Design and Use of Displays

S.J.P. McDougall and D.J. Oborne
Department of Psychology, University of Wales Swansea, UK

1. INTRODUCTION

Technological advances, particularly increases in computational power, mean that the ways in which displays can be used to support human–machine systems have multiplied. At the core of display design is the assumption that the information provided for the user should be appropriate to both user and system requirements at any given time. As Rolfe and Alnutt (1967) put it, "The display translates what is at first imperceptible to us into perceptible terms". At its best, providing appropriate information support in a way that is meaningful and easily interpreted will improve the overall performance of the human–machine system (Bennett, Nagy, and Flach 1997).

2. USES OF DISPLAYS

The diversity of ways in which displays are now employed means that it would be impossible to provide a comprehensive listing of their uses. At their simplest, displays may provide simple warnings or quantitative information. Other displays may provide information primarily about the quality of the machine state (e.g. in photocopiers). More complex displays often have multi-purpose goals. These include displays which are designed to track or control complex processes (e.g. in nuclear power and chemical plants) and should enable the operator to predict or anticipate the state of the system and provide warnings of system anomalies or danger. Other complex systems include tactical cockpit displays, air traffic control, and other command and control center displays. In these situations the amount of potential information which could be displayed is growing all the time and the trade-off between user support and display clutter constantly needs to be juggled in design. Furthermore, information requirements in complex systems may change quickly and dramatically and displays must be able to change and adapt to those needs.

Given the demands made of displays, it would be ideal if there were a "royal road" to optimal display design. There is not. What follows, therefore, are a series of considerations, heuristics, and procedures which can help the designer to create and evaluate displays. At the end of the day, however, it is often the imaginativeness and creativity with which these are employed by the designer that determines the effectiveness of a display.

3. DISPLAY DESIGN

Factors which need to be taken into account in display design will be considered in relation to (a) the design of symbols or icons for displays, (b) the use of words and alphanumerics, (c) the organization of displays, and (d) the process of creating and evaluating designs.

3.1. Symbols and Icons in Displays

Symbols and icons are commonly used in displays to indicate system functions and to provide information from the system. What follows is a general consideration of symbol characteristics that need to be considered in design and how these are likely to affect users' interaction with the display.

3.1.1 Pictorialness

Pictorial, or concrete, symbols depict objects, places, and people with which we are already familiar in the real world. Other symbols have less obvious connections with the real world and information is represented using graphical features such as combinations of shapes and arrows (figure 1 shows examples of pictorial and abstract symbols). Pictorial symbols are useful when someone is learning to use a display because real world knowledge can be used to guess what they mean. Users, particularly novices, prefer them and they give the feeling that the display is easy to use. Often lack of space and the complexity of the information to be presented makes frequent use of pictorial symbols impracticable. This does not matter too much since experienced users usually find more abstract symbols just as easy to use.

3.1.2 Visual complexity

This is the amount of detail or intricacy in a symbol (figure 1(i) shows a complex symbol, the others are simple). In general, it is important to follow a "simplicity principle" when designing symbols. Using many complicated symbols will mean that users will take more time to find the appropriate information in a display. Experienced users may be able to deal better with clutter on displays, but it will still slow them down and will lead to errors being made.

3.1.3 Color

Color can be used very effectively to support the organization and ease of use of displays (see Davidoff 1987 for a review). Color is particularly useful when displays are dense or complex because it can be used to direct attention to a particular symbols, to groups of symbols, or to particular detail within a symbol. As a result, it can reduce the time taken to identify appropriate information and help to create conceptually related symbol families. Color can be used to rank items in order along a scale (by using increasingly powerful shades of the same color) or to provide hazard warnings (red is commonly accepted in America and Europe). Unrestrained use of color should be avoided since it creates visual clutter and increases search times.

3.1.4 Size

The precise size of symbols in a display is usually determined by three features: typical viewing distances, display quality, and viewing conditions. Size requirements at different viewing

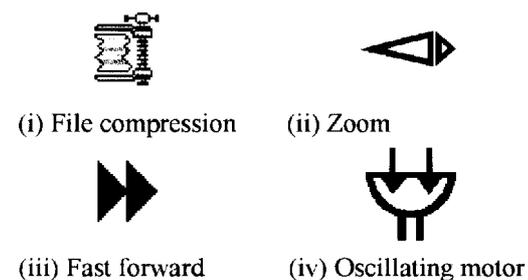

Figure 1. Examples of symbols used in displays.

distances are usually specified in detail by internationally agreed standards, individual company style, or by government. Display quality may vary in accordance with resolution, contrast, focus, and glare. Viewing conditions depend upon environmental factors such as noise, smoke or dust; they also include physiological and psychological factors such as fatigue, eye strain, workload, stress, and anxiety.

3.1.5 Shape

Shape can be used to improve discriminability between symbols in displays. If effective contrasts in shape are used they can reduce the time it takes for users to identify appropriate information. Symbol shape can also be used to help organize displays. Shape can highlight similarities between symbols which represent similar information and can be used. to create symbol families. Shapes can also be used to convey conventional meanings (e.g. figure 1(ii)).

3.2. Use of Words and Alphanumerics

Despite the increasing trend to move away from the use of words, and especially lines of text in displays, symbols in displays are very frequently accompanied by text. The most obvious reason for this is to reduce the ambiguity inherent in the use of symbols. Symbols often rely on visual associations and the context in which they appear for their meaning whereas words are rarely ambiguous. Words can also convey more complex meanings and ideas in a way that would be virtually impossible with symbols. Similarly, use of numbers is often the most effective way of conveying quantitative information, particularly where display space is limited. Despite the obvious differences between symbols and text, many of the design principles applied for symbols can be also applied in this domain.

3.2.1 Concreteness and meaningfulness

Where users may not always be experienced or have appropriate training, concrete words which have clear meanings should be used wherever possible. When words are abstract (e.g. "idea", "method", "justice') the meaning becomes more diffuse and harder to comprehend. For experienced users, however, the use of abstract or jargon terms which are specific to the use of the system can sometimes provide a useful shortcut to more complex meaning. Where words are being used as textual labels for symbols, there should be a clear match between symbol and label. Labels should be avoided where they are likely to be long (figure 1(iv)) or add little meaning.

3.2.2 Size, simplicity, and shape

As with symbols, the size of letters is largely determined by viewing distance, display quality, and viewing conditions. Font size is almost always determined via agreed international standards. Letters are usually kept as simple as possible in order to enhance legibility and decrease clutter on the display (e.g. avoiding the use of long or heavy serifs and hairline strokes). A feeling of clutter can also be avoided by ensuring that letters and words are adequately spaced. Providing they are not over-used, letters can provide a useful visual contrast to symbols on a display. This is because skilled readers can instantly identify text amongst other shape cues.

As Wright (1999) has noted, users tend to adopt the principle of "least reading effort'. Users' searches for relevant information may often be limited initially to viewing symbols; only where disambiguating or further information is required will text be consulted. Labeling or other textual information should be kept as legible and brief as possible to allow users to "skim" this information and direct their attention to what is relevant.

3.3. Display Organization

Good display organization is the most important determinant of whether or not users can direct their attention to the relevant information. It also plays an important part in determining how easy that information is to understand and respond to.

3.3.1 Configurality

Configurality refers to the way in which elements within displays are arranged in order to convey information effectively. Careful attention is paid to the nature of the relationship between elements in displays in order to allow easy interpretation. The different types of relationships are as follows:

(a) Separable relationships: There is no interaction between visual elements in the display (see figure 2(a)). These displays are better if users need to attend selectively to each display component (i.e. they need access to low-level data).

(b) Configural relationships: There is an intermediate level of interaction between visual elements. Figure 2(b) shows how providing a shape cue can aid interpretation of the graph in figure 2(a).

(c) Integral relationships: There is a very strong relationship between elements to the extent that unique perceptual identities are lost. Figure 2(c) shows an object display used to represent operation in a nuclear plant. The spokes of the polygon have been designed so that a regular polygon represents normal conditions and any distortions indicate an abnormality. This display integrates information from more than 100 individual sensors. What is clear is that this figure conveys meaning in a condensed way that would be impossible with words. Integral displays are better if users need to combine information to make a response or need to be aware of higher level constraints among several pieces of information.

Use of configurality is likely to be most useful where relationships between visual elements can be exploited to create new emergent features which aid interpretation, where information must be extracted from a complex screen, and where user workload is high.

3.3.2 Display complexity and layout

In addition to the use of simple symbols and text, the simplicity of the display as a whole needs to be considered. The need for display simplicity has become an increasingly important consideration as the amount of information has multiplied. Tullis (1983) suggests that four types of complexity need to be considered as follows:

(a) Overall density: this refers to the percentage of the total number of possible characters or symbols which could occur in the display space. High information density causes perceptual overload, increased errors and difficulties in finding appropriate information.

(b) Local density: this is the amount of space which is filled

Figure 2. Use of configural relationships in displays.

around a target area or symbol. This is important because blank spaces can be used to provide structure in a display and areas of high local density alert designers to areas where user performance may be affected.

(c) Grouping: this differs from local density because it considers how close items are and how likely they are to be perceived as conceptual groups.

(d) Layout: this builds on consideration of grouping and considers the irregularity, or layout complexity, of functional groupings in a display.

(e) Consideration of display complexity and layout should lead to a well organized display which is easy to interpret. The use of appropriate conceptual groupings allows the user to develop strategies to reduce mental workload.

3.3.3 Creating contrasts between groupings

Creating contrasts between different parts of the display layout can help users to direct their attention quickly to appropriate parts of the display. It can also help users gain a quicker conceptual understanding of the information being presented. Discrimination between symbol and text clusters, or families, can also be achieved by the use of elementary features in the displays. These features include:

(a) color
(b) size
(c) shape
(d) orientation
(e) increasing the size of critical symbol features

Other contrasts include the use of simple symbols in an otherwise complex display. Similarly, pictorial symbols are distinctive when most other symbols in the display are abstract. Overuse of contrastive features should be avoided since this will simply reduce distinctiveness across the display.

3.3.4 Conceptual complexity and "cognitive fit"

The assumption underlying concern with the visual aspects of a display is that good visual elements in a display will facilitate the users' interpretation and integration of information. Consideration needs to be given to the complexity of the information in layout groupings and the amount of world knowledge activation and processing required when this information is presented. The display should fit in as well as possible with users' current knowledge and expectations.

4. CREATING AND EVALUATING DESIGNS

Given the complexity and diversity of displays the process of creating and evaluating designs is likely to differ from one to another. Some of the methods typically used are considered briefly below.

4.1. Creating Display Designs

There a number of steps which designers typically follow when designing displays. The earliest phase of design usually consists of formulating a clear statement of requirements for the display. This will include not only details about what should appear in the display but information about the system operating environment and likely user groups. This is followed by, or carried out in conjunction with, a task analysis which will consider the nature and order of the tasks to be carried out by the system and the user. This will include consideration of context of use and workload. Once this has been completed, prototype display designs will be created. Ideas for displays may be elicited from focus and user groups. The precise nature of the display, however, will be determined to a greater or less extent by a number of other considerations. These include the tradition and philosophy of the company for whom the display is being created, precedents created by displays of a similar nature, customer expectations, recommendations from international standards along with government requirements, and the likely costs and time-scales for development.

4.2. Evaluating Display Designs

Once a prototype has been created, the designer may choose one or more of a variety of evaluation techniques depending on the nature of the display being created. These are as follows:

(a) Comprehensibility testing: This may be carried out by asking potential user groups to name, match, or rate the meaningfulness of symbols which will appear on the display.

(b) Discriminability testing: User awareness of information groupings in the display can be determined by asking potential users to sort information provided in the displays into groups. This is often done using simple card sorting tasks using cards with each piece of information noted on the cards.

(c) Surveys, questionnaires, and interviews: These are typically used to troubleshoot and provide information about areas of difficulty in the displays.

(d) User preferences: Indications of the kinds of displays that users will like using can be obtained by presenting users with a series of display possibilities and asking for rankings, ratings or "most preferred" statements. User preference does *not* always predict user performance.

(e) Prototypes and simulation: These are often created after the initial evaluation process. Simulations are particularly important in estimating likely user performance where systems are complex and workload is high.

5. CONCLUSION

At the heart of display design is the need to provide easily interpreted information which supports decision making and system control. There is no simple formula to allow the designer to do this. It is the combination of knowledge, experience, and creativity which most often leads to good design.

Handwheels

H.–J. Bullinger and M. Braun

Fraunhofer-Institute for Industrial Engineering (IAO), Stuttgart, Germany

1. INTRODUCTION

Generally, controls are the interface elements in a man — machine system through which energy or information is transferred from the user to the technical system. The most common way to transmit movement by mechanical controls is rotation. There are numerous different types of rotary controls which are normally standardized. In order to operate with rotary controls a torque is required. According to their shape different types of rotary controls can be differentiated: (hand)wheels, rotary disks, rotary switches, knobs and cranks. Rotary controls can be equiped with pointers or scales.

Design, selection and arrangement of handwheels — as one important type of rotary controls — must be considered especially according to the criteria of human factors and ergonomics. The dimension and the position of a handwheel affect the strain to which the user is subjected as well as the effectiveness and safety of the system. Design dimensions of a handwheel must be compatible with the anatomical, anthropometric, and physiological marginal human conditions. It is the intention of this contribution to provide some guidance in the selection, arrangement and design of handwheels.

2. OPERATIONAL CHARACTERISTICS OF HANDWHEELS

Wheels as torque transmitting elements are assigned to the rotary controls and can be shaped as handwheels (to be used with just one or with both hands) or as fingerwheels. They can be differentiated between disk handwheels with a closed stay and spoked handwheels, which consist of a rim to induce power, several spokes and the stock. The induction of power can be improved by a crank that is arranged with the rim. Handwheels are usually produced by casting or pressing material (metal or synthetic). Characteristic dimensions of handwheels, as well as permissible actuating forces and torques, are given in Figure 1.

Handwheels are recommended especially for the following control functions: continuous adjustment, precise adjustment, and large force applications. Quick adjustment and accidental actuation are acceptable with functional application. Handwheels

Dimensions		Moment M = f(D)	
Diameter	D = 100-800 mm	D = 100-200 mm:	M = 2-40 Nm
Rim Diameter	d = 30-40 mm	D = 200-250 mm:	M = 4-60 Nm

Figure 1. Characteristic dimensions of handwheels

are not suitable for control tasks requiring tactile and visible feedback. The main operational characteristics of handwheels refer to the control task and the coupling conditions, which are discussed below.

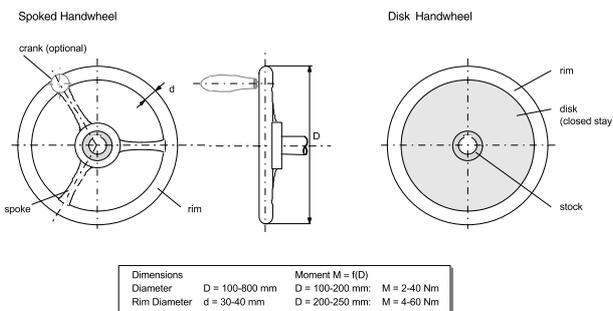
Force, speed and accuracy are regarded as the most important parameters of control tasks. These performance parameters are particularly influenced by the dimensioning and positioning of the handwheel. The maximum isometric muscle forces of humans in the hand–arm motion range constitute the basis for the transmission of forces to handwheels. The most important influential variables regarding the maximum isometric actuating moments, besides human muscular capacity, are technical parameters such as the force application point, the direction of force, and the type of coupling. The actuation of a handwheel should take place within the maximum force output range. With handwheels, the actuating forces or moments can be increased if the direction of force transmission is chosen in such a way that the body can find a support (backrest) or that, if possible, weight can be translated into actuating forces. The maximum isometric actuating moments for spoked handwheels are shown in Figure 2 by an example. As can be seen in Figure 2, body weight can be used if the handwheel is arranged at low positions, resulting in hight actuating moments. However, the effective translation of body weight is only possible if the handwheels have a larger diameter.

In the case of a frequent actuation of the handwheel, the actuation force, on account of the continuous performance limit of man, should not exceed 15% of the maximum force. If the actuation times are very short (< 5 sec) the resistance can account for approximately 50% of the maximum force. When designing safety equipment it must be ensured that, regarding the force to be developed, even the weakest person (fifth percentile) will still be able to actuate the handwheel.

The actuating speed depends primarily on the resistance of the used handwheel. The highest actuating speed can be obtained by a large motion area using a crank, because no regrasping of the handwheel will be necessary due to the static coupling.

The actuating accuracy of handwheels depends on the following parameters: dimensions and arrangement of the handwheel (front-, side-, height-position), motion range, type of coupling, forcing function, environmental influences, etc. Actuating movements can either be continuous or discrete — that is, in steps or stages. To set the intermediate positions, provision will have to be made for mechanical ratchets, so that the position can be safely identified.

The type of coupling can be determined according to whether coarse-motor or sensory-motor control tasks are to be performed. Clasping by the hand should be applied for coarse-motor control tasks, whereas gripping by the fingers should be applied for sensory-motor control tasks. The movements are further reduced in the event of a two-hand coupling on the handwheel.

The transmission of energy to the handwheel is usually frictional. In frictional coupling, the actuating force is transmitted through the friction forces that exist between the handwheel and the hand, with the necessary normal forces produced by the coupling forces (compare Section 3). In some cases a positive coupling will appear if actuating forces are induced by spokes


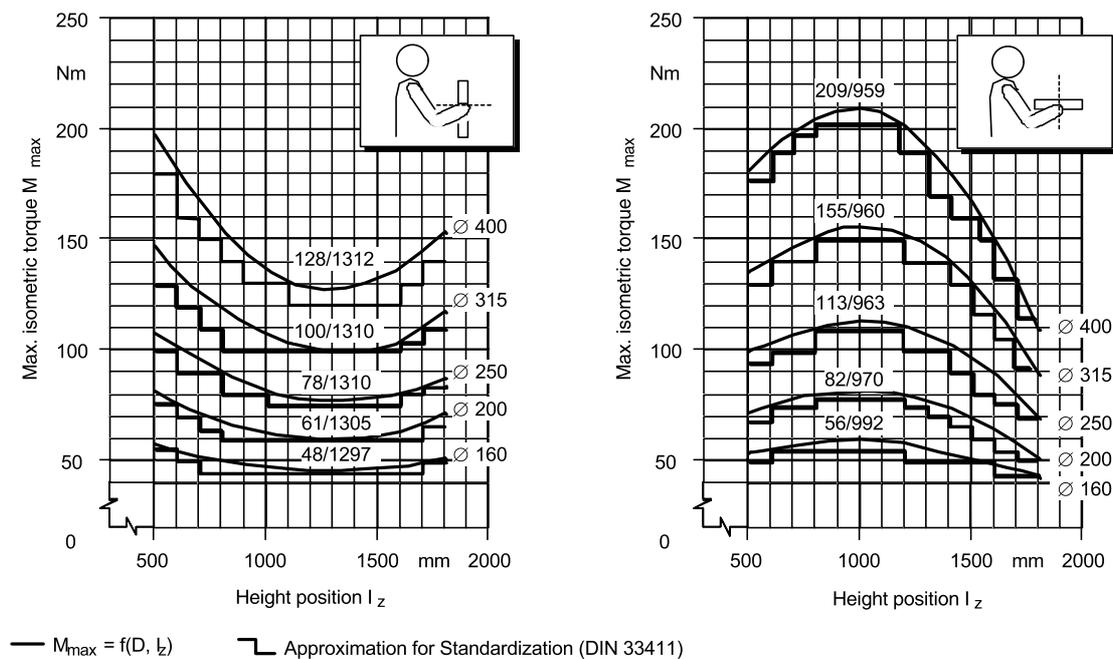


Figure 2. Isometric torques of handwheels (T = f {control diameter, height, direction}) (Mainzer 1982).

into the handwheel or if the handwheel is equipped with a crank. A positive coupling permits greater actuating force to be applied, but at the same time it also confines the possible movements of the hand–arm system.

Frictional coupling is favorable for dynamic coupling on the handwheel (regrasping). If the scope of movement of the hand–arm system is not sufficient for the required actuating distance, static coupling changes to dynamic coupling. In dynamic coupling, regrasping is necessary, so that the required movement can be performed. If the possibilities of movement are exhausted in static coupling, a larger scope of movement can be achieved only by movements of the trunk, resulting in additional stress and strain for the user (Kern, Muntzinger, and Solf 1984).

3. ERGONOMIC DESIGN PARAMETERS

The design dimensions of the handwheel — such as shape, size, material, and surface — are important factors influencing the operating effectiveness, with the characteristics performance, stress and strain of the user, and safety criteria. For defining the design variables, the control task, coupling conditions, and the user's capabilities and anatomy are of importance.

Designing the shape of one-hand- and two-hand-operated disk handwheels is regarded as being problematic. For safety aspects, disk handwheels must have a closed stay. The relationship between the maximum isometric actuating moment and the rim diameter has been approximated on the basis of experimental tests by a regression function for different handwheel arrangements (Kern *et al.* 1984). The regression function permits a rim diameter of approximately 45 mm to be derived. For reasons of economy and weight, the calculated rim diameter cannot be realized. Considerable savings of material and weight can be achieved by taking suitable design measures in which the stay of the handwheel can be used as coupling area. In the design of handwheels it will also have to be taken into account that the shape must satisfy criteria of ergonomics and safety for all relevant

positions and arrangements. As shown in Figure 2, the shape of the handwheel satisfies ergonomic criteria for both two-hand operation in the sagittal–horizontal axis and one-hand operation in the horizontal–frontal axis; that is, a large coupling area and thus minimum strain on the hand is guaranteed in all control positions.

In the case of frictional coupling of the hand with the handwheel, the power is transmitted by friction forces, where the normal force will be developed by the coupling force. The friction coefficient is determined by anatomical–physiological parameters such as the size of the coupling area, surface structure, and the skin's degree of moisture, on the one hand, and by the material's properties such as surface roughness and profiles, on the other hand. In frictional coupling the material must also be selected with respect to the frictional behavior that exists between hand/fingers and the handwheel. Unsuitable materials and surface structures lead very quickly to heavy strain and destruction of the upper skin layers. For detailed information on material friction properties, see Bullinger *et al.* (1997).

If the surface of the handwheel is profiled, the size and form of the profiles as well as the profile spacing will be important. Moreover, the direction of the profiles relative to the hand or the fingers is also relevant for power transmission. Because the strain on, and the danger of injury to, the skin becomes higher with increasing profile size, only fine profiles (profile spacing < 3 mm) are permissible for control element surfaces. In this case the profiles must be orientated vertically to the direction of force. The effectiveness of the profiles on smooth surfaces depends heavily on the normal force. Under smaller loads per unit area (normal forces), profiled surfaces show smaller coefficients of friction than smooth surfaces. The effective coupling area is considerably reduced by the profiles. Under higher loads per unit area, greater coefficients of friction result in the case of profiled surfaces, owed to a certain interlocking between skin and profiles.

If relative movements occur between handwheel and hand during operation, the thermal conductivity of the handwheel material will also have an influence on the operating effectiveness. The thermal conductivity of relevant control materials may vary between 0.15 W/Km (PVC rigid) and 70 W/Km (steel). At high actuating speed, the arising frictional heat can be dissipated only via the hand, which may result in an inadmissibly high temperature rise in the hand. With static coupling of the hand/fingers on the handwheel, materials with low thermal conductivity are required so that the hand´s temperature will not be imparted to the handwheel too rapidly, resulting in hypothermia of the hand.

If gloves have to be worn for performing control tasks, this must be accounted for in the dimensioning of the handwheels. Provision will have to be made for a plus or minus allowance of approximately 10% for inner and outer dimensions. With respect to the degree of fulfilling the control task, a reduced tactile sensitivity and lower mobility of the hand must be expected when wearing gloves.

4. ARRANGEMENT OF HANDWHEELS

The arrangement of handwheels is governed, on the one hand, by human capabilities such as anatomy, anthropometry, and physiology and, on the other hand, by the characteristics of the technical system to be manipulated. The most important criteria which have to be taken into account concerning the arrangement of handwheels are:

> Movement–physiological marginal conditions (as range of the hand–arm system, requirements made on actuating force, speed, accuracy)
> Coupling conditions
> Sequence of the process to be controlled (sequence and frequency of activities)
> Safeguards against inadvertent operation
> Operation while sitting or standing

According to the first aspect, it must be considered whether the handwheels will have to be actuated by women or men, or by both, and what percentile range will be relevant to the collective. For the transmission of greater forces and torques, provision will have to be made for operation while standing. On the other hand, operation while sitting largely eliminates the need for static posture energy. Depending on the type of handwheel used, its preferred vertical position will be between the elbow level and the shoulder level. Handwheels actuated by both hands should be positioned in the median plane.

To permit error-free operation of the handwheels, without inadvertently actuating any neighboring control element, certain distances must be observed. The minimum distance between two neighboring handwheels is about 20 mm, with the optimum distance at 50 mm, where the fingers are regarded as a crucial spatial condition (Grandjean 1991). If the operator wears gloves, provision will have to be made for a corresponding allowance. If the rear side has to be used as coupling area in one-hand- and two-hand-operated handwheels, a freespace between 20 and 35 mm will have to be provided between the rear side of the handwheel and the technical system.

5. COMPATIBILITY OF CONTROL–DISPLAY–SYSTEM

To ensure high effectiveness and safety of the system and a reduction of the response time as well as the learning phase, a high degree of compatibility is required between any control, technical system and display, taking into account the stereotypes of humans. Compatibility exists if the rotational movement direction of the handwheel coincides with the direction of movement of the technical system or the observable system variables. Thus, by clockwise turning of a handwheel, a response in a right direction or an extending or increasing function of the technical system is expected. Consequently, by counterclockwise turning a left direction, a retract or recrease response is expected.

The operation of a valve is an exception to these movement–effect stereotypes. To open the valve, it must be turned counterclockwise; to close it, it must be turned clockwise. These specifications may differ in different national standards and regulations.

6. SAFETY REQUIREMENTS

Improper actuation of a handwheel may be caused by the operator, unauthorized persons, or by surrounding influences. Inadvertent actuation of a handwheel by the operator may be caused by inadequate distance between one control and the next, getting one's clothing caught, or supporting oneself by holding onto a handwheel. Inadvertent actuation of a handwheel may also result from wrong operation by the operator, for example, due to unfavorable coding. The design principles discussed above should therefore also be seen in the light of safety aspects.

The marginal conditions of safety must be taken into consideration as early as in the definition of the design parameters. Shape and surface of the handwheel must be designed so that slipping off is prevented in order to avoid injury to the worker and improper actuation. If handwheels are mounted on rotating shafts, provision will have to be made for clutches so that the power transmission can be interrupted. If this cannot be realized, handwheels will have to be used in which clothing cannot get caught — that is, disk handwheels with a closed stay must be used instead of cranks and spoked handwheels. In the case of handwheels in which an inadvertent actuation would endanger persons and the system, provision will have to be made for

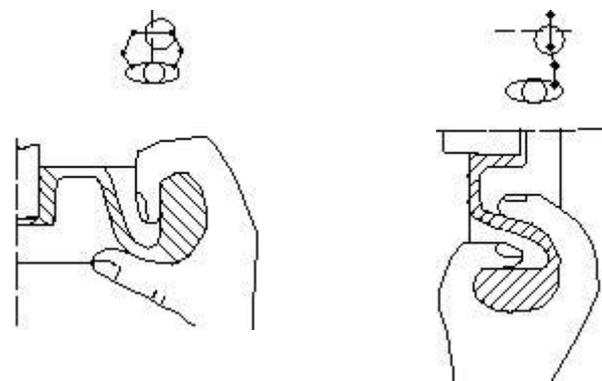

Figure 3. Shape for handwheels (disk type) and coupling conditions for different handwheel arrangements (From: Kern, Muntzinger, and Solf 1984).

additional safeguards. Such undesirable actuation can be prevented or minimized by making provision for large tripping forces, awkward handling by moving directions other than the preferred anatomical directions, shielding of the handwheel and using detachable or lockable handwheels.

The design measures mentioned above will have to be supplemented by notices or signs. It is obvious that in part safety measures do not satisfy the requirements of ergonomics. Thus it may be necessary to compromise, with due consideration to the priorities.

1. INTRODUCTION

1.1. Human Control of Machines

Control by a person over his or her immediate environment is necessary for survival and to fulfill all physical needs and desires. The advancement of civilization and standards of living accompanying it have been strongly affected by the type and quality of tools and machines employed to enable necessary work activities to be accomplished. Throughout history until the past two centuries, machines were driven by water, wind, human and animal power. Control by the human was of the most basic types: either one in which the human supplied all of the force, energy and direction of movement as in using hand tools, or one in which the human directed forces as in plowing with animal power or steering a sailing vessel. All feedback was through human perception of the controlled activity and environmental conditions. Machines powered by external and internal combustion engines and by electricity extended the concept of control to include the production of mechanical energy and the operation of a great variety of machines and processes. Feedback from the process could now occur by direct observation as in sawing a board with a power saw or through displays through which the machine provides representative information (quantitative, qualitative, digital, analog or graphic) about what is taking place or has taken place in the process.

Later, the introduction of automation enabled internal control of basic machine processes using feedback generated by sensors within the machine (e.g. thermostat) replacing operator perception and skill with electrical and mechanical functions. Human control now assumed a higher level with more emphasis on planning, interpretation and cognition than on neuromuscular dexterity. Later, process control by digital computer created yet another level of control in which two computers are involved: one that monitors and directs machine or process functions based on feedback from the operation being performed according to predetermined parameters, and one that instructs the machine controlling computer in machine language based on input supplied by the human operator as well as feedback on the status of the operation from the machine controlling computer. At this level of control, the task of the human operator as a controller is largely cognitive. Control of the machine or process is exercised as keyboard or touchscreen input to a digital computer based on information displayed on the monitor. In some cases human control is eliminated almost entirely in the normal operating mode with the human operator only monitoring intermittently as in the use of an aircraft autopilot. Finally, when a machine or process is completely automated, the human operator is an observer only and exercises no control other than to start or stop the machine or process as in an emergency, for tool changes or maintenance.

There are obviously many levels of variation and degree of human versus automated control in the higher levels of control. Sheridan (1992: 1–97) discusses the many cognitive aspects and human–computer interactive features that are possible through modern technology, including telerobotics and supervisory control of complex and remote operations. Decisions made in this realm of system design determine the types of computer workstations and other design features needed for effective human–machine interaction.

Meister (1971: 12–13) lists the following questions related to the role of the human operator in the design of complex human–machine systems that should be discussed in dialogue between the overall system designer(s) and human factors specialists:

1. What inputs and outputs must be provided to satisfy system goals?
2. What operations are required to produce system outputs? (What must the man–machine system (MMS) do?)
3. What should be the assignment of system responsibilities (i.e. what functions should the man perform within the system)?
4. What kinds of men are required to perform these functions?
5. What tasks should they perform? Can they respond to system inputs and produce the necessary outputs?
6. What equipment interfaces does the man need to perform his tasks (e.g. controls/displays, test points, diagnostic information, procedures)?
7. What is the effect of the machine on the man; the man on the machine? (Since there is an interaction between the two, the machine may demand more of the man than he can produce; likewise, the man may hinder the functioning of the machine.)

Carefully defined answers to these questions should provide a framework upon which specific issues relating to human control of the system being developed can be structured and related, with necessary design tradeoffs to assure optimum utilization of human and machine capabilities, including computer utilization, software and the cognitive aspects of human control. Questions relating to control system hardware in the control station should be addressed after the basic foregoing system design questions have been answered since they depend upon the latter. Hardware questions include those related to the type, location, priority, functional grouping, sequential use and physical design features of controls. This section will concentrate primarily on the physical design features of controls.

1.2. Human Error and Control

Whenever a human operator must perceive stimuli, process information, make a decision and take action, there exists the possibility for human error. Error can occur in any of the activities listed above and it may occur consciously as in misjudging clearance for a part or vehicle or unconsciously as in the accidental tripping of a switch. Human error may involve the omission of an act as in neglecting to activate a lockout control to prevent accidental operation of a machine while it is being services or the commission of an act such as opening a valve that should be closed or performing operations on the wrong sequence. The severity of the consequences of human error tends to increase with the size and complexity of the system being controlled and the amount of energy being controlled. System integrated human factors in designing control systems are of major importance for

aircraft, ships, nuclear power plants, railroad traffic control centers, public utility systems, oil refineries, chemical plants and other facilities where human error can lead to a disaster.

Poor ergonomic design can result in design induced errors. These are control errors likely to occur even with well-trained and dedicated operators because they violate basic principles of design in human factors engineering and are incompatible with operator expectations or capabilities. Consider, for example, the likelihood of an operator correctly performing a control function that requires the first and last pair of switches in a row of five identical switches to be placed in an upward position while the middle switch must be placed in the downward position while the operator is visually engaged in another task. In such cases even what would be considered to be a minor error from a human factors perspective (inadvertent activation or non-activation of a switch) could have major consequences. In contrast, a well-designed system could have interlocking controls and display feedback that would prevent any incorrect sequence or omission even if it was performed intentionally.

Human errors can be classified in a number of ways. Swain and Guttmann (1980: 2–8) classify human error in the following categories:

1. Errors of omission.
2. Errors of commission.
3. Sequential errors.
4. Timing errors.
5. Extraneous acts.

The fifth category includes actions that are not part of assigned tasks and could cause the other four types to occur. In terms of the human–hardware interface that exists in a human-controlled system, the following categories are convenient from an ergonomic design perspective:

1. Perceptive errors — failure to detect or interpret a signal or condition.
2. Cognitive errors — failure to understand information from a display or a control action.
3. Decision — failure to select the appropriate action or to act in the appropriate time frame.
4. Response — performing an incorrect adjustment, failing to execute a control function, or performing functions in the wrong sequence.
5. Behavioral — use of an incorrect procedure or disregard of a procedure.

Controls and their associated displays should be designed and arranged in ways that prevent or greatly reduce the likelihood of these types of error.

Fitts and Jones (1947) as presented in Sinaiko (1961: 322–58) studied 460 pilot errors in flying US Army transport aircraft during and following World War II. While this study is old, it is considered classic in revealing errors that have been common in operating many types of industrial, military and consumer hardware through many years. Errors were classified as:

1. Errors in control selection or operation resulting from a lack of uniformity or consistency (standardization) in location and mode of operation.
2. Substitution errors resulting from variable arrangement patterns, inadequate separation and a lack of shape-coding or warning lights
3. Adjustment errors that can be reduced by automatic features,

simplified one-step operations, continuous (infinite settings) adjustment and control locks.

4. Forgetting errors that can be reduced by lock-outs for incorrect sequences, uniform "off" positions, check lists and warning systems
5. Reversal errors that can be reduced through improved control display compatibility and logical geometric relationships between the task or function and the control movement.
6. Unintentional activation of controls preventable through the use of uniform, user tested design and by adequate separation of controls
7. Inability to reach controls reduced through proper use and acquisition (including measurement) of anthropometric data and the use of functional anthropometry (measurements done under real operating conditions)

The use of ergonomic principles related to control and control system design coupled with mockups and user testing of layouts and controls during the early phases of system or machine design will eliminate or minimize these ergonomic design problems.

1.3. Modes of Control

There are many interactive modes that can be used to link a voluntary human response to a desired machine action. For ordinary human–machine systems, for large, slow controls requiring high levels of force the arms and legs are used with force and position feed back occurring through the hands and feet as occurs in the use of levers and footpedals. For smaller controls hand rotation and finger actions permit quick, accurate and coordinated inputs as with toggle and rocker switches, rotary dials, thumbwheels, small cranks, buttons, keyboards, keypads and touch panels.

Other more sophisticated controls are used in special applications. In some fighter aircraft, force on a joystick with little or no movement is used as primary input in controlling the direction, acceleration and rate of turn of the aircraft. The inertial reactions of head movements (accelerations and decelerations) have been used to control powered wheelchairs. Quadriplegics have used tongue-depressed buttons to guide wheelchairs or to activate robotic arms. Voice commands have been used in some applications, primarily to execute emergency stops or perform special functions in critical situations. Corneal reflection of an infrared beam has been used as a control input in advanced military systems but the unstable nature of eye position and movement patterns makes this unsuitable for most other applications. Electromyographic signals from limb muscles or electro-oculographic signals from eye muscles are also feasible only in advanced research or clinical applications. Glove-mounted optic bundles, potentiometers and strain gauges can also generate control signals from finger movements. These biofeedback methods often present challenges in reliability and accuracy. They can be of use in basic research on reactions during perception and response in dynamic human–machine task interfaces. McMillan *et al.* (1997) provide an in-depth discussion of non-conventional controls.

1.4. Control Resistance

The physical resistance of a control to being moved provides information regarding its position and movement in the form of force feedback. There are four basic types of control resistance:

1. Elastic resistance.
2. Friction resistance.
3. Viscous resistance.
4. Inertial resistance.

1.4.1. Elastic resistance

In the use of elastic resistance, the reactive force is proportional to the control displacement. Force equals a constant multiplied by displacement. The control returns to its neutral position when the force applied to it is released. The control can be held in any desired position by applying and maintaining the appropriate force for that position. It permits quick changes and is unlikely to be activated unintentionally or by outside forces. Common examples of elastic resistance controls include throttles, accelerator pedals and clutch pedals.

1.4.2. Friction resistance

For friction resistance, there are only two levels of reactive force: one for static friction to initiate control movement and one for dynamic friction during movement. Reactive force equals one constant value or the other. Since dynamic friction between solids is always less than static friction, overshooting the intended control position is likely. Precise adjustments are very difficult. Such controls are less likely to be inadvertently moved by the operator or an outside force but they do not permit accurate adjustments using single movements. They are suitable for on–off mechanisms and for multiposition displacement if detents are provided (as with a lever) to define each position.

1.4.3. Viscous resistance

For viscous resistance or viscous damping, force is proportional to velocity. Force equals a constant multiplied by the control velocity in any given direction. Two directions (forward and backward) are commonly used. Viscous resistance reduces the likelihood of accidental control movement and prevents making large control movements rapidly. It facilitates smooth, precise control movements while also permitting rapid changes in direction. Small adjustments in position are easily made.

1.4.4. Inertial resistance

For a control providing inertial resistance, force is directly proportional to acceleration, paralleling Newton's Second Law. In this case, starting and stopping control movement are difficult thereby hindering precise movements or incremental adjustments. This type of control is unlikely to be accidentally activated or changed in its position. Since it requires large forces, frequent use should not be required. It also presents the problem of overshooting. Such controls appear in the form of large valve control wheels or cranks used to control the flow of water or other fluids or to operate heavy doors or hatches.

2. HUMAN FACTORS IN MANUAL CONTROL

2.1. Anthropometric Factors

Anthropometric factors to be considered in designing manual control systems include those related to clothed body dimensions for the desired population percentile range (typically 5th to 95th) for both genders considered in combination with reach capabilities, working positions for seated and standing operators as applicable, and mobility and access requirements. Mockups and simulators provide the best methods of evaluating proposed workstation and panel designs for the intended population. Simulators, although more expensive, also permit studies of human–machine interface dynamics. Strength, speed and accuracy of hand, arm and leg movements vary greatly with limb flexion, extension, orientation and direction of applied force. Hand, finger and foot dimensions must also be considered in providing adequate grip surfaces, contact areas and control separation. Avoiding accidental activation of controls for major functions is very important, especially when safety could be compromised. Some controls may have to be covered or placed in a mechanically locked position when not being used. In any application, dynamic functional anthropometry of representative users in their normal work clothing should be used in determining work space, layout and control selection.

2.2. Biomechanical Factors

Biomechanical factors include strength in terms of specific force exertion capability, type of control motions required to operate controls, speed and precision of control motion required, reach capability for given control operation and effects of body acceleration (as on a vehicle) upon performance. Good anthropometric design facilitates good biomechanical design since limb strength, speed and precision of movement are capabilities that depend upon body configuration. Very few control operations require a large fraction of an operator's maximum strength but excessive control force can cause fatigue and possibly neuromuscular disorders from repetitive usage over an extended period of time. Force requirements for controls should be within ranges provided in control design force recommendations for a given type of control. Control resistive force should be sufficient to prevent unintentional control activation or movement. Emergency controls and the forces needed to operate them should be determined on an individual case basis, considering the capabilities of the intended user population. Chaffin (1991) provides an in-depth analysis of many whole body and limb segment related strength capabilities.

2.3. Psychological Factors

Psychological factors designing manual controls include those related to control location, arrangement, spacing, kinesthetic and tactile feedback generated, and logic as affected by interaction with the operation of other controls. In addition, there are factors related to the compatibility between a control and its associated visual display. Many design principles, guidelines and recommendations have been derived for a multitude of applications and operational settings. A number of general design principles have been discovered and developed over the years. These apply to a broad spectrum of applications and can, in some cases, be said to resemble laws in science. Boff and Lincoln (1988) compiled human factors engineering data compendiums covering many aspects of manual control, visual, auditory and tactile displays plus many other cognitive aspects of control. Psychological factors related directly to controls, their operation and feedback include:

- Control spacing and arrangement.
- Control operational logic (control–display compatibility, sequencing, directional compatibility.
- Control feedback: position, resistive force, surface tactile

features, shape, appearance, transillumination, acoustic signal, detent resistance, labeling.

- Population stereotypes (preferences of the user population derived from operational experience).
- Sanders and McCormick (1993: 301–33) list and illustrate rules for spatial and movement compatibility between controls and their associated displays.

2.4. Operational Factors

Operational factors relate to the means by which human control is conveyed to the machine or process. These include choices between discrete and continuously variable positions for controls, the use of linear versus rotary controls, the control–display movement ratio (C/R or control–response ration, formerly called the C/D or control–display ratio), the simultaneous or coordinated control of multiple units or functions, and predetermined control logic (preventing unacceptable or unsafe combinations of control settings, lockin and lockout procedures, proper control activation or deactivation sequences, time delays, and other programmable features).

3. DESIGN CRITERIA FOR SPECIFIC MECHANICAL CONTROLS

3.1. Classification of Controls

Manual controls can be classified according to any number of functional categories depending on the technical aspects of the machine or process being controlled. Specific and highly detailed classifications and spatial arrangements have been developed for some applications such as aircraft and nuclear power plants. In developing control devices for the operator in these and other high investment applications, strong interaction occurs directly through experimentation or indirectly through standardization, training of operators and licensing of designed systems among human factors engineers, licensed professional operating personnel and cockpit/control panel design engineers. The use of detailed mockups and simulators is typical in evaluating proposed designs and selecting the one judged to be the best in terms of operational reliability and effectiveness.

From an operational viewpoint, controls are classified by the nature of their machine function, limb usage in operating them and by physical structure and appearance. A given control may operate according to discrete or continuous or unlimited settings. For example, a small tractor could operate at various speeds by discrete selection of the appropriate gear while engaging a clutch and then releasing the clutch when in the desired gear. A hydrostatic transmission permits speed selection over a continuous range of speeds and requires only one forward motion on a control lever to set the forward speed. Backing the tractor is accomplished by setting the control lever behind the central neutral position at a position corresponding to the desired reverse speed. Any manual control capable of multiple settings to control a single variable over a defined range can be made to operate in continuous or discrete settings.

