals of an organization. A combination of feedback from the personnel on work and organizational practice, and from clients about their needs and satisfaction, gives valuable development ideas for continuous improvement practices or quality management. These should also be related to so-called objective data on organizational effectiveness and personnel productivity. This information could be summarized in so-called human resource accounting and reporting of the enterprise, which gives summarized data for the management and the stakeholders about the human resources.

3.2. Personnel Surveys

Repeated personnel surveys should at least include measures about the task characteristics, like quantitative workload and the challenges and learning possibilities, as well as leadership practices and other organizational practices relevant for a healthy organization. The readiness to change and a sensitivity to external changes are important when striving towards continuous improvement practices. The quality of organizational practices and climate reveals the possible risks for individual ill health and organizational ill health, like social conflicts, dissatisfaction, burnout, and sickness absenteeism.

Longitudinal measures within the company and benchmarking possibilities with other organizations from the same field are valuable. Various survey methods for assessing these job and organizational characteristics are available, e.g., organizational health questionnaire (Cox and Leiter 1992), occupational stress indicator (Cooper and Cartwright 1994), and healthy work organization questionaire (Lindström 1997). These methods mainly measure job and organizational characteristics and can be completed by measures of well-being, like the Mashlach burnout inventory (MBI), and the general health questionnaire (GHQ). However, the most common practice is to tailor the methods for a particular company, but taking into account the availability of reference data and the scientific basis of the method. Repeated measures with the same method allow the effects of natural and planned changes to be monitored.

Organizational surveys are useful, not only for monitoring the current state but also for use by managements, teams, and employees when planning interventions. The survey feedback method followed by some interventions is the most traditional way to start an organizational intervention.

4. PROMOTING ORGANIZATIONAL HEALTH
4.1. Multilevel Approach

The main actors in an intervention should be the management in a participatory way; but human resource experts, occupational safety and health personnel, and training experts have a special role in facilitating the development. The characteristics of a healthy organization include organizational practices which can be seen in the form of developmental methods, like change management and continuous improvement practices. These organizational practices regulate job pressure and improve the functioning of the company. Access to occupational health services for the personnel, as well as implementing health promotion programs related to the job and the organization, can help to correct these problems.

Increasing ones own control at work and employee participation are fundemental issues in preventing harmful stress effects

and creating personal involvement in the job and commitment to the organization (Cooper and Cartwright 1994, Karasek and Theorell 1990). Especially in SMEs where no such institutional support and help is readily available, the management is more responsible for these aspects. The competence and material resources can nevertheless be problematic (Lindström *et al.* 1999).

Although the healthy organization is a multilevel model, the intervention actions should also be multilevel, and they should be implemented at the organizational and individual level, and preferably also at group level. Business organizations operate in a societal and global context where they are exposed to various challenges and threats. The organization's awareness of the market changes is the way to cope with them and maintain the inner healthiness and competence of the organization. The decline in profitability easily leads to negative consequences at company level, and the principles of the healthy organization are forgotten. The pure market economy approach at the organizational level with shortsighted profit making, this is a source of people's ill health.

4.2. Organizational Interventions

When thinking of recent ways to develop organizations, it is crucial to consider the values of the management and human resource management functions. Here it is advantageous to have value-based interventions investing in the long-term development of human resources. Generally it is possible to distinguish three different organizational change processes in which the principles of the healthy organization are relevant:

- Improve and promote existing ways to function, e.g., promote the health and work capacity of employees, the quality of services and products, or effectiveness in general.
- Shift towards a learning-oriented and knowledge-based organization, and implement or facilitate teamwork and networking
- Restructure the organization, e.g., downsize, outsource, and reengineer the business process.

Both the learning organization and knowledge management intervention are beneficial for a healthy organization, because they are usually based on long-term development of human resources. Structural changes like downsizing, business processes re-engineering, and outsourcing are today's practice and often unavoidable; the way in which these kinds of changes are implemented is crucial. They lead easily to adverse effects on business itself, loss of competence, and individual suffering. Here the participatory approach would soften the possible negative effects, and even innovative solutions may be a by-product.

Common organizational interventions usually aim to improve the present way of functioning (Lindström 1996). It is the easiest approach because the power structure of various interest groups is not greatly affected, and all efforts can be focused on the development itself. But without the management's commitment, this kind of implementation model can lead to ineffective or negative side effects in the long run, because when the participative approach is used in interventions, it commits people to the present way of functioning.