Controls will be classified in this section according to the following categories:

- LARGE LINEAR CONTROLS
- Pedals
- Levers
- Cranks
- Wheels (valve wheels)
- Steering wheels
- Yokes
- SMALL LINEAR CONTROLS
- Bars
- Slide controls
- Push–pull knobs and handles
- Push buttons
- SWITCHES
- Toggle
- Rotary
- Rocker
- LARGE ROTARY CONTROLS
- Cranks
- Wheels (valve)
- Steering wheels
- Yokes
- SMALL ROTARY CONTROLS
- Small cranks
- Thumb wheels
- Rotary knobs and dials
- L-handles
- KEYBOARDS
- Two-handed
- One-handed
- MOUSE
- TOUCH DEVICES
- Touch panels
- Touch screens and displays
- Membrane keyboards
- Light pens
- Pointers
- JOYSTICKS
- TRACKER BALL

3.2. Selection of Controls

Controls are summarized according to their use in Table 1 for the ease of discrete control settings. Examples of recommended functional uses for general classes of discrete controls are given in the right hand column. It is important in selecting controls to follow population stereotypes (preferences within a given application that has acquired a history of successful and favored control designs and arrangements). Population stereotypes often result in strong user habits that are likely to cause errors if control design is altered radically for a given function.

A guide for selecting controls whose settings can be made on a continuum permitting an unlimited number of positions to be selected over the range of control settings (hence the term "continuous controls") is given in Table 2 along with examples of recommended use. Both linear and rotary controls are included.

Controls should be selected or designed for functionality with aesthetic features or styling added later if desired, provided that these do not reduce operator performance. For example, a steering wheel for an automobile should be designed with proper consideration to turning force, grip strength and steering motions required in terms of its diameter and rim thickness before deciding upon the use of a wooden wheel or leather covering as classic material. Many functional criteria can be considered, depending on the application. A representative set of commonly used criteria

Table 1. Selecting discrete controls

Type	Users
Linear	
Pushbutton	Where a control or an array of controls is needed for momentary contact or for activating a locking circuit
Legend	Where an integral legend is required for pushbutton application
Slide	Where two or more positions are required or are arranged in matrix to allow easy recognition of relative switch settings (e.g., auditory levels across channels)
Toggle	Where two positions are required or space limitations are severe Three-position toggles used only as spring-loaded center-off type or where rotary or legend controls are not feasible
Rocker	In place of toggles where toggles may cause snagging problems or where scarcity of panel space precludes separate labeling of switch positions Three-position rockers used only as spring-loaded center-off type or where rotary or legend controls are not feasible
Push-Pull	Where two positions are required and such configuration is expected (e.g., auto headlights, etc) or where panel space is scarce and related functions can be combined (e.g., ON-OFF/volume control) Three-position push-pulls used only where inadvertent positioning is not critical
Rotary	
Selector	Where three or more positions are required In two-postion applications where swift visual identification is more important than positioning speed
Key Operated	In two-position applications to prevent unauthorized operation
Thumbwheel	Where a compact digital control-input device with readout is required

Table 2. Selecting continous controls

Type	Uses
Linear	
Lever	Where large amounts of force or displacement are involved or when multi-dimensional control movements are required
Isotonic (Displacement) Joystick	Where precise or continouse control in two or more relate dimensions is required
	Where positioning accuracy is more important than positioning speed
	Data pickoff from CRT or free-drawn graphics
Trackball	Data pickoff from CRT
	Where there may be cumulative travel in a given direction
	Zero-order control only
Mouse	Data pick-off or entry of coordinate values on a CRT
	Zero-order control only
Light Pen	Track-oriented readout device
	Data pick-off, data entry on CRT
Rotary	
Continous	Where low forces and precise adjustments of a continous variable are required
Ganged	Used in limited applications where scarce panel space precludes the use of single continous rotary controls
Thumbwheel	Used as an alternative to continous rotary controls where a compact control device is required

is presented in Table 3 along with a representative set of controls which may or may not meet a given criterion. It is important, therefore, that criteria be ranked or prioritized in a given application and that specific control selection is based on the prioritized criteria.

When many functions and controls are involved in control panel design, controls should be grouped according to function and arranged in sequential order of their use, when used sequentially, from left to right and from top to bottom. Importance and frequency of use should be used to decide which functional group should be located within the central visual and forearm reach areas and which ones should be located peripherally.

Table 3 lists some selected characteristics of controls, based on control design features discussed previously in addition to other control identification features along with ratings of commonly used discrete and continuous controls. It is important to note that every control has at least one fair or poor rating based on one or more particular characteristics listed. All controls listed also have at least one good rating based on a given characteristic. Many other characteristics and controls could be included in this type of table. The reasoning process involved in setting up such a table for a given application should be of value

in specifying or designing controls that will be effective functionally as well as ergonomically. Involving users in the design and selection of controls as through the use of mockups when final decisions need to be made can enhance operator compatibility even further. System users and operators can then be trained to operate a new system or become totally familiar with its controls before the system is introduced in an operational setting. This approach will eliminate or minimize design retrofit changes and complaints from system operators that "No one ever contacted us or asked our opinion. The designer has never had any operating experience."

Referring to Table 3, it is also important to note that the control itself provides operating feedback to the user through its design features, control setting and location. In this design aspect, the control serves as a tactile display indicating the status of operator commands to the system. Information from a control can be the result of several design features including its location, shape, size, mode of operation, labeling and color. Each of these forms of information or coding has advantages and disadvantages. These are summarized in Table 4. As with the comparison of controls in Table 3, no method of coding is without disadvantages or advantages. Depending upon the operating environment (e.g. use of gloves, poor lighting) tradeoffs can be made among the options available. In any case, simplification and standardization of controls and their operation are always important if errors are to be minimized.

Table 3. Comparison of common controls

| | Control Type | | | | | | |
| | Discrete | | | | Continous | | |
Characteristics	Rotary Selector	Thumb-wheel	Push-button	Toggle Switch	Continous Rotary	Thumb-wheel	Lever
Space requirement (location and operation)	medium	small	small	small	small to medium	small	medium to large
Likelihood of Accidental Activation	low	low	medium	medium	medium	high	high
Effectiveness of coding	good	poor	fair to good	fair	good	poor	good
Ease of visual identification of Control Position	fair to good	good	poor[a]	fair to good	fair[b] to good	poor	fair to good
Ease of Non-Visual Identification of Control Position	fair to good	poor	fair	good	poor to good	poor	poor to fair
Ease of Check Reading in Array of Controls	good	good	poor[a]	good	good[b]	poor	good
Ease of Operation in Array of controls	poor	good	good	good	poor	good	good
Effectiveness as Part of a Combined Control	fair	fair	good	good	good[c]	good	good

[a] Exception is when control is back-lighted and light comes on when control is activated

[b] Application only when control makes less than one rotation; round knobs must also have a pointer

[c] Effective primarily when mounted concentrically on one axis with other controls

Table 4. Advantages and disadvantages of various types of coding

| | Type of Coding | | | | | |
Advantages	Location	Shape	Size	Mode of Operation	Labeling	Color
Improves visual identification	x	x	x		x	x
Improves nonvisual identification (tactual and kinesthetic)	x	x	x	x		
Helps standardization	x	x	x	x	x	x
Aids identification under low levels of illumination and colored lighting	x	x	x	x	(when trans-illuminated)	(When trans-illuminated
May aid in identifying control position (settings)		x		x	x	
Requires little (if any) training: is not subject to forgetting					x	
Disadvantages						
May require extra space	x	x	x	x	x	
Affects manipulation of the control (ease of use)	x	x	x	x		
Limited in number of available coding categories	x	x	x	x		x
May be less effective if operator wears gloves		x	x	x		
Controls must be viewed (i.e., must be within visual areas and with adequate illumination present)					x	x

3.3. Recommended Design Features for Controls

3.3.1. Large controls

3.3.1.1. Foot pedals and switches

Recommended design criteria for foot pedals and switches are presented in Figure 1. Separation, as well as size and displacement, is important in avoiding accidental selection. Alternate shapes for foot switches are primarily for visual identification and familiarization. In terms of feedback, location provides the only mode of providing information in selecting a pedal or foot switch. In considering control resistance for any large control, it is important to limit control force to no more than 5% of maximum strength for continuous operation or 20%

when rest periods are at least ten times as long as holding time. Elastic resistance should be used in most applications with the pedal or foot switch returning to its neutral position when released. Depending on seat height the maximum pedal force should not exceed 89 N for high position seat resulting in a primarily downward stroke or 178 N for a mid-position seat resulting in a primarily forward (leg extension) stroke. If the seat is low enough to permit maximum leg extension force against a horizontally resisting pedal, the maximum allowable force based on strength should not exceed 800 N for male operators or 622 N for female operators.

For pedals requiring angular depression (pronation) of the foot, such as accelerator pedals, the resistive force at the ball

position on the foot should not exceed 44 N. The recommended angle between a foot rotated pedal and the floor varies with seat height. It is typically 20° or less for higher seats as on highway trucks. It should not exceed 35° for a seat height of 43 cm or 45° for a very low seat height of 15 cm or lower.

Recommended foot pedal stroke length varies with the type of vehicle or hardware being controlled. For pedals that require displacement of the foot by leg extension, a displacement range between 5 and 18 cm could be preferred. Larger displacements (10–18 cm) are desirable for brake pedals to provide kinesthetic feedback through leg extension since pressure feedback from the foot can be largely masked by footwear and proper displacement is essential for safe braking especially under slippery road conditions. Automatic brake adjustment systems on power assisted brakes provide an alternative to providing this amount of feedback to the operator.

For an operator who is normally wearing heavy work shoes, boots or snow galoshes, additional pedal stroke length (1.0–2.5 cm) should be provided to compensate for the additional sole thickness. Foot pedals should be approximately the same width as the sole of the shoe, typically 8–10 cm. Pedal separation should be at least 5 cm edge to edge. Pedal shape is not a significant factor except in providing initial visual orientation regarding location, provided that the area is sufficient for rapid location, stable contact and reliable operation. Pedals used occasionally or for short working intervals should have a length of at least 7.6 cm. Pedals used continuously or for long periods should be between 28 and 30 cm in length.

Pedals operated by leg extension should have an elastic resistive force within an overall range between 35 and 270 N. For pedals operated by foot pronation (forward rotation) with the heel fixed, elastic resistive force should be within a range from 16 to 23 N. Foot switches should have a displacement between 2.5 and 6.5 cm for ankle rotation only and between 2.5

and 10 cm when leg extension occurs in their operation. Their elastic resistance should not exceed 90 N and should be at least 18 N when the foot is not normally on the control or 45 N when the foot normally rests on the control.

3.3.1.2. Levers

Lever action controls occur in many forms. They are used for shifting gears, operating all types of large construction equipment, cranes, forklifts, farm machinery, aircraft and many types of industrial machines. The knob at the end of a lever can be shape-coded or labeled in many cases to facilitate identification with a particular function. A knob in the shape of an end rounded cylinder or ball is preferable when a firm or prolonged grip is required. Recommended ends diameters are 3.2 cm for full grip or 1.3 cm for a fingertip grip.

Levers can operate by discrete displacement settings as when detens are used to define control position as with a gearshift or by continuous positioning over a defined range such as a throttle lever.

A joystick is a special type of lever operable over a continuous range including combinations of front–back and side-to-side motions as if it were attached to a ball. Joysticks can also respond to force only and remain stationary. A joystick may have a large full-grip handle on which can be mounted other controls such as

triggers and pushbuttons. Joysticks are used widely in helicopters and in military aircraft. Human factors relating to joysticks are similar to those for other levers with regard to control of joystick shaft position. Recommended design criteria for levers and joysticks are shown in Figure 2. Maximum recommended forces in Kp (1 Kp = 9.8 N) are shown as related to the direction of application. The type of lever selected should also be related to the type of grasp that will be used. For a finger grasp only, the handle (or knob) diameter should be above 1.3 cm and below 7.5 cm. For a hand grasp, the handle diameter should be between 3.8 and 7.5 cm. Optimum recommended diameters are between 2.5 and 3.5 cm. The type of resistance force depends upon the application and the type of feedback and speed of operation desired.

As a general guideline, for a finger grasp, resistance should be between 3.3 and 9.0 N and for a hand grasp, between 9 and 90 N. An all purpose upper limit is difficult to specify since a large lever could be operated using two hands with push and pull forces up to 450 N. The maximum lateral (right–left) resistance for a one-handed lever operation should be no more than 90 N and for a two-handed lever operation no more than 130 N.

3.3.1.3. Cranks and handwheels

Cranks are effective as controls when continuous adjustments requiring multiple rotations must be made. Attainable turning rate increases with decreasing crank radius (arm length) and decreasing resistive torque. Cranks can also be attached to large rotary knobs or handwheels to facilitate large rapid changes in control setting. Cranks can be coded for identification by their location and color and also by labeling. While cranks can be designed for either one- or two-handed operation, handwheels are designed for two-handed operation. Handwheels permit greater torque to be exerted than cranks but are much slower for multirevolution movements. Recommended design criteria for cranks and handwheels are summarized in Figure 3. For small cranks (< 9 cm in radius) requiring rapid movement, the resistive force to be overcome in turning the crank or initiating turning should be at least 9 N but no more than 22 N. For large cranks (13–20 cm radius) requiring rapid turning at a relatively constant speed, the resistive force at the crank handle should be between 13 and 25 N. A crank should turn freely on its shaft. The handle surface should provide a high coefficient of friction for the hand or glove. The handle diameter should facilitate a firm grip.

Handwheels should facilitate two-hand control and permit rapid movements as well as accurate movements when needed. If rotations > 60° are required on a handwheel, the hands must be repositioned. Wheel displacement should be determined by considering the desired control/response or C/R ratio. For example, when the handwheel must be rotated on a large arc increasing the handwheel diameter can increase the C/R ratio. The thickness diameter of the handwheel diameter should not be less than 1.9 cm or more than 3.2 cm.

3.3.2. Small controls

Small controls may operate by either linear or rotary motion.

Linear controls include push buttons, push–pull knobs and slide controls. Rotary controls include thumb wheels, rotary knobs, L- and T-handles, and rotary switches. Controls that rotate partially in making discrete settings include toggle switches and rocker switches. Examples of recommended design criteria for small controls are given in Figure 4a. There are many ways of coding small controls including shape, color, surface knurling, size, location and labeling. Knurling or fluting on thumbwheels also helps to prevent hand slippage when rotating a control. A dot or line can be used to indicate the "on-off" position. Rotary

controls that produce a similar tactile sensation but correspond to different functions should not be grouped together. Toggle and rocker switches should be clearly labeled.

Push buttons controlling multiple functions or producing different operating conditions for the same machine or process can be coded by logical combination to prevent undesirable sequences or to lock out the system for safety or security. Many patterns of operating logic can be used. Examples include: momentary row lockout, clearing or neutralizing all functions, mutually exclusive actuation of functions, and singular fixed sequential operation.

All small controls should have a resistance force or torque sufficient to prevent accidental actuation or change in setting. For rotary selector switches and knobs, for example, a resistive force between 3.3 and 13 N at the outer edge or rim of the control is desirable. Control separation should also permit operation without accidental actuation of an adjacent control. For most applications, edge-to-edge control separation should be at least 5 cm for random selection or 2.5 cm for sequential selection. Allowance for the use of gloves will increase these values. Resistance resulting from friction or control inertia should be minimized.

When controls have discrete settings, elastic resistance should increase to a maximum and then cease as the control snaps into position. The recommendation applies to rotary selector switches, rocker switches, toggle switches and rotary L- and T-handles. If ambient noise is present, an audible click is recommended to indicate that the setting has been made. Click count also provides secondary feedback to the tactile sense of control position.

A series of toggle switches should be arranged horizontally rather than vertically. If toggle switches must be arranged vertically, larger spacing between switches is necessary to minimize accidental actuation.

3.3.2.1. *Direction of control movement*

To prevent control reversal errors, it is important for controls to operate in directions that are compatible with associated display or vehicle movement and operator expectations based on experience e with controls on and off the job. Factors to be taken into account include:

1. Location and orientation of the control relative to the operator.
2. Position of the display in relation to the control and the direction or system status change shown in the response indicated on the display.
3. Orientation of the operator relative to the controlled system or vehicle.
4. Type of action being caused by activating the control.

Many recommended control movements now have the status of being universal standards for nearly all applications. A representative set of common control directional recommendations is given in Table 5.

When it is necessary to locate controls and their associated displays in different orientations, right-to-left should correspond positionally with top-to-bottom. If several rows of controls are located beneath several rows of displays on a panel, the rows should be arranged similarly. Thus, displays 1-2-3-4 on a top row and 5-6-7-8 on the second row underneath should relate to respective controls 1-2-3-4 directly under the second display row and 5-6-7-8 located under the first control row. Another effective design, except for visual interference of some displays by the hand while making control adjustments, would locate each of the eight controls directly under its associated display. If controls are stacked vertically as concentric rotary dials (maximum of three with the largest on the bottom and smallest on top), their associated displays should correspond from left to right with the dials top to bottom. Rotating pointers and knobs with fixed surrounding numerical scales are preferable to fixed surface pointers and numerals on the rotating knob.

When several planes of motion are required for control panels, the relative positions, orientations and directions of control movement should be the same. That is to say that if the operator were to face a panel identical to one in a desktop position in front of him/her, located in a different place the positions, orientations and movements would be the same.

3.3.3. Keyboards and keypads

3.3.3.1. *Keyboards*

Alphanumeric keyboards serve a great variety of needs in providing data input as well as command and control of machines and processes. The standard QWERTY keyboard has dominated for many years as the chosen option for letter arrangement of keys despite the fact that this arrangement did not have its origin in ergonomic experiments or user surveys. Because of its extremely wide usage and standardization as a population stereotype throughout the western hemisphere and all countries where English is the standard language for commerce, finance and industry, the QWERTY arrangement will probably dominate for many years to come. Other arrangements, for example those using chord or combinatorial keying, could become popular as small computers become more powerful and versatile. Coupling the QWERTY keyboard with the computer has expanded the original typewriter keyboard with a top row of special function keys, cursor controls (keys or trackball) and a numeric keypad located on the right side. Function keys are sometimes placed on the left side.

The QWERTY keyboard arrangement had its origins in the 19th century when it was used to record telegraph messages and jamming of the mechanical typewriter (caused by collision and binding together of letter printing levers carrying the letter imprint pads) could be very disruptive as the levers were being manually

Qwerty Keyboard

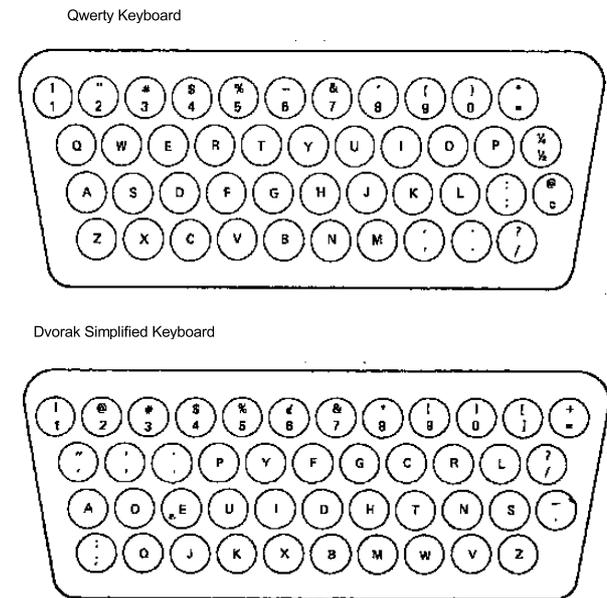
Dvorak Simplified Keyboard


Figure 5. Current QWERTY and simplified keyboard arrangements. The simplified keyboard is specified in American National Standards Institute standard ANSI X4.22-1983 and was derived from the Dvorak keyboard. Increase	Right, up, forward, clockwise
Decrease	Left, down, rearward, counterclockwise

separated. Jamming often occurred when typing was done too rapidly, thus resulting in a need for a keyboard that would reduce typing rate. As technology improved and the typing ball and word processor were developed, the QWERTY arrangement remained as a standard design. Under the QWERTY arrangement 57% of letters typed are performed with the left hand for typing in English. About 80% of the user population is right-handed. The impact of this imbalance in hand assignment upon overall productivity is reduced when the right hand can also be used alternately for writing or other tasks.

Dvorak (1943) developed an alternative to the QWERTY arrangement. The QWERTY and simplified Dvorak arrangements are shown in Figure 5. The Dvorak arrangement, designed according to hand and finger capabilities has been shown experientially to result in somewhat higher productivity, but not enough to justify a widespread change to the system along with the need for retraining. Norman (1983) concluded that a 5–10% improvement in productivity is likely. It is possible, but not yet popular, for keyboard manufacturers to offer an optional Dvorak arrangement in their product lines.

To improve productivity in the use of keyboards, there are issues that are more important than key arrangement. These include multifunction keys, chording for common letter combinations (ion, ing, ary, ory, ere, the, an, and, ph, est, qu), and automatic return. Rochester *et al.* (1978) designed a small keyboard based on chording. Their design objective was to create one hand typing capability similar to typing with a stenotype keyboard. Their design included a thumb key plate that could be moved laterally for right or left hand preference. This special keyboard consisted of two rows of five keys each, operated using the first three fingers and an additional set of four keys operated by the thumb. The keys included special raised tactile dots used to press one, two or four keys. Up to three dots could be pressed at the same time, thus forming a chord as on a piano. The designers conducted experiments using several typing rates and found that with training, typists could increase their rates by 10% using this chord keyboard. The one-handed operation permits other activities to be done with the other hand, provided that information overload does not occur. Chord keystroke data entry has been used successfully by post offices to sort letters in the USA, Canada and UK. Earlier experiments with chorded keyboards suggest that it may be possible to increase data entry rates by as much as 50% over standard rates using chording. This could justify training costs for many applications with specialized dedicated information systems.

There are also keyboards with several functions for each key. When this feature is used, it is generally restricted to the top row of keys. This feature is useful when the keyboard is used for process control. Typically a row of unmarked keys is placed under the monitor screen. Each key is represented by a small square on the screen. Text corresponding to the functional operation being performed appears in separate windows showing the key functions for a given frame on the screen. When several rows of unmarked keys are used, corresponding pictures can be projected from the screen onto the keyboard using mirrors to show the current key functions. Since fewer keys can be used on this type of keyboard, fewer hand and arm motions are needed. Errors also tend to be reduced. Another method involves providing lights inside the keys so that they light up for each individual function

when the appropriate key is pressed. Such a keyboard provides feedback that can cue and guide the operator through a sequence of operations. Non-illuminated keys cannot cause errors if inadvertently pressed since they are deactivated. This results in a very low error rate in addition to a higher data entry rate. A warning signal is needed when bulbs in the keys fail.

Pressure sensitive keys are also possible. For example, light pressure on key could cause the function to be displayed on the monitor whereas heavy pressure could result in immediate action being taken. Maximum key depression could signal needed changes in the process. When this happens, a display on the monitor indicates a new set of keys.

Pre-programming can virtually eliminate sequential errors in keyboard commands to a process. This has advantages in terms of system safety, but operators may resent being over controlled. Programming requirements can be extensive and may utilize more computer capacity than is feasible, considering other real time process control demands. The capabilities and flexibility of a standard keyboard can be greatly enhanced through pre-programming, providing many options in the type and level of control over the process.

When a standard keyboard is used and the hands are placed near the center of the keyboard, ulnar deviation (outward lateral bending of the wrist) occurs, causing stress in the wrist joint. Cumulative effects of this stress over time have produced cumulative trauma disorders such as tendonitis. Splitting and angling the keyboard appropriately for the given text eliminates this source of stress. Rotating the two halves of the keyboard inward from the edge of the desk or work table (outer ends in) is known as slanting. Lowering the outer ends of each half below the work table surface is referred to as tilting. Elevating the rear (forward) end of each half is referred to as sloping. Adjustability of these angles is desirable to accommodate a variety of tasks and operator preferences. Ilg (1987) recommends a 30° symmetrical slant separation angle between the halves of the keyboard and tilting of the outer edges of the keyboard halves to a depth of 5.3 cm. The slope angle of the keyboard can be between 0 and 15°. If the operator is standing, the slope should be between 0 and −30° (raised on the front edge to reduce wrist extension).

The size of the key surfaces must meet several criteria. First, the area of the keyboard should be kept as small as possible to minimize hand travel distances. Second, the key surface area and separation distances between keys must be adequate to accommodate the fingertips and prevent simultaneous key depressions. To fulfill these requirements, a square keytop surface 12–15 mm in length is recommended. For shop floor use or when gloves are worn by the operator, large key sizes and spacing are needed. Ordinary spacing between keytop centers has been standardized at 19.5 mm, satisfying the ergonomically derived recommendation of 18–22 mm.

The key depression resistance force should be common for all keys between 0.25 and 0.50 N with a displacement of 0.8 to 1.0 mm for skilled operators. For unskilled operators more feedback is needed. This can be accomplished by providing a resistance force between 1 and 2 N and a key displacement between 2 and 5 mm.

Feedback in keyboard operation occurs as tactile (touch) or contact feedback and also as kinesthetic feedback from finger muscle activity. In addition, there is visual feedback from the

keyboard or monitor screen display as well as auditory feedback from the keyboard. For skilled operators, the auditory feedback is not important. For operators who are learning or unskilled, auditory feedback is needed. It should be possible for operators to remove auditory feedback if it is not desired.

A contrast ratio of 3:1 should be provided for labeling keys. Coloring is normally not important. If the associated monitor displays are light on a dark background, the same relationship should exist for the keys. Keys should not reflect off the monitor screen. Matte finishes should be used whenever possible. Letters and numbers on keys should be at least 2.5 mm. Black lettering on white keys is recommended. The International Electrotechnical Commission (1975) produced color standards applicable to keys as well as illuminated information. These standards are recommended for use in keyboard design.

3.3.3.2. *Keypads*

Keypads are used when only numeric digital entry is required. The most common keypad entry device is used on the touchtone telephone. Other common applications occur in calculators, adding machines (printing calculators used in accounting and bookkeeping). Some keypads are included on keyboards as supplementary data entry devices. There are two accepted standard designs for keypads, one for the telephone and one for calculators. These are shown in Figure 6.

Both standard keypad layouts have three rows with three keys per row plus the zero button under the bottom row and in the center. The telephone layout obeys the ergonomic sequence principles of left to right and top to bottom. Conrad and Hull (1968) found the telephone arrangement to be slightly faster but with a more significant advantage in accuracy (8.2 versus 6.4% with the calculator arrangement). Alternating between the two keyboard arrangements caused an additional decrease in accuracy. The telephone layout is likely to be the standard for all telephones. It is recommended, from an ergonomics perspective, that all calculators and calculating machines, as well as keypads for numerically controlled machines, be fitted with this arrangement to prevent the transfer errors noted earlier.

3.3.4. Touchscreens

A touch screen is a keyless matrix-based touch-sensitive surface that overlays either a computer screen or projected beams (infrared or acoustic) that are interrupted when surface contact is made. A contact based screen typically has a thin metal net containing

Design of controls

| Push-button telephone layout | Adding machine layout |

**Figure 6. Layout of numerical keyboards**

Figure 7. Dimensions of touch-screen keys preferred by subjects and yielding the smallest number of errors. Source: Sanders, MS and McCormick, EJ, 1993, *Human Factors in Engineering and Design* (7th ed.) (New York: McGraw-Hill Inc.) p. 369, reproduced with permission of the McGraw-Hill Companies.

electrical circuits that are activated when the net is touched. Some designs use a transparent pressure sensitive material with special measurement bridges that detect variations in pressure distribution.

Pointing with the finger on a touch screen is often faster than pointing with a light pen, depending on target size and selection factors. The reliability of the touch screen is reduced by inaccuracy of pointing. Beringer and Peterson (1985) found that people tend to contact a touch screen between 3.2 and 6.4 mm below the intended target image. In their study, accuracy was highest at the bottom of the screen and lowest at the top. Reasons for this could possibly be attributed to excessive movement of the arm resulting from its resting position and from parallax in viewing the screen.

The size of the key targets to be touched on the screen also affects performance. Beaton and Weiman (1984) investigated the effects of horizontal and vertical target dimensions as well as target separation. Only the vertical dimension affected performance in terms of the number of errors. Larger target keys resulted in better performance than smaller target keys. The optimum target dimensions and arrangement resulting in the fewest errors and also preferred by subjects who participated in the study are shown in Figure 7.

The touch screen has an advantage over the traditional keyboard in its ability to present limited selections to untrained users. If messages or commands must be varied, the traditional keyboard should be used. Pfauth and Priest (1981) summarized the operational advantages and disadvantages of touch screen devices as shown in Table 6.

Factors influencing the acceptance of touch screen devices by users are summarized in Table 7.

The advantages to be realized from using touch screen devices depend upon the net gain achieved through simplicity of operation and reduced training over the loss of flexibility in user–computer dialogue and the additional dedicated design and programming.

3.3.5. Light pens

As suggested by its name, the light pen is shaped like a ballpoint pen and operates using a photocell to detect light radiated from a computer monitor screen. An electrical cord attaches the light pen to the computer. When the pen is pressed against the screen,

Table 6. Advantages and disadvantages of touch screen devices (from Pfauth and Priest, 1981)

Advantages

Direct visual-to-tactile control (input/output to one location)
Fast data entry and control for certain tasks
Minimal training (software flexible for different jobs and operator skill levels)
Only valid options are available
High operator acceptance
Immediate feedback
Symbolic graphic representation
Minimal operator memorization required
Minimal eye-hand coordination problems

Disadvantages

Potentially high initial cost
Increased programmer time
Not as flexible for some types of input (unless used in combination with keyboard)
Parallax affecting touch locations
Screen glare
Physical fatigue from reaching to screen
Finger visually blocking the screen
New method of programming interface software

Table 7. Factors in the acceptance of touch screen devices (from Pfauth and Priest, 1981)

Potential Users

Those in extremely high-stress enviroments
Completely naive users
Users who have a predetermined limited interface with the computer syster (e.g., management personnel)
Where available workspace does not allow a separate keyboard

Advantages

No prior training needed; no need to learn how to use a keyboard or memorize commands
Dialogue technique can guide system user toward the desired information
The user is likely to view the system as a partner in the problem-solving process
User does not need to understand the specifics of how the system works

Disadvantages

Data entry through the TSD will be considerable slower than through the traditional keyboard
High cost to implement
Flexibility of system is dependent upon software capability, i.e., limited number of display options

it senses the cathode ray tube (CRT) scanning beam as the beam illuminates the pixel directly under the pen. In this way the light pen serves a similar function as the touch screen. Since the computer receives the screen location coordinates of the pen from the screen and a simultaneous signal also passes from the pen through the cord into the computer, the computer can track the position of the pen on the monitor screen. The light pen can be used to query menu items or cause animated variation of a display such as opening or closing a valve. The light pen can also be used to move a cursor on the screen but it appears to have no advantage over other methods such as a mouse in this role.

Biomechanical fatigue can occur during prolonged use of a light pen. A properly designed armrest will prevent stresses causing this fatigue and its associated discomfort.

Since the light pen must be held close to the monitor screen a reflective shield or light filter cannot be placed on the screen. Thus, glare from outside light sources can present a problem. A light pen also requires accurate positioning. This can result in high visual demands and poor working postures. Care should be taken to assure that the entire workstation is designed for use of a light pen when this option is chosen.

3.3.6. Mouse and trackball

A mouse is a small hand positioned and hand-operated device typically 9–10 cm in length, 5–6 cm in width and ~3 cm high containing two-to-three control buttons, used to manipulate and select menu items and operations on a computer monitor screen. The mouse contains a built-in trackball on its lower side that rolls on a rubberized pad to produce corresponding cursor movements on the monitor screen. The mouse is an extremely popular data selection and manipulation device for desktop computers. The control/response (CR) ratio can be changed for selected applications or can be made velocity dependent instead of displacement dependent. From an ergonomics perspective, the mouse is generally very user friendly. As with any prolonged muscular tension, continuous intense gripping of the mouse can cause biomechanical stress and fatigue in the hand. The mouse is not suitable for drawing since it is moved by the wrist and arm whose extrinsic muscles lack the fine control of the intrinsic muscles located in the hand which control fine finger movements. When computer-aided drawing is desired, a graphics tablet (or digitizing tablet) should be used. These receive input from finger movement or from a stylus on the surface of the tablet.

The trackball is a small sphere inserted into a round hole in the keyboard or separately on a table using a separate mounting. Rolling the ball with the fingers effects two-dimensional positioning of a cursor on the computer monitor screen. There is a direct proportional relationship between the surface displacement of the trackball and the motion of the cursor on the screen. A joystick with two-dimensional movement is sometimes used in place of a trackball.

There has been no conclusive evidence favoring the mouse, trackball or joystick for controlling cursor movement. In general, the mouse is preferred whenever a clear space exists for the contact pad. Otherwise, the trackball is generally preferred for confined operating space.

4. RECOMMENDATIONS

Design of a control system and its associated human-operated controls should proceed according to the following sequence:

1. Design the overall system through interactive meetings between the engineering designer and the system user/operators and determine tasks to be performed by machines and tasks to be performed by people.
2. Define carefully these factors and system variables that must be controlled.
3. Consider human workload in terms of information processing and control operation. Determine task intensity and duration requirements and crew size. Determine necessary and desirable human functions in system operation.
4. Modify human and machine functions according to system performance requirements and human physical and psychological limitations.

5. Select controls and design control panels and operating stations according to ergonomic guidelines, operator preferences and accepted stereotypes. Stereotypes should not compromise safety or operational effectiveness.

6. Design the control/display layout and the human–machine interface environment (control cab, cockpit, workstation). Arrange controls according to function and by sequence within function. Locate important functions closer to the operator.

7. Consider anthropometric requirements for the user population. Include allowances for clothing, and movement within, entering and exiting the control area.

8. Design and simulate operator workstations using computer graphics. Build mockups for new workstations or control involving new technology.

9. Conduct operational simulation using ergonomic human operator software and/or conducting user testing in a mockup to reveal potential operating problems. Modify the design developed in step 8 according to the operational information obtained in step 9.

10. If warranted by technological complexity, time and cost limitations and designer/user agreement, develop and build a dynamic simulator for critical control stations to investigate time dependent human–machine control functions and relationships. Modify system hardware and software as needed to solve problems encountered in using the simulator.

11. Build the design prototype control station. Involve the user/operators in final design evaluations and changes.

Keyboards

D. A. Thompson

Department of Industrial Engineering and Engineering Management, Stanford University, Stanford, California, USA

1. INTRODUCTION

Keyboards allow informational interaction with machines (computers, calculators, telephones) instruments, process control, vehicles, etc. In this manner human users can communicate their instructions, requests, preferences, and knowledge manually to machines, which in turn display the results of their activities back to the human operators, closing the feedback loop. Keyboards remain the most versatile of the ways people communicate with machines, although other alternatives are becoming more available in specialized applications (e.g., mice, voice, tablets, scanners). This article will discuss the most frequently occurring keyboards in some detail, and by inference refer to other, less frequently encountered keyboards and their function.

2. TYPES OF KEYBOARD

2.1. Computer

In the late twentieth century, the word "keyboards" generally means computer keyboards. And the operation of computer keyboards has become an important manner in which vast amounts of information are stored, retrieved, analyzed, and shared with others over networks. Keyboards also represent a significant source of employment for millions of people who design, build, and use them. The following sections refer primarily to the use of computers for skilled text and data entry on detachable keyboards.

2.1.1. Types of keys

Typical full-sized computer keyboards have over 100 discrete keys, falling into seven key categories (Table 1). Portable, notebook, and hand-held computers generally follow this same pattern but with a reduced number of keys and keyboard space, and more compact key spacing.

As each key is struck, a unique ASCII signal is generated and sent to the computer's processors for interpretation and display on a visual display screen. Some function keys do not alter the computer display when pressed but rather switch, or toggle, between two states for other keys. For example, pressing and releasing *Insert* changes the manner in which characters are inserted into text—with replacement or without replacement.

Num Lock changes the entries on the numerical keypad from numerals to function keys for cursor movement. In both cases, a misunderstanding about which state the keyboard is in leads to confusion and errors. Therefore, each function switch key should have an unambiguous visual indicator of its state, typically a light on or adjacent to the key, or in a central location on the keyboard with proper labeling.

Control keys function in concert with other keys to their function. For example, *Alt + F* keys may pull down a file menu when struck together, or chorded, and *Ctrl + S* may save the current file when chorded. Other control keys relating to specific proprietary software may also be included.

2.1.2. Layout of keys

Computer keyboard design is an offshoot of typewriter keyboard design, keeping much of the same key layout proposed by Sholes in 1873 and first built by Remington & Sons in New York City. It is standardized in ANSI X4.23-1982. And although alternative key layouts have been proposed, including the well-known innovation by August Dvorak in 1936 (the Dvorak Simplified Keyboard), and a simple alphabetic sequence arrangement, the QWERTY key arrangement proposed by Sholes has become the dominant pattern. (QWERTY refers to the key sequence on the row above the left hand's home row.) Retaining this layout from typewriters into computer generations has allowed trained typists to move from one to the other and from one computer model to other computer models.

The present computer keyboard layout typically consists of a QWERTY layout of alphabet and punctuation keys, with a row of numerals across the top, and all surrounded by various function keys. To the right are additional function keys and a rectangular numeric keypad, duplicating the numeric keys above the alphabet keys for convenience. For additional comments on key layout, see ANSI/HFS 100-1988.

Since many typing tasks involve both numerical data entry and text entry, it is useful to the keyboarder to have the keys all arranged as close to one another as reasonable, avoiding open, unused space on the keyboard. This will minimize the movement of hands and arm rotation from one part of the keyboard to another. Differing types of keys may be color-coded to differentiate

Table 1. Categories of key characteristics on computer keyboards.

Key Type	Purpose	Examples	How activated
Printing keys:			
Alphabetic	Enter text	a through z	Strike key
Numeric	Enter numbers	0 through 9	Strike key
Punctuation	Format other entries	~ ' ! @ # $ % ^ & * ( ) _ - + = { } [ ] | \ / : ; " ' < > , . ?	Strike key
Non–Printing keys:			
Function keys:			
programmable	Perform specific software activity	F1 through F12	Strike key
preprogrammed	Manipulate other entries	*Enter, Tab, Home, End, Delete, Page Up/Down, Escape*	Position cursor, strike key
function switch	Alternate between two specific states	*Caps Lock, Shift, Num(eric) Lock, Scroll Lock, Insert*	Strike key to toggle between states
Control	No unique function	*Ctrl, Alt*	Chorded with one or two other keys to change their effect.

among them. Key tops are slightly concave for a more comfortable touch by the fingertip. Full-sized keyboards generally have square keys with a strike surface 12 mm on a side and 19 mm key spacing (center to center). Portable or hand-held computers often have a tighter spacing, making keyboarding slower and more difficult.

The early computer keyboards frequently had function keys off to the sides of the alphabet keys, where they were typically struck with the fifth, or weakest, finger. More recently, the programmable function keys have been moved above the alphabet keys, where they are easily accessible by all of the fingers. Unfortunately, many keyboard layouts still have some frequently used preprogrammed function keys off to the right of the alphabet keys closest to, and often struck by, the fifth finger of the right hand.

Virtually all keyboards have a row of numeric keys directly above the alphabet keys, numbered 1 to 0 from left to right. General-purpose computer keyboards also have a numeric keypad on the right end of the keyboard, arranged in a 3×4 matrix similar to that of a digital calculator. (The calculator layout is an inverted telephone keypad layout.)

2.1.3. Shape

The early computer keyboard shape uniformly followed the typewriter pattern of straight rows of keys in a stairstep fashion. Most still do, but since the early 1980s various ergonomic shapes are becoming available. The purpose of these improved geometries is to eliminate the keyboarder's ulnar deviation (hands rotated outwards) and pronation (palms downward), both of which require deviations from the hand's neutral posture (a thumbs-up handshake position).

One of the new geometries is a fixed slope upward from each side of the keyboard toward the center, and a fixed "opening angle", or rotation of each half of the keyboard into somewhat of an A pattern. A typical fixed geometry ergonomic keyboard, the Natural Keyboard made by Microsoft, is illustrated in Figure 1.

The other approach uses a variable geometry, allowing the ultimate shape of the keyboard to be adjusted to the most comfortable and useful shape by the keyboarder, and then locked into position. One of the more adjustable variable geometry keyboards, the Comfort Keyboard made by the Health Care Corporation, is illustrated in Figure 2. Both of these approaches reduce to varying degrees the musculoskeletal stresses on the hands, arms, and wrists by allowing more of a neutral wrist and arm posture. Because of the use of the familiar QWERTY key layout for both of these ergonomic keyboards, adapting to the new keyboard shape is generally not difficult for most users.

Figure 1. **Example of a fixed geometry ergonomic keyboard.**

Figure 2. **Example of a variable geometry ergonomic keyboard.**

A radical type of keyboard has been designed in recent years, and is favored by some users. It involves "chording" by the fingers from a stationary position on two hand-shaped keyboards. Chord keyboards are operated by striking a single key or chords of two or more keys simultaneously for each character desired. The hands rest in a single position that is seen by many users as more comfortable than the hand movements required by a conventional keyboard, but the higher information content of each keystroke tends to result in slower keying rates.

The height and slope of the keyboard should be such that neither significant extension nor flexion of the wrist occurs during keyboarding. Wrist extensions of 0-15° degrees are preferred, and extensions higher than this may be unhealthy. The wrist posture depends somewhat on the relative position of the keyboarder with respect to the keyboard. Some recent studies indicate that a negative slope (sloping downward and away from the user) minimizes wrist extension and its accompanying wrist strain.

2.1.4. Key travel

The maximum vertical displacement of keys when pressed should be 2 to 4 mm, but it should not be less than 1.5 mm or more than 6 mm. Most standard keyboards are in the range 3 to 4 mm. Ideally, there should be a soft, slightly cushioned bottoming of the keys at the end of their travel so as to minimize fingertip microtrauma.

2.1.5. Force

Many if not most keyboarding jobs are highly repetitive, applying small amounts of force many times a day. Text entry and data entry operators often average between 14 000 and 15 000 keystrokes over a 7-hour day, or roughly 100 000 keystrokes per day (60 words per minute for only six hours is 108 000 keystrokes). Because of this high repetition rate, the force of each keystroke must be kept to a minimum (but not below 0.25 N in order to avoid unintended activation). The ANSI/HFS 100-1988 standard puts forth a maximum allowable key force of 1.5 N (150 grams force), and a preferred key force of 0.5-0.6 N. Other keyboard literature recommends a maximum key force of 0.8 N Moreover, recent research indicates that typical keyboarders strike the keys with 3-5 times as much force as is required, depending on the design of the keyboard and their personal typing style. Clearly, the required force to depress the keys designed into the keyboard must be kept to a minimum when the number of keystrokes is very large.

Generally, required key forces should be uniform over the whole keyboard. This eliminates the need to remember which keys require extra force, or a lighter touch. Where the key activation force is highly variable among keys, keyboarders tend to use more force for all the keys, increasing their fatigue and possibly discomfort levels. And where a heavy stroke is applied to a key requiring only a lighter touch, the key bottoms out more sharply and may contribute to fingertip microtrauma.

2.1.6. Tactile feedback

Tactile feedback is the subtle but detectable change in fingertip force during the keystroke that tells the keyboarder the stroke has registered and the key can be released. It is typically described subjectively by keyboarders as the "feel" of the keys, and it is quantified as the force-displacement relationship of the keystroke. It is recommended by ANSI/HFS 100-1988 for all keyboards, but many keyboards built in the 1980s do not possess it. Its importance is that the presence of tactile feedback, detected as a snap or breakaway by the fingertip, reduces the amount of force that users naturally apply to the keys during typing.

Figure 3 illustrates tactile feedback as the relationship between force applied by the finger and the resulting key displacement for two typical key mechanisms. One key (linear spring) behaves much like a linear spring in compression; its displacement is essentially proportional to the finger force until it hits bottom at around 4 mm displacement. The first sense the keyboarder has that the keystroke is complete is the bottoming resistance starting at 135 cN (135 grams force).

The other key (tactile feedback) depresses under force to 60 cN, but at a displacement of 1 mm this force peaks out and the key begins to require less and less force to depress it. This force declines to an inflexion point of only 30 cN at 2.3 mm, and then rises to the key's bottoming point of 75 cN at about 3.5 mm. This pattern for the falling off of key force early in the keystroke represents the tactile feedback characteristic of the key and it is sensible to the keyboarder's fingertips.

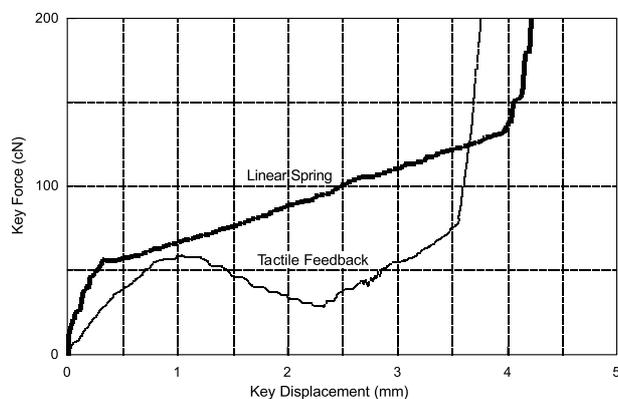
The "early warning" effect of the force inflexion allows the keyboarder to *begin* reducing their finger force on the keys and to *start* withdrawing their fingers in mid-stroke. And even though their follow-through of the keystroke generally results in the key bottoming out, their having begun finger withdrawal does lower the finger forces at the bottom of the keystroke. The first indication to the keyboarder that the key has been pressed sufficiently hard for the tactile feedback key is the peak force of 60 cN, but


Figure 3. Examples of force-displacement curves for keyboard keys with and without tactile feedback.

for the linear spring key it is the key's bottoming out at 135 cN. The difference between these two values contributes to the differences in "feel" and in workload.

Some early keyboards possessed auditory feedback as keys were struck, but this is not a useful substitute for tactile feedback. And because it may be rather distracting in a large office, there needs to be a way of turning it off.

2.2. Health Effects of Keyboarding

Within the last few decades, some negative health consequences have accompanied. the use of computer keyboards. Besides the design and use of the keyboard itself, other contributing factors are the design of the workplace, the manner and pace of the job, and the psychosocial job environment.

The combined work characteristics of excessive key force, high repetition, poor posture, and extended work duration have been identified as playing a role in the incidence among computer keyboarders of upper extremity musculoskeletal disorders (also known as repetitive strain injuries, cumulative trauma disorders, cervicobrachial disorders, occupational overuse syndromes, etc.). Keyboard designers can directly influence two of these four primary factors—key force and hand/wrist posture. They should also understand the health importance of the other two factors—repetition and duration—and alert keyboard users to practices that may relieve some of the musculoskeletal stress which accompanies keyboarding, such as the proper use of wrist rests, document holders, and ergonomic chair positioning.

3. OTHER KEYBOARDS

A wide variety of keyboards exist in out culture today, because of the wide range of machines and instruments we communicate with. Telephone keyboards (desk, cordless, and cellular) have increased their complexity and sophistication, as have those on television sets and VCRs (and their accompanying remote controls), desk and pocket calculators, automobile dashboards, machine controls, cash registers, and so on.

Generally, the computer key design characteristics can be considered as appropriate for these noncomputer keyboards as well, since they are often used by the same people. However, to the extent that we generally use these alternative devices and machines with less frequency than we use computers, the issues of key layout, key force, tactile feedback, and wrist postures have a lesser health and ergonomic design significance. Nevertheless, the keyboard designer is cautioned that a somewhat reduced keying frequency but with substantially higher key forces and possibly poor wrist postures (e.g., cash registers) may still result in health hazards for the users.

Manual Control Devices

T. Ivergaard
National Institute for Working Life, Östersund Branch, Sweden1.

1. INTRODUCTION

This chapter covers the design of the more traditional manual control devises, and the design of specific controls for communication with computers. Design of other forms of controls is dealt elsewhere, e.g. speech generation and recognition and human-to-human control.

The first step in the design of controls is to carry out a functional description of the task and to define the conceptual structure of which the task is a part. It is also important to analyze the logical functional relationships between the control devices and the information available to the operator.

Traditional control panels have the advantage that they give feedback to the operator of the maneuvers, which have been carried out. Examples of the advantages and disadvantages of each type of control are presented with design recommendations for these controls.

Keyboards are the traditional input devices used in data processing (DP) applications to communicate with computers. In the process control situation, it can often be advantageous to use other types of control such as multi-way joysticks or light pens. The advantages and disadvantages of each type of control are described.

2. FUNCTIONAL ASPECTS OF CONTROLS

The control device is the means by which information on a decision made by man is transferred to the machine. The decision may, for example, be taken on the basis of previously read information devices or on the basis of information from other sources, or from some form of cognitive process. Functionally, controls may be divided into the following categories:

1. Switching on/off start or stop.
2. Increase and reduction (quantitative changes).
3. Spatial control (e.g. continuous control upwards, downwards, to the left, or right).
4. Symbol/character production (e.g. alphanumeric keyboards).
5. Special tasks (e.g. producing sound or speech) (not included here).
6. Multifunction (e.g. controls for communicating with computers).

Examples of control type (1) include the starting or stopping of motors, or switching lamps on or off type (2) may consist of an accelerator pedal to increase and reduce the flow of fuel to the engine. Traditionally the best known example of spatial control (3) is the steering of a car. Examples of character production (4) include typewriting and telegraphy.

Of particular importance in control room design are the types of control (6) used in conjunction with computers. Controls operated by the hand are of particular use where great accuracy is required in the control movement. Hands are considerably better at carrying out precision movements than feet. Where a very high degree of accuracy of movement is required, it is best for only the fingers to be used.

Because the power available from the leg is considerably greater than that from the hands, foot controls are suitable for maneuvering over long periods or continuously. Foot controls are also valuable where very large pressures are needed, as the body weight can be added to the force of the strong leg musculature. It may also be necessary to use foot control devices where the hands are occupied in other tasks.

When designing traditional types of control, it is possible to design them in such a way that they naturally represent the changes one wishes to bring about in the process. For example, a lever that is pushed forwards may determine the forward direction of movement of a digger bucket. Or the flow in a pipe can be stopped by turning a knob which lies on a line drawn on the panel. In this way the design of the control increases the understanding of the current state of the process.

For communication with computers, the keyboard is often chosen for carrying out all the different control functions. Technically, it is often easy to connect a keyboard to a computer system. Other control devices also exist for communicating with computers, such as light pens. However, a particular failing of this type of multipurpose control device is that the control movements in themselves have no natural analogy with the changes, which they aim to bring about in the process.

3. ANATOMICAL AND ANTHROPOMETRIC ASPECTS OF CONTROL DESIGN

Some of the principal anatomical and anthropometric aspects will be considered (Grandjean 1988).

One important limitation of the recommendations available today is that they are based on the Caucasian races. For the Japanese population, for example, the measurements must be adapted for their proportionally shorter leg lengths. The following rules can be applied in the design of all types of control.

1. Maximum strength, speed, precision or body movement required to operate a control must not exceed the ability of any possible operator.
2. Number of controls must be kept to a minimum.
3. Control movements that are natural for the operator are the best and the least tiring.
4. Control movements must be as short as possible, while still maintaining the requirement for "feel."
5. Controls must have enough resistance to prevent their activation by mistake. For controls only used occasionally and for short periods, the resistance should be about half the maximum strength of the operator. Controls used for longer periods must have a much lower resistance.
6. Control must be designed to cope with misuse. In panic or emergency situations very great forces are often applied, and the control must withstand these.
7. Control must give feedback so that the operator knows when it has been activated, even when it has been done by mistake.
8. Control must be designed so that the hand/foot does not slide off or lose its grip.

3.1. Push–buttons and Keys

These are suitable for starting and stopping, and for switching

on or off. This type of control is also suitable for foot control, where it should be operated by the "ball" of the foot. The following recommendations apply to both hand- and foot-operated controls:

1. Resistance of the push-button should increase gradually, and then disappear suddenly to indicate that the button has been activated.
2. The top of the button should have a high coefficient of friction to stop the fingers/feet from sliding off. Where push-buttons are to be activated by the fingers, the concave form is preferable.
3. To indicate that the button has been activated, a sound should be emitted if the workplace has low light levels.

3.2. Toggle Switches

Toggle switches can show two or three positions. Where there are three positions, one should be up, the middle one straight out and the other one downwards. Toggle switches take up very little room. The following recommendations also apply to toggle switches:

1. A sound should be heard to indicate activation of the switch.
2. If a few switches are used, they should be placed in a row. Vertical positioning requires more space to avoid accidental operation.

3.3. Rotary Switches

These can be divided into two categories — cylindrical and winged. The primary difference is that the winged version has a pair of "wings" above the cylindrical part. The wings function both as a positional marker and as a finger grip. Rotary switches may have from three to 24 different positions. They require a relatively large amount of space because the whole hand has to have room to turn around the switch. However, where multiple position switches are used, they take up less space than the number of push buttons or toggle switches required to fulfil the same function. Rotary switches can either have a fixed scale and moving pointer or a moving scale and fixed pointer. A variant on the moving scale is to have a window, which only shows a small part of the scale. The following recommendations apply to rotary switches:

1. In most applications rotary switches should have a fixed scale and moving pointer.
2. There should be a detent in every position.
3. The turning resistance should steadily increase and then suddenly decrease as the next position is approached.
4. Cylindrical switches (knobs) should not be used if the resistance has to be high. In these cases, wing knobs are preferable.
5. Where only a few positions (2–5) are needed, they should be separated by 30–40°.
6. Where < 24 positions are used, the beginning and end of the scale should be separated by a greater amount than between the different positions.
7. Where the workplace has low lighting levels, a sound should be made to denote that the switch has been activated. In these cases there should also be a definite stop position at the beginning of the scale, so that the positions can be counted out.
8. The scale should always increase clockwise.

9. The hand should not shield the scale.
10. The surface of the switch should have a high coefficient of friction so that the hand does not slip.
11. The distance between panel and knob should be at least 3 mm.
12. The maximum amount of slope on the sides of the knob should be 5°.

3.4. Levers

Levers are activated either by the whole hand or just by the fingers. In general, where fine control is needed, only the fingers should be used. The following recommendations apply to levers:

1. The maximum resistance (force) for push–pull movements with one hand, with the control placed centrally in front of the body, is between 12 and 22 kg, depending on how far from the body the control is positioned.
2. The maximum resistance for push–pull movements for two hands are double that for one hand.
3. The maximum resistance for one hand moving in the left–right direction is ~9 kg, and is considerably lower in the opposite direction.
4. The maximum resistance for two-handed movements in the left–right direction is ~13 kg.
5. The lever movement should never be greater than the arm's reach without moving the body.
6. Where precision is required, a supporting surface should be provided for the part of the body used; an elbow rest for large hand movements and a hand rest for finger movements.
7. When levers are used for step-wise control (e.g. gear levers), the distance between positions should be one-third of the length of the lever.
8. Where the lever also acts as a visual indicator, the distance between positions can be reduced. The critical distance is then the operator's ability to see the markings.
9. The surface of the lever handle should have a high friction coefficient, so that the hand does not slip,

3.5. Cranks

These are suited to continuous control where there are high demands for speed. Cranks can be used for both fine and coarse control depending on the degree of gearing selected. The following recommendations apply to cranks:

1. Cranks are preferable to wheels where two or more revolutions are to be made.
2. For small cranks < 8 cm in radius, the resistance should be at least 9 N and a maximum of 22 N when rapid movement is required.
3. Large cranks of 125–220 cm radius should have a resistance between 22 and 45 N.
4. Large cranks should be used when precision is required (accuracy between a half to one revolution), with the resistance between 10 and 35 N.
5. The handle should have a high surface friction to prevent the hand slipping.

3.6. Wheels

Wheels are used for two-handed operations. Identification of the position is very important if the wheel can be rotated through

several revolutions. In addition, the following recommendations apply:

1. The turning angle should not exceed + 60° from the zero position.
2. The diameter of the ring forming the outside of the wheel should be between 18 and 50 mm, and should increase as the size of the wheel increases.
3. The wheel should have a high surface friction so that the hand does not slip.

4. CONTROLS FOR COMMUNICATION WITH COMPUTERS

The traditional controls in administrative computer systems are various different types of keyboard. There is often a numerical keyboard as well as the traditional typewriter keyboard. These types of keyboard have been tested over a long period and can be well specified. They are also thought to be well suited to most forms of administrative computer system.

For a more specialized application, for example, computer systems for control and monitoring of process industries, the situation is often very different. The requirement for control devices is unique to each type of process industry, depending on the process to be controlled and the type of computer system installed. It is thus impossible to give any specific guidelines for the control devices on computerized control systems. However, some overall guidelines may be given. The advantages and disadvantages of different control devices for computerized systems will be examined. Many of the devices are new and have not yet been subjected to ergonomic evaluation. It is therefore difficult to give detailed guidelines for all controls. Finally, some more detailed design recommendations for the different types of keyboard will be presented.

4.1. Advantages and Disadvantages of Different Controls for Computers

The more traditional types of control can of course also be used for computerized systems. Controls that have been produced specifically for communicating with computers include:

- keyboard with predetermined functions for various keys;
- keyboard with variable functions for the keys;
- light pen;
- touch screen;
- electronic data board;
- voice identification;
- trackball and joystick (multi-position lever); and
- mouse.

4.1.1. Keyboards with predetermined functions for the keys

Keyboards with predetermined functions for all keys normally have two main parts — an alphanumeric or a numeric part, and a function key part. The function key part has different keys for different predetermined tasks, such as starting, stopping, process a, b, c, etc. The keyboard works by the operator pressing the keys in a certain order, which he either remembers, or with the aid of some form of crib-sheet.

This type of keyboard is characterized by the need for a large number of keys, usually one per function. Where there are many functions and several subfunctions within every main function,

problems arise with grouping the keys in the proper way and in positioning the keys in a mutually logical way, which is consistent in terms of movements.

It is unusual to be successful with this at the first attempt; the keyboard will need to be redesigned when it has been operational for long enough to build up enough experience to determine its optimal design. Making changes to the keyboard are often costly, but if the keyboard is not redesigned at a later stage, it means that large and frequent arm movements become tiresome and time-consuming. The advantage of this type of keyboard is that it needs relatively little computer programming and, to a certain extent, a standard board can be used, at least for the alphanumeric part.

4.1.2. Keyboards with variable functions for the keys

Keyboards with a variety of functions for each of the different keys are relatively uncommon, but they often exist as part of the more traditional keyboard (e.g. the top row of keys on the keyboard). Keyboards with a variety of functions per key are often particularly useful in process industries. A common form is to have a row of unmarked keys under the monitor screen, and to have squares representing the different keys directly above them on the screen. Depending on the picture being shown on the screen, text appears in different windows showing the functions that the keys have for each frame.

Another application for this type of keyboard is to build lights into the keys. The relevant keys light up for each particular function. The lights in the keys are lit or extinguished when particular keys are pressed, depending on the sequence of operations required. In this way the operator is guided through the correct operation sequence.

Non-illuminated keys are then disconnected from the system. The risk of errors occurring with this type of system is very small, and work on this keyboard is also faster, particularly if the operator is not accustomed to the work. It is important, however, that if the lamps in the keys break a warning signal is produced.

There are also applications where keys can be pressed with different pressures. A light pressure on the key causes the function associated with that key to be written out on the screen, and the action is taken if the key is pressed harder. If it is fully depressed a signal is sent to the computer dictating changes to be made to the process. The operator can also receive new information on the screen, which informs him which new keys can be used.

Depending on its design, the keyboard can be pre-programmed to lead the operator naturally through the work. This type of programming of the keyboard functions may be an advantage for especially important types of operation, where errors could have serious consequences. A major disadvantage from the operator's perspective is that they may feel their work is being too highly controlled. Another disadvantage with this type of keyboard is that it requires a lot of programming, and this takes up a large part of the computer's capacity. An advantage is that the hardware does not need to be changed (re-building or extending the keyboard, etc.) to any great extent even if a major change is to be made in the function of the control. In other words, this form of control is very flexible.

4.1.3. Light pens

The light pen consists of a photocell that senses the light radiated

from the phosphor on a CRT screen. The light pen reacts every time a pixel on the screen is lit up by the electron ray within the tube. The signal passes from the light pen to the computer, which at the same time receives information on where and when the spot passes different places on the screen in this way the computer can identify where the pen is on the screen

The light pen can point to parts of the screen one wishes to know more about. It can also be used to activate different functions. If for example, one pointed to a valve, and at the same time pressed a button on the side of the pen, this may cause the valve to close. The light pen is suitable for moving cursors on a screen. However, it is difficult to see any operational advantages of light pens over other controls.

If a light pen is used over a long period, it is necessary to have a specially designed armrest to prevent discomfort. The light pen has to come close up against the screen, which means that it is impossible to have any form of reflection shield or filter on the screen and this can give rise to visual problems. Positioning of the light pen must be exact, which makes considerable demands on vision and also contributes to bad working posture in many instances.

4.1.4. Touch screens

Touch screens involve moving the finger, a pen, a pointer or some other object within an active matrix placed over the screen. This active matrix may be designed in several ways. It could be composed of a thin metal net, for example, on which an electrical circuit is made when it is touched. Electrical bridges and infrared beams can also be used to determine touch on the screen. Another type of touch screen is based on the use of a transparent material, which senses the pressure of the touch on the screen. Special measurement bridges are used to determine how the pressure field is distributed over the screen, and the position of the touch is deduced from this.

Functionally, the touch screen is very similar to the light pen and has similar advantages and disadvantages, although an additional disadvantage is that the screen becomes dirty. An advantage is that it is sometimes faster to point with the finger than with a light pen; however, the technical reliability of the touch screen is usually considered to be lower than that of the light pen. If it is necessary to send a large number of different types of words and information to the computer, the traditional keyboard is preferable.

4.1.5. Electronic data boards

Electronic data boards consist of a rectangular plate, which represents the surface of the screen. Some form of electric field is created over the plate. When a sensor is run over the board's surface, it "senses" its position on the board. One common form of board is placed directly onto the screen, and in this case functions very like a light pen or touch screen. Another form of board is placed beside the screen, and one can work with a transparency of a picture. One of the advantages of the electronic data board is that one can very quickly make drawings or change them.

4.1.6. Trackball

The trackball is a mounted sphere that can be rotated in all directions and can be placed on a table or special fixing. The ball is usually used for moving the cursor on a screen. The cursor moves a certain distance (x/y directions) or with a speed proportional to the movement of the ball.

4.1.7. Joystick

The joystick, which is a lever movable in all directions, has a similar function to the trackball.

4.1.8. Mouse

The mouse is a small device with wheels or a ball mounted on the underside. If it is moved to the left or right, this represents a corresponding movement on the screen. The mouse is especially suited for moving the cursor and for transferring graphic information.

There is no conclusive evidence to produce recommendations for the use of the trackball, mouse or joystick. In practice most people seem to prefer the mouse if one has access to a free table surface, otherwise the trackball is generally preferred.

5. KEYBOARD

The keyboard is still the most common computer input device. The design of the keyboard has a significant effect on the operator's performance in terms of speed and accuracy.

The most common keyboard layout is the QWERTY layout. Where two hands are used on the keyboard, 57% of the workload is on the left hand, even though 80% of the population is right-handed. This is advantageous for the type of job where the right hand alternates between handwriting and typing. It is also important to have one standard keyboard layout. Although the QWERTY layout is not the most efficient (it is said to have been designed for slowness, so that early mechanical typewriters did not become overloaded), it is now the best compromise as it has become the standard keyboard.

Keyboards are usually designed so that the alphanumeric section is in the center, with the cursor, editing keys and numeric keypad to the right. Function keys may be placed anywhere on the keyboard, but to give an aesthetically pleasing design they are often placed on the left-hand side. Lateral hand movements also require less energy than longitudinal (front to back) one.

There are no specific recommendations for keyboard layout, as their design is extremely sensitive to the task being carried out. However, a degree of flexibility must be incorporated in the design to cater for all variations in user requirements. One solution to this would be to develop a modular keyboard consisting of several units. Each unit would be made up of a different set of keys. The units could be arranged in the desired layout based on the results of the task analysis. However, care must be taken in using a flexible keyboard configuration due to the risk of a negative transfer of training. For example, if an operator carries out a number of different tasks, and different keyboards are used for each of the different tasks, then high error rates must be expected.

Chord keyboards are a combination of a keyboard and a coding system. In a similar way to keys on a piano, one can press several keys at the same time. The advantage of this type of keyboard is that key-pressing speed compared with a standard typewriter is considerably > 50% faster. There are, however, no special design recommendations for this type of keyboard. In

general, it may be said that this type of keyboard needs further study before any firmer recommendations can be given regarding suitable areas of use and suitable design.

The numeric keyboard appears in two different designs. The accepted layout is a 3 _ 3 plus a key set, but there are two alternatives within this. Adding machines have the 7, 8 and 9 keys on the top row, while push-button telephones have the 1, 2 and 3 keys at the top. Nearly all telephones use the 123 keypad. It would be advantages that all numeric keyboards are of this design. Uniformity is important, and the user should not have to switch from one keyboard design to the other while working.

The height of the keyboard is largely determined by its physical design, for example, electrical contacts and activating mechanism. Thicker keyboards (> 30 mm thick) should be lowered into the table surface to ensure a correct user posture. This unfortunately does not allow for flexible workplace design. Ideally, keyboards should be as thin as possible (< 30 mm thick from the desk surface to the top of the second key row and not need to be lowered into the surface

Keyboards can be stepped, sloped or dished. There is no evidence on the relative advantages of any of these profiles. The most important factor is for the keyboard to be able to be angled between 0 and 15° up at the back and, if the keyboard operator is standing, it is advantageous if it can be raised at the front from 0 to 30°.

The size of the key tops is a compromise between producing enough space for the finger on the key, while at the same time keeping the total size of the keyboard as small as possible. Key tops should be square and 12–15 mm in size. This size is quite sufficient for touch typing, but in cases where keyboards are used for other tasks, for example on the shop floor, key sizes can be larger. The spacing of keys is standardized to 19.05 mm between key top centers. This is within the ergonomic recommendations of between 18 and 20 mm. The force required for key displacement should be the same on all keys.

For skilled users, the actuating force should be 0.25–0.5 N. and the key displacement (travel) 0.8–1.0 mm (from rest to activation of system). For unskilled users the force should be 1–2 N and the displacement 2–5 mm. The user requires feedback to indicate that the system has accepted the keystroke. This is an important keyboard characteristic, although the exact requirements vary according to the individual levels of user skill.

In normal typing and other key-pressing tasks, there is

kinesthetic (muscle) and tactile (touch) feedback from the actual depression of the key, auditory feedback from the key press and/or activation of the print mechanism, and visual feedback from the keyboard or from the output display. For skilled operators, feedback from the keyboard (sound and pressure change) is of little importance. When learning, and for unskilled operators, this feedback is important. The operator should be able to remove the acoustic feedback.

The color of the keys is not generally regarded as important. A dark keyboard with light lettering is preferable when used in conjunction with light-on-dark image displays, and care should be taken not to cause any distracting reflections on the screen by light key colors. Matt finishes should be used where possible.

Care should be taken when using colors to code various function keys. Attention should not be drawn to a red key or a group of red keys if their importance in the system is minimal. These principles concerning color may also be applied to any information lights found on the keyboard.

Multivariate Visual Displays

C.M. Carswell and S.E. Waters
Department of Psychology, University of Kentucky, USA

1. INTRODUCTION

Human understanding of any object, concept, or process usually requires the observation and measurement of multiple variables. The economic status of a nation, for example, is typically described by a number of financial indices. Likewise, the operational status of a process, such as the conversion of solar energy into electricity, depends on system inputs and component efficiencies. The present article discusses the progress made, and problems encountered, in using multiple attributes of a visual display as analogs for the multiple measures used to describe such physical and conceptual entities. The article also describes some of the principles used in the design of such displays.

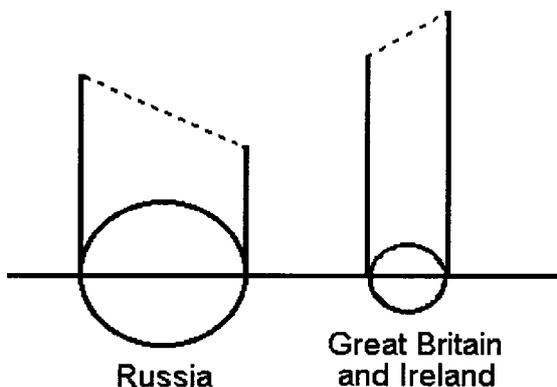
2. EVOLUTION AND FUNCTIONS OF MULTIVARIATE DISPLAYS

2.1 Statistical Graphics: the Third Dimension and Beyond

The earliest multivariate displays used spatial variation in two dimensions to represent two variables of scientific interest. For example, in 1686 Sir Edmund Halley created a plot of barometric pressure as a function of altitude. This early scatterplot used the vertical and horizontal positions of points to represent altitudes and pressures, respectively, of different observations.

Representing a third variable on the printed page proved to be more challenging. One of the first solutions was offered by William Playfair (1759–1821), the Scottish economist and political scientist, who developed and promoted many of the graphical formats still in use. Rather than trying to use the artist's illusions of depth to create variation in perceived distance, Playfair used transformations of the various features of abstract objects. Figure 1 presents an early example of this technique. Here, each object represents a different country, with the length of the left ray representing population, the length of the right ray representing total revenues, and the circle size representing geographic area. Contemporary statisticians have used the same approach, with both abstract and familiar objects (e.g. faces), to represent three or more variables.

Russia

Great Britain and Ireland


2.2 Dynamic Displays of Two or More Variables

The main goal of statistical graphics is to facilitate the exploration of data sets, allowing for comparisons across specific variables and observations. Such graphics are also used to communicate findings to relevant audiences. Thus, statistical graphics aid both discovery and disclosure. Transportation and industrial technology added new requirements to the design of multivariate displays. These displays were designed to facilitate the supervision and control of the dynamic systems they represented. They were frequently updated, introducing the appearance of constant motion. This motion added several new dimensions, such as speed and direction, to the designer's repertoire, thus allowing the presentation of still more variables. Recently, statisticians have begun to incorporate some of the dynamic properties of industrial graphics into statistical graphics (Cleveland and McGill 1988).

3. PRINCIPLES BORROWED FROM UNIVARIATE DESIGN

Many of the design principles applied to univariate displays are equally valuable for the design of multivariate displays. While the success of a multivariate display is certainly more than the sum of its component codes, the following guidelines for representing individual variables are still valuable.

3.1 Visual Analogies

When possible, designers should choose display dimensions that are direct visual analogs of the variable being represented. In Figure 1, Playfair used the area of different circles rather than the lengths of rays to represent the areas of different European countries.

3.2 Linguistic Conventions and Population Stereotypes

Even when describing abstract concepts, it is common to use directional or geometric terms. Visual displays should conform to these linguistic conventions whenever possible. For example, when graphing the mean affective state of a sample of subjects, the designer should keep in mind that negative affect (e.g. depression) is often referred to as "feeling low," while euphoria is associated with "things looking up." Thus, affect should be represented by varying vertical position, with higher positions representing happier moods.

3.3 Comparisons versus Classifications

The visual attributes that best support classification are sometimes not the same attributes that support accurate comparisons. For example, if an absolute judgment is required, then the hue of a light would be preferable to its brightness, and geometric shape would be preferable to area. If comparisons are more important, then dimensions close to the top of the following list, especially the top three, should be favored (Carswell 1992; Cleveland and McGill 1985):

> position on common aligned scales
> position on common nonaligned scales
> length
> slopes/angles
> area
> volume/density/color saturation
> hue

3.4 Redundancy

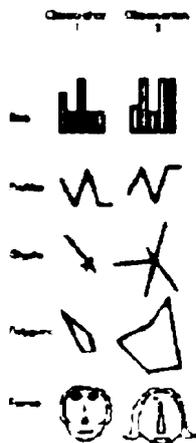
For particularly important variables, designers should use more than one visual dimension to represent their values. For example, if information about temperature is crucial, then temperature might be coded as (1) position along a vertical scale (keeping in mind that higher positions should stand for "higher" temperature) and as (2) colors (with higher temperatures coded as "warmer" colors such as orange and red).

4. PRINCIPLES SPECIFIC TO MULTIVARIATE DISPLAYS

When more than one variable must be represented within a display space, the arrangement of these representations becomes as critical as their individual designs. The viewer's subjective organization of a particular arrangement is referred to as the *perceptual organization* of the display. A viewer's perceptual organization determines which elements appear to go together to form groups, configurations, or objects. This, in turn, determines how accessible (or inaccessible) specific variables will be and may produce new visual dimensions, called *emergent features*, which can sometimes be useful to the viewer.

4.2 Influencing Perceptual Organization

The gestalt laws of perceptual organization have been applied to display design to ensure that some displayed variables appear to go together while other variables appear quite separate. Figure 2 illustrates how these laws might be applied to hypothetical variables A, B, and C, each of which is represented by the height of a bar. In this example, design manipulations are intended to encourage the grouping of variables B and C while separating the B–C group from variable A. A variety of techniques, alone or in combination, can be used to achieve the desired effect:

As shown in Figure 2, variables B and C can be effectively grouped by increasing their *spatial proximity* to one another while increasing their average distance from variable A. The perceptual grouping of variables B and C can also be accomplished by giving them a *similar color or fill pattern* and ensuring that this shared feature is sufficiently distinct from the color/fill used for variable A. Variables B and C may also be included in a *common region* by enclosing them in a framework. In addition, *contours* may sometimes be added to connect the parts of the individual representations that actually vary, in this case the bar tops. The


orientation or overall shape of the contours can sometimes serve as additional cues to the viewer. This design strategy is the basis for profile and polygon displays, discussed below. Finally, in order to more strongly group variables B and C, several of these strategies may be combined, as in the bottom display in Figure 2.

4.3 Object Displays

The most extreme technique for promoting perceptual grouping is to represent each variable as a different attribute of a single object — for example, Playfair's "sunburst" object in Figure 1. When considering object displays, it is important to note that the attributes or dimensions of an object can interact with one another in different ways. The most important distinction for design purposes is the difference between homogeneous and heterogeneous displays.

Homogeneous object displays are those composed of repetitions of a single dimension, for example the repeated use of point position in a line graph. Such displays are likely to produce emergent features. Alternatively, *heterogeneous object displays* mix and match visual dimensions, as when ray length and circle area are combined in Playfair's "sunburst." Such display dimensions are less likely to interact, fuse, or create emergent features. For example, a colored light that indicates temperature may be integrated with an analog clock that shows elapsed time by making the clock's hands vary in color. The clock is perceived as a single object, but the perception of the hand's position is not influenced by its color (or the color by the hand position). However, the combined value of both may be easier to perceive because of the spatial integration.

According to Carswell and Wickens (1996), homogeneous object displays should generally be used when mathematical integrations or comparisons are required by the viewer. For example, the horizontal and vertical extents of a rectangle are homogeneous dimensions that interact to produce its overall shape and size. This display would be useful if the viewer needs to know the relative value or the product of the two variables represented by height and width. Heterogeneous object displays should generally be reserved for situations where conjunctions of values (or value ranges) along several variables are necessary for the user to appropriately recognize specific conditions or states.

4.4 The Proximity Compatibility Principle (PCP)

The PCP assumes that display elements that form strong perceptual groups allow viewers to more easily divide attention across the component variables. Divided attention will be useful if all the variables in the group must be used, in conjunction, to perform the viewer's task. However, there can also be costs associated with perceptual grouping, particularly when grouping is strong as in object displays. The cost comes when the viewer must "zoom in" or focus attention on one variable in the display without distraction from the others.

The general guideline that follows from the PCP is that the designer should try to fully understand how information from the displayed variables would be used. If the 2-, 3-, or k-displayed variables must be used in conjunction, then arrangements that promote strong perceptual grouping are indicated. However, if the viewers must deal independently with the variables across

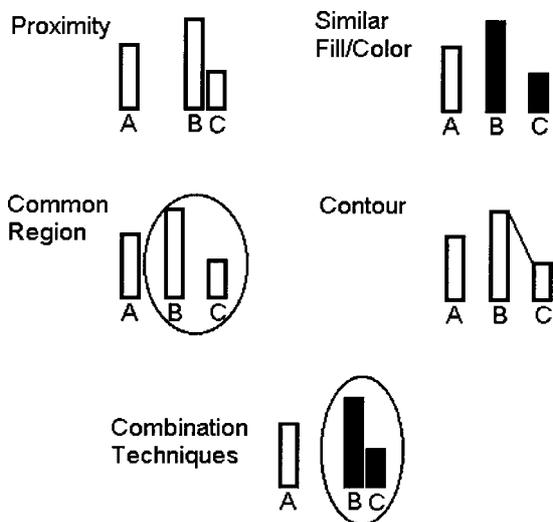
time, then arrangements that promote a looser, even isolated perceptual organization will result in better performance. The general guidelines have, overall, gained empirical support. However, the advantages of unified or integrated displays for divided attention tend to be greater than the costs associated with integration when focused attention is required (Wickens and Carswell 1995).

4.5   Representation Aiding (RA)

This approach is particularly appropriate when applied to displays that must support the supervision of processes or systems that have well-defined physical constraints and for which the goals of the viewer are well understood. Clearly outlining these constraints and goals is a fundamental step in using RA. The designer's task is to ensure that these constraints and goals are adequately reflected in the perceptual organization of the displayed variables, especially in the perceptual interaction and relative salience of display attributes (Bennett *et al.*1997).

Research on both RA and the PCP has revealed that one way perceptual grouping leads to enhanced performance is through the production of salient emergent features. However, rather than allowing these emergent features to emerge by chance, RA emphasizes the intentional use of emergent features to represent important system constraints or relations. Emergent features should be designed to adhere to the normal standards for individual codes discussed above — they should make use of spatial and linguistic analogies, they should support either classifications or comparisons, as appropriate, and, if especially critical, their salience should be increased by the use of redundancy.

5. MULTIVARIATE FORMATS: FROM THE COMMON TO THE CONTROVERSIAL

Since the early 1970s, a variety of multivariate formats have found their way into scientific journals, business magazines, intensive care units, and nuclear power plant. Some of the more common (or more controversial, in the case of the face display) are illustrated in Figure 3. With the exception of the bar charts, all of these formats are considered to be object displays.


5.1   Bars and Profiles

These formats are familiar to most people because they are used extensively in the presentation of univariate and bivariate data. For example, the daily newspaper often shows a series of bars that each represent different instances of the same variable (e.g. temperature measured on different days). However, each bar can also be used to represent a different variable (e.g. temperature, pressure, or humidity on a single day). If meaningfully scaled, these variables can be compared with one another, or compared as a unit with other observations.

Bar charts are among the most common and flexible of formats. Functionally, they balance the demands to focus on one variable with the need to integrate or compare all of the variables. The individual values remain relatively easy to locate because they are represented by separate objects. However, bar graphs can also produce emergent features such as colinearity and symmetry that can communicate a more integrative message.

If bar tops are replaced by points, and these points are then connected by line segments, a profile plot similar in form to the familiar line graph is created. Profile plots increase the salience of the emergent features found in bar charts, but they may make the use of the individual data values more difficult. Such plots should be reserved for situations where the overall configuration rather than the individual variable values are of prime importance.

5.2   Glyphs and Polygons

These formats are similar to bars and profiles except that they are plotted in a polar coordinate space. The prime advantages of these displays over linear forms are twofold. The individual variables may be easier to locate because they are each presented at a distinct orientation and location, unlike bars and profiles which vary only in location. In addition, emergent features such as overall size and shape may be available in the polygon display.

5.3   Face Displays

Face displays resulted from the observation that humans can perceive and remember small differences in faces. In addition, faces have emotional significance which is familiar to everyone (e.g. sadness, happiness, fear).

Seeking to capitalize on these assets, Chernoff (1973) developed a caricature face that could display a maximum of 18 variables by using separate facial features.

The face display is a heterogeneous object display that is best used when specific feature conjunctions rather than configurations must be identified. However, special care must be taken in assigning variables to features since some, such as the mouth, seem to be more salient than others. The mouth should thus be reserved for variables that are themselves most critical to the viewer's task. In addition, the natural meaningfulness of faces can be a tremendous asset, allowing a potential viewer to have a general idea of what the data mean even without extensive training. However, if care is not taken in assigning facial features to variables in a manner consistent with facial stereotypes (as when a negative financial variable is assigned to a smiling mouth) then miscommunication is almost a certainty. Face displays have remained the most controversial multivariate format largely due to the possibility of such errors.

5.4 Other Multivariate Formats

A variety of other formats have been designed, including trees and castles for the display of hierarchical variables, perspective displays, and animated graphics. These and other formats are discussed in Chambers *et al.* (1983).

Pointing Devices

C. Baber

University of Birmingham, UK

1. INTRODUCTION

The notion of "pointing" at objects on the computer screen, using some form of pointing device, is central to the "direct manipulation" paradigm of contemporary computing. Rather than having to recall obscure commands or ambiguous file names, the user of a direct manipulation interface is able to look for and recognize the object or function that they are seeking (Shneiderman 1982). The purposes of this entry are to provide an overview of pointing devices and their performance.

2.0 TYPES OF POINTING DEVICES

Having established that a pointing device allows the user of a computer to select objects on the screen, we can now consider different ways in which this task can be performed. The obvious approach would be to find the object required and simply reach out and touch it, i.e. users would select an object on the screen by touching it with their forefinger (alternatively, selection could be performed using a stylus or pen). These are direct pointing devices: the user is able to touch directly or otherwise select the object required. In comparison, indirect pointing devices — such as mice, trackballs, joysticks — require the user to manipulate a control in order to move a cursor in order to select the object.

2.1. Touchscreen

With a touchscreen, selection can either occur when the finger "touches" the object, or can occur when the finger "touches and then lifts off" the object. The advantage of the latter approach is that the user is able to drag the object around the screen. There several ways in which touching can be detected. The finger can interrupt a field above the screen, e.g. beams of infrared light or acoustic waves. The point of interruption is detected and used to signal the co-ordinates of selection to the computer. One potential problem with this approach is that accuracy depends on the relative distance between screen and overlay. As the distance between the two surfaces increases, so the possibility of parallax increases. There are three ways of reducing parallax:

1. make the object at least 20 mm² to give a reasonable surface area for the finger to touch;
2. tilt the screen to around 30° to the horizontal, so that the user's line of sight is on a similar plane to their hand movement;
3. bring the touch surface as close as possible to the screen. This is the idea behind overlay touchscreens, e.g. resistive and capacitive. In these designs, pressure from the finger changes the capacitance or resistance of the overlay and this change is used to indicate coordinates of touch. Comparative studies of the different types of touchscreen suggest that capacitive overlay and infrared beam produces slightly better performance than the other types.

2.2 Pens

Rather than using a finger to interrupt a touch-sensitive surface, it is possible to use a pen. Early versions of pens tended to rely on light, e.g. the pen contained a probe that detected bursts of light from the computer screen which could then be used to determine the coordinates of the touch. Alternatively, a pen or stylus could be used with a touch-sensitive tablet. In resistive tablets, pressure from the pen onto the tablet led to two separate sheets being brought together at a specific point, thus indicating the point of touch; in magnetic tablets, the pen incorporated a probe which detected changes in magnetic field of the tablet. Some of the contemporary pen-based Personal Digital Assistant (PDA) devices tend to use a plastic stylus which is used to press on surface overlay on the screen. The majority of PDA systems use a touch to select approach (as opposed to touch and lift off — see 2.1). Recent developments in pen-based technology have meant that PDA can incorporate some form of handwriting recognition so that the pen can be used for drawing or writing as well as pointing.

2.3. Mice

The mouse contains a ball mounted against several sensors which can detect movement around 360°. While the majority of mice use leads to communicate with the computer (to either a mouse port or the RS232 port), there are mice which use either infrared or ultrasound. The mouse, like other indirect pointing devices, is primarily a cursor-control device; in order to select objects on the screen, an additional button is required. Typically the gain of a mouse should be set to around 1:1, i.e. movement of the cursor on the screen corresponds to movement of the mouse. Rate-controlled mice relate the velocity of cursor movement to the distance the mouse travels, but it is unlikely that this will benefit performance; providing acceleration during the ballistic phase is likely to lead to overshooting of targets. There have also been efforts to improve the homing phase through provision of additional feedback. The body of the mouse can be modified to incorporate actuators which can press against the user's fingers as an object is approached. Objects on the screen require some form of force field (defined by their relative position on the screen), so that as the cursor enters a field the user will receive additional feedback. Usually, incorporation of additional tactile feedback tends to improve positioning times (although accuracy may be compromised, which increases the likelihood of over-shooting the target).

2.4. Trackballs

The trackball can be thought of as a mouse inverted in its socket. The movement of the ball against the sensors corresponds to movement of the cursor on the screen. The direction and velocity of cursor movement mimics the movement of the ball. This means that a fast spin of the trackball can produce fast movement of the cursor over the screen. Thus the trackball offers additional functionality over, say, a mouse. On the other hand, the task of dragging objects across the screen can be difficult with the trackball because one finger needs to hold down a button while the rest of the hand manipulates the trackball. This problem can, of course, be handled by either having a button which stays down or by using two hands.