When structural changes based on business are implemented soon after these kinds of interventions, the results of the intervention are lost, and people are dissappointed; their commitment and belief in joint development decrease in the future. The

vision and the new strategic goals should therefore be the starting point in order to facilitate real changes. Practical experience has shown that the management as well as the personnel should be committed to the goals and process of the intervention, and both business and well-being goals should be combined. This is especially important in a rapidly changing, turbulent environment undergoing unpredictable changes. Joint participation of management and personnel gives more sustainable results and corresponds to the definition of a healthy organization.

Interventions can also be focused on traditional job redesign, which has proved successful in large companies and in SMEs. Starting the developmental process with working seminars based on democratic dialog strengthens commitment at all levels in the organization. All the developmental ideas of the participants are then based on that vision and the ways of implementing it. Opening channels for ideas within the organization and supporting their growth, both require an atmosphere of trust. Creating trust is a demanding task which takes time and requires positive feedback, so that individuals get enough courage to express their own ideas without fear of being ignored or punished. This kind of innovative climate has been very successful in developing SMEs (Lindström *et al.* 1999). Innovative interventions also require time and financial resources.

4.3. Individual interventions

At the individual level, a healthy organization means that individual job redesign solutions are undertaken and social support is available when needed. Both aspects require an infrastructure to be created at the workplace and there should be access to consultative help. Work-related risks and their harmful effects, such as job stress and burnout, are two particular situations requiring individual support. The ideal would be access to occupational health care services outside the work. However, the development of individual competence is the best assurance for the individual when considering the continuity of his or her life-long work career. At the individual level, the crucial point in a healthy organization is respect of people and investments in long-term individual growth and learning. Therefore the idea of the learning organization should also include development of the personnel's professional and organizational competences. In summary, the key elements in the healthy and productive organization approach are respect of people, simultaneous development of business and personnel, and an open-minded approach to the society and the business partners and clients.

1. INTRODUCTION

Work-related musculoskeletal disorders (WRMD) are increasingly a concern to occupational health and safety professionals, ergonomists, industrial engineers, employers, unions and workers. The US Bureau of Labor Statistics (BLS) has shown that all types of WRMD have increased as a percent of total occupational illnesses. In 1995, WRMD associated with repeated trauma accounted for 308 000 cases or 62% of new illness cases in private industry (BLS 1997). WRMD include tendon disorders (e.g. shoulder tendinitis), nerve disorders (e.g. carpal tunnel syndrome, thoracic outlet syndrome), muscle disorders (e.g. tension neck syndrome), joint disorders (e.g. osteoarthrosis), vascular disorders (e.g. hypothenar hammer syndrome), bursa disorders (e.g. knee bursitis) and unspecified musculoskeletal symptoms or multiple-tissue disorders (Hagberg *et al.* 1995). Recent studies indicate a potential link between work organization, job stress and WRMD (NIOSH 1992, Smith *et al.* 1992), and theories on these links have been proposed (Sauter and Swanson 1996, Smith and Carayon 1996). Here are reviewed theories and empirical studies on the relationship between work organization, psychosocial work factors, stress and WRMD.

2. CONCEPTUAL FRAMEWORK

Work organization has been defined as the way in which work is organized, supervised and carried out (Hagberg *et al.* 1995). It can contribute to WRMD problems by specifying the nature of the work activities (variety or repetition), the extent of loads, the exposure to loads, the number and duration of actions, workstation design, tool and equipment design, and environmental features. The policies and procedures of a company can affect WRMD risk through the design of jobs and the defining of work-rest cycles, work pace (i.e. work pressure), the psychological climate regarding socialization, career and job security, the level of employee training, availability of assistance and supervisory relations. All of these factors interact as a system to produce an overall stress load on the person that can lead to WRMD (Smith and Carayon-Sainfort 1989). Stress may logically have a role in WRMD because such disorders are much more prevalent in occupations with features that produce job stress, i.e. short-task cycles, monotony, low control, low content and high work pace.