2.5. Joysticks

On a displacement joystick, the stick moves proportionally in the direction of force supplied by the user and remains in the

end position. This means that the user receives kinesthetic feedback from the actual movement of the joystick, in addition to visual feedback received from watching the moving object. On the other hand, an isometric joystick remains fixed in response to user action; gauges sense the magnitude and direction of pressure exerted by the user and move the object accordingly. In this design, the user has similar visual feedback but quite different tactile feedback to that obtained from the displacement joystick. The rate-controlled joystick provides the additional function of increasing rate of movement relative to increasing force against the stick, i.e. the harder the user presses, the faster the object moves. A spring-loaded joystick, which moves in response to user action, but moves back to a central position once the action is complete, can be seen to represent a combination of the other two types. Spring-loaded joysticks have been introduced into laptop computers to provide a convenient pointing device that can be situated in the keyboard (usually in the center of the home row of the keyboard).

3.0 DEVICE PERFORMANCE

System designers are primarily interested in which device would be best for a given application. This brings us to the question of how to compare pointing devices. The most common form of comparison between devices involves using the devices to perform specific tasks and then comparing their performance on some measure. The measures used are typically speed and accuracy, with some measure of user preference included. As noted in the discussion of device characteristics, pointing devices differ on several dimensions so that finding a task which does not unduly favor any one of these dimensions can be very difficult. For example, if we compared a mouse against a trackball on a task involving fast movement of the cursor from one part of the screen to the other, then we might find in favor of the trackball; on the other hand, if we compared the same devices on a task involving dragging an object onto a small target then we might find in favor of the mouse. Thus, in addition to measuring gross performance, such as speed, we ought to think of measuring (or at least defining) "task-fit".

3.1. Speed

Cursor movement is rarely performance for its own. Usually one moves the cursor as part of another task, such as object selection or movement. It is this point at which "task-fit" can be a significant variable in performance. For example, cursor keys are universally shown to be an inferior means of moving the cursor, in comparison with mice or trackballs, but this finding is reversed if the cursor only has to move a small distance or if the cursor can be made to "jump" to the next object in a given direction. For the most part, direct pointing devices, such as touchscreens, tend to produce the fastest selection time. As far as indirect pointing devices are concerned, the mouse tends to outperform other devices, such as joysticks and trackballs, and has been found superior to some direct pointing devices, i.e. pens. Comparison of devices in terms of speed have tended to flounder on differences between device characteristics. This means that while device A is better than device B for task X we cannot say with certainty that the same will hold for task Y. This has led several researchers to consider alternative ways of defining performance time. One approach which has proved popular over the past decade or so is

Fitts law (see MacKenzie 1992 for an excellent review of this work). If the values of a and b were "constants", then one might anticipate that they would hold for a given device over different experiments (or at least be quite similar). Unfortunately, work to date does not show this to be the case, e.g. Baber (1998) reports that for mice, one study found that a = 108, b = 392, while another study, by different researchers, found a = 107, b = 223. An alternative perspective, put forward by MacKenzie (1992), is that one should look at the Index of Performance (IP), i.e. the ratio between Index of Difficulty and Movement Time. By taking the ratio of IP between two devices, one might get an idea of relative difference. Using this measure, he showed that one study yielded an IP of 2.3 while another study yielded an IP of 2.2 for the mouse over the isometric joystick. While this looks impressive, Baber (1998) suggests that it does not hold for other device comparisons. This suggests that comparisons based on performance times will be suitable for specific comparisons but might not be suitable for generalization to other applications or tasks.

3.2. Accuracy

Accuracy usually refers to whether the user can move a cursor onto the target. Inaccurate movements could consist of over- or under-shooting the target. As one might expect from the discussion of Fitts law above, accuracy is also affected by target size and movement distance. Often when one looks at the "hits" on a target, one sees a clustering of "hits" around the center. This indicates the active target width at which people aim. Where comparisons have been conducted in terms of accuracy, researchers have tended to find that direct pointing devices do not fare as well as indirect pointing devices. However, this might relate the fact that driving a cursor onto an object involves quite different psychomotor skills to simply reaching out and touching the object. One might find that the principle differences between direct and indirect devices lie not so much in time taken to move toward a target as in the time available to make corrections to the movement.

3.3. User Preference

In many studies, users are asked to provide an indication of which device they prefer. One should bear in mind here that preferences are typically recorded by asking people to rank the devices. Consequently, one needs to be aware that ranking between devices A, B, and C might produce quite different results to ranking between devices A, B and F. However, one interesting pattern that emerges from these studies is that user preference typically follows a similar trend to speed; users tend to rate touchscreens higher than other devices, even when touchscreen accuracy is sufficiently low to require users to make repeated attempts to select an object.

4.0 FUTURE DEVELOPMENTS

Buxton (1986) has noted that the majority of pointing devices require one-handed operation. He argues that future computer systems ought to allow people to exploit bi-manual activity. Fitzmaurice and Buxton (1997) demonstrate a computer-aided design package which allows the user to combine activity with both hands using different devices. Design was also the focus of a device proposed by Kameyama and Ohtomi (1993); a

manipulable object which can be modeled and shaped as if it were made of modeling clay. This means that the physical activity of the person can be captured directly for use by the computer. An extension of this concept is the use of gestures as a means of interaction, e.g. through physical pointing at an object in space, or through "miming" the use of a specific tool, or through the use of sign language. An excellent introduction to these ideas can be found in Bolt (1984). These developments can be applied equally well to conventional desktop computers or to virtual reality.

Systematic Control of Exposure to Machine Hazards

J. Etherton

Division of Safety Research, National Institute for Occupational Safety and Health, J. E. NIOSH/Division of Safety Research, 1095 Willowdale Rd., Morgantown, WV 26505.

1. INTRODUCTION

Engineering controls to prevent human contact with hazardous machine motion are a vital element in working safely with machinery. In the hierarchy of steps that can be taken to prevent injury, engineered controls are less effective than eliminating the energy source entirely. Nevertheless, they are more effective than personal protective equipment or training. Typically, the safety professional's job, as a machinery builder, user, or modifier, is not to design machine safety devices, but to effectively apply purchased devices. The user should understand the limitations of particular devices and should select and use only those devices that eliminate task risks or reduce them to an acceptable level. This chapter is organized under the following headings: (1) introduction; (2) hazardous machine motion; (3) injury risks; (4) safeguarding; (5) safeguard reliability; and (6) safeguarding and mode of actuation.

2. HAZARDOUS MACHINE MOTION

Prime movers impart motion to the working elements and tooling of industrial machinery. By timely interruption of power to prime movers, motion can be stopped before a human is in the motion path. Machinery motion can result from: (1) normal operation; (2) inadvertent human actuation of control switches; or (3) a failure within the machine control.

For each of these circumstances, the way that components and devices are designed and arranged in the machine control system is critical to injury avoidance.

3. INJURY RISKS

For 1992–95, the US Bureau of Labor Statistics (1997a) reported 588 occupational fatalities involving caught-in-machinery. Fosbroke *et al*. (1997) identify three machinery occupations among the 50 highest fatal injury risk occupations. Their listing is based on lifetime risk/1000 workers, with an assumed 45-year working life. For millwrights, 9.17 of 1000 millwrights die of a fatal work injury before their working life is completed. For machinery maintenance personnel the rate is 7.32 deaths per 1000 workers, and for other precision metal workers it is 4.01. The highest occupation is timber cutting and logging with a lifetime risk of 62.7.

As for non-fatal injuries, for 1992–95 there were between 34 000 and 36 000 non-fatal injuries per year involving caught-in-machinery according to the US Bureau of Labor Statistics (1997b). The incidence rates (cases involving days away from work/10 000 full-time workers) for that same time period for all of private industry ranged from 5.0 to 4.2. The two highest rates were in the manufacturing industry (14.4–12.2) and agriculture (12.1–

5.3). The reasons for human exposure to machine hazards are diverse, but a recurring scenario involves clearing and cleaning.

4. SAFEGUARDING

Machinery safeguards control the actions of the operator or they control the machine as operators move toward hazards. To qualify as a valid safety control, standards of performance must be met. Performance requirements can be found in the standards of the Occupational Safety and Health Administration (OSHA), American National Standards Institute (ANSI) and International Standards Organization (ISO).

4.1. Barrier Guards

Barrier guards are a fixed, protective fence between the operator and the machinery hazard and are used during normal operation. This is the most basic form of protection because the person is kept away from machine motion. The machine controls operate independent of this safeguard. Barriers are suited to hand feeding or automatic feeding. On general-purpose machines, adjustable guards may be needed to accommodate the size of various work pieces.

4.2. Interlocked Guards

For guards that need to be moved from their protective position, safety interlock switches can be placed such that they send a stop signal when the guards are out of position. Interlocked guards are appropriate when frequent adjustment or cleaning is performed during normal operation. Replacing the movable guard should not result in machine motion immediately restarting. A separate, deliberate action should be required to initiate action. Mechanical mounting of switches must be such that they cannot be easily taped or wedged closed, bypassing their intended purpose. Protective covers are an important feature for interlocks used in contaminated environments.

4.3. Devices

Machine safeguarding devices rely on a machine's control circuit to stop motion before human contact. Human approach or entry into dangerous areas can be detected by sensors, constrained by hand attachments, kept at a safe distance by location of manual controls or impeded by gates that open and close automatically.

4.3.1. Presence-sensing devices

These devices generate a sensing field that detects the location of a person. They are installed and adjusted to initiate stopping of hazardous motion before it can be reached inadvertently. They only are applicable on machines that can be stopped in mid-cycle. There are two main types: electro-optical and radio-frequency (RF). Both types should establish a safety distance from the hazard, which is the distance at which they signal the machine to stop. If a person can step completely through a light plane, the device should issue a stop command. Care must be taken to see how far fingers can penetrate the plane of a light curtain and what effect this has on safety distance. Likewise, fluctuation in the sensitivity of a RF field should be adjusted for. These fluctuations can be due to other objects entering the field or changes in the grounding of the protected person.

4.3.2. Two-hand control

This type of device usually is comprised of machine activation palm buttons that are a safe distance from the point of operation. After releasing the buttons, time is not sufficient to reach the point of operation before it ceases to be hazardous. The safety distance that is used equates a reach time based on hand speed (1.6–2.0 m/s depending on waist-level or shoulder-level button location; Pizatella and Moll 1987) to machine response time (control signal processing time + braking time). Both buttons should be pressed almost at the same time, e.g. within 500 ms of each other, and the release of either button should stop the machine. Two-hand trip is used on machines that cannot be stopped in mid-cycle. In two-hand trip safeguarding, the distance between buttons and hazards must be great enough to prevent hazard contact before the machine's cycle is completed. A variation on the use of buttons is using two sensing devices that actuate the machine when each hand is on or near its respective sensing pad.

4.3.3. Safety mats

A safety mat detects a person standing on or stepping onto it and signals hazardous motion to stop. They should be fixed to the floor; large enough not to be stepped over; and initiate stopping before someone stepping toward the hazard at a normal speed can reach the hazard.

4.3.4. Automatic gates

Gates that automatically open and close are another safety device. Some automatic gates will lock closed until machine motion has stopped. Others will lock closed while tooling is closing and then open for parts feeding during non-hazardous machine motion away from the operator.

4.4. Emergency Stops

Emergency stops are manually operated stop controls intended for use when a person detects that they or a co-worker have become exposed to a hazardous condition, or to prevent further injury after being caught. The common human interfaces are large mushroom-shaped buttons, safety bars and trip wires. Hard-wiring these into the control circuit is recommended. The effectiveness of emergency stops depends on how easily they can be reached, how much resistance they have before actuating and how quickly the machine actually stops after they are used. Since they are not used very often, a periodic check that they are functional is appropriate.

4.5. Safeguarding by Distance

Some machines, such as press brakes, require humans to hold work at a safe distance from tooling. Workers do not come in contact with machine motion because the workpiece is between them and the hazard. The administrative controls and training needed are high and more effective safeguards should be used when possible. Safeguarding by location means that machinery hazards are out of reach overhead or at locations where only servicing or maintenance tasks are performed, using lockout/tagout procedures.

5. SAFEGUARD RELIABILITY

The level of risk for which safeguarding is most effective varies with respect to: (1) mechanical reliability, (2) control reliability and (3) accommodating human reliability.

5.1. Mechanical Reliability

Mechanical reliability is a safety control characteristic that relates to both machine components and to machine guarding. Brakes, clutches and mechanical power transmission components that are involved with the timing of machine motion will need to be of sufficient strength to be reliable. Mechanical strength is also a defining aspect of barrier guard effectiveness (European Committee for Standardization 1996a). Verification may be required for the resistance of guards to impact from persons, parts of tools, high-pressure liquids, etc. Before carrying out this verification it is necessary to identify the foreseeable impact hazard to which the guard may be subject, e.g. low velocity impacts from persons, high velocity impacts from broken parts of tools, impact from high-pressure fluids. When verifying the impact strength of a guard, it is necessary to take account of the properties of the materials from which the guard is constructed. This examination should include the strength of joints used and the strength of fixing points, slides, etc. by which the guard is attached to the machine or other structure.

Factor of safety (FS) is a common way to specify a design so that it will have adequate strength. Factor of safety for a guard can be defined as FS = S_u/S_a, where the ratio of the ultimate strength (S_u) of its material and fasteners to an allowable, working stress (S_a). Using a factor of safety permits the design to not waste material, yet be strong enough to prevent failure in case loads exceed expected values or other uncertainties react unfavorably. In general, the ductility of the material determines the property upon which the factor should be based. Materials having an elongation of > 5% are considered ductile. Factor of safety can be based upon the yield strength or the endurance limit. For materials with an elongation < 5%, the ultimate strength must be used because these materials are brittle and fracture without yielding (Avallone and Baumeister 1986). Factors of safety based on yield are often taken between 1.5 and 4.0. For more reliable materials or lower-risk design and operating conditions, the lower factors may be appropriate.

Guarding for agricultural equipment (ASAE 1993) is required to retain adequate strength under expected climatic and operational conditions for their intended use. The reference force that the guard must withstand a 123 kg (270 lb) person leaning or falling against it.

5.2. Control Reliability

Control reliability means the capability, by design, for a safety control to provide a protective function even when its design has been compromised due to component failure. OSHA's only control reliability standard applies to hands-in-die operation of mechanical power presses. OSHA 1910.217 (b)(13) requires that the control system will be constructed so that a failure within the system does not prevent the normal stopping action from being applied to the press when required, but does prevent initiation of a successive stroke until the failure is corrected.

The failure will be detectable by a simple test, or indicated by the control system. This requirement does not apply to those elements of the control system which have no effect on protection against point of operation injuries.

The logic embedded in a safety control system derives from a combination of relays, microprocessors, and/or pneumatic components. The failure modes of these components are quite

different. Electrical noise and power supply spikes can cause problems with microprocessors, but not with relays. Design should include: active redundancy; comparison between outputs of redundant components; and regular exercising of components to ensure their functionality. Shielding against electromagnetic interference can also be appropriate.

Five categories of safety device control reliability are set forth in EN 954, *Safety of Machinery; Safety-related Parts of Control Systems* (European Committee for Standardization 1996b). The categories in order of increasing fault tolerance are: controls that simply operate to perform the intended product function; well-tried safety control components; a fault in the safety circuit is detected on start-up (start-up check); a single fault in the safety circuit does not lead to failure of the safety circuit (redundancy); and a single fault is detected at or before the next call on the safety system. The interested reader should refer to the actual standard.

5.3. Design that Accommodates Human Reliability

People do not always do the safe thing. Sometimes they will reach toward hazardous locations, they will not put a safeguard back in place because it is too burdensome or they will simply bypass a safeguard. Industrial anthropometry is the science concerned with determining the dimensions of the human body and defining how these dimensions apply to work tasks. Percentile (%ile) is a convenient way of indicating how much of the range of human variability is accommodated by a given dimension, or the fraction of the population who measure less than this dimension. For example, the 95%ile US civilian male hand length is 20.6 cm; with 5% of the population having longer hands (Kroemer 1987). For hand-reach dimensions through long parallel openings, Villaincourt and Snook (1995) give the most current US dimensions.

The agricultural machinery standard ASAE S493 (1993) provides a set of rules for openings that will impede exposure of hands, arms, feet and the whole body to dangerous machine areas. The functional anthropometry of whole-body reaching should also be considered when installing barriers that can be leaned over, or for standing reaches (Etherton 1991).

The weight of a guard that can be completely removed from a machine is a factor in its easy replacement. Yet, guarding must be substantial enough for rugged use. Thus, there may be a design tradeoff if a guard is made of materials that are too dense.

6. SAFEGUARDING AND MODE OF ACTUATION
6.1. Foot Controls and Barrier Guards

Trump and Etherton (1985) describe the likelihood of inadvertent actuation with foot controls. When a foot control is used, safe-

guarding should be especially difficult to circumvent, or redundant safeguarding may be considered. When safeguards have been removed for cleaning, clearing or set up, users of foot controls should be particularly cautious. These guidelines also apply to foot-controlled press brake applications that are safeguarded by work holding at a safe distance.

6.2. Presence-sensing Device Initiation

Presence-sensing devices can be installed and operated automatically to cycle some machines once hands have been withdrawn from the sensing field. Because of the sensitivity limitations of some devices, this option should never be used without a thorough safety review of the entire machine and safeguarding system.

Visual Display Technology

D. L. Post and H. L. Task

Air Force Research Laboratory, Wright-Patterson Air Force Base, OH45433-7022, USA

1. INTRODUCTION

Many of the design problems encountered by human factors professionals involve electronic visual displays. Although modern human factors training often covers the psychophysical, perceptual and cognitive aspects of information display, education about display hardware — which is often needed to understand and solve display design problems and work productively with display engineers — is rare. This problem is exacerbated by the fact that most of the literature on display hardware is written for engineers and many aspects of the field are evolving quickly. This entry summarizes the major human factors parameters that are relevant to electronic visual displays, explains the principles of operation for the display technologies of greatest importance today and describes their characteristics insofar as they affect visual performance, and discusses the most common types of display systems that incorporate these technologies.

2. DISPLAY HUMAN FACTORS PARAMETERS

2.1. Photometric Characteristics

One of the most fundamental display characteristics is brightness. Brightness is assessed usually by measuring its psychophysical correlate, luminance, with a photometer. Another basic characteristic is contrast, which is a ratio of on and off pixel luminances; Table 1 lists common measures. Ambient illumination often reduces display contrast by adding reflected light to that coming from the display. Display screens are usually treated to reduce this problem, although most treatments reduce display luminance.

Grayscale is the number of luminances the display can produce at a fixed setting of the brightness and contrast controls, expressed usually as the base-2 logarithm of that number with units called "bits." For example, "8 bits" of grayscale denote 256 levels. The visual system's response to differing luminances is compressive, so technologies having exponentially increasing video-input-to-luminance response functions come closest to providing equally discriminable grayscale levels (although single steps may not actually be discriminable).

For most display technologies, grayscale limits are not inherent and result instead from built-in digital drivers. The exceptions are technologies having pixels that can only be fully on or off. A few technologies — notably CRT — have analog grayscale, which means their luminance can vary continuously and grayscale is limited, if at all, only by their video input signal. Grayscale can be produced in technologies having only on and off pixels by temporal multiplexing, which involves turning pixels on for varying fractions of a frame period, or by dithering, which is a type of spatial multiplexing that involves turning groups of adjacent pixels on and off so the group average has the desired luminance. Usually, dithering is used only as a supplement to temporal multiplexing. Emissive on–off technologies can be dimmed only by using up some of their grayscale (non-emissives can be dimmed by adjusting the illuminant), so they may exhibit contrast artifacts if they are dimmed.

The angular distribution of light emission for some display technologies is approximately Lambertian, which means their luminance is essentially independent of viewing angle; others depart from this ideal in ways that usually make the display harder to read as one moves off axis. LCD often exhibit additional anomalies off axis, namely reduced or even reversed contrast and color shifts, although manufacturers are using increasingly sophisticated methods to reduce these problems.

2.2. Spatial Characteristics

"Resolution" is used widely, but inconsistently, to describe the amount of spatial detail a display can produce. Display designers often specify resolution in cycles or pixels per unit distance on the display (e.g. cycles/cm), where a cycle is one complete sine wave. Sometimes, the unit distance is implicitly the display's width or height, in which case the specification gives the total number of cycles or pixels that can be produced. Specifications for television sets often state only the number of raster lines that can be displayed. Although conventional television broadcasting provides only 525 lines in the USA (only 483 are visible, though) and 625 lines in the UK and Europe (575 visible), the capacity to display more implies higher resolution within each line.

Table 1. Common measures of contrast.

Name	Defining equation[1]
Contrast ratio[2,3]	L_{max} / L_{min}
Relative contrast[2,3]	$(L_{max} - L_{min}) / L_{min}$
Luminance contrast[3]	$(L_{max} - L_{min}) / L_{max}$
Luminance modulation or Michaelson contrast	$(L_{max} - L_{min}) / (L_{max} + L_{min})$

[1] L_{max} is the greater of the two luminances; L_{min} is the lesser.

[2] The contrast ratio and relative contrast are undefined when $L_{min} = 0$.

[3] For symbology, L_{max} and L_{min} are replaced sometimes by the symbol and background luminances, respectively, in the first three equations, which creates the possibility of contrast ratios < 1 and negative values in the other two cases.

Table 2. Contemporary digital resolution standards.

Label	Aspect ratio[1]	Resolution (H $\times$ V) in pixels
QVGA	4:3	320 $\times$ 240
VGA	4:3	640 $\times$ 480
SVGA	4:3	800 $\times$ 600
XGA	4:3	1024 $\times$ 768
SXGA	5:4	1280 $\times$ 1024
UXGA	4:3	1600 $\times$ 1200
SDTV[2]	4:3 or 16:9	704 $\times$ 480
HDTV[3]	16:9	1920 $\times$ 1080
	16:9	1280 $\times$ 720

[1] Aspect ratio is the ratio of image width to height.

[2] SDTV approximates the resolution of the 525-line analog system used currently in the USA. It requires rectangular pixels in one of two possible sizes to achieve the stated aspect ratios. All other entries in Table 2 use square pixels.

[3] HDTV offers two possible resolutions.

Psychophysicists usually prefer cycles or pixels per unit angle subtended at the viewer's eye (e.g. cycles/degree) because these measures account for the effects of viewing distance and display size on image appearance. Thus, two displays having equal resolution from a display designer's perspective may have different resolutions from a psychophysicist's perspective and vice versa.

Additional confusion is introduced sometimes by failing to distinguish between the resolution of the display and that of the video system driving it or the image it is displaying. For example, using an SXGA (Table 2) graphics card does not give a display SXGA resolution, nor does showing a VGA image yield VGA resolution. Another poor practice is confusing resolution with the amount of visual information in an image. For example, a photograph may be described as having higher "resolution" than a drawing of the same scene.

CRT produce images by drawing on a screen with a continuously moving electron beam. Their resolution is mainly a function of their video bandwidth, refresh rate and electron-beam spot size. These parameters' effects are described most completely by the spatial modulation transfer function, which graphs the response to sinusoidal inputs as a function of their frequency, in a manner analogous to the frequency–response plots one often sees for audio equipment.

Other display technologies consist of a matrix of discrete pixels that are set to the desired luminances by addressing them one or possibly several rows at a time, with all columns loaded simultaneously — methods called "line by line" and "multi-line" addressing, respectively or, more generally, "matrix addressing." For these technologies, resolution is simply a function of the number of horizontal and vertical pixels. Another addressing method is to connect each pixel to its own driver. This "direct" addressing technique allows each pixel to be driven throughout each frame, but is practical only for simple applications, requiring only a few dozen pixels or segments (e.g. watches, calculators, and home appliances) because otherwise the number of connections and drivers becomes prohibitive.

Matrix displays come in two types: passive, which have only a pair of electrodes at each pixel, and active, which add a switch (typically, a thin-film transistor, or "TFT," but sometimes a diode) at each pixel so voltage can be maintained throughout the frame period. Passive-matrix displays are cheaper but can apply voltage to the pixels only while their row is selected. Therefore, their luminance and contrast tend to be inferior to otherwise identical active-matrix displays and diminish as the number of rows increases, thus limiting the number of rows that can be provided.

2.3. Temporal Characteristics

It is obvious that changing a display image requires redrawing it, but it is less obvious that, for most display technologies, the image fades unless it is refreshed. (The exceptions are bi-stable technologies, which have pixels that remain on or off until they are switched.) In the USA, television refreshes at 30 Hz by alternately drawing all the odd- and then even-numbered lines at 60 Hz. Each set of lines is a "field," both fields constitute a "frame," and this alternating system is called "2:1 interlacing." (In the UK and Europe, the field rate is 50 Hz, yielding a 25-Hz frame rate.) Interlacing reduces bandwidth requirements while avoiding flicker for typical television images, but tends to produce jitter in text. Therefore, computer images are usually non-

interlaced (this method is known also as "progressive scanning") and refresh at 50 Hz or more. The rate needed to prevent flicker increases as display luminance, contrast, and angular subtense increase. Sometimes, the rate must also be adjusted to prevent beats with fluorescent lighting from becoming visible.

Display luminance is greatest if the pixels emit throughout each frame, but this can cause image smear if the observer tracks a moving object. Therefore, motion rendition is best for display technologies that produce adequate time-averaged luminance while emitting only for small fractions of a frame period. A display having pixels that cannot switch completely during one frame will exhibit contrast losses for moving images, so it is also important that the pixels respond quickly. Most LCD technologies are troublesome in this regard. Speed is even more crucial for technologies that rely on temporal multiplexing to achieve grayscale or use temporal integration to produce color, because in these cases the pixels must switch more than once during each frame.

2.4. Colorimetric Characteristics

The range of colors a display can produce is called its "color gamut" and is determined by its red, green and blue (RGB) primaries. The closer the primaries come to being monochromatic, the more saturated they become and the larger the gamut becomes; however, no finite set of primaries can reproduce the entire range of colors humans can perceive. Furthermore, increasing a primary's saturation requires reducing its spectral bandwidth, which typically reduces its luminous efficacy; therefore, primary selection often involves a tradeoff between gamut and luminance.

Television broadcasting uses a standard set of primaries that have been chosen for compatibility with available CRT phosphors. Developers of other color display technologies generally try to match or exceed television's gamut. For emissive technologies, one approach uses a white emitter with a patterned RGB color filter in front; another uses RGB emitters, possibly enhanced by a patterned color filter. For non-emissive technologies, the common approach uses a white illuminant and color filters. Luminous efficacy can often be increased by selecting an illuminant having its radiance concentrated in three RGB wavebands and matching the filters' transmittances to those wavebands.

Every color display has a "white point," which is the chromaticity it produces when its RGB channels are driven equally and may or may not be user-adjustable. Television broadcasting and a few other applications use standard white points, defined in terms of Commission Internationale de L'Éclairage (CIE) chromaticity coordinates. Differences in white points are often at least partly responsible for problems in obtaining accurate color transfer when images are viewed on different displays, printed, or scanned.

Most displays produce color by spatial integration: The screen is divided into RGB subpixels, which subtend a visual angle so small that the diffraction patterns they produce on the retina overlap and mix. Varying the subpixel luminances produces what appear to be full-color pixels having any color an RGB mixture can produce.

A similar method, used by most projection displays, is addition: Separate RGB images are produced by three

monochrome displays and superimposed internally or at the screen. Addition can yield higher resolution than spatial integration because every pixel can take on any color, but it requires three displays and is therefore bulkier and more expensive.

Color can also be produced by temporal integration — a technique often called "field sequential": the display generates spatially superimposed RGB fields in rapid sequence, within a single frame period, and the visual system integrates them temporally to form a full-color image. Temporal integration has the same resolution advantage as addition, but requires fast displays, sacrifices luminance because each color field is displayed for no more than one-third of each frame, and the images can break up into their RGB components if there is relative motion between the image and the viewer's eye.

Finally, a subtractive process can produce color: white light passes through a stack of three transmissive displays, and each display modulates the R, G, or B component of the light so a full-color image emerges at the front. Subtraction also has a resolution advantage, but requires three displays, careful design to minimize transmission and contrast losses as the light proceeds through three apertures, thin displays to avoid parallax in direct-view applications, and may require special optics to focus the layers simultaneously in head-mounted and projection applications.

2.5. Size and Weight

CRT tend to be the heaviest and bulkiest of the display technologies because they are funnel-shaped glass vacuum tubes. Their shape results from the need to provide space for the electron beam to scan the screen. Their weight increases exponentially with screen size because the glass must be thickened to withstand the atmospheric pressure resulting from the internal vacuum. Most other technologies consist only of thin, lightweight layers sandwiched between two flat pieces of glass, so they are more compact and their weight is proportional with screen size. LCD usually require a backlight, though, which can increase their weight and depth substantially.

3. EMISSIVE DISPLAY TECHNOLOGIES

3.1. Cathode-ray Tube (CRT)

A CRT produces images by modulating an electron beam as it scans across a phosphor screen. The electrons are produced by heating a cathode, accelerated toward the screen, and focused and scanned by dynamic electromagnetic or electrostatic fields. Dynamic focusing compensates for the changing distance to the screen as the beam scans. Most CRT scan the beam in a repeating "raster" pattern, consisting of closely spaced horizontal lines; however, oscilloscope CRT — and some that are used exclusively to show symbols and line graphics — use a "stroke" pattern that moves the beam as if it were a pen. Stroke writing provides increased luminance (because the phosphor can be excited more times per s) and resolution.

Most color CRT scan three electron beams across a patterned screen containing RGB phosphor dots or stripes, thus producing color by spatial integration. A metal structure ("shadowmask") behind the screen, having one opening for each RGB triplet, helps ensure that each beam strikes only the appropriate phosphor; adjustable magnets also assist. Older, "delta-gun" CRT arrange the beams in a triangular pattern and include user-adjustable

circuitry to ensure a condition called "convergence" that, if violated, produces color fringes that are noticeable especially around white objects on the screen and reduce resolution. Modern, "in-line gun" CRT arrange the beams in a row and use circuitry and magnets, which are set at the factory and rarely adjusted afterward, to achieve convergence. Color can also be produced by temporal integration, using a white-phosphor CRT in conjunction with a switchable or rotating color filter — this approach is used sometimes in head-mounted systems.

3.2. Vacuum Fluorescent Display (VFD)

The VFD is a type of flat CRT that excites a low-voltage phosphor using electrons produced by heating a cathode grill consisting of fine, heated wires. The flow of electrons is controlled by a wire grid that lies between the cathode and a phosphor-coated opaque anode array. The photons then pass through the grid, cathode, and a cover glass. Another arrangement, which deposits the phosphor on the cover glass, is also used sometimes. The anode array can be matrix addressed or, more commonly, arranged in segments. Usually, a blue-green emitting phosphor is used because it has the highest luminous efficacy, but a good range of hues up to red are available.

VFD are used widely as simple numeric, alphanumeric, and bargraph displays measuring a few square centimeters in products like VCRs, but it has not been practical to > ~160 cm^2 for more general-purpose use because this would require adding internal support to control the gap between the cathode and anode, which would interfere with the electron flow. Grayscale and dimming can be produced by varying the anode voltage. Motion rendition is good due to low response time and the emission is Lambertian, so viewing angle is not a problem. Color can be produced by spatial or temporal integration, but multicolor units consisting of differently colored monochrome areas are far more common.

3.3. Field-emission Display (FED)

The FED is another type of flat CRT, in which a phosphor-coated glass screen is excited by electrons produced by an addressable matrix of tiny cathodes. There are basically two types: low-voltage (40–100 V), which require special phosphors and have not yet matched the luminances available from CRT, and high-voltage (5–10 kV), which use conventional phosphors and can match CRT luminances but are vulnerable to damage and failure caused by arcing. Grayscale and dimming can be produced by temporal multiplexing, cathode modulation, or dithering, although multiplexing supplemented by cathode modulation usually yields the best result. The response time is low and the emission is Lambertian. Color is produced by spatial integration, using RGB phosphors, although temporal integration is also feasible.

3.4. Image Intensifier Tube (I²T)

The I²T is a unique combination of sensor and display in one package. Contemporary third-generation I²T consist of three primary elements: (1) a photo-cathode screen, which converts photons to electrons; (2) a micro-channel plate (MCP) that accelerates and multiplies the electrons; and (3) a phosphor screen — coated on a fiber-optic or plain glass faceplate — that converts the multiplied electrons to photons. Typically, a power supply is included, to convert battery power to the relatively high voltage needed by the MCP. In operation, an image is focused onto the

photo-cathode, which then emits electrons in the general direction of the adjacent MCP. The MCP contains millions of tiny tunnels (micro-channels), which amplify the incident electrons in proportion to their number. After exiting the MCP, they are accelerated toward the nearby phosphor screen by an electric field. The phosphor nearest each micro-channel glows with a luminance that is proportional to the number of incident electrons, thus producing a monochrome image that replicates the image focused on the photo-cathode, except that its luminance is greatly amplified. See the section on NVG for information on typical uses of I²T.

3.5. Light-emitting Diode (LED)

An LED is basically a solid-state material — typically gallium phosphide or gallium arsenide — that has been treated so it consists of two layers that form a P-N junction diode, and passing a current across the layers causes them to emit light. A reflector is placed behind the diode to direct rear-emitted light toward the front, and a lens is often incorporated at the front to further shape the output. The diodes can be arranged in segments to form numeric, alphanumeric, or bargraph displays or laid out as an addressable matrix. A full range of colors, including RGB, is available, so color displays using spatial integration can be created. Grayscale and dimming can be produced by varying the current or temporal multiplexing. The reflectors and lenses are usually designed to produce non-Lambertian emission, to increase on-axis luminance. Large matrices of LED for use as general-purpose desktop color displays have not proven to be practical, mainly because of the difficulty of assembling discrete devices at the required densities (producing different colors on one substrate has proven impossible, thus far), but are used widely as message signs. Numeric units — which were once common in wristwatches and calculators until being replaced largely by LCD — are used in clocks and, along with alphanumeric and bargraph units, as instrument readouts.

3.6. Organic Light-emitting Diode (OLED)

An OLED display consists of a thin transparent layer of organic semiconductors or polymers, sealed usually between two glass or plastic substrates bearing orthogonally oriented electrodes on their inner surfaces. The front electrode is transparent and the rear is reflective. Applying a current across the electrodes causes the organic layer to emit visible light. Plastic substrates may make it possible to produce flexible displays, which can be rolled up or folded. Silicon substrates have also been used in experimental, miniature active-matrix OLED designed for head-mounted applications. Currently, this technology is under development, and although it is regarded widely as very promising, there are few commercial products. Grayscale and dimming are produced by varying the electrode current. Viewing angle is good due to Lambertian emission. OLED materials capable of producing RGB light are available, so full color can be produced by spatial integration or, if the substrates are stacked, by addition; however, in the latter case, the stack must be very thin to avoid parallax.

3.7. Electroluminescent (EL) Display

The most common type of EL display today uses alternating current to excite a thin-film EL phosphor, yielding the "ACTFEL" structure. The phosphor is sandwiched between thin insulating layers and this multi-layer structure is deposited typically on a glass substrate bearing transparent electrodes. Reflective, orthogonally oriented electrodes are then applied and the phosphor is viewed through the glass. Thus, only one substrate is required and the display can be substantially thinner and lighter than other flat panel technologies. Ceramic and silicon (supported by ceramic) substrates are also used, although these designs require a cover glass. Miniature devices using active-matrix addressing have been produced for head-mounted use. The angular emission is Lambertian. Grayscale and dimming for EL use temporal multiplexing, enhanced sometimes by dithering. Color is achieved by spatial integration, using either patterned phosphors or a white phosphor plus color filter array.

3.8. Plasma Display Panel (PDP)

A PDP consists mainly of a gas that is sealed between two glass substrates bearing orthogonally oriented electrodes on their inner surfaces and, usually, a reflective coating at the rear. Passing a current across the electrodes ionizes the gas, producing a plasma that emits light. Monochrome PDP use neon, which emits reddish-orange light. In color displays, an ultraviolet-emitting gas is used and the ultraviolet excites phosphors that are coated on the inner surface of one of the substrates. Thus, a color PDP is similar to a fluorescent light bulb. Either alternating or direct current can be used, but the former is more common today. PDP are inherently bi-stable, so grayscale and dimming are produced by temporal multiplexing, enhanced sometimes by dithering. Response is very fast, so motion rendition is good. Color is produced by spatial integration. The emission angle is Lambertian for color panels but is isotropic for monochrome panels, causing luminance to increase with viewing angle.

4. NON-EMISSIVE DISPLAY TECHNOLOGIES

4.1. Illumination Sources

Non-emissive displays require a light source. For some applications, such as LCD wristwatches, ambient illumination reflected off the display may be sufficient, but usually a built-in source is needed. Most direct-view LCD use one or more tubular fluorescent lamps, mounted in a box containing a reflector or coupled to a light guide. Other approaches that provide more uniform illumination have been tried, though, including EL panels, flat and serpentine-shaped fluorescent lamps, and CRT. Projection systems require more light than can be provided compactly by a fluorescent source; they use xenon or metal-halide arc lamps. Xenon has a broad spectrum that must be filtered heavily to produce acceptable RGB primaries, thereby reducing overall luminous efficacy. Metal-halide lamps emit mainly in narrow wavebands dictated by the choice of halides, thereby reducing the need for spectral filtering; the fill gas is unavoidably excited too, though, adding at least some broad-spectrum light. Compact, solid-state lasers producing RGB wavelengths have become available recently. Their narrowband spectra are advantageous for many display purposes, and their prices, efficiencies, lifetimes, sizes, weights and cooling requirements are moving rapidly to a point that may make them attractive for projection uses.

4.2. Liquid Crystal Display (LCD)

Liquid crystals (LC) are elongated molecules that flow like liquids

at typical ambient temperatures and tend to align with one another. There are many types of LC and ways of using them to make displays, but the most common today are nematics, sealed between two pieces of glass that have been treated so the LC lie parallel with the glass surfaces and undergo a rotation top to bottom, forming a helix — a configuration called "twisted nematic" (TN). In a transmissive TN-LCD, polarizers and transparent electrodes are added to the glass surfaces, and light passing through one polarizer rotates with the twist until it strikes the second polarizer, which either passes or absorbs it, depending on whether the polarizers are aligned with each other or crossed. Applying a voltage across the electrodes rotates the LC so they are perpendicular to the glass, destroying the twist and thereby reversing the second polarizer's effect. Intermediate voltages produce intermediate transmittances and, hence, grayscale. Reflective TN-LCD have a reflective surface at the rear and only a front polarizer, but work basically the same way. The electrodes can be segmented or arranged in a matrix.

Most passive-matrix LCD today use a twist ranging from 180 to 270°, called a "supertwisted nematic" (STN) configuration, which increases the number of rows that can be addressed but reduces viewing angle, response speed, and grayscale. Active-matrix LCD (AMLCD) provide the best viewing angle, speed, and grayscale, but are more costly. Other important types of LCD today are ferroelectrics (FLC), which are bi-stable and respond to control voltages very quickly but have difficulty producing grayscale, polymer-dispersed (PDLC) and nematic curvilinear aligned phase (NCAP) LCD, both of which vary between transparent and light-scattering states and use no polarizers but have trouble producing high contrasts, and polymer stabilized cholesteric texture (PSCT) LCD, which are bi-stable and therefore do not produce grayscale readily.

4.3. Digital Micromirror Display (DMD)

A DMD is an addressable array of tiny mirrors, each of which is mounted on a flexible stalk. Each mirror can be rotated very quickly (e.g. 10 ms) to either of two orientations, thereby deflecting incoming light out to a projection lens or an absorber. Thus, each mirror is a pixel that can be either on or off. Grayscale is produced by temporal multiplexing; dimming is accomplished by modulating the illumination. Color is produced usually by temporal integration using a filter wheel, but triple-DMD systems using addition and dual-DMD hybrids are also available. DMD do not lend themselves to direct-view applications because of the need for a projection lens; furthermore, it is impractical at the moment to make them bigger than a few square centimeters in area. They are used widely in projectors, though, and head-mounted applications are also possible.

5. OPTICAL DISPLAY SYSTEMS

5.1. Projectors and Screens

Projection displays use one or more lenses to enlarge and focus an image of an internal display onto a screen. Rear projectors usually incorporate the screen into the housing and therefore tend to be bulky, whereas front projectors use a separate screen and are therefore more compact but require the screen to be distant from the projector. Rear projection screens are usually treated to reduce reflections from room lighting and incorporate lenses to produce a non-Lambertian light distribution that reduces the image's viewing angle but provides greater luminance within the intended angle — a feature called "gain." Front projection screens can also have gain.

Some projectors use CRT to create an image; others, termed "light valves," use non-emissive displays. The least expensive, lightest, and most compact design for a color projector uses a single display and lens system; field-sequential color is most common in self-contained versions, whereas spatial integration is the norm in LCD overlays for overhead projectors (subtractive overlays have also been produced). Greater luminance can be obtained, though, by using three displays to produce separate RGB images that are combined additively; this design is more common in self-contained systems. Most triple-display projectors use dichroic beamsplitters, which reflect one band of wavelengths while passing the rest, to add the images internally and, in light-valve projectors, to first separate white light into R, G, and B so each component can illuminate the appropriate display. Most CRT projectors, however, use a separate projection lens for each CRT and add the RGB images at the screen.

The most important human factors issues for projectors are resolution, luminance, contrast, optical distortion, viewing angle, size, and weight.

5.2. Head-up Display (HUD)

As the name implies, a HUD is intended to permit the operator of a vehicle (originally an aircraft and, more recently, an automobile) to view a display without looking down toward the instrument panel. It does this by superimposing a display image on the outside world. The original intent was only to assist weapon aiming, but another advantage has been recognized since: The virtual image is normally at or near optical infinity, so the operator does not have to refocus when switching from viewing the world scene to viewing the display.

A HUD consists of three major components: (1) an image source (e.g. a CRT); (2) optics to produce a virtual image of the image source; and (3) an optical combiner, which combines the virtual image with the directly viewed exterior world scene. There are basically two types of HUD: those that produce a real exit pupil and those that do not. If the HUD uses relay optics, it has a real exit pupil, which means at least one eye must be within the exit pupil to see any part of the display. If the HUD uses simple magnifying optics, it does not have a real exit pupil and eye position is less critical, although at least one eye must still be positioned within a limited volume of space to see the entire display.

The most important human factors issues for HUD are the combiner ratio (which affects the relative luminances of the symbology and outside world scene), viewing location, exit pupil size or viewing volume, symbology size, type, luminance, and color, stray reflections, and the size and shape of the field of view.

5.3. Head- and Helmet-mounted Display (HMD)

An HMD consists typically of three major components: (1) a miniature display; (2) optics to convey a virtual image of the display to the eye(s); and (3) some (usually adjustable) means of mounting the display and optics to the head. The optics may or may not include a combiner: If the HMD is meant to provide an image that can be superimposed on the external world scene,

the optics must include a see-through combiner; if the HMD is for "immersion" only, a combiner is unnecessary and the optics are easier to design. Most HMD use miniature CRT or LCD, which must have very high resolution (in terms of cycles/mm or pixels/mm) to produce a satisfactory image after magnification by the optical system. One exception is the "virtual retinal display," which produces an image by scanning a modulated laser beam directly across the retina in much the same way a CRT scans an electron beam across a phosphor screen. Another exception scans an image of an LED array back and forth across the retina.

HMD can be monocular, bi-ocular, or binocular, monochrome, multi- or full-color, see-through or non-see-through, adjustable focus or fixed focus, and real exit-pupil forming or non-pupil forming. The most important human factors issues associated with them are weight, comfort, size, luminance, binocular alignment, resolution, optical distortion, optical distance of the image, size and shape of the field of view, exit pupil size or viewing volume, and the distance the eye can be from the optics ("eye relief").

5.4. Night Vision Goggle (NVG)

NVG are a special type of HMD. Most NVG are binocular, with each ocular consisting of three major components: (1) the objective lens, which produces an optical image on the input side of an (2) I^2T; and (3) an eyepiece lens to produce a virtual image of the I^2T's output. NVG typically include assemblies that permit them to be adjusted and worn on the head. NVG containing second-generation I^2T are most sensitive to wavelengths from 400 to 750 nm; third-generation devices are most sensitive to 650–900 nm.

The most important human factors issues associated with NVG are ocularity (binocular, bi-ocular, or monocular), output luminance, signal to noise ratio, optical distortion, eye relief, gain, adjustability (fore/aft, interpupillary distance, focus, tilt, up/down), weight, size, and comfort.

5.5. Three–dimensional (3D) or Stereoscopic Display

"3D" is used sometimes to refer to images seen on a conventional display that include depth cues such as perspective, surface shading and hidden lines. A stereoscopic 3D display, however, provides binocular disparity, so each eye sees a slightly different image that corresponds to what it would see in the real scene. There are several ways to produce binocular disparity. One is to use two independent image sources (e.g. CRT) and an optical system that presents a different image to each eye. Another approach is to use a single display and encode or multiplex the left- and right-eye images so each eye sees only the appropriate one. A common encoding technique, used with projection displays, polarizes the left- and right-eye images oppositely and

superimposes them on the screen; the observers wear oppositely polarized lenses, so each eye sees only the appropriate image. A common multiplexing technique, used with direct-view displays, places electronic shutters in front of the eyes and alternates the left- and right-eye images on the display in synchrony with the opening and closing of the shutters.

The most important human factors issues associated with stereoscopic displays are the accuracy of the binocular disparities and hence depth cues, visibility of the images to the wrong eyes ("crosstalk"), frame rate, luminance, color, binocular alignment, and the effects of mismatch and lack of normal covariance between the images' optical distance (which is usually fixed) and the varying vergence cues and requirements produced by the binocular disparities.

1. INTRODUCTION

The use of new visual informational displays such as head-mounted displays for virtual reality, heads-up displays for automobiles and stereoscopic displays for industrial design, medical training and entertainment has been steadily growing. Along with this increased use, there are scattered reports (Peli 1996) that visual fatigue might be induced by prolonged use of those displays. Although accommodation and vergence have a close relationship with such phenomena, few objective studies exist.

This chapter firstly explains specific characteristics of accommodation when looking at two-dimensional (2D) drawings with ample depth cues. Then it presents the difference between visual responses when subjects are looking at a moving object in a realistic or virtual three-dimensional (3D) space. The fact that accommodation can be evoked by 2D drawings from an acquired depth sensation and the remarkable difference in the accommodative responses in the real or virtual 3D space are attributed to be a cause of visual fatigue while using these new stereoscopic visual informational displays.

The control mechanism of the eyes consists of accommodation, eye movements and pupil reflex subsystems. These subsystems interact with each other considerably and, hence, are called the "near triad" system. Primary characteristics of each subsystem have been studied objectively over 40 years. However, the dynamic features of accommodation in realistic visual environments and especially the interactions between the subsystems have not been thoroughly clarified. The main reason has been that accommodation could not be measured while subjects were looking at real objects while moving their eyes.

In a pioneering study of accommodation to apparent distance, Ittelson and Ames (1950) reported that (1) with monocular vision, subjects showed a mean accommodation of 0.46 D (diopter, which is defined as the reciprocal of focal distance) and vergence toward the apparent distance indicated by the continuously varying size of a card presented by a projector, and (2) with binocular vision, the subjects showed no vergence.

Kruger and Pola (1989) recorded definite accommodative responses for sinusoidal size changes of the stimulus with an infrared optometer. They analyzed the role of blur, chromatic aberration, and size change of a target and measured the influence of the size change on accommodation. However, the stimuli were presented in an optical system that required subjects to gaze into the instruments monocularly.

Enright (1987) measured the vergence response monocularly with two TV monitors when subjects scanned line drawings. He found that the vergence changed if subjects shifted fixation within the drawings while one eye was covered, but the vergence did not change with binocular vision. However, he could not measure accommodation simultaneously.

Takeda *et al.* (1990) measured accommodation and eye movement of the right eye while subjects were looking at stimuli binocularly under normal viewing conditions. Then they measured the influence of line of sight and found that (1) vertical shifts of eye direction had a slight influence depending upon focus distance, and (2) horizontal shifts had virtually no influence (Takeda *et al.* 1992). Afterwards, they identified objectively the influence of size change of a spotlight in a totally dark room. It was found that accommodation was really influenced by the depth sensation induced by the change of spotlight size.

However, they could not measure vergence in those experiments because the apparatus used could not measure left eye movement. They improved the apparatus to enable vergence measurement. The results showed that accommodation was sensibly influenced by many kinds of depth sensation but vergence was less influenced by such sensation under binocular viewing conditions. Then the characteristics of accommodation were explored when looking at stereoscopic images and some peculiar responses were found and thought to be a cause of visual fatigue.

2. METHODS

2.1. Experimental Design

The principle of measurement system TDOIII (3D optometerIII) and the stimulator TVS (3D visual stimulator) are explained elsewhere in this volume.

In the first two experiments, two different drawings with ample depth cues (*Christina's World 1948* by A. Wyeth; *Mt Fuji Viewed Through Waves off the Coast of Kanagawa* by K. Hokusai) were used to examine what kind of influence on accommodation might be posed by watching them while subjects are moving their eyes. The measurement was performed under normal lighting conditions. The drawings were placed 40 cm from the subjects' eyes.

In the third experiment, a Maltese cross image formed by the TVS was used to examine the influence of a stereoscopic virtual image on accommodation. The visual angles of the target were 0.67° at 1 m (1D) and 0.67 or 2.00° at 33 cm (3D). The Maltese cross was white with a black background. The luminance of the cross was set at 6 cd/m², which was determined to avoid any unexpected influence of stray reflections, to lessen the influence of changes in light amount on pupil size and also to increase the pupil size to make measurement easier. As the TDOIII and the TVS were covered with a black cloth, the target was the only visible light and, hence, was subjectively rather bright.

2.2. Subjects

Subjects were two males and three females who had visual acuity of > 1.0 with correction. Their age was 31.8 ± 5.9 years and accommodative amplitude 5.2 ± 1.2 D (mean ± SD). S5 was −5.5 D myopic and wore a soft contact. All subjects were trained as observers for visual experiments generally, but they had no prior experience of experiments with the TDOIII. They were not informed as to the purpose of the experiment in which they were participating. Their only defined task was to obtain as clear an image as possible.

Table 1. Amount of evoked accommodation and overshoot when subjects gazed at the three different stimuli. Upper rows of respective stimuli are the evoked accommodations (EA) and lower rows are overshoots (OS); SD, standard deviation. (a) Wyeth; (b, c) Hokusai; (d) Realistic target, condition R; (e) stereoscopic target, condition S. Apparent depth sensation of 2D stimuli evoked real accommodation. Larger evoked accommodations resulted from stimuli associated with binocular parallax; overshoots were evoked by stereoscopic images.

Stimuli		S1	S2	S3	S4	S5	Mean	SD
a	EA	0.59	0.68	0.68	0.65	0.78	0.68	0.07
Wyeth	OS	0.07	0.32	0.23	0.21	0.33	0.23	0.10
b	EA	0.25	0.29	0.41	0.36	0.44	0.35	0.08
Hokusai (Left)	OS	0.08	0.17	0.10	0.12	0.11	0.12	0.03
c	EA	0.29	0.26	0.29	0.32	0.31	0.29	0.02
Hokusai (Up right)	OS	0.10	0.10	0.08	0.09	0.14	0.10	0.02
d	EA	1.24	1.52	1.51	1.59	0.82	1.34	0.32
Condition R	OS	0.26	0.17	0.28	0.09	0.28	0.22	0.08
e	EA	0.33	0.79	0.75	0.50	0.57	0.59	0.19
Condition S	OS	0.13	0.81	0.34	0.26	0.58	0.42	0.27

2.3. Procedure

Visual conditions were changed stepwise every 10 s by computer control (beep or image change) to get 60 single responses. One session consisted of five presentations of each state and 12 sessions were done with 30-s interval recesses, during which subjects were instructed to relax their eyes at their own discretion. All the experiments were carried out binocularly and the 60 responses were averaged. Steady-state accommodation was defined by the average of the last 3 s of each response to eliminate transient responses. Then the difference between the two steady-state accommodations was defined as the evoked accommodation level in the two different visual conditions (EA in Table 1). The peak of accommodation was determined by the initial peak value. Overshoot (OS in Table 1) was defined to be the absolute value of the difference between the peak and the evoked steady state accommodation. Vergence was calculated by subtracting the horizontal eye positions of both eyes.

3. RESULTS

3.1. Actual Artwork Experiments (Experiments 1 and 2)

Subjects were instructed to gaze binocularly at predetermined points in a reproduction of *Christina's World 1948* (Figure 1a). The photograph was 31 x 23 cm and was placed 40 cm (i.e. 2.5 diopters) from the subject's eyes. They gazed alternately at N and F for 10 s each. Gaze positions were not recorded on the picture, but their location was specified verbally. Averaged responses of subject S1 are shown in Figure 1b in which the subject shifted his eye position at 5 and 15 s. If accommodation was purely controlled by blur there would be no need to change accommodation while looking at the drawing because it is kept at a fixed distance. However, when the subjects shifted their eye position from the shoulder of Christina (indicated by N) and looked at the horizon near the small hut (F), accommodation level (Acc) clearly receded. Inversely, when they looked back at the shoulder of Christina (N) an apparently near target, the accommodation level increased. The mean averaged

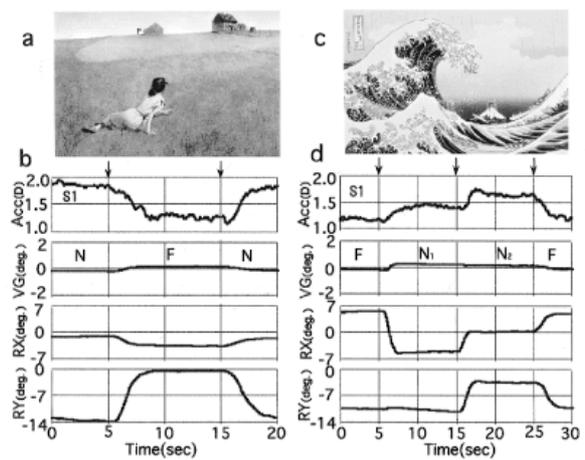

Figure 1. Drawings used for stimuli and resultant evoked accommodation. Both apparent depth and vertical gaze direction evoke accommodation without vergence. Accommodation evoked by the apparent depth sensation was larger than that due to raising eye position. Acc, accommodation; VG, vergence; RX, horizontal right eye position; RY, vertical right eye position. Gaze shift occurred at 5 and 15 s as indicated by the arrows.

accommodation of the five subjects was 0.68 ± 0.07 D (Table 1a). It is noteworthy that virtually no vergence (VG) was induced by this response.

By using a subjective measurement, Ripple (1952) reported that accommodation level decreased after raising the line of sight. Thus, there is a possibility that the accommodation measured might be induced by that effect. To check directly whether accommodation is really evoked by depth sensation independent of vertical eye movement, the second experiment used a reproduction of a woodcut made by K. Hokusai (*Mt Fuji Viewed Through Waves off the Coast of Kanagawa* from his "Thirty-six Views of Mt Fuji"; Figure 1c). The photograph was 37 x 25 cm and also was placed 40 cm from the subject's eyes. They gazed at F, N1 and N2 sequentially; these were separated by 7 cm each (visual angle was 8∞) and again the symbols were not only displayed on the picture, but only specified verbally. Subjects were instructed to look at the top of Fuji (F) in the middle of the picture, and then at two different points on the wave (N1, N2); the points were all at about the same distance from each other, but had different relative vertical positions.

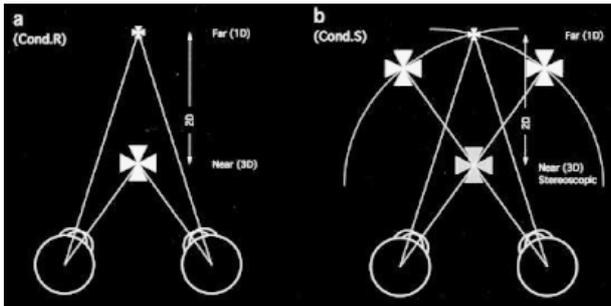
Figure 1d shows averaged responses of subject S1. Abbreviations are the same as in Figure 1b. Gaze shifts occurred at 5, 15 and 25 s. A small but significant amount of near accommodation was recorded on shifting eye position from F to N1; N1 and F were at the same vertical level. Then an additional small amount of near accommodation was induced when eye position moved obliquely from N1 to N2. The difference between the accommodation levels when looking at F and N1 can be considered as the amount of accommodation evoked purely by apparent depth; the difference in accommodation levels when looking at N1 and N2 can be considered to be accommodation evoked by apparent depth minus the accommodation evoked by raising the line of sight of 8°. The accommodation due to the depth cue was larger than the one due to moving the gaze direction vertically (Table 1). Also the vergence remained virtually constant.


Figure 2. Representation of stimuli in experiment 3. (a) A realistic image of a Maltese cross was presented; (b) a stereoscopic image of a Maltese cross was presented in which the real images were presented at 1D with proper binocular parallax and, hence, formed a stereoscopic image at 3D.

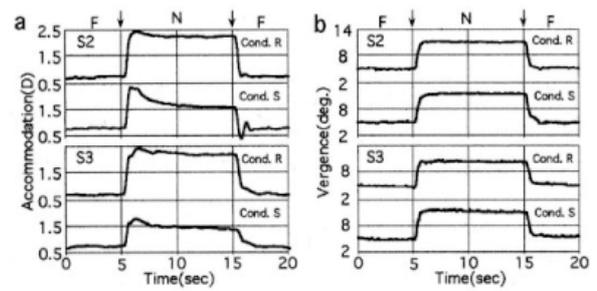

Figure 3. Accommodation and vergence responses of subjects S2 and S3 when they gazed at the Maltese cross in the TVS under conditions R (distance, binocular parallax and size were changed) and S (binocular parallax and size were changed but distance was kept constant).

3.2. Three-dimensional Experiment (3)

As there are many types of stereoscopic displays using binocular parallax and these displays are the easiest way to provide free stereoscopic images, it is interesting and necessary to know how accommodation is influenced by such devices.

Target distances of the Maltese cross were changed stepwise between 100 cm (1D) and 33 cm (3D) as shown schematically in Figure 2. In condition R, binocular parallax and target size were changed together with distance as if a real target had moved between the two points (Figure 2a). Then binocular parallax and target size were changed similarly to condition R, but the optical distance was kept fixed at the far point (1D) simulating stereoscopic displays (condition S; Figure 2b). Condition R simulated a real target movement between the two points and condition S simulated a virtual target movement.

Figure 3a and b shows the averaged accommodation and vergence responses of subjects S2 and S3 respectively. They showed larger accommodation shifts than they did for the previous stimuli (Figure 1). The amount of accommodation toward the realistic target (Table 1d) was about double that toward the stereoscopic target (Table 1e). Vergence responses were roughly equal for both conditions in both subjects, which roughly coincided with the amount expected from geometrical calculation.

Accommodative responses in condition S showed an additional interesting feature. The accommodation of subject S2 exhibited considerable overshoot (OS, defined as the absolute value of the difference between the peak and the evoked accommodation) then receded to a steady-state value. The overshoot of subject S3 was somewhat moderate. As for S2, S4 and S5, the overshoots in condition S were more than twice those in condition R (Table 1).

By expanding the time scale to between 5 and 7 s with subject S2's responses, it was found that vergence responses started 115 ± 19 and 120 ± 21 ms earlier than accommodation responses in the respective conditions (Figure 3c). Vergence was clearly driven by the change in binocular parallax; likely in condition S, accommodation was partially driven by the vergence and partially by perceived depth sensation. However, blur increased because the target was presented at a fixed distance of 1 diopter. Most likely, accommodation receded due to that increased blur. Accommodation recession was not clearly noted with the 2D picture stimuli (Figure 1, Table 1a–c).

4. VISUAL FATIGUE VIEWING STEREOSCOPIC DISPLAYS

It was shown that larger accommodation associated with vergence was evoked when looking at a stereoscopic image of the Maltese cross formed by the TVS binocularly (condition S in experiment 3). The accommodation evoked by the image should have been caused by the vergence and the perceived depth sensation. The amount of evoked accommodation reduced considerably from 1.34 ± 0.32 D in condition R to 0.59 ± 0.19 D in condition S.

The overshoots of accommodation in condition S were clearly larger than in condition R with S2, S4 and S5. It was moderately large in S3 and not large enough with S1. The hypothesis that the overshoot was larger in condition S than in condition R was not statistically significant. However, if we define the ratio of overshoot by overshoot/static evoked accommodation, the ratio in condition S was larger than the ratio in condition R.

From the above analyses, the overshoot in condition S seems somewhat larger than that in condition R. It was supposed that the vergence and strong depth sensation evoked larger accommodation in condition S compared with the previous two experiments (experiments 1–2), and the blur induced by the large accommodation reduced the accommodation in the condition S.

As the use of new visual informational displays has been steadily growing, there are emerging reports (Peli 1996) that visual fatigue might be induced by prolonged use of these displays. Although accommodation and vergence might have a close relationship with such phenomena, there has been no objective research on this issue. It is common to try to induce very strong depth sensations in stereoscopic movies so that audiences are attracted. Stimuli with considerable depth are presented with stereoscopic designs because they use displays at relatively close positions. The screens of head-mounted displays are very close to the eyes and it is easy to present stronger depth sensations even though the image is located optically farther than the physical distance with the aid of lenses. The strong 3D sensation evoked by those displays should produce large amounts of accommodation. Although such accommodation responses are natural when looking at real objects, it is not desirable from the standpoint of the visual system when viewing display because it increases the amount of blur and imposes an unnatural visual environment. Hence, this unnatural visual environment may produce a heavy visual burden and severe visual stress. Removal

of unnecessary wide-scale problems may occur in the near future, by achieving necessary improvements in modern informational displays.

In conclusion, it has been shown that (1) accommodation was evoked by the apparent depth sensation created from fine drawings or motion parallax, (2) the evoked accommodation was separated from the accommodation evoked by line of sight, (3) vergence was not affected by depth sensation with 2D stimuli under binocular viewing conditions, (4) stereoscopic stimuli (condition S) evoked larger accommodation compared with 2D stimuli, but evoked smaller accommodation compared with a realistic target (condition R), and (5) the near accommodation evoked by the stereoscopic condition receded considerably after an initial peak of near accommodation, probably because evoked near accommodation produced excessive amounts of blur. The results imply that the growing number of complaints in using the various stereoscopic displays or head-mounted displays largely come from this aspect of accommodation.

Warning Design

A. S. Adams

School of Psychology, University of New South Wales, Sydney NSW 2052, Australia

1. INTRODUCTION

A warning, for present purposes, is a safety communication device that should be designed to attract attention to itself, to give information about a hazard, its degree of seriousness, its probable consequences and of the way in which those consequences can be avoided. This chapter will discuss what is known about the principles that determine the effectiveness of a warning. It will not deal with legal questions such as requirements for particular wording, nor, except indirectly, with the question of when a warning should be used. In many countries there is legislation governing the design and use of warnings and such legislation will always take precedence. National standards associations, workplace safety organizations and consumer organizations are a good source of relevant information.

It may come as a surprise to some to hear that warnings often do not work, but that is indeed so. Why do we not obey warnings? Some claim that it is the severity of the consequence that determines behavior and that if the consequence warned about is severe, even though of low probability, we will be likely to obey a warning. Others claim it is the probability of injury that is critical, so that if a warning is about a low probability event, even if life-threatening, it is likely to be ignored. The details of this equation are still unclear. On a pharmaceutical product, for example, a warning about a very small probability of a life-threatening side effect will often cause a consumer to avoid the product. On the other hand, a workman who feels he can complete a job much faster by ignoring a warning and not using protective equipment may take the shortcut to save time even if the hazardous event to which he thereby lays himself open is life-threatening. There is evidence that such people see that the warning as being for other, possibly less skillful people, or simply that the accident will happen to others, not to them.

2. WARNINGS AS COMMUNICATION DEVICES

Although we may at times choose to ignore a warning of which we are well aware, the warning as a communication device can nevertheless perform more or less effectively. Many variables that determine the effectiveness of warnings have been studied. To place these variables in context one must first examine how a warning achieves its aim. Various models have been proposed, but broadly speaking if a warning is to be complied with it must first be seen and understood, and then, after that, there must be appropriate attitudes and motivation to comply on the part of the receiver.

The first two processes of seeing and understanding each require something of the warning device on the one hand and of the receiver of the warning on the other. If either factor in any sense "scores a zero" there will be no communication. Most of this article relates to the design of the warning device, but it is important to note that if the intended receiver of the warning is not in some sense receptive to it, the warning, no matter how well designed, will be ineffective. Thus, someone who is familiar with a situation may not see a prominent warning. Even if the warning is seen, someone who assesses the situation and feels that that they can function without heeding the warning may well do just that, possibly judging that the warning is there for the benefit of others who lack their skill or knowledge.

Action in the presence of a warning has many determinants, the information received from the warning itself being only one of them. Because this article is concerned with warning design, variables relating to the receiver of the warning or the circumstances in which the warning occurs will not be discussed, except indirectly. These include the age and sex of the receiver of the warning, the cost of compliance – for example how easy it is to obtain and use any equipment referred to in a warning – and social variables such as whether or not others are seen to comply with the warning. Suffice it to say that all these variables have been found to be important determinants of compliance.

3. DESIGN VARIABLES AFFECTING THE PERFORMANCE OF WARNINGS

Some 55 papers concerned with the ergonomics of warnings have been gathered in Laughery et al. (1994). Laughery and Wogalter (1997) also provide more details than can be covered here. What follows is a brief overview of the principles that have emerged from this research.

3.1. Signal Word, Color and Size

A warning must first attract attention to itself. One way most written warnings do this is by using a prominent signal word that both draws attention and provides an indication of the level of urgency of the warning. The words DANGER, POISON, DEATH have been shown to connote the highest level of urgency, followed by CAUTION and WARNING.

The way in which the wording on a warning is displayed is of obvious importance. A general principle governing the perception of written material is that high contrast is required for good legibility. The use of the color red is of assistance in drawing attention to a warning as it has been shown to be associated with higher urgency. However, this will only apply when red is not used extensively in the area immediately surrounding the warning.

Size is also of importance, although practical considerations usually set a limit to size. In a consumer survey on product warnings a householder commented on a large warning found on a household product by saying, "It's big, they must mean it." However, size or other features designed to ensure prominence will have a diminishing effect if they are used too extensively. We have already reached a point with road warnings where inordinate size is now needed to draw attention to a sign warning of some new and possibly unexpected hazard.

Finally, the font used is important, particularly where space is at a premium and a warning is designed to be seen from some distance – road signs, for example. Recent research has resulted in the development of a new font called Clearview that provides better legibility on a sign of a given size than existing fonts. In general, where more than a few words are involved, all upper case should be avoided.

3.2. Hazard Information, Consequences and Instructions

The signal word used with a warning draws attention and provides some information about the severity of the hazard – DANGER usually signifies a potentially life-threatening hazard, and CAUTION or WARNING something less significant. The remainder of the warning must then provide sufficient detail to enable those to whom the warning is directed to determine the severity of the hazard, the consequences of not complying with the warning and the behavior needed to avoid the stated or implied consequences.

In many work situations only a minimal amount of information is required to impart the appropriate message. In a steel foundry, for example, a sign saying "DANGER, Molten Steel" may be quite sufficient to remind workers of a whole range of possible hazards, consequences and appropriate avoidance behaviors. In other circumstances a warning may be required precisely because a given hazard is not well appreciated. Hazards associated with chemicals or solvents, for example, are often ill appreciated.

3.3. Use of Pictorial Devices such as Symbols

Many warnings use symbolic devices as part of the warning. There are a number of reasons for this. The most obvious is that a warning imparted by means of a symbol can communicate without the use of language and may therefore obviate the need for a multilingual presentation. Another reason is that the use of symbols may enhance the attention-getting aspects of the warning as a whole and may also make the warning visible from a greater distance. Finally, a warning presented in the form of a symbol may be understood more rapidly than one that requires the reading of a complete phrase or sentence.

A rather different reason for using a symbol is that even though it may not convey sufficient information, the symbol may serve the alerting function otherwise achieved with a signal word such as DANGER. For example, it is a convention embodied in a number of national and international standards that warnings should be symbolized by using a black symbol on a yellow triangular or diamond background with a heavy black border.

Figure 1. The poison warning symbol: an example of a warning symbol that is not well understood.

Figure 1 shows two warning signs using these conventions. Often the diamond is used within the road context and the triangle, as shown, within industry.

The warning shown in Figure 1 has been chosen because it is not well understood. However, the effect of using these symbols on a product, in a brochure, or at a work site is to draw attention and suggest danger, all without words. Often the exclamation point is used in conjunction with a worded sign primarily as a device to draw attention, and only secondarily to convey to at least some people the idea that the wording contains a warning.

Symbols are not an easy solution for problem warnings, nor for the language problem. Any warning, whether conveyed through the medium of words or of a symbol, must be clearly understood. Let one assume that 75% of a population as a whole can understand a poison warning written in English on a pesticide product, and that the 25% who cannot is made up of a significant proportion who can read only some other language. A judge in a court case suggested that in these circumstances a skull and crossbones poison warning symbol (Figure 1b) would have been an appropriate alternative to a multilingual warning. However, in a random-sample survey in the UK in 1977 this symbol was shown to 479 respondents. The symbol was shown within the triangle shape commonly used for warnings and was tested together with other symbols. On a very lenient criterion only 48% of the respondents correctly identified the symbol as indicating a poison. Thus the symbol used alone would have communicated successfully with a smaller proportion of the population than the English language warning used alone.

When designing a warning symbol there are guidelines that can improve legibility and comprehension. These are embodied in a number of national and international standards dealing with the use of symbols in signs in general, and in warnings in particular. International Standard ISO 9186:1989 (currently under revision) and Australian Standard 2342 – 1992 give guidelines for designing legible symbols and methods for testing their comprehension. ANSI Z535 from the USA gives extensive guidelines. For common warning symbols, such as "No Smoking", "No Swimming" and "Danger, electrical hazard," standardized symbols exist that have been subject to testing. Designing successful symbols for new concepts, however, has proven more difficult. The standards mentioned above require between 66 and 85% comprehension among a representative sample of users. In general these targets have been difficult to meet for complex concepts such as, "In case of fire do not use lift" or "Danger, freak waves — do not fish off the rocks."

In some circumstances it may be possible to convey a concept by means of several symbols in succession, much like a cartoon strip. This method has been used successfully to produce a warning for use on packets of candles to indicate that lighted candles should not be left unattended. If color is available for a symbol such as this the negating cross should be in red.

3.4. Location of Warnings

Much research has gone into the design details of warnings, but rather less into the question of where a symbol sign should be located to enhance its attention-getting properties. From the small pharmaceutical vial that provides insufficient space, to the household product on which the manufacturer deliberately wishes to minimize the prominence of a warning, each product presents

its own challenges. For a warning to be useful it must be appropriately attention getting and it must be present at the time the user needs it. This may be at the time of purchase, possibly to alert the user to the fact that certain protective equipment is required, or at the time of use to remind the user to make use of that equipment or to follow certain safety instructions. It is easy to say that the warning must be prominent, but how is adequate prominence to be judged? There is no easy answer as few situations requiring a warning are so standardized that a ready-made solution is available. The only recourse is to appropriate testing.

4. TESTING

Whenever a solution is proposed to a warning problem, the question, "How do we know it will work" should always be asked. Traditionally, a number of alternative solutions are proposed and each is examined experimentally to determine the best. This approach, however, is highly resource intensive; for example, it requires that each proposed alternative be designed to the completed stage. ISO 9186 presents methods for testing the comprehension of symbol signs that might be used as warnings. Over the years the methods proposed in the various drafts and revisions of that standard have become more and more efficient. A recently proposed method simply requires a group of respondents to record their judgements of how effective they think a given symbol will be. A formalized method of aggregating this data is presented in the standard so that the method can be used as a useful preliminary check. Adams (1998) describes the use of efficient testing-as-you-go methods. These methods are based on an iterative "process" testing method rather than the single-shot "outcome" experimental method often used to compare alternatives.

5. AUDITORY WARNINGS

Finally, nothing so far has been said about auditory warnings, as an entire article would be required to do justice to the problems they present. Briefly, the informational properties of an auditory warning must be entirely learned. An auditory warning such as an alarm in an intensive care unit does not of itself provide information about the hazard, its consequences or about how to avoid the hazard. However, the relative urgency of the situation signaled by an auditory warning can be indicated by the judicious choice of the warning's sound. Where a number of such warnings can occur in the same space, such as in an aircraft cockpit or an intensive care unit, care must be taken that interference, or masking, of one sound by another does not occur. For further information about problems such as these, and appropriate design solutions, see Edworthy and Adams (1996).

Workplace and Equipment Design

Active Safety in Car Design

S. Doi

Human Factors Division, Toyota Central R&D Labs., Inc., Nagakute, Aichi, 480-1192, Japan

1. INTRODUCTION

In car design, it is indispensable that there is compatibility between safety, comfort, and energy consumption and environmental safety along with traffic smoothness and efficiency. In future transport systems, driver/vehicle/environment interactions are major issues in active safety of vehicle operations.

Human factors are the major cause of vehicle accidents. Almost all the causes of accidents are related to human factors involved in the driver's maneuvers: especially on the errors of recognition, judgement and operation. Human response and sensitiveness are very individual matters and completeness of driving safety is not merely obtained not only from the averaged value of the operational characteristics, but also from the accomplishments of the grasping the limits of the performances. Improving the maneuverability of the vehicle is an urgent problem for vehicle-based technologies like collision avoidance systems. In this field of studies it is necessary to discuss from the point of view of the man-in-the-loop to consider active safety performance of the vehicle.

2. FUNDAMENTALS OF VEHICLE SAFETY

2.1. Classification

Vehicle safety is usually classified into active and passive safety according to the situations before and after accidents. In active safety emergent operations of drivers and human errors are the main causes of accidents. Just before an accident emergency, avoiding performance is needed for vehicle. Prior to the accidental situations, driver-aid systems are necessary for maintaining safety driving and for preventing accidents. On the contrary, in passive safety, various driver protections are equipped in the vehicle and life-saving infrastructure.

2.2. Roles of Vehicle, Driver and Traffic Environments

2.2.1. Vehicle

The role of vehicle for active safety is:
- Principal performance of fundamental functions (stopping and steering).
- Driving visual cues and visibility.
- Maneuverability of steering and other operations.
- Free from stress and fatigue for long-term driving.
- Emergency-avoiding operations.

2.2.2. Driver

Depending on driver performance, the role of the driver is demanded as:
- Consciousness of safety driving.
- Adequate operation for smooth driving.
- Concentration for driving manners.
- Reflective operations for emergency avoidance.

2.2.3. Environment

Regarding traffic information, the role of traffic environments is:
- Suitable traffic infrastructure.
- Fully traffic information.
- Safety road environments.
- Roadside infrastructure and environments.

2.3. System Architecture

2.3.1. Intelligent transport systems

The goal of the ITS (intelligent transport systems) is multimodal effectiveness in every traffic system. Above all, vehicle safety is the key technology uniting with drive/vehicle/environment in these movements. System architecture is most important for a worldwide standardization of the apparatus.

2.3.2. Road traffic system

The next subsystem is the road traffic system whose elements are constructed with road information systems and the communicate systems between cars and roads. Each subsystem has an interface with other systems. Between these interfaces, the human–machine interfaces are more complicated for designing the equipment.

2.3.3. Vehicle safety system

Another subsystem is vehicle control and driver-aid, which consists of an information system like navigator and steering/braking operational systems. These components should be organized in human–machine system for the active safety of the vehicle. Both system technologies are composed with various systems:

1. Warning system technologies:
- Warning system for emergent driver conditions.
- Warning system for dangerous vehicle conditions.
- Vision enhancement system.
- Vision enhancement in nighttime driving and nighttime object detection.
- Blind area monitoring/warning system.
- Surroundings warning system.
- Road environment information acquisition/warning system.
- Inter-vehicle communication/warning system.
- Driver workload warning/reduction system.

2. Avoidance system technologies:
- Intelligent vehicle control system.
- Driver's hazardous condition detecting system.
- Blind area accidental avoidance system.
- Collision avoidance system with surrounding obstacles.
- Collision avoidance system utilizing road information.

2.4. Tools for Investigations

2.4.1. Driving simulator

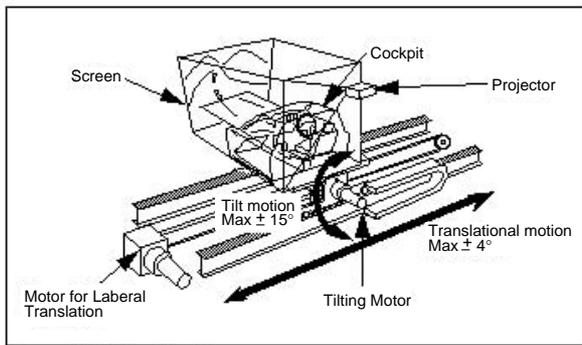
Supposing a road traffic situation and information system in the car, driver/road/information interactions are used to investigate in the virtual environment of driving. The remarkable tools for such kinds of research are so-called driving simulators. Examples used in these studies are illustrated in Figure 1. The simulator is constructed with the moving base of 2 degrees of freedom, namely roll and lateral motions. On the moving base, the systems are mounted with driving cockpit and visual screen. Driving seat is


Figure 1. Driving simulator.

installed in the half-cut vehicle body and the visual scenes given by computer graphics systems according to the driver's operations.

2.4.2. Elements of simulator

Both of the motion and visual systems are controlled by computational vehicle model. The vehicle model has 3 degrees of freedom: longitudinal, lateral and yawing motions. The tires are modeled by an equation with combined status of lateral and longitudinal acting forces. The dynamic vehicle motion is calculated with a computer from the input signals of the driver, namely gas and brake pedal stroke, and steering wheel angle. The projected visual angle is 60° wide at the screen located at 2.5 m ahead from the driver. Inside the cockpit, imitating systems are equipped for steering efforts and interior noise/vibrations corresponding to the state of the running conditions.

The motion base is moved laterally by chained belts along the pair of lateral rails and rotating by another motor installed under the bottom of the cockpit. In the systems, the lateral motion is controlled proportionally by the calculated lateral displacements of the vehicle model and the rotational motion is also controlled according to the centripetal acceleration by the vehicle speed and the road curvature of supposed situations. Using the simulator, driver's behavior and vehicle performance are measured quantitatively in the same time.

3. DRIVER AND VEHICLE SYSTEMS

3.1. Emergency Avoidance Maneuvers

3.1.1. Emergent situations

Several kinds of experimental tasks for emergency avoidance are used to examine driver and vehicle systems. One is a stationary obstacle avoidance task, which can regenerate the same situations in the proving ground. The next case is a sudden emerged moving obstacle during running on the road. The other is an unexpected road surface change during running on curved roads. These tasks are supposed to be ordinary roads and the experimental subjects are used to be ordinary drivers, including female and elderly drivers. In more detail, these driving behaviors are examined by imitating obstacle emerging behind walls beside the way and sudden change to slippery surface on cornering.

3.1.2. Reaction time

From the results of these obstacle avoidance, the database of driver's operational characteristics depended on the modes of avoiding maneuver is derived. Comparing with the individual

operational characteristics, the difference of reaction time between the case of success and fail (collision) and the amount of each operation is clarified. According to the reaction time, in the emergent behaviors, driver response time for releasing the gas pedal is ~0.6 s and braking pedal reaction time is ~0.98 s. On the contrary, the steering reaction time is ~0.64 s on average. Comparing with these data from observation of driving managing behaviors leads to the relation between reaction time of braking/steering in various situations.

3.2. Driver Behavior Model

3.2.1. Model structure

A mathematical driver-operating model is derived from experimental data of emergent situations. The model is constructed with steering (lateral control) and the braking (longitudinal) operation.

3.2.2. Steering model

The parts of steering operation are based on the variable preview time and variable preview point. The model is constructed with three parts: prediction, target course generation and steering control block. In the prediction block, it is assumed that the driver involves the simple vehicle model and predicts the future vehicle position and vehicle state values. In the target course generation block, the driver's operating model generates the course of before and after the obstacle emerging. In the steering control block, steering angle is derived as a type of integral control that minimizes the both of corrected steering angle and the deviation between generated and predicted courses.

3.2.3. Braking model

The braking operation is expressed with the first-order delay system with lag time from the basis of experimental results. The lag time is equivalent to the braking reaction time. The gain of the first-order delay system is the maximum brake pedal stroke. The time constant corresponds to the time from the beginning of the braking operation to reach the maximum brake pedal stroke.

3.3. Evaluation of Active Safety Performance

3.3.1. Evaluation methods

Combining the driver model with the vehicle model, using the database of driver behaviors, driver–vehicle performance in the so-called man-in-the-loop is calculated for various cases of emergency. An example of a schematic diagram of performance evaluation methods is shown in Figure 2.

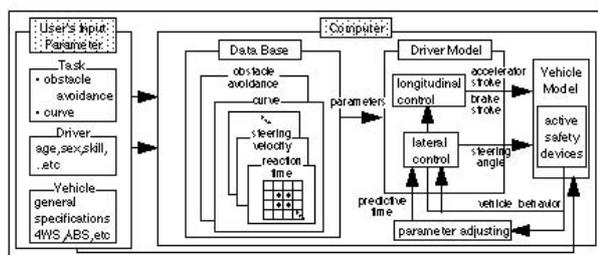

Figure 2. Schematic diagram of driver–vehicle performance evaluation system.

3.3.2. Flow of evaluation

First the user chooses the certain emergent task depending to the road situation and driver/vehicle specifications. Next, he selects the driver's characteristics from the database. As these supposed parameters are fixed, the last part of vehicle performances on the emergency is estimated by calculating the combined models.

3.4. Verification of the Effect of Control for Safety Driving

On design of vehicle control, using the above evaluation methods, the estimated effect is verified with the experimental behaviors in the driving simulator, for instance whether the trajectories of the vehicles would be similar with each other and steering maneuvers would be also improved. The subjective judgements of the drivers are also checked to be better operational feeling and the recovery of vehicle direction would be fairly improved. Thus, the driver-managing performance of the emergent situations is evaluated in advance with estimation of the effect of assistant control of vehicle.

4. DESIGNS FOR ACTIVE SAFETY PERFORMANCES

4.1. Stopping with Brake Assistance

4.1.1. Braking task

The design of braking characteristics is executed by the simulations with obstacle avoidance performance of the driver. In the case of emerging obstacle, supposing vehicle speed is 60 km/h, the gap length to the obstacle is 40 m in time of obstacle start to emerge, the avoiding performance is evaluated for associated behaviors with braking and steering. The driver's skill is supposed to be below the averaged, namely maximum steering velocity is 200°/s. The obstacle avoidance performance is shown with braking stroke as the functions of brake and steering reaction time.

4.1.2. Performance estimation

Performance is classified in three cases: avoidance, namely success to avoid the obstacle, the collision to the obstacle and the road-departure from the road edge. According to the results of avoiding ability concerned with both of brake and steering reaction time, the drivers who operate in a greater than steering reaction time of 1.0 s would came into collision to the obstacle. On the contrary, even if for rapid steering, delayed braking action over 0.8 s leads to the road-departure from the road edge. According to the amount of brake stroke, the avoiding ability would be increased with the stroke and the braking assistance control system is expected to be effective for poor power drivers.

4.2. Cornering with Vehicle Steering Control

4.2.1. Emergency on a curved road

Another emergent situation is sudden surface change to a slippery condition during a curved road. In the case that frictional coefficient of road surface is changed from 1.0 to 0.5 in rear wheel, supposing vehicle speed is 70 km/h and the curvature of the road is 100 m, the managing performance of the vehicle is evaluated in three kinds of steering reaction time. In these cases the prediction time in the driver model is supposed to be changed from 0.7 to 0.5 s before and after entering the low frictional area. The estimated results are shown that there are three patterns for managing performance on slippery curved roads.

4.2.2. Effect of steering control

Driver's assistance in emergent situation would be of necessity to improve driver–vehicle closed loop performance. Supposing the assistant steering controls, the effects of the control on the performance are evaluated.

In the cases of differential steering control and yaw-rate feed back control, the estimated vehicle trajectories, steering angles and front steer angle at that time are calculated. From the computational results every controlled case is effective for preventing the divergent phenomena of the vehicle after entering the low frictional area. The controlled case is fairly stable in the trajectory of the vehicle and would be estimated to stay within the lane. Thus, the driver-managing performance of the emergent situations is evaluated with estimation of the effect of assistant steering control.

4.3. Running with Mental Workload

There are many factors including environmental, mechanical and human factors that cause driving fatigue. Among these factors, vibration is one of the major factors because drivers are usually exposed to sustained mechanical vibrations including mental as well as physical stress.

Design of suspension is related to fatigue of the driver with mental workload during long-term driving. The influence of vibrations at low frequency, corresponding to the resonance of human head, is derived from basic statistical analyses of the relations between subjective ratings of fatigue and physiological variables. The suspension control capable of reducing the vibration prevented driver fatigue at a significant level in actual driving.