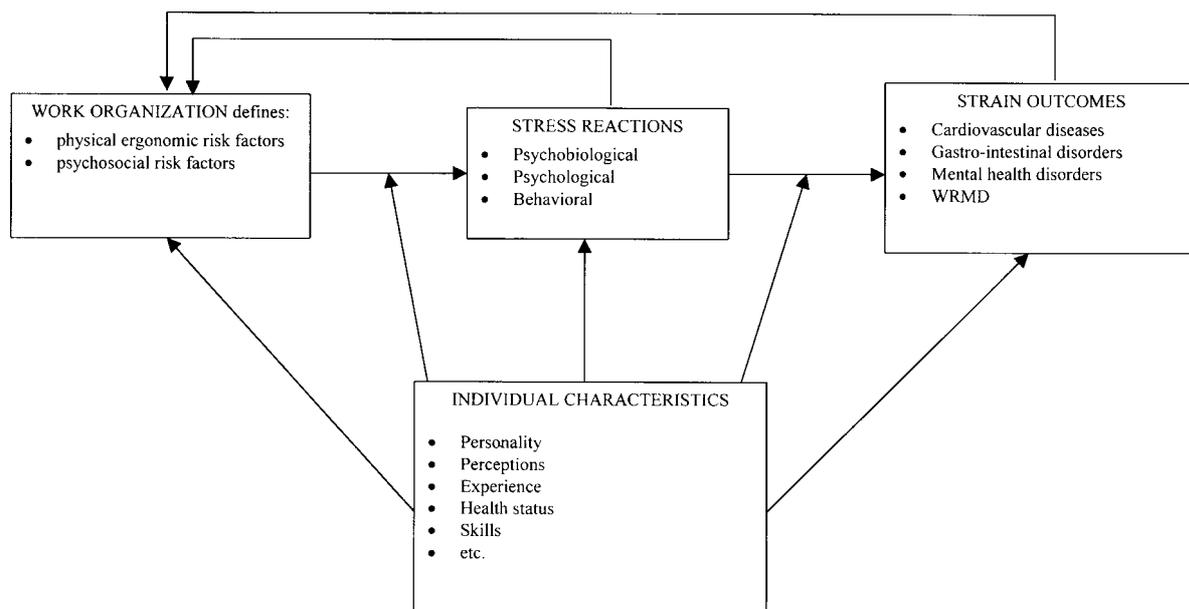
There are theoretical reasons to believe that work organization factors can play a role in the report and development of WRMD (Sauter and Swanson 1996, Smith and Carayon 1996). The model presented in figure 1 suggests the potential relationship between work organization and WRMD. Mediating this relationship are (1) stress reactions and (2) individual factors. Organizational, ergonomic and psychosocial factors can produce stress reactions on the individual: these stress reactions can have physiological, psychological and behavioral aspects, such as biomechanical loading of muscles or joints, increased levels of catecholamine release, or adverse psychological mood states (Smith and Carayon-Sainfort 1989, Hagberg *et al.* 1995). Stress reactions can lead to various types of strain, including WRMD. These various concepts


Figure 1. Model of the relationship between work organization and WRMD.

of work organization, ergonomic and psychosocial work factors, stress reactions, and strain are hypothesized to describe various stages of the chain of events that links work organization to WRMD (figure 1).

Work organization determines the psychosocial work factors and ergonomic risk factors to which employees are exposed. For instance, an organization based on teamwork may provide for high levels of worker participation, therefore fostering a positive psychosocial work environment. It may also allow workers to rotate between tasks, therefore reducing exposure to high physical loads of certain tasks. According to Smith and Carayon-Sainfort (1989), a work system is composed of five elements: (1) individual, (2) tasks, (3) physical and social environment, (4) tools and technologies and (5) organizational conditions. The way work is organized, structured, supervised and carried out (i.e. the design of the work system) will define the various elements of the work system, as well as their interactions. These elements and their interactions can have positive and/or negative aspects that represent various psychosocial work factors and ergonomic risk factors. For instance, an assembly-line organization is characterized by short-cycled, fast-paced tasks. These tasks not only have negative psychosocial work factors, such as little variety and job control, but also negative ergonomic risk factors, such as high repetitiveness.

3. MECHANISMS

There are psychobiological mechanisms that make a connection between job stress and WRMD plausible and likely (Smith and Carayon 1996). Psychological stress can lead to an increased physiological susceptibility to WRMD by affecting hormonal, circulatory and respiratory responses that exacerbate the influences of the traditional ergonomic risk factors. In addition, psychological stress can affect employee attitude, motivation and behavior that can lead to risky actions which increase WRMD risk. Here the importance of work organization and job stress in the development, reporting and experience of WRMD is emphasized. Two different mechanisms for the relationship between WRMD and job stress are proposed: (1) a psychobiological mechanism and (2) psychological and behavioral reactions to stress. Highlighted are the importance of work organization in the development, experience and reporting of WRMD.