5. DESIGN OF HUMAN–MACHINE INTERFACE FOR ADVANCED TRAFFIC ENVIRONMENT

The new century is the age of advanced traffic environment organized by information as well as the cooperative relations of driver and vehicle. It would be of great issues how to construct

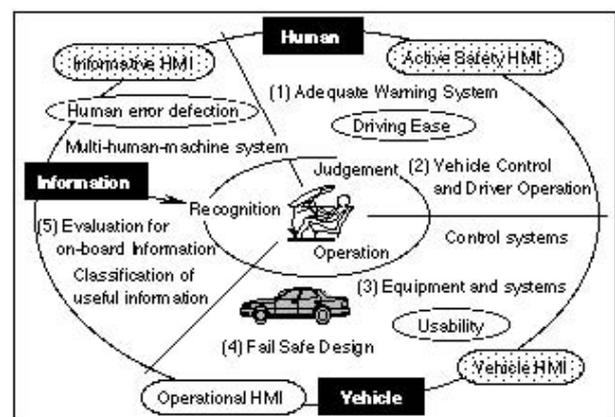

Figure 3. Human–machine interface (HMI) in active safety.

the human–machine interface toward driving support equipment and on-board information systems maintaining and improving the optimal and interactive relations with drivers.

In advanced active safety, there are four categories of the human–machine interface and five aspects of design problems as followings and they are illustrated in Figure 3 concerning to driver functions.

- Timely and adequate warning for driver.
- Sharing the responsibility with vehicle control and driver's operation.
- Equipment and system for understandable limit of vehicle critical performance.
- Fail safe design for total man–vehicle system.
- Setting criteria for on-board information system.

To make better solutions for these problems, it is more effective and necessary to take the considerations for analysis of physiological aspects for driver recognition and judging mechanism. A more psychological approach would be expected for human operational behaviors corresponding to the mental workload due to information during driving.

6. INTERACTIVE DESIGN WITH THE DRIVER

There are new approaches to develop the system technology to make the driver environment suitable to individual driving behavior. Aiming at better interactive design with driver, the behavior-based safety driving technology is consisted with three steps:

- Real-time measuring of personal behavior and learning the pattern of the individuals.
- Comparing with the accumulated database of behaviors to

understand the driver's situations and making a model-based approach to follow the individual manners.
- Fitting with individual personal behaviors by driver-aid systems.

According to our senior designer's remarks, preferable features of vehicle in the future are:

- Behind the wheel and willing to turn.
- Enjoyable to run about.
- Feel freely and operationally with ease.
- With comfortable sound and vibration.
- Affective and thrilling to drive.

Active safety design is still on the way to realizing the goal, but much remains to be done. Finally, taking these evaluation criteria into account, it should be more effective and adequate when designing the driving safety devices to make a better human interface in future transport systems.

Analysis of Office Systems

M. M. Robertson

Liberty Mutual Research Center, Hopkinton, MA 01748, USA

1. INTRODUCTION

Intensive use of computer and information technology for long periods of time in the office workplace calls for an examination of employee performance and possible work-related health and stress problems. The nature of these technologies and the work environment influence employee musculoskeletal fatigue, discomfort, and pain (e.g. Cakir, Hart, and Stewart 1978; Smith and Carayon 1989; Sauter, Dainoff, and Smith 1990), and may have an adverse effect on work effectiveness, stress and work-related musculoskeletal disorders (WMSDs) (e.g. Bongers, De Winter, Kimpier, and Hildebrandt 1993; Kuorinka and Forcier 1995).

Office systems, by their nature, are complex and multivariate. Understanding the potential causal factors of problems arising from poorly designed office systems, requires a macroergonomic approach using systems analysis and processes. The traditional *microergonomic* approach to office work environments emphasizes the microscale aspect of the work environment at the individual workstation (e.g. keyboard, screen image, manuscript placement, etc.) (see, for example, Sauter, Dainoff, and Smith 1990; Robertson and Rahimi 1990). Broadening this approach to a macroergonomic level, other office system components including physical environmental variables (e.g. layout, storage, and adjustability), work tasks, work organization, organizational structural, technology characteristics, and psychosocial variables are recognized as impacting individual, group, and organizational performance (Smith and Sainfort 1989; Robertson and Rahimi 1990; O'Neill 1998; Swanson and Sauter 1999). Understanding the interrelationships of these elements and their effects on health, stress, work, and organizational goals is necessary to provide a comprehensive or systems perspective of office environments.

With a macroergonomics approach, systems tools and processes are used to develop strategic criteria for the design of an office work system where the social and technical sub-systems are congruent with the organizational mission. Directed by strategic level criteria, problem-solving tools such as ergonomic analysis for workstation or job design enhances organizational effectiveness. Prior research suggests that there is the potential for translating the findings from a macroergonomic approach into relevant office system design and organizational planning interventions (e.g. O'Neill 1998; Hendrick 1997; Robertson and Robinson 1995).

This article provides an overview of a systems analysis tool using a macroergonomic approach to understand and identify problems and probable causal factors related to such office environments. Systems analysis also provides a *process* for developing strategic and systematic solutions for solving problems arising in a computer intensive office environment. The interventions and solutions presented here are based on 20 years of research and case studies drawn from a global sample of office technologies environments. Systems analysis also provides for the development of alternative solutions with techniques for evaluating the cost/benefits of each alternative, selecting and implementing solutions, and providing feedback and measurement of improved worker performance. By applying this systems analysis tool, the interaction and fit of the office worker, the job tasks, the organization structure, and the physical environment is improved, resulting in a more effective office as well as healthful work environment.

2. APPLYING A SYSTEMS ANALYSIS TOOL: UNDERSTANDING OFFICE WORK SYSTEMS

In applying systems analysis, the level of analysis is targeted at the business unit or departmental level, where specific objectives and issues are identified. Individual and group needs are also identified.

The following systems analysis tool is one frequently used in business and industry and is a modification of one proposed by Mosard (1982), which is based on earlier work in systems engineering. There are six analytic steps:
1. Defining the problem: The problem factor tree (see figure 1).
2. Setting objectives, developing an evaluation criteria table, and developing alternatives: The objectives/activities tree (see figure 2).
3. Modeling the alternatives: The input–output flow diagram (see figure 3).
4. Evaluating alternatives: The criteria scorecard: cost/benefit analysis (see table 1).
5. Selecting an alternative: The decision table: selecting an alternative based on future conditions (see table 2).
6. Planning for implementation, evaluation and modification: Scheduling and management project flow.

3. STEP 1: DEFINING THE PROBLEM: THE PROBLEM FACTOR TREE

Complexity is inherent in performance problems, therefore a systematic analytic approach to issue definition is necessary. From data previously collected or recently observed, a problem factor tree is constructed which identifies the problem, sub-problems, and causal factors, including their interrelationships (Mosard 1982).

A completed problem factor tree depicts a hierarchical, logical structure identifying the problematic elements (see figure 1). To develop a problem factor tree, work issues and problems are precisely stated and linked together through an iterative process (Mosard 1982). The lower level causal factors in the tree contribute to the major problem. Feedback loops may also be incorporated. The problem in an office work system is defined as: "An increase in turnover, lost work days, and claims disabilities, and a decrease in performance and effectiveness of office workers caused by occupational stress from office technologies and office system design" (see figure 1). It is hypothesized that the problem is caused by occupational stress from office technologies and workplace design. Further research revealed two contributory sub-problems: (1) psychosomatic stress, and (2) physiological stress. In addition, two sub-problems of psychosomatic stress were found: (1) psychosocial disturbances, and (2) perceived lack of environmental control.

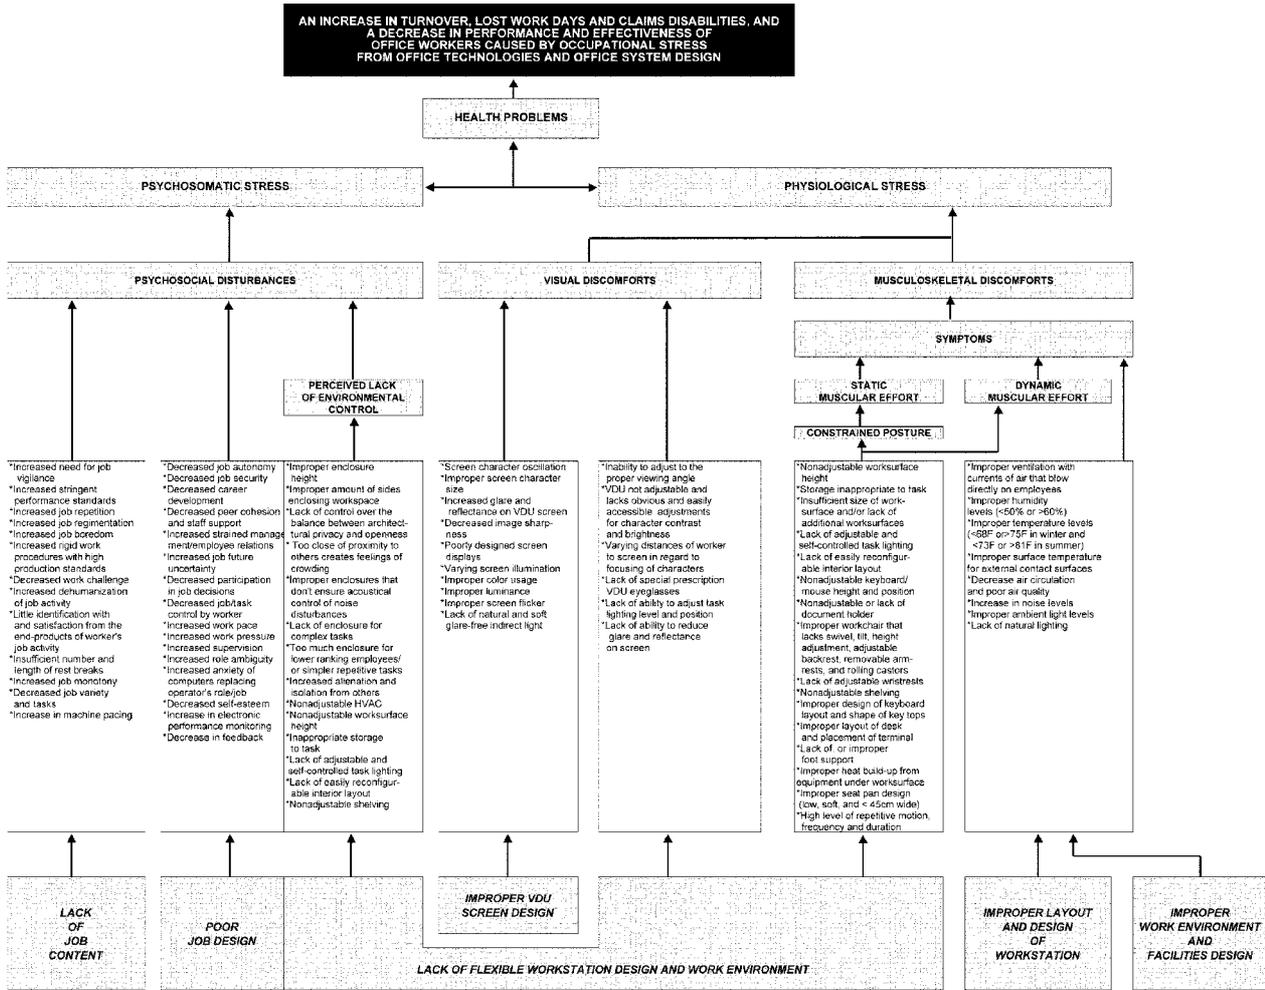
Figure 1 also shows other potential causal factors which contribute to the defined problem: lack of job content, poor job design, and lack of flexible workstation design. These are depicted


Figure 1. Increase in turnover, lost work days and claims disabilities, and decrease in performance and effectiveness.

at the base of the hierarchical structure. For the potential causal factors in job content and job design, several individual and group level factors are identified and shown in the middle of the tree. Poor job design components may include teamwork or collaborative issues at the departmental level, such as cross-functional teams, or at the individual level of a small, informal group gathering. Job content and job design should be viewed as the main element of the social sub-system. Potential casual factors in the technical sub-system are primarily located in the workstation design, layout configuration of the workspace, and screen design. Of the many sub-problems identified in regard to physiological stress, two are of paramount importance: visual and musculoskeletal discomforts. Numerous potential factors are shown, contributing to both of these sub-problems, including lack of flexible workstation design, improper VDU screen design, and improper layout and design of the workstation.

The problem factor tree depicts the causal factors and sub-problems that represent the integration of *microergonomic* and *macroergonomic* office system components and sub-systems, including organizational and job design issues. This initial step of the system analysis lends itself to developing an understanding of the technical and social sub-systems as well as the work environment sub-system. Other robust and valid systems tools

based on sociotechnical processes can be applied together with this particular system approach and model (e.g. Smith and Sainfort 1989; Hendrick 1997).

4. STEP 2: SETTING THE OBJECTIVES AND DEVELOPING ALTERNATIVES: THE OBJECTIVES/ACTIVITIES TREE

Objectives and evaluation criteria are developed for use in selecting the best alternative to address the causal factors. An "objective tree" is a hierarchical, graphical structure of objectives that address previously identified problems (Mosard 1983). The tree is created by identifying major needs, goals, objectives, and sub-objectives. In figure 2, the objective tree is depicted in the upper half of the figure and shows the major goals as: (1) "Decrease lost work days, claims disabilities, and turnover", and (2) "Increase performance and effectiveness of office workers by alleviating occupational stress from office system design and technologies."

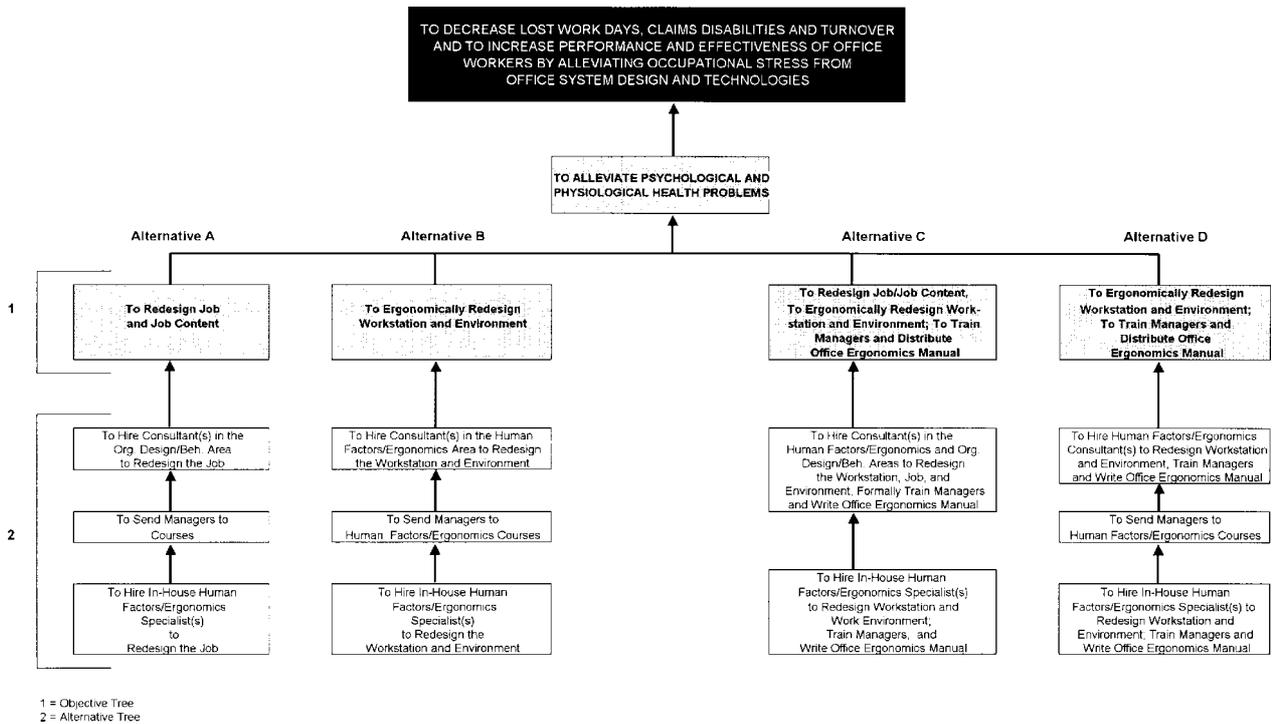
The objective tree shown in figure 2 addresses the inherent psychological and physiological health problems. Alternatives are defined as a specified set of activities, tasks or programs designed to accomplish an objective (Mosard 1982). The objective/activity tree in figure 2 illustrates four alternatives, A through D, and


Figure 2. Ways of decreasing lost work days, claims disabilities and turnover, and increasing performance and effectiveness.

their appropriate set of activities. Four sub-objectives are defined: (A) redesign the job and job content; (B) ergonomically redesign the workstation and environment; (C) redesign the job, and (D) ergonomically redesign the workstation and environment and to train managers in job and workstation redesign and awareness and to write an office ergonomics manual. The degree of interaction between objectives, constraints, and the persons/ groups involved in the process should also be analyzed (Mosard 1982). Hybrid alternatives may be created which incorporate the best features of any of the initially identified alternatives. Alternative C is a hybrid alternative representing one of the many possible combinations of common activities. The four alternatives depicted were derived from case studies, field research, and longitudinal studies representing typical approaches implemented by companies to achieve the objective listed at the top of figure 2 (Smith and Sainfort 1989; Robertson and Robinson 1995; Robertson, Robinson, O'Neill, and Sless 1998; O'Neill 1998).

After the objectives and alternatives are selected, a preliminary decision criteria table is developed. This table is used to evaluate the "usefulness" of each of the alternatives as methods for accomplishing the objectives. Decision criteria typically include risks, costs, expected benefits, and measure of effectiveness, based on short-term and long-term perspectives (Mosard 1982).

5. STEP 3: MODELING THE ALTERNATIVES: THE INPUT–OUTPUT FLOW DIAGRAM

A descriptive or predictive model representing either each alternative set of activities or representing the entire system is developed. This is designed to allow alternative configurations to the systems to be analyzed. The system element interrelationship and/or gross resource requirements are depicted in order to determine the effectiveness of each alternative set of activities (Mosard 1982). Modeling techniques such as flow charts,

simulation, and systems dynamics modeling may also be used in this step.

The model used in this analysis is an input–output flow diagram (Mosard 1982). This modeling technique allows alternative configurations of the systems to be analyzed. In utilizing the input–output flow diagram, the inputs consist of people, resources, and information, and the outputs are the results and products. These outputs can, in themselves, become the sources of inputs to other sub-systems, and thus extend the diagram to fully represent the entire system being analyzed. Figure 3 illustrates the two phases of this model: the redesign phase and the operation phase. Inputs for the redesign phase include contributions from two general areas, human resources and financial resources. In the human resources component, individuals such as industrial psychologists, managers, employees, human resource managers, ergonomists, facility operations, trainers, and health and safety managers are included. The activities for each redesign project or program listed for phase 1, are shown in the left input box in figure 3. At the end of the redesign phase, the outputs become the inputs for the second phase, the operation phase. For example, in the job redesign program, managers and employees have acquired new skills and the jobs have been analyzed and redesigned. The managers and the employees will now interact within their own work systems and the results of these interactions are presented in the outputs (e.g. increase in performance, decrease in job stress, decrease in injury claims, and worker's compensation cases). Overall, these outputs fall into the categories of: changes in employee and group behaviors, organizational factors and reduction in business costs.

* Job Analysis and Job Evaluation
* Development and Use of the Office Ergonomics Manual

Managers and Employees Acquire New Skills; Job Design as well as Ergonomic Design

IMPLEMENTATION OF CHANGES

Increase in employee Performance

Increase in Employee Morale

Increase Work Group Effectiveness

Decrease in Absenteeism

Reduction to Health Risks

Decrease in Job Stress

Decrease in Employee Turnover

Improved Manager/ Employee Relations

Decrease in Litigation Cases

Decrease in Insurance costs

Decrease in Worker's Compensation Cases

Figure 3.   The two phases of an input–output flow diagram.

6. STEP 4: EVALUATING THE ALTERNATIVES: THE CRITERIA SCORECARD: COST/BENEFIT ANALYSIS

Evaluating alternatives is accomplished by measuring and comparing each alternative set of activities utilizing major decision criteria. These criteria generally include: project cost, risk of failure, effectiveness, and benefits for all appropriate future conditions. An evaluation criteria scorecard is developed for use in evaluating and comparing alternatives shown in table 1. The scorecard is based on a long-term perspective and incorporates the preliminary decision criteria previously defined in step 2.

Four alternatives were selected based on experiences that many organizations have had regarding activities for the implementation of office technologies (Robertson *et. al.* 1998; Sauter, Dainoff and Smith 1990). To complete a comprehensive cost-effective analysis for these alternatives, an economic advantage analysis is conducted. The economic advantage analysis identifies costs and benefits to provide an economic analysis for each alternative (Robertson and Rahimi 1991). This analysis further provides the detail which links the costs for each internal *micro* and *macro* work environment program and/or features of the physical work environment to the potential leverage in the investment in annual compensation for the employees in the improved environment.

The economic advantage analysis identifies costs and effectiveness metrics, including: (1) human resource costs (e.g. compensation, salary, turnover, and absenteeism, workers' compensation costs, injury costs); (2) facilities costs (work environment), (e.g. rentable space, operating costs, annual facility costs, furniture investments, technology and information investments, work environment strategy costs, construction costs); and (3) effectiveness measures (organizational (e.g. process

Table 1. Criteria Scorecard:Cost/Benefit Analysis[1]

Alternatives	Project Cost	Risk of Failure	Effectiveness	Benefits	Overall Rating
ALTERNATIVE A: Redesign job/job content Ratings:	–3 ($175,000)[2]	–2	+5	+6 (10%)[3]	6 (moderate)
ALTERNATIVE B: Ergonomically redesign workstation and enviroment Ratings:	–4 ($370,000)[2]	–3	+5	+6 (10%)[3]	4 (moderate)
ALTERNATIVE C: Redesign job/job content, ergonomically redesign workstation and enviroment, train managers and distribute office ergonomics manual Ratings:	–8 ($590,000)[2]	–1	+9	+9 (26%)[3]	9 (High)
ALTERNATIVE D: Ergonomically redesign workstation and enviroment, train managers and distribute office ergonomics manual Ratings:	–6 ($440,000)[2]	–2	+7	+8 (17%)[3]	7 (Moderate– high)

[1] In the four categories of Effectiveness, Risk of Failure, Cost and Benefits each alternative (A thru D) was subjectively rated on a scale ranging from 0 to 10 or 0 to –10. Since Risk of Failure and Project Cost are potentially negative characteristics, a rating scale ranging from 0 to -10 was used. A 0 rating indicates no cost; a -10 rating indicates a high cost. Effectiveness and Benefits are positive outcomes and therefore were rated on a 0 to 10 scale. A 0 rating indicates a low level of benefit/effectiveness. The scores from each of the four categories were summed to determine the "Overall Rating" for each alternative. Along with the numerical ratings, table 1 shows subjective descriptors of the ratings in parenthesis below each number in the "Overall Rating" column. Along with the numerical ratings table 1 shows the potential percentage increase in employee performance for each alternative in parenthesis below the ratings. Along with the numerical ratings, table 1 shows the approximate "project cost" in dollar amount for each alternative in parenthesis below the ratings.

[2] Costs are calculated per 100 employees.

[3] Benefits are evaluated in terms of % increase in worker and group performance.

efficiency, work environment changes, customer satisfaction, space utilization, unit/department (e.g. product development time, successful projects, number of customers; group and individual (e.g. error rates, amount of completed work, quality). These costs/benefits metrics are used for each proposed alternative to determine the economic advantage of each alternative or program/activities and may be expressed as a percentage of annual compensation demonstrated over "X" years.

7. STEP 5: SELECTING AN ALTERNATIVE: THE DECISION TABLE

The importance or weight as specified for a future condition is established for each evaluation criterion as determined by the system analyst. These weighted values are based on objective and subjective measures. A decision table similar to table 2 is developed structuring the evaluation information with alternatives listed on the "Y" axis and the future conditions statements on the "X" axis. A probability is determined for each of the stated future conditions. An example of future condition could be the probability and level of funding for the program. Each alternative would be evaluated in terms of level of funding and the probability of being funded.

8. STEP 6: IMPLEMENTATION, EVALUATION AND MODIFICATION

A schedule and sequence of tasks, responsibilities, and

requirements is developed for the implementation activities. This schedule might include a contingency plan with scheduled decision points and decision responsibilities. There are several scheduling techniques that are available that can be used as well as various database software programs for creating new databases containing effectiveness measures, costs, and other pertinent metrics collected during the systems analysis. Several other activities also occur in this step in order to define, establish, and develop the evaluation processes of providing feedback to the appropriate strategic decision-maker in the company regarding the results of the work environment–macroergonomic program. Using information gathered from the evaluation and feedback processes, selected modifications and changes to the program also occur. This process is a continuous feedback loop of applying the systems analysis approach to solve problems and to measure the effectiveness of any selected program.

9. CONCLUSION

The systems approach identifies the salient variables which influence employee health, stress, and performance within office systems. Described in this chapter is the use of a systems model incorporating the findings of empirical and field research, as well as case studies collected from a global sample related to office systems. Typically, companies focus on simplistic, microscale solutions for reducing occupational stressors associated with

Table 2. Decision Table: Selecting an Alternative Based on Future Conditions

Future conditions (eg.funding) Probability of funding	High level of funding 0.5	Moderate level of funding 0.25	Low level of funding 0.25
Alternative A: Redesign job/job content Ratings[1]	4	2	2
Alternative B: Ergonomically redesign workstation and enviroment Ratings[1]	5	1	3
Alternative C: Redesign job/job content, ergonomically redesign workstation and enviroment; train managers and distributeoffice ergonomics manual Ratings[1]	1	6	7
Alternative D: Ergonomically redesign workstation and enviroment; train managers and distribute office ergonomics manual Ratings[1]	2	4	5

intensive computer work. Such solutions yield limited, short-term gains and create an imbalance among the office sub-systems. The important benefits of the systems model is the understanding of office systems, and the effective integration of *micro-ergonomic* and *macro-ergonomic* approaches for solving organizational problems related to office environments for the longer term. This analysis assists ergonomists, health and safety professionals, and strategic organizational planners to evaluate alternative office environment intervention programs designed to address the identified objectives and problems based on direct and indirect

economic metrics. Due to rising healthcare costs, operating costs, as well as recent state and pending federal legislation, companies are now determining how to allocate corporate resources to address issues associated with employee problems related to the introduction of office technologies. Applying a systems analysis approach enhances an organization's competitive edge by improving the interaction and fit of the office worker, the job, the physical environment, and the organizational structure. The result is a healthy and effective office system work environment.

Anthropometry for Design

E. Nowak

Institute of Industrial Design, Warsaw, Poland

1. INTRODUCTION

The aim of this article is to present anthropometry as a set of measuring techniques and methods, and to prove its usefulness for the needs of design. Anthropometry originates from anthropology and is directed towards obtaining measurements of the man. Anthropology is the science about man. It deals with the changeability of the physical characteristics of man in time and space, and particularly with race differentiation, individuals' differentiation, ontogenesis and phylogenesis. In the English and US approaches, anthropology embraces the complete knowledge of man and can be divided into physical (biological) anthropology and cultural anthropology. In addition, there are other types of anthropology such as social anthropology and criminal anthropology.

Physical anthropometry is particularly useful for practical purposes. According to the accepted divisions most often used, physical anthropology can be separated into the following three basic parts:

- *population anthropology* (known earlier as race anthropology), which is the study of the intraspecies differentiation of man — including living conditions, history, and the present state;
- *ontogenetic anthropology*, which is the study of the ontogenesis of man;
- *phylogenetic anthropology*, which deals with the phylogenesis of man — that is, the origin of our species.

Anthropology is related in its research to biology and the humanities (archeology, prehistory, psychology, and pedagogy) as well as the technical sciences. Ergonomic anthropology deals with man as the basic unit of the man–technique system and, as such, has evolved and developed in tandem with technology and engineering. Together with other disciplines (including physiology and psychology), it aims at obtaining the best conditions for this system to function.

Ergonomic anthropology makes use of the scientific output of phylogenetic, ontogenetic, and population anthropology, and as a result of the problems it concentrates on, it benefits from various sections of medicine and psychology. An anthropologist dealing with ergonomics makes use of the classical anthropological science and develops this science for the needs of technology and engineering. Thus, he or she utilizes classical anthropometry, that is, the basic research methods applied to anthropology.

2. AIMS AND TASKS OF ANTHROPOMETRY

2.1. Measuring Methods

The basic anthropometric measurements of humans include:

- linear measurements
- angular measurements
- circumferences
- force measurements

Linear measurements include: breadth, height and length measurements. These are measured between recognized anthropometric points. Angular measurements are carried out between planes and lines that cross the human body. Body movements in the sagittal plane are termed flexions and extensions; back and head movements in the sagittal planes are termed bending to the right and to the left, and extremities' movements are termed adductions and abductions. According to these extremities, movements in the transverse plane are termed pronations and supinations, and back movements are termed left turns and right turns.

Circumferential measurements of the body are mainly carried out for the purposes of clothing design and for physical assessment. The basic measurements include: head, neck, chest, hips, arms, thigh, and shin circumferences. Force measurement is done in order to define the physical predispositions of man. In general, force is defined in relation to that exerted by the hand and foot. Moments of forces are used as data applied to the design of hand and foot control systems.

The basic aim of classical anthropometry is to provide objective and precise data on the somatic structure of man. In population anthropology, for example, anthropometry is used as a set of methods applied to defining biological differences that occur between human populations. Anthropometry in ontogenetic anthropology serves to assess the ontogenetic development of man, and provides data for defining the development process, the process of puberty, and the aging process.

Following the development of the body segments in particular ontogenetic periods, anthropometry describes changes in the proportions of the human body. During the physical development of humans, head measurements increase twofold, trunk measurements increase threefold, and limb measurements increase between four- and fivefold. The aim of anthropometry is not only to define differences in human body structure in relation to age, but also in relation to sex and the type of somatic structure. Significant differences can be found in somatic characteristics in men and women. In general, women are about 8–15 per cent smaller than men and are physically weaker.

Following the development of successive generations, anthropometry assists in defining and foreseeing developmental trends of populations. These concern such phenomena as development acceleration and secular trend. These phenomena result in significant differences between generations in somatic, morphological, and functional characteristics. Anthropometry describes these differences and provides data of somatic changes that occur in given populations. Pediatrics and ergonomics are able to make use of this data: pediatrics applies population data as biological standards to the evaluation of individuals; on the basis of somatic characteristics of a given population, ergonomics creates products adjusted to the body structure. This development in ergonomics has resulted in the production of methods and measuring techniques applied to anthropometry, and new techniques aimed especially at the needs of ergonomics, termed ergonomic anthropometry, have gradually evolved.

The main aim of ergonomic anthropometry is to provide data describing physical predispositions of humans in order to aid the design of work and living environments. This objective has resulted in the modification of existing methods and the development new ones. For example, in ergonomics many anthropometric measurements are performed on the basis of

classical anthropometric points and new fixed references. In classical anthropometry, The main reference basis for height measurements is the horizontal place of footrest — Basis (B). An additional vertical plane basis — Basis dorsalis (Bd) - has been introduced to meet the needs of ergonomics. This basis is mainly applied in the determination of body dimensions in the sagittal plane. These dimensions include depth measurements and reaches. To measure the body in the sitting position, two additional reference planes have been introduced. These are the horizontal seat plane — Basis sedilis (Bs) and the vertical plane — Basis sedilis dorsalis (Bsd). Ergonomic anthropometry has frequently developed reference systems to solve specific problems in respect of the requirements of constructors and designers of technical machines and appliances. The application of this method was used to determine the dimensions of the spatial zone of upper limb reaches (Damon *et al.*1966; Bullock 1974; Nowak 1978).

Initially, during the development of ergonomic anthropometry, adults were the main subject since at that time ergonomics dealt with the work environment of man. As ergonomics developed, its interests were extended to the life environment of man and included home ergonomics and leisure ergonomics. As the role of ergonomics increased, it was able to benefit from the use of data that contemporary anthropometry could supply on the various stages of human development. Assuming ontogenetic periods as the criteria for division, we can distinguish anthropometry for children and young people, adults and the elderly. Anthropometry applies adequate measuring techniques for investigating each of these group. For example, the length measurements of children up to one year old are done in the prone position by means of a special type of liberometer. The same measurements of the adult population are performed in the sitting position by means of the vertical anthropometer. The majority of methods and measuring techniques applied in anthropometry can be used for measuring disabled people. However, some of these are modified or simplified in view of the difficulties in obtaining measurements. For example, special measuring chairs are constructed to study people with lower extremities dysfunction as they can be studied only in the sitting position.

It is not easy to study the disabled using the methods applied by classical anthropometry. It requires a great deal of experience from those performing the experiments since the measurements need to be taken very quickly. The measuring methods that make it possible to carry out investigations at a distance are the most convenient, both for the subject and the investigator; these are termed non-tactile methods.

This type of method was applied by the Swedish researcher Thoren (1994) in carrying out measurements on a group of the disabled. A set of mirrors and cameras properly arranged and interrelated to CAD/CAM software made it possible to obtain anthropometric data in a spatial system very quickly. Photogrammetric methods are most often used in the measurements of disabled people, as these make it possible to assess deformities and changes in the body structure, dislocations of bones segments. It is also possible to define the shape and dimensions of the body regardless of the body position and its changes in time (Das and Kozey 1994). It should be mentioned that these kinds of methods are relatively expensive and not all research units can afford to use them.

Summarizing the above, it can be said that the sets of

Figure 1. Distribution of body height (stature) in Polish girls (18 years). About 90 per cent of all girls are between 157 and 178 cm tall; about 10 per cent are either shorter or taller.

measuring techniques and methods of the classical and ergonomic anthropometry can be applied to the measurements of the disabled. Some of these methods, however, require verification from the point of view of the arduousness of investigations.

2.2. Statistical Methods

Individuals with various body dimensions (tall and short) and body proportions (long or short extremities, or long or short trunks) exist in every population. In order to characterize a given population — that is, evaluate it in terms of numbers — anthropometry utilizes the basic statistical characteristics. Usually anthropometric features have the normal distribution and are arranged according to the "Gaussian distribution". Figure 1 illustrates such distribution.

It presents the body height of Warsaw girls aged 18 (Nowak 1993). The values of this feature were presented on the frontal axis, and the frequency of occurring (possibility) on the horizontal axis. Two basic statistical parameters are used to determine the distribution of features in a population. One of these parameters is the mean (m). It indicates where the distribution is located on the horizontal axis. The other is a quantity known as the standard deviation (S), which is the index of the degree of variability in the population under study — the "width" of the distribution or the extent to which individual values are scattered about or deviate from the mean. Mean values (m) and standard deviations are used to determine the statistical characteristics called percentile. They are useful both in developing biological standards and preparing standards for the needs of ergonomics. Assuming that the features investigated in the random test of the population have the normal distribution, as seen in figure 1, we can call percentile (Cp) the value of the feature that does not exceed p% of individuals. The values of particular percentiles (Cp) are calculated according to the following formula:

Cp = m + Sz

where Cp is the characteristics value on the level of the *p* percentile; *m* is the mean; S is the standard deviation; z is the constant for the percentile concerned (see statistical tables).

In order to obtain a better percentile interpretation we need to come back to figure 1. The height measurement of the investigated population of boys aged 18 distributes in a symmetrical way (Nowak 1993). Its highest point is the average stature, otherwise known as the mean. Since the curve is symmetrical, it follows that 50% of the population of girls are

shorter than average and 50% are taller. In this distribution the mean is equal to the 50th percentile. Other percentile values are also marked on the horizontal axis. The 5th and 95th percentile are used for designing purposes. The 5th percentile located closer to the frontal axis means that the 5% of the boys are shorter. Similarly, an equal distance from the mean towards the right of the chart is a point known as the 95th percentile. Hence, we can say that only 5% of the girls are taller. Ninety per cent of the population are between the fifth and 95th percentile in stature. Thus, using the values of the 5th and 95th percentile and applying the rules of ergonomics, products for 95 per cent of the population can be designed.

3. APPLICATION OF ANTHROPOMETRY

Examples of the applications of anthropometric investigations are given below; they are designs for work spaces, handles and holders, and working clothes.

Work space is determined mainly by the reach zone of the upper extremities defined in relation to three planes: sagittal, transverse and frontal. The first attempts to define the upper extremities reach zone concerned one-dimensional or two-dimensional configurations determined in frontal or transverse planes. Barnes (McCormick 1964) defined the upper extremities reach zone determining the so-called the maximum and normal zones. These zones were determined by the radii, which constituted the length of the arm or forearm. Further investigations aimed at determining the reach zone concerned three-dimensional configuration. Reach zones were defined on the basis of experimental research. Research works conducted in the USA (Damon *et al.* 1966) and Australia (Bullock 1974) should be mentioned here. The results of both experiments provided data for military purposes. The results of investigations conducted in Poland (Nowak 1978), thanks to the fact that the measuring system was "suspended" on acromial points, can be used while designing all kinds of work stands intended for work in both the standing and sitting positions. Work space of the upper extremities was defined based on investigations of 226 men and 204 women aged from 18 to 65 (Nowak 1978).

In these investigations, a spatial measuring system consisting of three inter-perpendicular axes is assumed to determine the arm reach area. The measuring system of the arm reach area was determined by the intersection of the following planes: the frontal plane, tangential to the vertical plane of the seat back, the sagittal–median plane, the transverse plane, crossing the acromial points.

The intersection of these planes marks the origin of the polcor co-ordinate axes of the measuring system (point C). The "C" point is fundamental to defining the reach areas for any working plane. The whole reach space of arm reach was divided into ten horizontal measuring planes. That which crosses the acromial points was accepted as the basis and marked "O". From this plane upwards four others follow every 120 mm and five follow downwards. The reach ranges of the left and right arms were recorded on each plane in a polar system with its center being the "C" point.

The investigations resulted in obtaining ten arm reaches for the left and right extremities. These reaches determined in a polar system define spatial area of arms. This space is a basis for designing spatial structures of machines, installations, and workplaces. Figure 2 shows an example of utilizing the data on

Figure 2. An example of utilizing the data on the reach area of arms in the design process.

the reach area of arms in the design process of a real workplace situation.

For the correct design of all kinds of handles and holders it is necessary to determine the functional capabilities of the hand and its anthropometric dimensions. The human hand belongs to specific and highly precise work tools. The grip capabilities of the hand are supported by the opposition of the thumb. This enables the hand to perform a wide range of manipulation tasks.

Figure 3. Hand grip named according to different classifications: power grip, hammer grip or clench grip palmar.

Almost all types of activities require different hand arrangements, which means using different types of grips. The performance of a handle — that is, its shape and form — should be adjusted to the grip most convenient to perform a specific activity. There are many grip classifications. One of them assumes, as a criterion of division, the form of hand arrangement or its parts in relation to the object and direction of effective force used (Nowak 1993). Figure 3 shows one of these hand grips.

Following Nowak (1993), this is a hand clamp grip making use of the thumb opposition. According to other authors, this grip is defined as a cylindrical or coiled grip. This grip is applied while using hand tools including saws, drilling machines or hammers, as well as when opening a door with the use of a door handle. When we know the dimensions of the space occupied by the hand grasped on a cylindrical handle and a handle diameter, we can easily determine the distance of a door handle in relation both to the door plane and the door frame.

Anthropometric measurements taken for the purposes of clothes design embrace a different set of characteristics from measurements made for the purpose of designing work spaces, machines, and tools. First of all measurements of the following circumferences are needed: neck, chest, waist, hip, wrist, and thigh. For the design of working clothes angular measurements of the extremities movement ranges are also essential, as well as measurements defined as arcs: for example, the arcs of the front length of the trunk, the length of the back, shoulders, upper and lower extremities are all very important. The dimensions of the arcs are determined in a motionless standing position and while changing body position — for example, moving to squatting, kneeling, and standing positions, for the latter, both bending forwards and bending backwards. Additionally, the construction of garments for wheelchair users is based on data obtained in a sitting position with consideration given to the trunk movement forward and movements of the lower extremities. Figure 4 shows selected anthropometric characteristics and their application in clothes design (Dabrowska-Kielek *et al.* 1993).

Anthropometry: Definition, Uses and Methods of Measurement

R.E. Herron

Professor of Ergonomics, Department of Environmental Health, Colorado State University, CO 80525, USA

1. DEFINITION

The word "anthropometry" was coined by the French naturalist Georges Cuvier (1769—1832). It was first used by physical anthropologists in their studies of human variability among human races and for comparison of humans to other primates. Anthropometry literally means "measurement of man," or "measurement of humans," from the Greek words *anthropos,* a man, and *metron,* a measure. Although we can measure humans in many different ways, anthropometry focuses on the measurement of bodily features such as body shape and body composition ("static anthropometry"), the body's motion and strength capabilities and use of space ("dynamic anthropometry").

2. ORIGINS

The origins of anthropometry can be traced to the earliest humans, who needed information about body parts for many of the same reasons which apply today — to fit clothing, design tools and equipment, etc. No doubt they also used body measurements for other, "non-design" purposes, such as footprints to estimate the body size of potential adversaries. These and other early applications called for the measurement or estimation of height, as well as the shape and size of hands, feet, and other body parts. Such needs gave rise to the very early use of the terms, "span," "cubit," and "canon," which connote extended arm width, height, and a standard, respectively.

Body proportions were of great interest during classical times, which is clearly evident in the work of artists and sculptors of the period. Around the year 15 BC, the Roman architect Vitruvius wrote about the potential transfer of harmonious body proportions to the design of beautiful buildings. However, it was the work of Renaissance artist-anatomists, including Alberti, Pierro della Francesca, Leonardo da Vinci, and especially Albrecht Durer, that ushered in the scientific beginnings of anthropometry. Durer's four-volume publication on human proportions was the first serious attempt to systematize the study of human size and shape.

3. USES OF ANTHROPOMETRY

Today, anthropometric measurements are used in a remarkably wide variety of scientific and technical fields, ranging from genetics and nutrition to forensics and industrial design. Within the field of ergonomics, there are myriad applications of anthropometry, primarily associated with different aspects of design for human use.

The goal of ergonomics is to design tools, workplaces, and environments in such a way that humans can function most effectively — in other words, to *optimize* human performance by achieving the best possible fit between the human operator, the equipment (hardware and software), and the working environment (physical and psychosocial). This fit is often referred to as "the human–machine interface." Anthropometry can and does play a major role in achieving this goal because variations in bodily features, such as shape, size, strength and reach, affect the way people perform tasks and, thus, have an important influence on whether the human–machine interface is a good one. The breadth of possible applications of anthropometry for improving the human interface is remarkably wide-ranging, from industrial equipment, clothing and furniture, to surgical tools, farm implements, aircraft controls, and virtually every item in the environment with which humans interact.

Over the years, engineers, designers, architects and others who design products or processes have increasingly recognized the need for anthropometric data on the users of their creations. Of course, the need for anthropometric information and the type of data required varies greatly from one application to the other. In some areas, the fit is "soft," as in a loose garment such as a bathrobe; in other areas, the fit is "hard," for example, in a respirator for protection against breathing toxic fumes. The fit of the bathrobe can be an approximation and still serve its intended purpose, whereas the respirator mask must conform closely to the geometry of the face in order to maintain adequate contact and prevent leakage. In the case of the bathrobe, data on height and a few body girth measurements for the prospective user population may be all the information needed to ensure adequate body coverage for a good interface. However, for the respirator mask, it may be necessary to obtain detailed three-dimensional measurements of individual facial geometry to ensure a satisfactory fit.

4. METHODS
4.1 Traditional methods

The earliest methods and tools for making anthropometric measurements were very simple, but they were quite effective and some of these rudimentary devices, such as measuring sticks and calipers, have endured to the present day. The types of data that result from the simple tools shown in figure 1 are quite varied and include numerous length measurements — e.g. height, various widths, such as the shoulder and pelvis, and circumferences, such as the waist and chest.

These tools appear to be deceptively easy to use but, in fact, when used for scientific or engineering purposes, they require a high level of care in order to achieve acceptable levels of validity

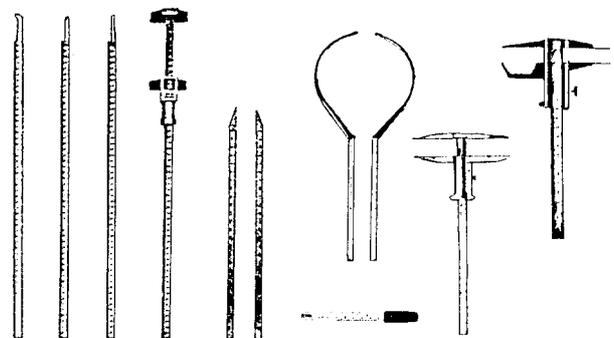

Figure 1. An array of traditional anthropometric measurement tools

and reliability. For example, it is important to know where to locate and how to align the measuring device (tape, caliper, measuring stick or whatever) on the body surface and to do so in a consistent, reproducible manner. In using a measuring tape, the tension in the tape and the degree of tissue compression must be suitably controlled.

Over the last hundred years, many volumes have been written about how to perform traditional anthropometric measurements and the reader is referred to the list of publications given below for further details.

4.2   Modern methods

Over the last thirty years the tools of anthropometry have changed dramatically, propelled by advances in computer and shape-sensing technology. Traditional linear measures of the body and body parts have gradually given way to 3-D and 4-D measures, computer models and, most recently, fractals, using new multi-dimensional sensing devices which capture considerably more of the subtle variations of human form and function.

The transformation of traditional anthropometry took a major turn in the 1960s with the growing recognition that the human body is an irregular, three-dimensional, dynamic organism, which calls for different strategies of mathematical abstraction and different measuring instruments than those used for obtaining traditional linear dimensions. This development led to greater use of mapping approaches, using contours and coordinates, and mathematical approaches based on polynomials, nurbs, b-splines, and other strategies for representing the irregular, multi-dimensional bodily features. A recent conference report (Vannier, Yates and Whitestone 1992) provides a valuable overview of these 3-D anthropometric methods and their future prospects.

Traditional anthropometry has been largely confined to surface measurements of the body, with the exception of a rather limited use of X-rays. The recent rapid growth of Computed Tomography (CT), Magnetic Resonance Imaging (MRI), Positron Emission Tomography (PET), and other new medical imaging devices has exposed the potential for generating previously inaccessible anthropometric data on internal body structures and functions. Obviously, knowing the dimensions and the motions of internal body parts can provide invaluable information for many ergonomic needs. For example, it would certainly be helpful

Figure 2. Modern anthropometric measurement methods

to know what happens to the geometry of internal organs and systems during the performance of various tasks and when the body adopts different postures.

Other recent developments in anthropometric recording and instrumentation strategies include the use of 3-D images for matching body parts in reconstructive surgery, automated hip surgery, measurement of heart and other organ volumes for transplants, stereometric brain surgery, and dose radiation measurements. Although, it may not be immediately obvious, all of these recent applications can translate into new potentials for advancing the use of anthropometry for ergonomic design and fitting purposes.

The use of 3-D and 4-D computer models to represent human form and function is still in an early stage, but already over 200 models have been developed for various ergonomic applications. Interest in creating more accurate and more versatile computer models of the human body has received a major impetus from the growing use of animation in the motion picture industry. This line of activity can be expected to grow dramatically in the near future as better (more comprehensive and statistically valid) multi-dimensional body data become available and the power of micro-computers continues to grow. Having a wide range of human models covering myriad details of human form and function stored in an immediately accessible form would seem to be the preferred *modus operandi* for helping engineers and designers to extend their uses of anthropometry for ergonomic purposes.

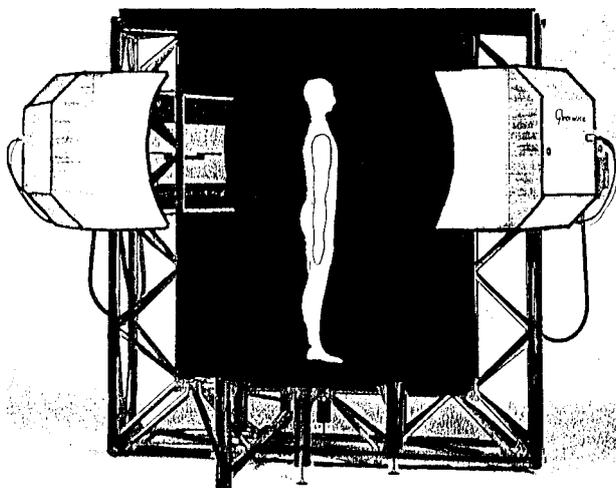
5. WORK SPACE–ENVELOPE MEASUREMENT

The measurement of the work space-envelope for different occupational activities is an important aspect of ergonomic design. The space-envelope occupied by the body while performing a task is larger than the space taken up by the body itself. The first measurements of this type were made using simple mechanical devices but, over the last twenty years, this approach has been superceded by non-contact, three-dimensional video imaging techniques. The video methods are portable, inexpensive, and easy to use.

6. STRENGTH MEASUREMENT

The measurement of human strength is important for the design of tools and equipment and other ergonomic applications. The growing availability of modern electronic dynamometers and strain gauges linked to computers has made the taking of human strength measurements a relatively simple operation; however, the acquisition of valid and reliable strength data requires considerable care and skill. Details about the different methods for measuring human strength can be found in the publications listed below.

7. RANGES OF ANTHROPOMETRIC DATA

In many ergonomic applications, it is necessary to know the ranges of pertinent anthropometric measurements found among a particular population, e.g. the prospective users of a new piece of equipment. The words "average" and "percentile" often appear in discussions about such matters, and the way these terms are used in anthropometry requires special attention. Although a single bodily characteristic, such as height or weight, can be expressed as average or at a particular percentile level, e.g. at the


50th percentile level, there is no such thing as an "average" human or a "50th percentile human." This stems from the fact that the position of each individual relative to an average value or a percentile scale varies from one bodily feature to the other. An individual's height may be at the 75th percentile level (i.e. 75 % of the population are the same or of lesser height), but his weight may be at the 60th percentile and his chest girth at the 50th percentile. Thus, there is no such thing as a 95th percentile human — except as it relates to a specific bodily feature — because combining several 95th (or any other single) percentile values for various dimensions on the same body produces an unrealistic human form. Anthropometric variables can be combined, but this requires the use of multi-variate and other statistical methods, which are described in one or more of the publications listed below. These references also discuss the correct use of means, medians, standard deviations, standard errors, and other statistics for ergonomic purposes.

Another major issue in obtaining or producing representative anthropometric data relates to problems of population sampling. For example, if the goal is to design a piece of equipment for the general US population and there is a need to know the range of body shapes and sizes, there is no extant database of such information. The available anthropometric databases do not include a statistically valid sample of the US population. Therefore, it is often necessary to find a compromise, which might involve combining anthropometric information from various sources, such as military populations, and from limited samples of the general population. Furthermore, the ergonomic needs of special populations such as the elderly, disabled, infant/child and ethnic groups often call for anthropometric data which are representative of the particular segment or segments of the population.

Sampling strategies and tactics are explained in more detail in the references given below. However, the current problems in this area will not be alleviated in any significant way until a comprehensive anthropometric survey of the US population is completed. Recently, several countries have conducted national anthropometric ssrveys and others plan to follow suit in the near future. The cost and logistical difficulties involved in such surveys will probably limit them to the more prosperous nations for the foreseeable future, so that the development of a truly global anthropometric data base is unlikely for many years to come.

8. THE FUTURE OF ANTHROPOMETRY

Although the tools of modern anthropometry have already become quite sophisticated, no doubt the future will bring even more dramatic "high-tech" advances. These will include a wide range of new sensors (non-contact, multi-dimensional sensors, etc.) to measure the changes (static and dynamic, as well as internal and external) in body shape and size which accompany everyday activities, as well as those which are associated with growth, disease, aging, etc. Computer body models will reach a new level of realism based on more comprehensive and valid population data on a wider range of useful measures.

Another noteworthy development that illustrates what the future holds is the National Library of Medicine project launched in 1992 to create 3-D "visible humans." Each visible human is graphically reconstructed from the images of a series of fine cross-sections, taken from head to foot, of two "representative" human

cadavers — one male and one female. The first dissections of this type were conducted by Eycleshymer and Schoemaker in 1911 when they selected a "representative" series of cross-sections from a sample of fifty individuals. In 1974, a group at the Biostereometrics Laboratory, Baylor College of Medicine, similarly sliced a cadaver into 92 cross-sections, using a specially designed saw. The images of successive cross-sections were then used to reconstruct the 3-D geometry of selected internal organs and systems for use by army ballistics researchers studying what body tissues would be affected by different missiles entering the body at various locations and angles. Already, the National Library of Medicine visible humans have been widely used and have met important needs for teaching and other purposes, but their representativeness of anthropometric variation among humans is obviously quite limited.

Future anthropometric methods will cope better with the fact that humans are not fixed objects like statues, but are dynamic organisms whose structures and postures change daily and throughout life — these methods will recognize that there are no fixed points on the body, just ever-changing irregular forms. We must exploit the potential of more "holistic" parsimonious mathematical abstractions for representing, measuring, analyzing, and interpreting the subtleties of human form and function, both internally and externally, from conception to death. Comprehensive multidimensional human models based on statistically valid anthropometric data for a wide variety of populations and specialized groups will be instantly available for use by engineers, designers, and others, in their computers and virtual-reality simulators. Such a development will help to elevate the science and technology of anthropometry to a new level of precision and utility.

Biomechanics of Wrist in Computer Keyboarding

R. W. Marklin† and G. G. Simoneau‡

†Department of Mechanical and Industrial Engineering, and ‡Marquette University, Physical Therapy Department, 346 Walter Schroeder Complex, PO Box 1881, Marquette University, Milwaukee, WI 53201-1881, USA

1. INTRODUCTION

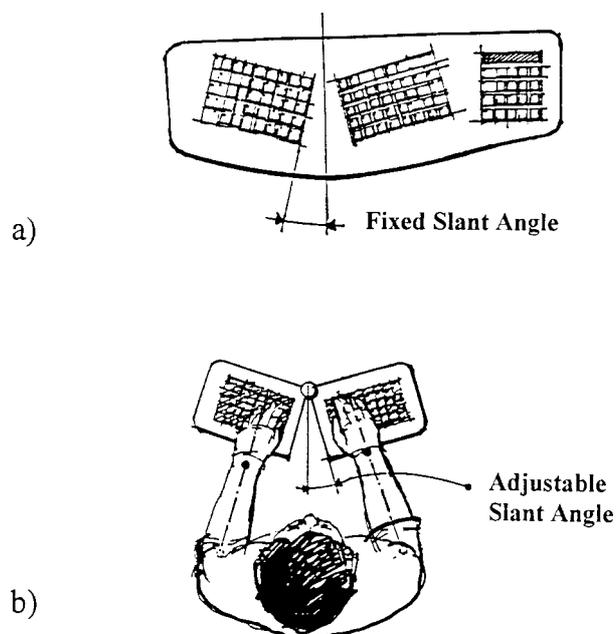
Within the past three decades of published literature upper extremity WMSD has often been attributed to mechanical and electronic keyboard usage (Tichauer 1978, Kroemer 1972, Armstrong 1986, Smith *et al.* 1981, Sauter *et al.* 1991, Bergqvist 1995). Based on published literature, it appears that the design of the conventional computer keyboard is implicated in the etiology of upper extremity WMSD among keyboard users for the following two reasons: (1) the often-cited occupational risk factors of repetitive movements and deviated posture of the wrist in the flexion/extension and radial/ulnar planes are an inherent part of typing on a computer keyboard; and (2) there are several cross-sectional studies that have shown a strong positive relationship between musculoskeletal discomfort or pain and keyboard usage (Duncan and Ferguson 1974, Smith *et al.* 1981, Sauter *et al.* 1991, Bergqvist 1995).

1.1. Design of Conventional Computer Keyboard

The conventional flat computer keyboard requires the operator to hold the hands and forearms in a relatively awkward position. With this keyboard, the operator needs to pronate the forearms substantially in order to hold his/her palms almost horizontal. In addition, the operator must deviate both wrists in the ulnar direction in order to rest his/her fingers on the home keys. Ulnar deviation from subjects typing on a conventional keyboard is typically 10° or more. Computer keyboard users typing on conventional keyboards also extend their wrists ~20° (Simoneau *et al.* 1999).

1.2. Design of Split Computer Keyboards

Typically, the design of split computer keyboards differ from the conventional keyboard in their slant angle (Figure 1). The typical conventional keyboard has a slant angle of 0°, a slope ranging from 0 to 15°, and a tilt angle of 0°. Fixed-angle split keyboards typically have 12.5° of slant (25° opening angle) and the adjustable-angle split keyboard can be adjusted from 0 to 90°. (Some adjustable-angle split keyboards can be separated at pivot point connecting the halves.) Studies have investigated whether commercially available split keyboards place the wrist in a more neutral posture than a conventional keyboard (Honan *et al.* 1995, Marklin *et al.* 1999). In summary, it appears that if a commercially available split keyboard has an opening angle of ~25° (12.5° slant angle), then wrist ulnar deviation is reduced to almost a neutral position in the radial/ulnar plane. Marklin *et al.* (1999) conducted a study on 90 experienced office workers to determine how commercially available split computer keyboards af-



a)

Fixed Slant Angle

b)

Adjustable Slant Angle

Figure 1. (a) Sketch of a commercially available split fixed-angle keyboard. (b) Sketch of a commercially available split adjustable-angle keyboard

fected ulnar deviation of the wrist. As illustrated in Figure 1, the split keyboards tested had the QWERTY layout of keys and were of two designs — split fixed-angle and split adjustable-angle. The slant angle of the split fixed-angle keyboard was 12.5° (25° opening angle). The halves of the split adjustable-angle keyboard were adjusted to each individual so that each subject's wrists were aligned with the forearms, resulting in an approximately neutral radial/ulnar angle. The mean slant angle for all subjects who typed on the adjustable-angle split keyboard was 10.5° (SD 3.6°; range 5–20°). Therefore, the opening angle on the split adjustable-angle keyboard varied from 10 to 40° with a mean of 21°.

Compared with a conventional keyboard, the results from Marklin's *et al.* (1999) study indicate that split fixed-angle and split adjustable-angle keyboards reduced mean ulnar deviation of the right and left wrists. The split adjustable-angle keyboard reduced mean, maximum and minimum ulnar deviations by ~8° compared with the conventional keyboard. Compared with the conventional keyboard, the split adjustable-angle keyboard decreased mean ulnar angle from 13.3 to 5.7° for the left wrist and 10.7 to 2.5° for the right wrist. These differences in mean, maximum and minimum ulnar deviation were statistically significant. The split fixed-angle keyboard reduced mean, maximum and minimum ulnar deviation angles significantly by ~10° (mean left wrist: 16.5 to 5.8°; mean right wrist: 7.9° ulnar to 1.2° radial). Note that for all keyboards ulnar deviation of the right wrist was significantly less than the left wrist. This difference ranged from 3 to 7°.

The finding that split keyboards place the wrist closer to a neutral posture in the radial/ulnar plane substantially reduces one occupational risk factor of WMSD, namely ulnar deviation of the wrist. However, the two alternative keyboards had minimal influence on wrist extension. Both split keyboards resulted in wrist extension of ~15° (no significant difference between split fixed-angle and adjustable-angle keyboards), which was ~5° less

wrist extension than when typing on a conventional keyboard (Simoneau *et al.* 1999). Therefore, these two types of split keyboards did not fully address the posture component of wrist extension, which has been shown to have more effect on carpal tunnel pressure than radial/ulnar deviation. However, with respect to biomechanical factors other than carpal tunnel pressure, reduction in ulnar deviation is theoretically beneficial. This article explores in depth these biomechanical factors, namely carpal tunnel pressure and resultant reaction force on the tendons and median nerve.

2. CARPAL TUNNEL PRESSURE

Compared with a conventional keyboard, the goal of split keyboards is to decrease ulnar deviation of the wrist during typing. Although the ergonomics literature is replete with recommendations to reduce ulnar deviation of the wrist, experimental studies on carpal tunnel pressure have not shown an increase in carpal tunnel pressure from wrist ulnar deviation up to 15° (compared with a neutral wrist position). Weiss *et al.* (1995) used needle catheters to measure the effect of wrist position in the radial/ulnar and flexion/extension planes on carpal tunnel pressure. Although these researchers found the lowest carpal tunnel pressure of ~8 mmHg when the wrist was deviated ~2° ulnarly and 2° extension, the range of 10–15° ulnar deviation was the position where the greatest number of their 20 subjects recorded the lowest carpal tunnel pressure. Compared with neutral wrist posture, 10° of ulnar deviation does not increase carpal tunnel pressure, as supported by data from Rempel *et al.* (1997a, b). With six newtons of force applied by the fingers and the absence of fingertip loading, Rempel *et al.* found that carpal tunnel pressure for 10° of ulnar deviation was 36.1 and 15.4 mmHg respectively, while pressure for neutral position in the ulnar plane was 44.6 and 19.7 mmHg respectively. At 20° ulnar deviation, the carpal tunnel pressure increased to 40.9 and 21.5 mmHg respectively for 6 N and no loading on the fingertips. The effect of wrist extension on carpal tunnel pressure was more evident as contrasted to the effect from ulnar deviation (Rempel *et al.* 1997a, b). Compared with 15° wrist extension, carpal tunnel pressure increased from 41.1 and 18.5 mmHg respectively to 53.5 and 27.7 mmHg respectively for 6 N and no loading on the fingertips when the wrist was extended 30°.

In physiological studies on animals, pressures even as low as 20 mmHg could result in damage to the neuron, as demonstrated and reported by Dahlin and Lundborg (1990). Axonal transport decreased 75% when pressure applied to the vagus nerve of a rabbit increased from 10 to 20 mmHg. When the pressure increased to 30 mmHg, the nerve showed marked morphological changes, such as displacement of the neuron's nucleus and changes in the neuron's metabolism. If one were to generalize Dahlin and Lundborg's (1990) findings of detrimental changes to nerves from pressures as low as 20 mmHg to the human wrist, then wrist ulnar deviation up to 20° with no loading on the fingertips would not be a risk factor of WMSD. However, whether the wrist was in a neutral position or ulnarly deviated 20°, loading on the fingertips of 6 N could possibly expose one to WMSD because carpal tunnel pressure is > 30 mmHg. In studies where forces on computer keys were measured during typing tasks, peak key forces ranged from 2.5 to 4.4 N (Sommerich *et al.* 1996, Rempel *et al.* 1997a, b). Research is needed to determine the effect of repetitive applied forces in the above range on carpal tunnel pressure across a range of wrist ulnar deviation postures.

3. MODELING OF RESULTANT REACTION FORCE ON TENDONS AND THEIR SHEATHS

Although 10° of ulnar deviation of the wrist appears to have negligible effect on carpal tunnel pressure when compared with neutral posture, the greater ulnar deviation would increase theoretical resultant forces exerted against the flexor tendons passing through the carpal tunnel (Armstrong and Chaffin 1978, Schoenmarklin and Marras 1990). The increased resultant forces on the tendons and their sheaths could contribute to inflammation, possibly causing tenosynovitis. Swelling due to tenosynovitis could result in compression against the median nerve (carpal tunnel syndrome).

Modeling of tendons wrapping around a deviated wrist joint provides a basis for the etiology of WMSD affecting the wrist joint. As a forearm muscle contracts and moves its tendon accordingly, the tendon passing through the wrist can rub against its adjacent surface, usually a bone or ligament, as a rope rubs against a non-rotating pulley. Likewise, when the muscle lengthens, the tendon moves in the opposite direction against its adjacent structures. In the wrist area, the repetitive rubbing of the tendons against the carpal bones and flexor retinaculum (carpal ligament) could cause tenosynovitis, which is inflammation of the tendon's sheath.

Based on Landsmeer's (1962) model, Armstrong and Chaffin (1978) developed a static model of a tendon wrapping around a joint. Landsmeer's model of a tendon is analogous to a rope bent around a non-rotating pulley, and Figure 2 illustrates Armstrong and Chaffin's (1978) model as a reasonable representation of Landsmeer's model. When the wrist is flexed, the flexor tendons

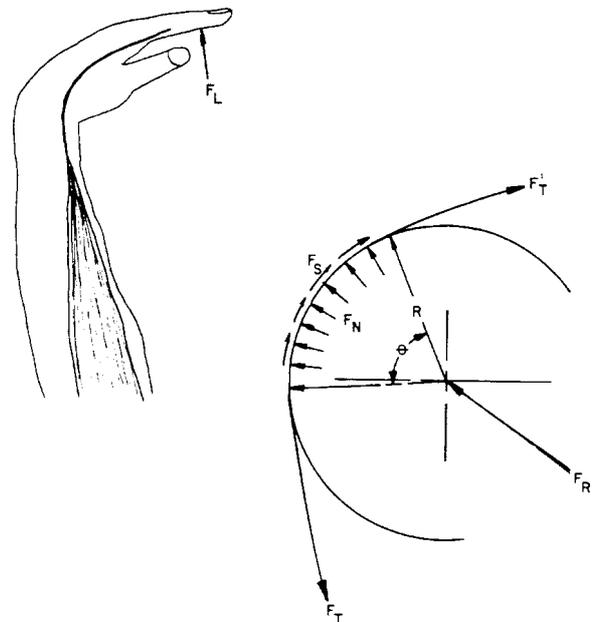


Figure 2. Armstrong's and Chaffin's (1978) biomechanical model of a flexor tendon wrapping around the flexor retinaculum. F_t, tendon force; F_r, resultant reaction force exerted against the tendon (Chaffin and Andersson 1991)

bend around the flexor retinaculum that is assumed to have a constant radius. When the wrist is extended, the flexor tendons are supported on the dorsal side by the carpal bones that are also assumed to have a constant radius. Armstrong and Chaffin (1978) found that the radius in a flexed posture is larger than in an extended posture.

The arc length of the tendon wrapping around the pulley is defined in equation (1) (Chaffin and Andersson 1991):

$$X = R \bullet q \tag{1}$$

where

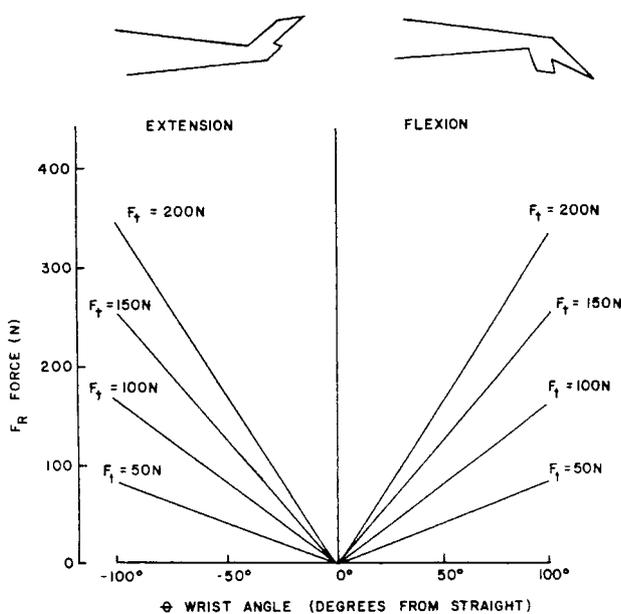
X = tendon arc length around pulley (mm)
R = radius of curvature of supporting tissues (mm)
q = angle of deviation of wrist from neutral (in radians).

The resultant reaction forces acting normal to the tendon are shown in Figure 3 and defined in equation (2) (Chaffin and Andersson 1991):

$$F_n = (F_t \bullet e^{(m \bullet q)})/R \tag{2}$$

where

F_n = normal supporting force per unit of arc length (N/mm)
F_t = average tendon force in tension (N)
m = coefficient of friction between tendon and supporting synovia
q = wrist deviation angle (radians)
R = radius of curvature of supporting tissues (mm).

Since m is considered small (~0.0032; Fung 1981), it can be approximated by zero. This changes equation (2) to equation (3) (Chaffin and Andersson 1991):


$$F_n = F_t/R. \tag{3}$$

Figure 3. **Resultant reaction force (F_r), as modeled by Armstrong and Chaffin (1979), that is exerted against the flexor tendons as a function of wrist angle and tendon force (Chaffin and Andersson 1991)**

Equation (3) reveals F_n is a function of the tendon force and radius of curvature. As the radius of curvature decreases, the normal supporting force per unit of arc length increases. The normal supporting force for women would be greater than for men because women have smaller wrists. Also, as the tendon force increases, the normal supporting force increases.

The resultant reaction force, F_r in Figure 2, is the force of the carpal bones pressing against the flexor tendons. F_r is defined in equation (4) (Chaffin and Andersson 1991):

$$F_r = 2 \bullet F_t \bullet \sin(q/2) \tag{4}$$

where

F_r = resultant force exerted by adjacent wrist structures on the flexor tendons (N)
F_t = tendon force (N)
q = wrist deviation angle (in radians).

Equation (4) indicates that F_r is a function of the tendon force and wrist deviation angle, but is independent of radius of curvature. Figure 3 illustrates this relationship in that as the tendon force and wrist angle increase, the resultant force F_r increases linearly.

Dynamic movements that accelerate and decelerate the tendons around a non-rotating pulley could exacerbate the trauma imposed on the tendons. Schoenmarklin and Marras (1990) developed a dynamic model of a flexor tendon bent around the carpal bones or flexor retinaculum, taking into account the acceleration and deceleration of a tendon's movements. This model analyzes the effects of peak angular acceleration on the resultant reaction force that the wrist bones and ligaments exert on tendons and their sheaths in the flexion/extension plane. Like the Landsmeer (1962) and Armstrong and Chaffin (1978) models, Schoenmarklin and Marras (1990) model the tendon as a rope bent around a fixed pulley.

The quantitative effects of the wrist's peak angular acceleration on resultant reaction forces were based on the free body diagram (FBD) and mass·acceleration diagram (MAD) approach in engineering dynamics. The maximum tendon force ($F_{t\text{-max}}$) was computed as a function of five peak angular accelerations (3000, 6000, 9000, 12 000 and 15 000°/s²). Based on empirical data from normal subjects, 15 000°/s² was ~50% of peak wrist acceleration in the flexion/extension plane (Schoenmarklin and Marras 1993). $F_{t\text{-max}}$ is derived from equation (5) (LeVeau 1977):

$$F_{t\text{-max}} = F_{t\text{-min}} \bullet e^{(m \bullet q)} \tag{5}$$

where

$F_{t\text{-max}}$ = maximum force in flexor tendons, which is the force that the extrinsic flexor muscles in the forearm exert on their tendons (N)
$F_{t\text{-min}}$ = minimum force in flexor tendons, which is the force that the flexor tendons transmit to the hand and fingers (N)
m = coefficient of friction between tendons and their sheaths
q = wrist deviation angle (radians).

Since the coefficient of friction for human synovial joints bones is estimated to be very low (0.0032 according to Fung 1981), then the calculation of the $F_{t\text{-max}}$ force is very close to $F_{t\text{-min}}$. F_r expressed in equation (4) was calculated as the resultant force necessary to resist $F_{t\text{-max}}$ and $F_{t\text{-min}}$.

5. RESULTANT REACTION FORCES FROM ULNAR DEVIATION

As shown in Figure 4, the resultant reaction force exerted against the tendon (F_r) increases approximately linearly as wrist angle or angular acceleration increases, resulting in a curved plane that signifies an interactive effect between wrist angle and angular acceleration. The greatest F_r occurs when wrist is accelerated at a deviated wrist posture. The large peak reaction forces exerted on the flexor tendons and their sheaths are due solely to deviated wrist position and motion *without* any externally applied load in the hand. If loads were applied in the hand (e.g. power grip or pinch grip) while the hand was accelerated in deviated postures, then F_r would increase even more, resulting in even more stress on flexor tendon tissue.

Compared with an approximately neutral wrist posture from typing on a split keyboard, ulnar deviation of 10° or more from typing on a conventional keyboard would result in increased resultant reaction forces on the tendons passing through the wrist (see equation 4). The resultant reaction force would increase even more if the wrist were accelerating (or decelerating) (Figure 4) or if the fingertips were applying a load (see equation 4). Since typing requires acceleration (and deceleration) of the wrist in the ulnar plane and forces exerted by the fingertips, then the resultant reaction force on the tendons would be greater than a static ulnar position of the wrist. The resultant reaction forces on the tendons could cause the tendon and its sheath or the fibrous sheath moored to bone or ligament to hypertrophy or inflame, which could result in tendinitis or tenosynovitis. The occurrence of either tendinitis or tenosynovitis would most likely increase m in equation (5), thereby increasing F_{t-max} and F_r even more (equation 4). Inflamed tendons or their sheaths would occupy more space in the carpal tunnel, thereby exerting more pressure on the median nerve and theoretically contributing to the etiology of carpal tunnel syndrome.

Although the results from modeling of tendons in Figures 2–4 are theoretical (and to the authors' knowledge there are no published literature on measurement of resultant reaction forces), histological experimental studies on tendons passing through the carpal tunnel have shown degenerative changes in tendon structure from wrist deviation. Armstrong *et al.* (1984) found hypertrophy and increased density in the synovial tissue of the tendons passing through the carpal tunnel. These authors suggested that biomechanical factors, such as repeated exertions with a flexed or extended wrist posture, could have partially caused degenerative changes in tendon tissue. In an investigation of the viscoelastic properties of tendons and their sheaths, Goldstein *et al.* (1987) found that flexion/extension wrist angle increased the strain difference between tendons, their sheaths, and bones and ligaments that form the anatomical pulley. When the wrist was extended ~10°, the strain in the flexor digitorum profundus (FDP) tendons, which pass through the carpal tunnel and move the fingers, was ~10–15% lower on the side distal (hand side) to the flexor retinaculum than the proximal side (forearm side). This difference in strain within a tendon creates shear traction forces, which are magnified when the wrist angle is deviated to 65° flexion or extension.

Although Armstrong *et al.* (1984) and Goldstein *et al.* (1987) discussed degenerative changes to the tendons passing through the wrist with respect to wrist flexion/extension, their theories could possibly apply to ulnar deviation. The strain difference on the tendons from 10° ulnar deviation could possibly cause hypertrophy of tendon tissue in the carpal tunnel, thereby leading to the etiology of tenosynovitis or carpal tunnel syndrome from inflamed tendons and their sheaths pressing against the median nerve. Experimental research is necessary to validate whether ulnar deviation of 10–15° would generate a magnitude of resultant reaction force detrimental to the health of tendon tissue.

6. CONCLUSION

The reduction of ulnar deviation to almost a neutral position from typing on split keyboards minimizes one of the occupational risk factors of WMSD associated with typing, namely, ulnar deviation. The findings from Simoneau's *et al.* (1999) study and others reported in the literature that conventional computer keyboards consistently require ~10° or more of ulnar deviation could explain why typing on conventional keyboards has been problematic with respect to WMSD. Theoretically, as the wrist angle approaches neutral, the resultant reaction forces from the carpal bones and carpal ligament on the tendons and their sheaths passing through the wrist decreases (Armstrong 1986). Less net reaction force pressing against the sides of the tendons and their sheaths would theoretically decrease the incidence of tenosynovitis (Tichauer 1978). However, the theoretical benefits of reduced ulnar deviation from alternative keyboards are mitigated by carpal tunnel pressure studies that have shown that ulnar deviation of 10° to 15° degrees does not increase pressure in the carpal tunnel compared with neutral position (Rempel *et al.* 1997). Further reductions of WMSD risk factors from typing on split keyboards could be achieved by addressing wrist extension.

Figure 4. **Resultant reaction force (F_r) exerted by the carpal bones or flexor retinaculum against a flexor tendon and its sheath as a function of wrist angle and acceleration (Schoenmarklin and Marras 1990)**

Consumer Product Design

A. Hedge
Department of Design and Environmental Analysis
Cornell University, Ithaca, New York, USA

The creation of consumer products drives much of the world's industrial economy. Consumer product usability provides a competitive advantage to companies in today's market place. Human factors deal with the application of human–system interface technology to enhance usability (Hendrick 1996) and it plays an important role in all phases of the consumer product design and development process. The label "ergonomically designed" is applied to a diverse array of products, from simple products, such as erasers and pens, to more complex products, such as computers and cars. Ergonomic design is used to denote improved product usability, whether the label is applied to hardware products, or to software. The label "ergonomically designed" is also used to differentiate between the depth and quality of thinking in the design. By definition, an ergonomically designed product should be one that is most appropriate to the task to be performed, that best fits the range of product users in terms of their dimensions, abilities, expectations and skills, and that is the easiest to use in an efficient way. Ergonomically designed products are not inherently more expensive to produce than non-ergonomic counterparts. What truly differentiates ergonomically designed products is that they are the outcome of a systematic application of human factors principles and knowledge to the product design and development process.

1. DEFINITION OF A CONSUMER PRODUCT

The label "consumer product" is very broad, and it encompasses a diverse array of products, ranging from comparatively simple products, such as kitchen utensils, to much more complex technologies, such as a car. Figure 1 shows a useful taxonomy in which products are categorized along two dimensions, design complexity, which ranges from simple to complex, and cognitive demands, which range from low to high. Products shown in this figure are organized according to these two dimensions, for example, a television (TV) is a high complexity product in terms of its electronic design and manufacture, but it poses a low cognitive demand on users, often requiring little more than pressing an on/off switch, channel changer and volume control for successful operation. By way of comparison, a car is also a complex product, but driving a car places a high cognitive demand on users, and consequently users need to be trained in how to operate this product successfully. The fundamental goal of human factors in consumer product design is to reduce the cognitive demands as much as possible so that even the most complex of products is inherently easy to use by the broadest possible range of people.

2. PRODUCT DESIGN PROCESS

Consumer products are the outcome of a product design process. The length and complexity of this process varies according to

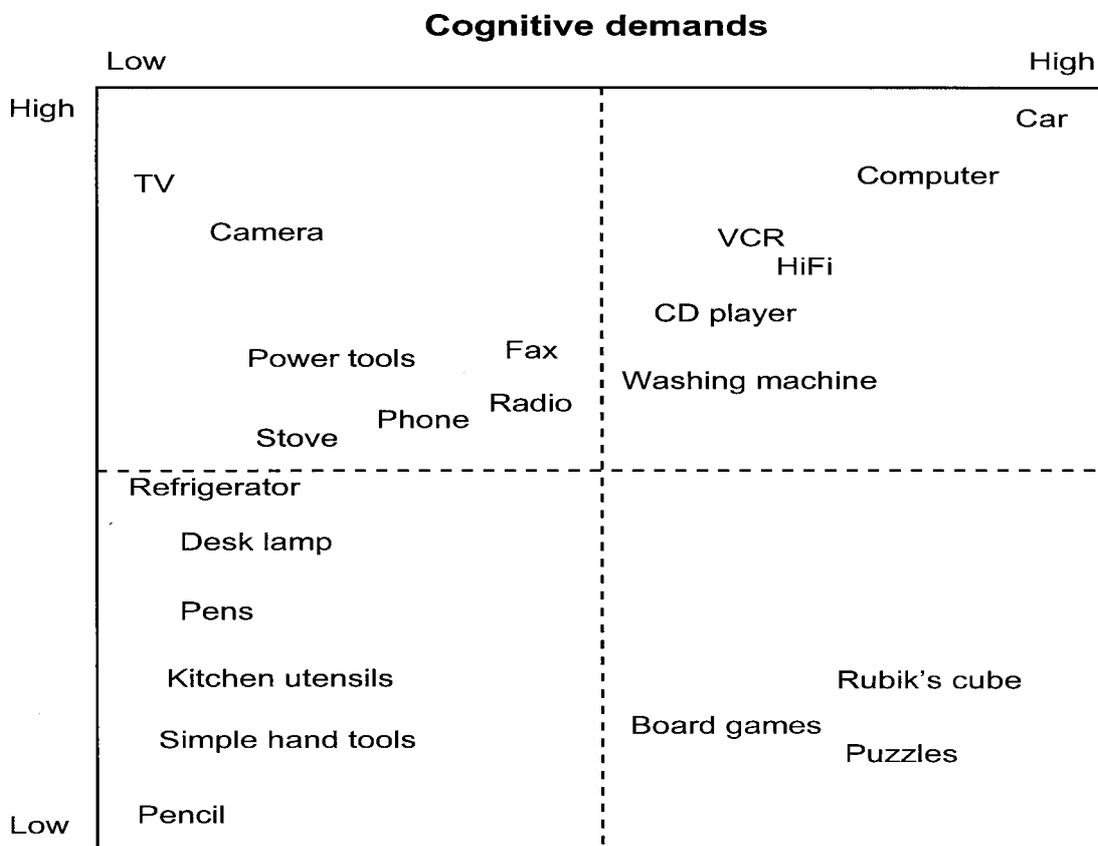

Figure 1. Taxonomy of consumer products

Figure 2. Five functional stages in the design process for a consumer product

the complexity of the product. The design process is less complex and faster for a simple product, such as a can opener, where the design process may occupy only a few weeks, than it is for a complex product, such as a car, where the process may include consideration of a much wider variety of human factors issues and extend over several years. Human factors specialists are not designers, and typically they work with designers and other professionals on a product design team providing information input as appropriate.

The diversity of consumer products makes it difficult to define a universal design process. Also, the design process does not tend to be a linear sequence of activities and it may be an almost continuous activity. As soon as one model design is finished, work starts on revising this for the next model. Consequently, it is useful to think of the design process as a general sequence of five stages of functional activities, and good ergonomic design requires human factors input at each of these stages, regardless of the nature and complexity of the product (Figure 2).

2.1 Design Need

All product design starts with the identification of a need. This need may involve defining the capabilities of a new product or it may involve defining design changes required to improve an existing product. Human factors specialists use a variety of information sources to help in this stage of the design process. Developing a clear understanding of user requirements is critically important to the development of useful and usable products.

Sometimes this involves gathering information directly from users through interviews and surveys, and sometimes it involves processing data on user accidents, injuries, and errors in operating the product, which can help to pinpoint deficiencies in current product designs that can be rectified in future designs.

Often, new product development or product redesign rests on developing a clear understanding of the consumer's wants or needs. This requires the application of techniques that can profile consumer desires and behavior in a way that produces appropriate design-oriented information. Various methodologies are employed at this stage, and typically they include at least the following:

- *User Requirements Analysis* — determining what the user really needs. This may be done using focus groups, consumer interviews or consumer surveys. It may also involve applying techniques such as Delphi analysis and Brainstorming.
- *Competitive Analysis* — comparison of features and capabilities for existing products with a view to identifying gaps.
- *Product Safety Assessment* — assessment of safety and performance issues with current products. Ensuring product safety and designing for accident prevention is the designer's responsibility. To achieve this requires ideally anticipation of all possible patterns of use and misuse. The best designed products will enhance usability and, at the same time, prevent injuries and accidents. A common approach to improving product safety is to provide warnings, labels, and instruction manuals which inform and warn the user about appropriate and inappropriate product operation. There is a substantial human factors literature on these issues.
- *Task Analysis* — systematic evaluation of the tasks to be performed and an assessment of how well existing products meet the requirements of each task. Task analysis provides details of user expectancies, knowledge, and actions during product operation.
- *Allocation of function* — functional analysis of the existing tasks can help to identify gaps in current product offerings that may offer new market possibilities. For a particular functional requirement, an allocation of function exercise can clarify what functions are required of a product and what a person will perform. For example, the development of the autofocus capability for cameras has automated a once manual function, and this has helped to improve product performance by reducing photographic errors (blurry, out of focus images), and it has also simplified the use of even complex cameras.

The human factors professional can also help to define specific requirements for different user populations — for example, defining the different ranges of issues when designing for children, adults, differently abled people, pregnant women, the young or the elderly.

2.2 Design Concept

Once design needs have been agreed by a design team these must be translated into design concepts. Design concepts are design ideas that can be built if desired. The translation of design needs into design concepts may involve writing a document — the design program — which states the goals of a design and ways in which the concept will satisfy these goals. It may also involve

preparing preliminary design drawings, either sketches or computer simulations of the product. This allows the design team to gauge product appearance and to work with clients to determine which concepts will be pursued. Usually, several different design concepts can satisfy a design. Human factors help in the process of selecting between alternative design concepts by analyzing alternative product designs based upon detailed consideration of the interactions between the user and features of the product. This systems analysis of the user–product interaction is the unique domain of human factors and the information produced allows the designer to identify product strengths and weaknesses.

At this stage there is also a need to consider relevant safety and design standards for products, as well as potential product liability issues.

2.3 Design Prototype

Often it is difficult to select among alternative design concepts without building corresponding design prototypes to be able to hold and manipulate. Human factors can play an important role in testing the ergonomic design of alternative product prototypes. This testing can take various forms. In terms of product dimensions and shape the testing might involve comparing product dimensions against appropriate anthropometric norms for the range of user dimensions. Other relevant dimensions may be tested, such as reach distances, clearance dimensions, strength.

The testing of a design prototype may also include evaluating other design attributes:

- design of displayed information, either as text, symbols, images.
- use of color, shape, and texture, especially for the design of any controls.
- weight of the product and its center of mass.
- arrangement of displayed information and controls.
- spatial mapping relationships between controls and displays, to check for concordance with any population stereotypes.
- sight lines and user orientation to the product.
- user expectations about how product features will work.
- overall user reactions to the product appearance, features, and comfort, and especially to its ease of use.

The ease of use of a product depends on the goodness of fit between the design features and the user's characteristics. Product features must match the user's anthropometric, biomechanical, sensory, and cognitive capacities and limitations. This can be particularly challenging when a diverse user population will use a product. In such situations, the human factors specialist may test the prototypes with those at the extremes of the user population, as well as those around the average, to determine the performance limits of product performance.

Human factors testing of a design prototype may be done in several ways:

- on paper, where it might involve comparisons between designs using a scaled 2D anthropometric mannequin.
- on computer, using a 3D virtual mannequin.
- in focus groups where alternative prototypes can be evaluated and information collected on the group likes and dislikes of specific products features.
- as fitting trials in which people actually hold and handle the product prototype.