3.1. Psychobiological Mechanism

When an individual undergoes the psychological, physiological and behavioral effects of job stress, there are changes in body chemistry that may increase the risk of WRMD. Changes in the body include: increased blood pressure, increased corticosteroids, an increase in peripheral neurotransmitters, an increase in muscle tension, less effective immune system response and hyperventilation or overbreathing (Selye 1956, Levi 1972, Theorell and Karasek 1996, Westgaard 1996). While it has long been known that these stress reactions can contribute to increased cardiovascular and psychological strain (Cooper and Marshall 1976, Smith 1987), it is believed that they also can increase the risk of WRMD.

Several studies have shown a link between blood pressure and job stress. In particular, high workload and work pressure, and lack of job control have been related to an increase in blood

pressure (Matthews *et al.* 1987, Schnall *et al.* 1990). The increased blood pressure may reduce blood flow to the extremities, which could accelerate or exacerbate tissue damage during high workload, and may precipitate the occurrence of WRMD. An increase in corticosteroids is another physiological reaction to stress (Frankenhaeuser 1986, Daleva 1987). Increased levels of corticosteroids, in particular cortisol, can lead to increased fluid retention in body tissues. This could be an important risk factor for carpal tunnel syndrome (CTS). Corticosteroid-induced fluid retention may be similar to the fluid retention in the extremities of the pregnant woman, which is believed to increase their risk of CTS. Excess fluid and tissue swelling can place pressure on and pinching of the nerve(s) that can cause the parasthesia and pain associated with peripheral neuropathy. Another consideration related to physiological stress is the amount of tension in the muscles. With increased levels of norepinephrine, the tension in muscles has the potential of being greater, as does the extent of recruitment of the muscle fibers in performing an activity (Westgaard 1996). This heightened muscle tension may be increased by adverse psychological moods such as anxiety or anger, and can lead to excessive muscular force when working. Some studies have suggested that increased muscle tension may be a mediating variable between negative psychosocial work factors and psychological stress, on one hand, and musculoskeletal disorders on the other hand (Theorell *et al.* 1991, Waersted and Westgaard 1991, Westgaard 1996).

Schleifer and Ley (1996) assert the importance of breathing as a psychophysiological pathway through which work organization and psychological stress factors contribute to WRMD, in particular among computer users. Under stressful conditions, a chronic hyperventilation/overbreathing response occurs, which is characterized by reductions in the percent of CO_2 in exhaled air, as a psychological stress effect. Physiological effects of overbreathing include heightened muscle tension and paresthesia, which may lead to WRMD. An experimental study of computer workers under stressful conditions provides some empirical support for this model (Schleifer *et al.* 1996). At some point in the stress process, the organism is unable to continue responding normally and exhaustion occurs (Selye 1956). During this stress-induced exhaustion, the immune system cannot function normally and thus cannot provide the typical resources for repairing damaged tissues. Studies by Vaernes *et al.* (1991) and Endresen *et al.* (1991) have shown that job stress, anxiety and depression are correlated with changes in the immune system. Chronic exposure to ergonomic risk factors while the organism is undergoing psychological stress may create micro damage that cannot be fully repaired, and which over time can lead to permanent damage.

3.2. Psychological and Behavioral Reactions to Stress

A second major way in which stress can influence the occurrence of WRMD is through its effects on a person's psychological and behavioral reactions. Thus, stress can affect psychological moods, work behavior, coping style and actions, motivation to report injury and motivation to seek treatment for a WRMD injury, or symptoms of impending injury.

WRMD involve significant pain. Many times, diagnosis of a disorder is based on the nature and extent of pain reported by

the person. Stress may serve to increase the frequency of reporting of pain because of a general increase in personal sensitivity to pain brought on by negative psychological moods. Increased pain or greater severity of pain has been related to psychological stress among patients with low back pain (Atkinson *et al.* 1988) and among large samples of adults (Mechanic and Angel 1987, Korff *et al.* 1988).

A related issue is a social psychological aspect of illness behavior. It is possible that a person under psychological stress could develop specific physical symptoms (such as sore wrists) that would "legitimate" their general psychological discomfort and pain. Having pain in the wrists and fingers is an acceptable disorder, while feeling depressed is not considered as acceptable. Thus, the effects of psychological disturbances may be reflected in physical disorders of the musculoskeletal system. This is similar to mass psychogenic illness (Colligan and Murphy 1979) and psychosomatic disorders (Wolf 1986) where psychologically induced disturbances lead to physical impairment.

The occurrence of WRMD can itself act as a source of stress. Experiencing WRMD can trigger a stress reaction. This relationship has been found between back pain and stress (Feuerstein *et al.* 1987). Job Stress can also affect the behavior of a person in dealing with the work environment. For instance, a person who is stressed may become angry, and this could lead to using improper work methods and/or forceful work techniques (e.g. gripping a tool too tightly). Persons under stress often develop poor attitudes and motivation about the job and about their personal health and well-being (Caplan *et al.* 1975, Kahn 1981). Maladaptive coping behaviors could make people more susceptible to injury or disease and lead to a diminished capacity to work, both conditions increasing the potential for WRMD.

3.3. Work Organization and WRMD

Work organization can influence job stress which, as shown earlier, can affect the risk of WRMD. Work organization can also determine or influence ergonomic risk factors of WRMD. Studies have shown a link between work organization, psychosocial work factors and musculoskeletal disorders, such as symptoms in the back, neck and shoulders (Bongers *et al.* 1993, Moon and Sauter 1996). Some empirical studies have also examined the relationship between work organization and upper extremity WRMD (NIOSH 1992, Smith *et al.* 1992, Ferreira *et al.* 1997). For instance, studies by Smith *et al.* (1992) and Schleifer *et al.* (1996) have shown a link between electronic performance monitoring and musculoskeletal discomfort.

NIOSH (1992) conducted a cross-sectional study of 533 telecommunications workers in five different jobs. Several measures of work organization were related to upper extremity musculoskeletal disorders and symptoms. For instance, fear of being replaced by computers was related to increased neck and elbow symptoms, while high information processing demands were related to increased neck and hands/wrists symptoms. Other work organization factors, such as surges in workload, lack of decision-making opportunities, high task variety and the lack of production standards, were also related to upper extremity WRMD (Hales *et al.* 1994). A more recent cross-sectional survey study of 114 teleservice representatives also conducted by researchers at NIOSH shows further evidence of a link between work organization, psychosocial factors and WRMD (Hoekstra

et al. 1996). Those employees who reported a lack of control over their job tended to have a higher risk of back WRMD, and perceived workload variability was associated with neck WRMD.

Some studies have examined the effect of both psychosocial and ergonomic risk factors on WRMD. Kerr *et al.* (1997) show that psychosocial work factors, such as decision latitude and co-worker support, are important predictors of low back pain, even when adjusting for biomechanical factors. Similar results are reported by Skov *et al.* (1996) in a group of salespeople and by Wahlstedt *et al.* (1997) in a group of 655 postal workers. Wahlsted *et al.* (1997) found that high psychological work demands was associated with symptoms in the lumbar region and that low social support at work was associated with symptoms in the neck–shoulders–thoracic region. Another study of computer users shows that occupational stress can even have a determinant effect on WRMD that outweighs the effect of workstation design (Patterson 1997).

Work organization can define or influence ergonomic risk factors of WRMD, such as repetition, force and posture (for a review of ergonomic risk factors of WRMD; Putz-Anderson 1988). Work organization can define the nature of, strength of and exposure time to these ergonomic risk factors by specifying how a job is to be carried out, establishing product levels and defining pay structure. Work organization may define, for instance, the degree of repetitiveness of the job. In a highly fractionalized job, the worker tends to do the same tasks over and over, which produces repetition and boredom. The work organization also establishes cycle times, through the design of tasks. Short-cycle times and task repetitiveness define the repetition of motions. In this example, the work organization defines that the worker will be exposed to high repetition, which is an ergonomic risk factor for WRMD (Silverstein *et al.* 1987). Work organization also defines the strength of the ergonomic risk factors. A work organization that designs job tasks that do not encourage movement, and do not allow workers to take mini-breaks when needed, may induce static awkward postures. For instance, machine-paced work is a work organization system where workers have little freedom for influencing the pace or standard operation of their work. Such a work system does not allow for any variation in work, and usually does not give workers time to take mini-breaks when needed (Smith 1987). Work organization can also define the exposure time to ergonomic risk factors. By setting work standards and pay schemes, management sets the pace at which a worker is supposed to work. This will then define the exposure time to certain risk factors. For example, if the worker is supposed to produce a certain number of products per time period, then this work standard will in turn define the duration of exposure to certain forces and postures. In addition, management defines the number of hours of work. Overtime, for instance, is a work organization factor that increases the duration of exposure to ergonomic risk factors. Such exposure may be particularly risky, due to increased worker fatigue.

4. CONCLUSION

To control, reduce, eliminate and prevent work-related musculoskeletal disorders, it is important to consider the range of factors which can directly and/or indirectly influence them. Here we argue that from an ergonomics point of view work organization is the driving factor that determines the exposure

to physical ergonomic risk factors and psychosocial work factors. We have defined two types mechanisms of the potential role of stress in the relationship between work organization and WRMD: (1) psychobiological mechanisms (e.g. increased blood pressure, muscle tension and cortisol) and (2) psychological and behavioral reactions to stress (e.g. sensitivity to pain and reporting of symptoms). Several empirical studies have demonstrated a link between work organization and WRMD. Other articles in this volume (e.g. Work Organization Interventions) propose models and methods for reducing WRMD with emphasis on work organization.

1. INTRODUCTION

Although the first definitions of the concept of Ergonomics go back to the previous century, ergonomic guidelines have been developed mostly during the past 15–20 years thanks to the increasing interest in biomechanical factors (force, posture, frequency, vibrations) and work tasks (manual handling of loads, repetitive movements) related to musculoskeletal disorders.

Ergonomic standards appeared late compared with the guidelines of other work-related disorders, such as the those caused by chemical and physical agents.

The development of guidelines in fact reflects the prevalence of the interest in a certain subject at a certain time. Thus, during this century, in the industrialized countries heavy industry prevailed first and chemical and petrochemical later, with the occupational risks related to chemical (metal, dust) and physical (noise, radiation) agents. Starting from the 1970s, the tertiary sector rapidly expanded and at the same time informative systems spread in all the working places. At the same time, great industrial hygiene problems in the work environments (noise, dust, fumes, gas and vapors in the air) were solved or drastically reduced and the prevalence of work-related pathologies changed as a consequence of the prevalence of other risk factors: biomechanical and relational factors. Today, upper limb and back musculoskeletal disorders prevail in terms of health and costs for the worker, industry and society.

This led to the need to develop ergonomic standards for the prevention of work-related musculoskeletal disorders (WRMD) of the upper limbs and back. The development of this type of standards presents many difficulties since the WRMD is a complex group of disorders in terms of definition and content. These difficulties will be clarified if, for example, the pathways to develop guidelines for chemical agents versus ergonomic standards are compared.

In Industrial Toxicology guidelines for prevention of disorders due to the exposure to chemical substances hinge upon the possibility of establishing threshold limit values. The limit values of exposure to chemical substances are fixed by experimental studies on animal models: increasing doses of toxic substances are inoculated in guinea pigs to establish the no-adverse effect level (NOAEL). At the same time data from epidemiological studies are evaluated, in which adverse effects are related to levels of exposure. Therefore, threshold limit values of exposure guaranteeing reasonable protection can be defined.

To define ergonomic standards preventing the WRMD is not easy because:

- musculoskeletal disorders are multifactorial and occur also in the absence of exposure (work environment);
- causal factors such as force, repetition, posture, vibrations can be conceptually difficult to evaluate. For instance, is repetition a primary causal agent or a different way of expressing another causal factor such as for example strength? In Industrial Toxicology this problem is easier to solve: in fact the causal agent is the chemical substance and the level of exposure can be measured quantitatively;
- dose–effect curves are difficult to define due to intrinsic difficulties (absence of animal models for experimental research/studies) and extrinsic (WRMD are also caused by factors other than working activities). Consequentially it is difficult to establish a cause–effect relationship between biomechanical factors and WRMD.

As Bernard (1997) reported in a literature review, epidemiological studies identified a number of mechanical agents strongly associated with WRMD when exposure was intense, prolonged and most of all if a combination of factors occurred.

Despite the difficulties underlined above, in the past two decades many ergonomic standards to prevent WRMD have been developed. They can be divided as follows:

1. Standards with limit values of exposure.
2. Organizational-preventive standards.

Prescription type standards define an acceptable limit of exposure to biomechanical factors related to WRMD. These limits were developed from the evaluation of different biomechanical parameters. These standards usually involve both employer and employees. The employer is required accurately to estimate the risk of WRMD, while employees need to be given an adequate ergonomic training so that the working task can be carried out avoiding or minimizing the risk factors.

Organizational standards assume that you cannot define reliable numerical values to be considered as acceptable limits of exposure. The ergonomic approach is less strict. These standards indeed define general ergonomic measures, delimiting a field of action in which the employer has large liberty of movement. In other terms, the employer is free to create the ergonomic program according to his business.

These standards are directed mostly towards employers who are advised to have a flexible organization able to:

1. survey the working environment and the employees;
2. seek the presence of problems; and
3. develop strategies to decrease or eliminate the problems.

Employee training is always regarded as an essential component because it is a valid measure in order to limit risks.

There are various guidelines for preventing WRMD. Some are laws, some are just technical suggestions: the difference is substantial mostly for the results obtained. Ergonomic standards with the value of law come from countries with a political awareness of the significance of ergonomics concerning health and safety prevention and economical aspects.

Compulsory application of ergonomic parameters in the short-term has a purely educational meaning, whereas in the long-

term it aims to decrease the frequency of WRMD, occupational accidents, amount of sick leave and related health costs.

Among the best-known ergonomic standards there are standards indicating limit values such as the revised NIOSH equation for the design and evaluation of manual lifting tasks (NIOSH), ISO 11228-1 and organizational standards such as the National Standard for Manual Handling (Australia), Ergonomics for the Prevention of Musculoskeletal Disorders (Sweden), Occupational Health and Safety Regulation of Worker's Compensation Board of British Columbia (Canada), OSHA Draft Ergonomics Program (USA) and ANSI Z-365 (USA).

2. STANDARD WITH LIMIT VALUES

2.1. USA: Revised NIOSH Equation for the Design and Evaluations of Manual Lifting Tasks (NIOSH)

In 1981 the NIOSH published *Work Practices Guide for Manual Lifting*. This standard presented analytic procedure including a lifting equation for calculating a recommended weight related to symmetric lifting tasks with both hands and suggestions for controlling the risks of occupational accident to the back due to manual lifting.

In 1993 the revised lifting equation was published. This reflects the result of newer and wider research, but was developed on criteria (biomechanical, psychophysical, physiological) used also in the previous standard and coming from the review of the literature and advice of experts in the field. In the revised equation differences are concerned with: standard position of lifting (increased), limits of weight (lower), multiplicational factors (increased from four to six).

The new standard covers a wide range of tasks. This has a double advantage: on one hand it also allows the evaluation of asymmetric lifting tasks and of the lifting of objects with difficult handles; on the other hand it involves an increased number of protected workers and, since recommended limit values for weight are stricter, also more protection/safety for workers.

The revised lifting equation has application limits. It applies only if the load being lifted:

- is carried with both hands;
- is carried standing;
- excludes other manual activities (pushing, pulling, carrying). These can be if necessary very small (< 10% of the worker's total activities);
- has an adequate friction between floor and feet;
- is carried out smoothly;
- concerns loads not too hot, cold or contaminated with unsteady content; and
- occurs in good microclimatic conditions.

2.2. ISO 11228-1

The International Organization for Standardization (ISO) in 1998 proposed the international standard ISO 11228 (*Ergonomics-manual handling*). ISO 11228 is divided into three parts: (1) lifting and carrying; (2) pushing pulling and holding; and (3) handling of low loads at high frequency.

The first part (ISO 11228-1) is a typical prescriptive standard. ISO 11228-1 has an ergonomic approach similar to that of NIOSH (revised NIOSH equation for the design and evaluation of manual lifting tasks, 1993) for the type of analysis and the evaluation of

manual handling of loads, and for the ergonomic recommendations. ISO 1128-1 does not apply if the object to be handled weighs < 3 kg. Evaluation of the risk of manual handling is made according a step-by-step approach, considering the weight of the object, its initial and final position, the frequency, and duration of the task. This step-by-step approach ceases only when ergonomic conditions of the task are adequate or re-established.

Risk evaluation implies identification, estimation and reduction of risk. The tasks of just lifting and of lifting and carrying are analyzed comparing the weight of the object handled, its initial position, frequency and duration of handling with the suggested related limits. Quality of handling is also considered. Each suggested limit is expressed in equations summarized in tables that show all the other parameters at the same time, supplying in this way an accurate ergonomic evaluation. Limits suggested by ISO hinge on integration of data from epidemiological, biomechanical, physiological and psychophysical studies.

ISO 11228-1 is directed towards designers, employers, employees and anyone involved in the ergonomic programs. In fact, given the complexity of ISO1128-1 (contemporary evaluation of different parameters, comparison with limit values) its application is limited mostly to those in the know. ISO 11228-1 is described as applicable to both the working and domestic population doing manual handling. It is clear that the involvement of the non-working population implies diffusion of ergonomic practices and the consequent familiarity with them: this being just a future goal at the moment.

ISO 11228-1 includes two annexes. Their aim is to simplify and make more understandable what has been previously illustrated in the standard. The first attached sheet gives instructions about factors you must take into account in manual lifting and carrying. It is thus useful to quantify the manual handling risk and define the related ergonomic intervention. The second attached sheet gives examples of evaluation and ergonomic approach to manual lifting tasks. Thus, it makes it possible to apply equations and lifting limits previously determined, and puts into practice the necessary ergonomic intervention.

3. ORGANIZATIONAL STANDARDS

3.1. Australia: National Occupational Health and Safety Committee

In Australia, in 1990, the National Occupational Health and Safety Committee (NOHSC) approved the National Standard for Manual Handling with the ambitious goal of developing, facilitating and increasing a national strategic program for health and safety in the working environment. This standard has legal value and proposes a multifactorial ergonomic approach (risk identification, evaluation, control) and is believed to be better than the simple use of the suggested limit values. Its aim is to prevent accidents due to manual handling or at least to decrease their severity. It includes precise duties for employers and for employees. Employers have duties about design, risk assessment and risk control.

The National Standard for Manual Handling comes together with the National Code of Practice for Manual Handling which supplies explanations about the former, by suggesting the right tools for identification, evaluation and control of manual handling risk. The National Code presents many illustrations, checklists,

questionnaires, tables and summaries of the standard to simplify for employer and employees its application and understanding.

3.2. Sweden: Ergonomics for the Prevention of Musculoskeletal Disorders

In Sweden AFS 1998:1 (*Ergonomics for Prevention of Musculoskeletal Disorders*) is a standard developed by the Swedish National Board of Occupational Safety and Health. It consists of two parts: (1) Provisions; (2) General Recommendations on the implementation of the Provisions. Provisions have a legal status. They define responsibilities in the prevention of WRMD of the employer and other professional figures such as producer, importer and supplier.

In accordance with the traditional attention of the Northern European Countries to psychosocial factors, among the employer's duties it is compulsory, for example, to minimize monotony and repetition. All these relational factors may increase the risk of accident or illness due to manual material handling. Furthermore, the employer deals with his employee's training and they are reprimanded when they do not follow the instructions.

Unlike the other ergonomic standards, AFS 1998-1 gives responsibilities also to the producer, importer, supplier of weights which are dangerous for the health of the people handling them. This illustrates how Sweden has created an ergonomic standard which makes everyone (importer, producer, trader) comply with ergonomic requirements. Special dispensation to this law is represented by products from the European Union in order to avoid hindering free commerce among the different countries. This shows how far European Countries are from Sweden concerning ergonomic programs for prevention and how Europe still lacks unitary ergonomic perspective.

The National Board of Occupational Safety and Health promulgated also General Recommendations on the implementations of the Provisions. Unlike Provisions, Recommendations do not have mandatory value. They rather consist of a wide collection of useful explanations to clarify the meaning of Provisions through images, examples of cases, information and references. Thus they explain and comment on the law that might be difficult to understand as it is basic and concise.

3.3. Canada, British Columbia: Occupational Health and Safety Regulation (Workers' Compensation Board)

In Canada, British Columbia, the Occupational Health and Safety Regulations (1998) was developed by the Workers' Compensation Board. Occupational Health and Safety Regulations consists of three main parts: (1) core requirements; (2) general hazard requirements; and (3) specific industry requirements. Ergonomic requirements (general conditions) are in the first part. They aim to eliminate, or at least minimize the risk of musculoskeletal accidents. Ergonomic requirements are:

1. Definition of risk of musculoskeletal accident.
2. Detection, evaluation and control of the above. Risk factors to be taken into account are related to physical factors, layout and workstation, characteristics of the weight handled, microclimate and work organization.

3. Preparation and training of workers including identification of signs and symptoms of WRMD.
4. Employer and employees' evaluation of efficacy of ergonomic measures selected through a program based on periodic monitoring.
5. Consultation of employees and the Health and Safety Committee by the employers on all the above.

3.4. USA: ASC Z-365 (ANSI)

In 1999 the American Standard Institute (ANSI) was developing an ergonomic standard (ASC Z-365) for the control of cumulative trauma disorders (CTD). ASC Z-365 describes processes and principles for the control and management of CTD and it is directed towards people who have responsibility tasks in health surveillance and security programs, or people who design working environments and procedures. ASC Z-365 clearly requires professional expertise and trained personnel in order to be applied as a general way of controlling specific working situations. The control process of CTD involves mostly employers who are responsible for the health and safety of their employees: this responsibility of course includes CTD.

Compared with other ergonomic standards, ASC Z-365 introduces a novelty: it provides periodic training not only for employees, but also for managers. It aims at a continuous confrontation and the creation of a common ergonomic language about periodic surveillance, work analysis, working place planning and medical care. Involving employees it is relevant and it implies active attendance to ergonomic programs.