2.4 Usability Testing

Those design prototypes that show the most promise may be built as functional prototypes or as functional computer simulations. These functional prototypes can then be tested more extensively in either laboratory or real-world settings to establish their usability and performance. Usability testing of a product should be undertaken prior to market release because it provides invaluable information about the product in operation. Stanton, 1998) proposes that in consumer product design at least four factors determine usability:

- *Learnability* — the product should allow users to attain an acceptable performance level in a reasonable time.
- *Effectiveness* — the product should attain acceptable performance over a desired range of tasks, in a specified range of environmental settings when operated by a specific user group.
- *Attitude* — attaining acceptable performance must be possible without undue user fatigue, discomfort, stress, frustration, or dissatisfaction.
- *Flexibility* — the extent to which the product can deal with tasks beyond those originally specified.

2.5 Product Release

When a product is ready for release into the marketplace, human factors also play an important role in defining the learning and training requirements for appropriate product use. Often the correct use of a product requires the creation of appropriate documentation, such as user manual or on-line help system. If the product is sufficiently complex it may require actual user training, and human factors plays a role in instructional design to ensure efficient acquisition of the requisite knowledge and skills to be able to use the product in a proficient way.

3. EXAMPLES OF ERGONOMIC PRODUCT DESIGNS

There are numerous examples of products that have benefited substantially from human factors input into their design. Examples include:

- bent handle tools, such as hammers and pliers, designed to improve wrist posture and reduce upper-limb injuries (Dempsey and Leamon 1995)
- domestic appliances, such as washers and dryers (Martel 1998)
- assistive chair designs that help the elderly and those with disabilities to sit and rise with ease (Mizrahi *et al.* 1995).
- electric guitars (Marmaras and Zarboutis 1997)

4. BARRIERS TO THE ERGONOMIC DESIGN OF CONSUMER PRODUCTS

Human factors input into the product design process can be substantial when there is early involvement, but frequently this does not occur and the process is suboptimal for various reasons:

- *Professional barriers* — product design is frequently undertaken by industrial designers or engineers who may have only a rudimentary understanding of the discipline.
- *Organizational barriers* — top management are often unaware of the human factors , and consequently they fail to include a human factors professional as a design team member from the outset.

- *Process barriers* — often human factors input is not sought until a late stage of product design process. Early design decisions may be made based upon engineering and economic considerations, and by the time a human factors analysis is undertaken it may be too late to change the product design fundamentally in order to enhance usability.
- *Temporal barriers* — with economic pressures to shorten product development cycle times, human factors may be excluded when companies erroneously believe that human factors input will substantially lengthen the product design process.
- *Product barriers* — although human factors professionals can usually demonstrate performance differences between alternative product designs, users may prefer designs that perform suboptimally for a variety of non-ergonomic reasons, such as appearance and familiarity (Andre and Wickens 1995).

5. PROFESSIONAL ACTIVITIES

In 1998–9 the consumer products Technical Group was the fifth largest technical group of the human factors and Ergonomics Society with 496 members, which represents some 10% of society membership. The topic of consumer products was the largest single category in survey of ergonomics research publications between 1990–3, with some 4,500 papers, which represents over 20% of publications during this time (Stanton 1998). In 1993 the human factors and Ergonomics Society began publication of a design-oriented journal, *Ergonomics in Design*.

Design of Automobile Interiors

L. Bandini Buti

Società di Ergonomia Applicata, Milan, Italy

1. INTRODUCTION

The ergonomic aspects of motor vehicle interiors are not explicitly treated by the European Community directives on "approval of motor vehicles," which, on the other hand, define performance in relation to active and passive safety, to emissions and to the characteristics that various vehicle typologies must have.

The SAE normatives (Society of American Engineers) apply to the safety of motor vehicles, and define the anthropometric standards for the dimensional relationship between man and automobile. Car manufacturers have agreed on a common normative standard based on those of the SAE (European normatives ECIE — European Car Manufacturers Information Exchange Group) to diffuse and elaborate criteria for habitability and to define the car interior "package." The Community Directive for cars, which, on the other hand, explicitly requests that ergonomic principles be respected, is not, however, applicable to vehicles in movement, and therefore not to motor vehicles.

Industry has felt the need more and more to introduce ergonomic principles into the design of vehicle interiors, irrespective of the need to comply with laws and to adhere to regulations. In fact, the major car manufacturers have created bodies and laboratories concerned with ergonomics, some of which indeed have been active since the 1960s (Wisner *et al.* 1965).

2. EVOLUTION OF INDUSTRIAL PRODUCTS

The request for the introduction of ergonomic concepts into industrial products has been increasing since the beginnings of industrialization in proportion to factors regarding consumer expectations, developments in technology and the involvement of those carrying out the planning. In the evolution of industrial products there are homogenous periods.

2.1. First Period, up to the 1950s — Technology Engineers

In this first period design is characterized by the supremacy of technology and engineers. Products are "simple" from the point of view of use in that every function is performed by an easily identifiable component. One need only think of the structure of the mechanical typewriter, which is heavily conditioned by the levers that control the hammers. The structure of the product unequivocally indicates its function.

The automobile of the 1930s and 1940s was a product determined by technology. It is in this period, in fact, that those technological and mechanical innovations that will profoundly change it and give it the characteristics of a mature product are developed. Engineers conceived the functional aspects of the vehicle produced, and the vehicle was then "dressed up" by bodywork and parts design specialists and craftsmen. The purchaser of the automobile was interested above all in performance offered and technological innovations, which were often revolutionary. In this period ergonomics, in terms of an organic attitude of attention to the characteristics and needs of the user, may be considered absent.

2.2. Second Period, up to the 1990s — Image Designers

The second period, which continues to the present day, is characterized by the supremacy of image and designers. Products, materials and technology are still reasonably simple, and so can be easily dominated by designers by means of a general knowledge of their field. Technological aspects are considered as an important part of the design process but are, however, subordinate to the objective of providing products with original formal qualities.

In the 1970s the evolution of the market and various other factors, among which was the petrol crisis, began to exacerbate competition between car manufacturers who started investing, above all, in image. Also buyers, more frequently, choose according to image, which moreover responds very well to new life-styles. This is why many products with a fairly poor or traditional technological content are renewed by means of design inventiveness, which is also the invention of new modes of use that are more coherent to the evolution of society. One may take as an example portable televisions that destroy the myth of the television as a status symbol.

Respect for human characteristics in the design of motor vehicles comes from the sensitivity of the designer. Ergonomics begins to be introduced, but as an interventional option near the end of the design process, with the aim of adding further qualities, which are considered, however, as accessories.

2.3. Third Period, from the 1990s — Quality Work Groups

In the past few years, the organizational model that left the development of mass-produced motor vehicles to the creativity of designers and their reliability to technicians has found itself in crisis because it has been seen that the product, as realized by the technicians, ended up corresponding less and less to the synthetic and ingenious images of the artist. This has been proven by the constantly increasing complexity of the design and realization process, owing to norms and regulations (for safety and comfort), to the request for ever increasing levels of performance (usability), to new trends (ecology and energy efficiency), and to obligations dictated by marketing, technology and Information Technology (IT). An ever higher level of specialization in design and production is also called for, along with a new role for component suppliers who end up conditioning overwhelmingly the development of the design concept.

Thus, we arrive at the third phase, which represents the tendency currently in development, and which is characterized by quality and work groups.

Users take it for granted that a product will meet expected levels of performance, they appreciate more and more the qualities of use of a product, and they evaluate characteristics of comfort and pleasantness which, in the end, influence and direct their

choice of purchase. To meet these needs, many areas of manufacturing, but in particular that of motor vehicle production, are developing new organizational models that have quality as their objective and propose a design phase organized in work groups, in which specialists from various sectors relative to the development of the project and to various disciplines participate. Among these, those who study usability and pleasantness are becoming ever more important. At this stage, the application of ergonomics to design becomes a necessary phase, not just a verification of the finished product.

3. ERGONOMIC QUALITY IN MOTOR VEHICLES

In the automobile industry, the focus on ergonomics in the design of vehicles is, these days, automatic in that it is foreseen and imposed by procedure. Ergonomics is therefore present right from the start of the design process, and the possibility of making changes is still great, which allows ergonomics to have a great influence right from the initial stages of conception of the product. In fact, if one waits until a prototype is available to carry out ergonomic verifications, as still happens with some cases, the possibility of making significant changes becomes almost zero and any changes would generate extremely high costs of intervention.

Analysis and research of automobile interiors during the design process vary in terms of means, methods and instruments depending on the phase of development of the project, from the non-material idea to the functional prototype.

In the first, non-material phase, the design of the vehicle is presented purely as an idea, in that it is made up of briefing documents and graphic or virtual suggestions. In this phase there is very little possibility of getting the opinions of people who represent the actual user in order to obtain directions and ideas relative to the use of the product (which does not yet exist), while it is possible, on the other hand, to involve experts.

Following this, the idea can be represented making use of mock-ups (as a whole or in parts) which faithfully represent the dimensional aspects, but tell one very little, if anything, about finishes and functioning. Mock-ups allow one to carry out verifications of use on subjects, but they do not provide a complete experience of use at all (for example, changing gears, even though this cannot be done when stationary; evaluating the comfort of seats in the absence of the vibrations associated with the movement of a vehicle; the quality of feel of a steering wheel which is related to the surface finish and to the "grip" of the materials used; qualities of noise and force which can only be evaluated meaningfully on finished products fitted to the actual structure they will be used on). The sample of subjects interviewed cannot be made up ordinary people, but rather it is necessary to obtain the services of selected subjects who can mentally simulate real conditions of use, people, in other words, who can operate in the abstract. When it is possible to create fully or partially functional vehicles, analyses can be carried out with real subjects under real conditions of use. Experience has shown that even when functional prototypes are available it may not be easy to carry out tests using ordinary people, for reasons relating to the classified nature of a product not yet on the market or for reasons of safety relating to products that are not yet approvable.

The ergonomic quality of motor vehicles regards the quality of the relationship between the user and the product during use;

it is, therefore, the result of the interaction of the ergonomic characteristics of the product with specific users in specific environments and in specific contexts of use.

To define ergonomic qualities it is necessary to compare the reactions of users (either single users or homogenous groups of users) to the ergonomic characteristics of the product in order to define a scale of quality. Ergonomic characteristics are therefore aspects, of themselves neither positive nor negative, that have to be studied during analyses and the definition of design.

In relation to motor vehicle interiors, the parameters able to influence psychophysical well-being or pleasure of use are habitability, accessibility, comfort, pleasantness, usability and external visibility.

3.1. Habitability
This is the ability of the motor vehicle to accommodate the user.

3.1.1. Postural comfort
The driving arrangement refers to a posture conditioned by the constraints imposed by the act of driving (awareness of the road, awareness of the dashboard and displays, operating the steering wheel and other controls, operating the pedals).

Passenger arrangement (both front and back) refers to postures that are very different with respect to that of the driver, as they are only slightly constrained by the criteria of safety norms and regulations (the use of safety belts, normatives relating to the carriage of children).

3.1.2. Spaciousness
The spaciousness required by the upper body refers to the restrictions, both while moving and stationary, of the trunk and arms. The spaciousness required by the lower body refers to the restriction of the legs and their movement.

3.1.3. Perceived habitability
The perception of space is a determining factor in the general sensation of comfort and it is provided by the complex relation of the physical dimensions of the inside of the vehicle to the perception of that which is external to the vehicle (by means of the windows and windscreen), and to ease and liberty of movement inside the vehicle and the image that forms and colors create.

3.2. Accessibility
This is the absence of restrictions of movement in getting into and out of the vehicle. It is the capacity to allow these movements to be carried out with a minimum of postural change and the maximum possible naturalness.

For the upper body, this may be conditioned by the thickness of clothes, by the mobility they allow, and by the presence of objects being carried (bags, umbrellas, etc.), while for the lower body, the posterior, legs and feet, it can be conditioned by the clothes (skirts, trousers) and type of shoes being worn.

3.3. Comfort
This is the general state of well-being that derives from the reduction or absence of perceived disturbances. It is a passive and sensorial concept, synonymous with convenience.

3.3.1. Vibrational comfort

This regards the effects of the mechanical vibrations induced by the motor and those induced by the road surface, transmitted through the suspension system.

3.3.2. Acoustic comfort

This regards the effects of noise produced by the mechanical parts and of the noise of movement (air turbulence, road surface). It is influenced by the mechanical characteristics of the vehicle and by the degree of soundproofing of the vehicle interior.

3.3.3. Tactile comfort

This regards the quality of contact with the surfaces of the vehicle interior. It is conditioned by the intensity (touch only, operating, operating with force) and duration of contact.

3.3.4. Comfort of vision

This regards the quality of forms and colors.

3.3.5. Thermal comfort

This regards the quality of the microclimatic conditions of the interior and the thermal sensations of the contact surfaces. These can derive from the influence of the external climate on a stationary vehicle (a hot or cold vehicle), and from the microclimate owing to the systems of air treatment in the vehicle.

3.3.6. Comfort relating to smell

This regards the effects of odors given off by materials and surface treatments.

3.4. Pleasantness

The sensorial pleasantness of products regards qualities perceived through the human senses (touch, sight, hearing, smell, kinesthesia) that cannot be absolutely measured, qualities that are valid for all and for always. It is an active and cognitive aspect that responds to expectations coming from a mental model, recalled by the product and re-projected onto the product itself.

3.4.1. Acoustic pleasantness

This regards the quality of perception of the noise produced by the vehicle while in movement, during the operation of its parts (e.g. the opening and closing of doors) and of the artificial noises of signaling and warning.

3.4.2. Tactile pleasantness

This regards the pleasure that can derive from bodily contact with surfaces. It is influenced by the quality of the surface and the intensity and duration of the contact.

3.4.3. Visible pleasantness

This regards the pleasure that can be derived from the sight of forms and colors that are perceived as harmonic or meaningful.

3.4.4. Thermal pleasantness

This regards sensations of warmth or cold that can derive from contact with the materials that go to make up the interior (heat isolators or conductors).

3.4.5. Pleasantness relating to smell

This regards the pleasure that can be derived from the presence of odors that are perceived as pleasant.

3.5. Usability

This is the effectiveness, efficiency and satisfaction with which specific users can achieve specific aims in particular environments (ISO 9241, which regards the design of equipment with video terminals for use in offices). It is the ability of the system to perform its task, when operated by the user in the operative environment. It is measured in terms of cognitive charge, sturdiness and accessibility of the system.

3.5.1. Visibility

The ability to distinguish a stimulus from a background. It regards the capacity to identify the subsystems (and in particular the controls) interior to the vehicle.

3.5.2. Legibility

This regards the visual quality of symbols, signs and indicators of the control system, and the graphic or descriptive indications of the operation of the controls.

3.5.3. Intelligibility

This regards the quality of the message transmitted by the control and its interpretation on the part of the user. It depends on the user's knowledge and experience, on their cultural characteristics, and on their individual ability to perceive the symbolic messages.

3.5.4. Ease of reach

This regards the ease of reach of the controls. It depends on the anthropometric characteristics of the subjects and postures assumed.

3.5.5. Ease of operation

This regards the characteristics of the controls as a whole, that allow the user to achieve the result expected in an effective, efficient, and satisfactory manner. It regards:

- the mode of operation (number of fingers employed, direction of movement, characteristics of handling and holding during operation and on letting go);
- prehensility (dimensions, shape, surface design, grip, softness of parts to be handled and gripped);
- perceived weight and effort of operation (the effort necessary for carrying out the movement from one position to another on the part of the user, expressed as maximum force required and the relation between force and movement);
- form (the semantic message transmitted by form to its operational characteristics); and
- the space that allows function in movement to take place.

3.5.6. Feedback from controls

This is the quality of the message given off by the completed operation. It regards:

- visible feedback (warning and indicating lights and symbols);
- acoustic feedback (significant mechanical noise, artificial noises and sounds); and
- immediate feedback (perception of the completed operation, variations in the force required for the operation, perception of the end of the operation.

3.6. External visibility

This is the external field of vision perceived from the positions assumed by the occupants of the vehicle.

3.6.1. Fields of visibility

The direct field of visibility is the quantity of the external environment visible from the seating positions through the windows and windscreen of the vehicle. The indirect field of visibility is the dimension of the external environment visible through mirrors or videocameras.

3.6.2. Quality of vision

- Transparency characteristics of the windows and windscreen.
- Characteristics of the removal of rainwater and mist.
- Reflections on the windscreen caused by the illumination of the instrumentation and incidental light on the dashboard.

4. OPERATIVE ASPECTS

Ever increasing competition demands a reduction in the time to market and a response to the needs of the user, and imposes stringent constrictions on the designer. Today, the buyer is much more pragmatic than in the past and so is prepared to pay when faced with an adequate equivalent, which he or she also identifies with convenience and ease of use. As a result of this, even style has to adapt to the presence of ergonomic obligations as well as normative and technological ones.

In the automobile sector ergonomics aims to introduce the concepts of habitability, accessibility, comfort, usability and pleasantness into vehicles in such a way that they respond to the needs and desires of the user. Ergonomic intervention must not, under any circumstances act as a substitute for stylistic creativity. It will provide, along with technology, marketing and production, important elements for a formulation based on the incoherent obligations and propositions that go to make up the project "input," that the designer, with his creativity, will have to transform into a functional, coherent and purposeful product.

To achieve these results ergonomic principles must be introduced during the vehicle design process by an ergonomics body that will also carry out verifications on the finished product. This body's objective is to provide the ergonomic input necessary for the stylistic definition of the design plans, so that any modifications that would have to be made after the definition and freezing of the style (both interior and exterior) are reduced to a minimum or eliminated. Ergonomics bodies in companies carry out both autonomous and applied activities.

4.1. Autonomous Activities

- Strategic activities — above all these are speculative and experimental activities for the definition of the methodologies, instruments and means required for achieving the expected results. They refer to the particular articulation in bodies and to organizational structure proposed for the development of the products typical of the motor vehicle sector and of the specific manufacturer.
- Normative activities and those of standardization — consist of the diffusion of the normatives relating to the relationship between man and machine, of the definition of specific ergonomic norms and standards, and of their application and verification.

- Preparation and up-dating of an ergonomics data base — consists of the definition of ergonomic parameters for comparing different motor vehicles, and of the up-dating of a data base which all designers have access to.

4.2. Applied Activities

These are the planned and regulated activities that are developed by ergonomics bodies in collaboration with platforms for the development of a specific model. The introduction of ergonomics into the standard design procedures avoids the episodical nature of intervention and has substituted the traditional activity of "consultation on request" on behalf of those in charge of the models or the platforms. The activities of the ergonomics body within a work group that is developing a model foresee:

- the definition of the ergonomic objectives for the specific model. This is based on analysis of the competition, on studies made with panels and on specific choices for the model;
- the definition of the packaging and the graphic representation of the ergonomic aspects predicted for the interior and exterior styling of the specific model. Values are represented as ranges of accessibility in such a way as to direct, yet not constrict, the activities of the designers and stylists; and
- collaboration on the introduction and verification of ergonomic parameters in the project development of the model (continuous feedback).

5. MEANS AND INSTRUMENTS

The introduction of ergonomic principles into projection and design requires the definition of standards, ranges of values and methods of verification that must be obtained from tests with subjects on physical objects or with virtual tests.

5.1. Tests with Subjects

- *Movement analysis* — carried out by means of the video recording of predefined or free tasks with products, prototypes or mock-ups. The analysis of the filmed material based on accepted standards and the elaboration of the data collected, allow one to formulate conclusions. The complexity of the tests tends to limit the number of subjects to between 20 and 30.
- Survey of the pressure of contact between the human body and the seats — carried out in a static environment or with tests on the road using sensors, making use of subjects of various sizes.
- Physiological tests — carried out in order to evaluate the physiological parameters of subjects undergoing road tests.
- Usability tests — carried out on the finished product or on prototypes using subjects with differing psychophysical characteristics depending on the nature of the product being studied. Evaluations are carried out with one or more methods of measurement: error analysis, time and operational analysis or analysis of the strategies employed by subjects in order to achieve their objective.
- Pleasantness tests — carried out on finished products, on prototypes or on mock-ups, using subjects to evaluate the sensorial qualities perceived by the user through the senses (touch, sight, hearing, smell, kinesthesia). Pleasantness is subjective and heavily linked to variable aspects of the user relating to their ethnic or social background, to different

individual perceptive characteristics, and to the evolution of society's general or individual "tastes."

5.2. Virtual Tests

- Modeling — use of three-dimensional mannequins/dummies to evaluate certain ergonomic parameters of the vehicle. They are not intelligent and therefore do not require preliminary calibration with subjects. They are applicable to the analysis of posture, visibility and usability. They can be effectively applied when graphic representations of the project are available but solid or operational representations are not.
- Simulation — use of computer packages to simulate the movements of entry to and exit from the vehicle and the movements carried out when inside the vehicle. As they are simulations of human behavior, they require the definition, through testing, of the strategies and mathematical models of behavior (biomechanical model).

6. CONCLUSIONS

The attitude that left to the intuition and sensitivities of the designer, the response of a product to the needs and characteristics of the user, no longer seems to satisfy the complexities of user demand, technological specialization and the complex organization of production. Common sense, which may still preside over the design of simple products, must give way to methods and means, and to suitable and replicable concepts, which yield results that can be evaluated.

More and more, ergonomics is becoming a body of specific knowledge that proposes sophisticated methods of investigation and study. Confirmation of this is provided by the fact that, in ergonomic centers in the motor industry the presence of specialist mathematicians and bioengineers, as well as cognitive psychologists, has become indispensable. It should be added that the formation of "on the job training" and "apprenticeships" providing contact between apprentices and those with greater expertise, is rendered difficult by an elevated staff turnover, and so formation and continuity of company discipline relies more on the memory of the body itself than on that of the staff. Another observation relates to the professionalism of designers, which is becoming ever more accentuated in the direction of specialization in formal aspects, an inclination of the evolution of academic studies that tend to favor aesthetic and formal aspects over humanistic ones.

Design of Visual Displays for Teleoperation

S. H. Park† and J. C. Woldstad‡

†School of Industrial and Mechanical Engineering, Hannam University, 133 Ojeong-dong, Taeduk-gu, Taejon 306-791

‡Department of Industrial Engineering, Texas Tech University, Lubbock, TX 79409-3061, USA

1. INTRODUCTION

Human exposures to hostile work environments can be reduced when tele-operated systems are used to remotely control manipulators in these environments. Tele-operation systems were initially developed by the nuclear industry, but are currently applied in areas including surgery, construction, mining, warehousing, firefighting, undersea exploration, military operations, and space. The role of human operators in tele-operated systems varies with the level-of-automation of the system. Some systems require only supervisory control from the operator, while many others require direct manual manipulation through a controller. However, even for highly automated systems, human operators play an important role as a backup when the system fails.

Telepresence can be achieved through sensing appropriate information about the tele-operation task environment, and providing this information to the human operator at the remote site (Sheridan 1992). A great deal of human engineering information concerning the design of workstations for telerobotic systems is closely related to meeting telepresence requirements. In this regard, human depth perception (as a third dimension) based on the information provided by the two-dimensional (2D) surface of a video display terminal (VDT) very much determines the quality of a tele-operation system.

2. DEPTH PERCEPTION

A visual display has a basic limitation in that the surface of the display screen is two-dimensional. However, when designing a visual display for tele-operation tasks, it is necessary to represent depth or distance as a third dimension along the line of sight. Depth and/or distance perception are achieved through the combination of several depth cues. The term, cues, has been utilized to formalize the specification of stimulus conditions for space perception (Carr 1935).

In the study of perception, an object and its properties in the world are called distal stimuli. They only stimulate our nervous system by patterns of energy (e.g. light energy, sound pressure wave). We call the patterns of energy that reach and affect our sense organs proximal stimuli. Therefore, a depth cue is a pattern of proximal stimulation that contains information about the spatial location of distal objects. Depth cues can be classified into two types: monocular and binocular. Monocular depth cues require the activity of a single eye; binocular depth cues require the use of two eyes.

2.1. Monocular Depth Cues

2.1.1. Relative size

The same-sized objects produce smaller tracings when they are at greater distances: this is called the cue of relative size, or size perspective. By comparing the apparent size of a distant object with that of a similar, much closer object, the relative distance of the distant object can be approximated.

2.1.2. Interposition

A nearer (overlapping) object interrupts the outline of a farther (overlapped) object. This is an effective depth cue, but it can only indicate which object is in front, not the distance separating them.

2.1.3. Linear perspective

If the size of a distal object is fixed, the visual angle will be inversely proportional to the distance from the object: this is called linear perspective. A constant distance between points subtends a smaller and smaller angle at the eyes as the points withdraw from the eye. For example, telephone wires appear to approach each other (i.e. the retinal images of the lines converge) as the distance from the eyes increases although they are parallel. Therefore, converging lines are a cue that they are parallel and receding in depth.

2.1.4. Monocular movement parallax

When a subject's eye moves with respect to the environment, or vice versa, there exists a differential angular velocity between the line of sight to an object (fixated) and the line of sight to any other objects. For example, far objects move with the direction of movement, while near objects move against the direction of movement (Graham 1965). By observing the amount and relative direction that a given image moves on the retina, its distance can be approximated.

2.1.5. Familiar size

We can use objects known size to infer relative depth. For example, we know a man is taller than a boy. However, if they produce the same size of retinal image, then we deduce the man is located farther away than the boy. This is often a weak or ineffective cue (Hochberg 1978).

2.1.6. Light and shadow distribution

Shadows provide some information about the orientation of the objects and their three-dimensional (3D) shapes. Objects may appear to lie at different distances and have different dimensions as combinations of shadow and highlight change (Graham 1965). If objects have a light source from one direction, they will have shadows unique to their shape and orientation.

2.1.7. Gradient of texture-density

A gradient is the rate of some measured property changing over a continuous, extended stimulus. The surface of most objects is likely to be covered with a reasonably uniform texture or pattern. When looking straight ahead at a textured surface, the gradient of texture-density is zero; as the slant increases, the gradient increases. The gradient of texture-density can provide precise and relatively unambiguous information about the distances and sizes of surfaces and objects in the world (Hochberg 1978).

2.2. Binocular Depth Cues

2.2.1. Convergence

The eyes are capable of convergence, in which both eyes turn inward toward the medial plane. A large convergence corresponds to near objects and a slight convergence corresponds to far objects. The ocular muscles control the angle of convergence. The brain receives proprioceptive messages from the ocular muscles about the degree of convergence (Wickens 1992). By analyzing the information received, the brain can approximate the angle of convergence. In this way, convergence may serve as a depth cue. A large convergence may lead to the response "far-off", while a slight convergence may lead to the response "nearer."

2.2.2. Stereopsis

The retinal image of a distal object in the right eye is different from that of the same distal object in the left eye. The difference in the retinal image plays a great role in spatial discrimination. In the 3D world, the view each eye receives is somewhat different because the two eyes see the object from slightly different positions. Differences in these views give two possible depth cues: double image (each eye contributes different image of far object when viewing near, and vice versa) and binocular disparity (Hochberg 1978). The disparity is the difference between where a target falls on the right eye and the left eye.

The disparity can generate a powerful depth cue. This depth cue can be obtained by taking two photographs of a scene (a stereoscopic picture pair, stereogram), one from the position of each eye (65 mm apart average), and presenting each picture to its appropriate eye, and then viewing such photographs with special devices called stereoscopes. The stereoscope is composed of two conversing lenses and a supporting frame that simply separate right and left views.

3. VISUAL DISPLAYS

3.1. Principles of Display Design

3.1.1. Visual momentum

Visual momentum refers to the visual landmarks that film editors generate to reduce visual inconsistency among several scenes when editing a film. The concept of visual momentum can be applied to integrate information of one display into the other displays among multiple displays. For example, a visual interface for a telerobotic system can be composed of multiple 2D displays having different reference frames (e.g. a plan view and side views). In such a case, human operators must integrate information across multiple displays in order to control the robots arm. The concept of visual momentum can be applied by presenting a line originating from the face of the gripper of the robot. The line always aims the direction of the gripper, and therefore visual momentum is provided across the displays having different reference frames.

3.1.2. Object integrality and the principle of proximity compatibility

An object (or integrated) display is a display which integrates multi-dimensional information into one object. For example, the conventional attitude indicator in aviation represents the aircraft's pitch and roll information (2D) in one display. It should be noted that integrating two dimensions into an object will help performance if the information associated with those two dimensions is relevant, but decrease performance if the information is irrelevant.

The integrality of displayed was further expanded by Wickens and his colleagues, introducing the proximity compatibility principle — "To the extent that information sources must be integrated, there will be a benefit to presenting those dimensions in an integrated format (high mental proximity). In contrast, to the extent that information must be treated separately (low mental proximity), the benefits of object displays will be reduced" (Wickens 1992: 98). In summary, close proximity can be used to increase performance if parallel processing is guaranteed in the object display. However, it may cause problems and decrease performance if tasks require focused attention on a particular dimension in the display.

3.1.3. Working memory

New information is stored temporarily at a working memory until it is used or stored in a long-term memory. It is well known and accepted that human working memory is limited in size and time. The concept of chunk has been employed to define the working memory limit, where a chunk can be any set of information associated with long-term memory. Based on the concept of chunk, human working memory is limited by 7 ± 2 chunks of information (Miller 1956). When designing visual displays, it is desired to avoid exceeding the limit of 7 ± 2 chunks of information at the level of working memory.

3.1.4. Mental rotation

The time required to compare two visual images increases linearly as the angular disparity between the two images increases. For example, using multiple displays having different reference frames, human operators must mentally rotate a standard alignment in congruence with the alignments of other views. The mental rotation requirements of a task are more demanding if human operators must frequently scan different views.

3.2. Dimensionality

3.2.1. 2D displays

A 2D display is an orthogonal-view that provides spatial information about two dimensions. The only depth cue that can be provided using a 2D display is interposition, which only indicates which object is in front of the others, not the distance separating them. A multiple 2D display can be composed of a plan-view, a front-view, and/or side-views (i.e. all 2D orthogonal views). In the multiple 2D display, 3D spatial information is provided by the combination of at least two views; for example, the plan-view provides spatial information about two dimensions while the side-view or the front-view provides spatial information about a third dimension, such as altitude.

A 2D display does not provide any depth information in a third dimension. However, it provides unambiguous depth information in two dimensions and removes ambiguous pictorial depth cues. The 2D display, if provided with other 2D displays (i.e. forming the multiple 2D display), can provide unambiguous depth information in 3D. As compared with the perspective display, however, one of the main disadvantages of the multiple 2D display may be additional scanning and integrating effort among separate displays.

3.2.2. 3D displays

A 3D perspective display can be achieved by projecting an object onto the view plane (projection plane) and then mapping the view plan onto the display screen. The 3D perspective display provides more natural spatial information about 3D environments by creating the appearance of depth along an observer's line of sight, as compared with the 2D display. Most of the monocular depth cues can be achieved through the 3D perspective display. However, the monocular depth cues are inherently ambiguous. Based on the human stereoscopic vision capability of fusing two retinal images into one image, a stereoscopic display can be generated by adding a depth cue (called stereopsis) to the perspective display.

3.2.3. 2D versus 3D displays

It is hard to conclude that 3D displays are superior to 2D displays, or vice versa. A multiple 2D display can improve tele-operator performance as compared with the perspective display if the task requires frequent use of focused attention on a particular dimension. In general, the choice of display format is dependent on the specific task being performed (e.g. gross positioning tasks requiring global attention or dexterous tasks requiring focused attention).

3.3. Use of Visual Aids

Using computer generated visual enhancement cues can enhance the communicative purpose of a visual display. Figure 1 shows several visual enhancement cues that extend from the point of motion (gripper of the robot) and allow the user to orient the manipulator in space. In Figure 1b a solid reference line is placed orthogonal to the face of the gripper of the robot allowing the user to orient and aim the gripper and objects attached to it. The reference line is a useful cue that has been found to help operators orient and position the gripper when performing a telerobotic task. However, it does not provide appropriate depth information. A translucent reference cylinder or four solid lines (Figure 1c and d) are better enhancements. These cues have volumes in 3D space; therefore, they not only aim the orientation of the gripper but also provide depth information by overlapping other objects in the work environment.

4. CONTROL FACTORS

4.1. Display–Control Correspondence

One-to-one correspondence between display and control devices, ensuring that a control movement and a resulting change in the display are in the same relative location, should be provided as far as possible (Sheridan 1992). In general, lateral displacements < 15° can be adapted to by humans almost completely. However, the ability to adapt to mismatches is decreased for angles > 15°. Any type of inversed feedback is most disruptive.

4.2. Force Feedback

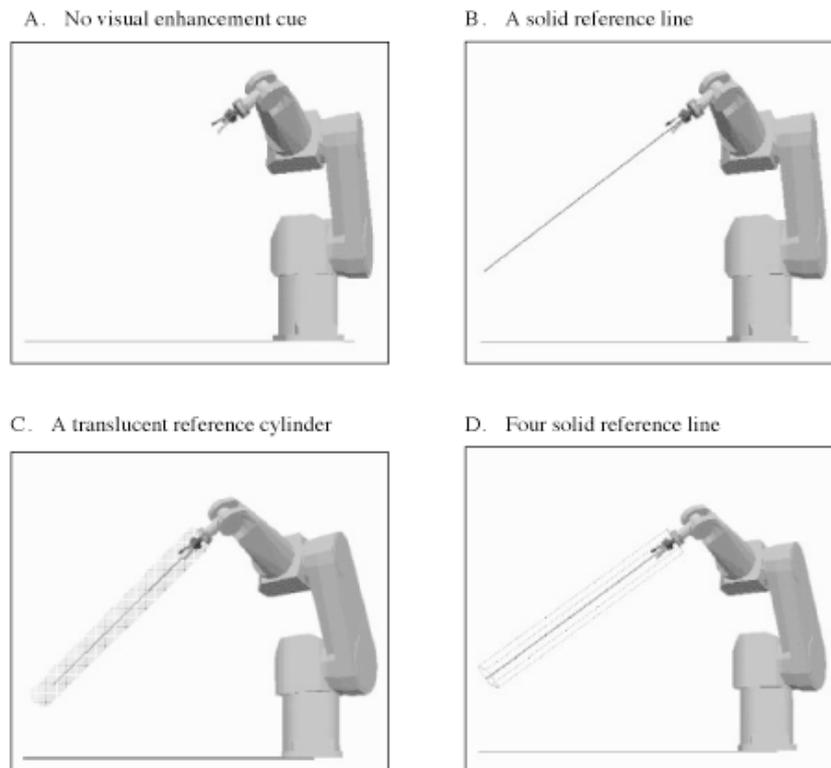
Tele-operation performance can be improved when force feedback is provided. The human body's joint, muscle, and tendon receptors sense the net reaction force and torque acting on the hand (i.e. resolved force sensing as defined by Sheridan 1992). Force feedback to human operators can be achieved by measuring the force and torque acting on the tele-operator, and then driving motors on the controller which provide the hand of the human operators with the same force and torque. However, there is little information about the effectiveness of this method. As an alternative, display of force feedback to the operator can also be


Figure 1. Level of visual enhancement cues for a telerobotic task. (A) No visual enhancement cue; (B) a solid reference line; (C) a translucent reference cylinder; (4) four solid reference line.

achieved through the use of computer graphic force-torque display.

4.3. Teletouch

Teletouch refers to the remote sensing of differential forces acting on the skin in time and space. Teletouch has been found to support depth perception, provide detailed information about surfaces of objects contacted by grippers, and provide information about surfaces visually occluded by other objects. A major problem associated with teletouch is the difficulty associated with displaying artificially sensed pressure patterns to the skin on the hand, when the hand is at the same time operating the control stick (Sheridan 1992). One useful way to present teletouch information to the operator is the use of visual display method (i.e. visually representing tactile data).

5. RECOMMENDATIONS

- Select display dimensionality based on the given task being performed. Consider a multiple 2D display format if the task requires frequent use of focused attention.
- For 3D perspective displays, provide visual enhancement cues to aid depth perception.
- As a visual enhancement cue, a single line is not sufficient enough to aid depth perception. Design a visual enhancement cue which itself has a volume in 3D space.
- Consider task difficulty when selecting the level of visual enhancement.
- For 3D perspective displays, ensure that the control movement and the resulting change in the display are in the same relative location. Maintain lateral displacements to < 15°.
- Provide the hand of the human operator with the same force of the manipulator (force feedback). Consider a display of force feedback as an alternative.

Ergonomic Design of Factory Buildings in Tropical Countries

R. Nath Sen

Ergonomics Centre, Multimedia University, 63100 SelangorMalaysia

1. INTRODUCTION

Those who build factories and office buildings seldom consider the use of the principles of ergonomics (the science, technology and art of people at work) with special reference to the effects that rooms, spaces and buildings have on people and their performance. A factory building may be suitable for today's needs but would almost certainly be inadequate for the needs of the future.

Many of the factories in the tropical countries are, unfortunately, mere copies of the design of the factories built earlier in the cold climate and hence not appropriate to what is required for such an environment. Many of the new types of factory buildings, therefore, are worse than those found with traditional factory buildings in hot climate.

The problems of the working environment, especially in hot tropical climate in the developing countries are even more numerous and of higher magnitude than those in cold climate. Unless correct measures are taken at the very beginning of the design of the working environment, so that the workplaces are physically and mentally satisfying as well as efficient and economic, it may be too late to do much at later stages or it may be too costly to effect modifications, if at all possible.

The ergonomist and architect should design the factory buildings as to bring out the best of the natural possibilities. The task of the environmental control is to ensure the best possible thermal conditions by relying on structural (passive) controls, which may obviate the need for any mechanical or electromechanical (active) controls; but even if these controls have to be used, their task will thereby be reduced to the minimum.

2. BASIC ELEMENTS IN DESIGN PROBLEM

Four basic determining elements in every design problem are function, form, fabricating material and finance. An ergonomist must bring a harmony between these elements in the design of factories for hot tropical climate.

The important factors in the proper design of the factories are :

(1) The site relation to human habitation, landscape, vegetation, altitude, and others, whether near the periphery of a town or in rural situations or in a valley, to protect from flood, earthquake, storms, insects, termites, to avoid inversion temperature (figure 1), pollution, etc. to have good ventilation, low humidity, etc.

(2) The orientation of the building, including roofs, walls, doors and stairs, windows, etc., in relation to the wind direction, and the angle of solar radiation, to have the best natural ventilation and minimal thermal heating of the buildings, in relation to human comfort, activity and efficiency.

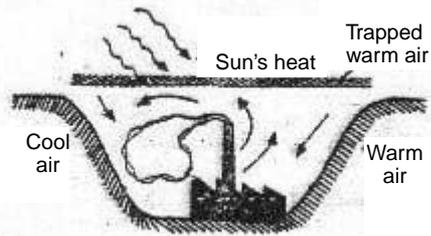
(3) The insulation and thermal capacities of the building materials.


Figure 1. Possible effects of temperature inversion on a factory in a valley.

(4) The use of sound material and the form of the construction.

(5) Correct design of workspaces, windows, doors, stairs, corridors, etc., based on the static and dynamic body measurements and movements of the workers.

It is so obvious that the types of factory buildings and building materials for cold climates cannot solve the problems of the factories in countries where heat is the dominant problem, where, due to economic reasons, the consequences of poor design cannot be compensated by very costly electromechanical air conditioning, and where the workers differ in body form, thermal responses, etc.

3. DESIGN IN RELATION TO METEOROLOGICAL CONDITIONS, SITE, LOCATION AND LAYOUT OF SURROUNDINGS

It is very important to the location and design of factory buildings to consider the meteorological data over the years concerning rain, temperature, sunshine, humidity, speed and direction of wind, smog, etc. If the yearly data are not recorded and analyzed, it is essential to have at least data for 12 months for the selection of sites and design of factory buildings. Analyses of many of the elements of microclimate have a deciding role on the sites and location of the factory buildings, particularly in tropical climates.

The air temperature in a city can be about 8ºC higher than in the surrounding countryside and a difference of even 11ºC has been observed.

Local features, including the different types of buildings can substantially modify the air movement and the air temperature of working environment. In olden days, heavyweight stone or brick building with high thermal capacity and with high ceilings were being used in tropical climates to provide comfortable conditions during the summer months as well as in the winter. Nowadays, because of the cost, very lightweight buildings with low thermal capacity and with thin concrete slabs are being used, which would heat up quickly during the day and cool down quickly during the night. When large glass windows are provided to increase the natural daylight, it facilitates entry of solar radiation also, which warms the surfaces inside the room, which in turn re-radiate, and this results in the uncomfortable conditions experienced inside the building.

It is important to know the frequency, like duration and nature of some rare events such as dust storms, thunder storms, earthquakes, tornadoes, hurricanes, floods, etc., since the designer must classify these rare events into those which affect human comfort and those which may endanger the safety of the factory, buildings and the lives of the workers.

3.1 Wind Speed

Wind speed is very important for comfort in the humid climate of tropical countries. There is always a reduction in wind speeds near to the ground- down to 40 percent over rough terrain and 30 percent in urban centres. Under certain conditions with fewer slopes, funnelling effect, sharp ridges and solid obstructions, wind speed may increase due to suction, turbulence and vortexes. It is possible to locate sites, which would experience a considerable degree of natural wind. The wind speed on urban sites is reduced to less than half of that in the adjoining open country. The funnelling effect along the closely built-up street or through gaps between tall building blocks can be more than double the speed. At the leeward corners of obstructions, strong turbulence and eddies can also be set up.

Wind speed can be reduced by 50 per cent by a long horizontal barrier at a distance of 10 times the height and by 25 per cent at a distance of about 20 times the height. Trees reduce dust movement, give a "green" outlook from windows and provide desirable shades from solar radiation. The advantages and disadvantages of trees, hedges, shrubs, etc. should be carefully considered.

All the internal roads leading to the different buildings of a factory should have shade from the trees planted on the sides of the pedestrian pavement.

3.2. Humidity

The higher the temperature of the air, the more water vapour it can hold. Due to the lowest layer of air being heated by the ground surface during the day, its relative humidity (RH) is rapidly decreased and, as a result, the rate of evaporation is increased when water is available to be evaporated as with an open surface of water, with rich vegetation or with higher air movement. The situation is reversed during the night. On a clear night, especially with still air, the RH increases as the lowest layer of air cools.

3.3. Absorption of Solar Radiation, Materials and Form of Construction

The ground loses much heat by radiation, particularly on clear nights, and soon after sunset, its temperature falls below that of the ambient air. The direction of the heat flow is reversed from the air to the ground. The lowest layer of air becomes cooler.

The greatest source of heat gain can be the solar radiation entering through the windows. This could, in fact, increase the indoor temperature far above the outdoor air temperature. Overheating is a problem in all tropical climates. For the reduction of solar heat gain through windows, four variables are within the control of the designer :

1. Orientation and size of windows;
2. External shading devices;
3. Internal blinds, curtains, etc.;
4. Special glass.

3.4. Design of Shading Devices

In hot climates, it is very important to shade the outside walls of a building exposed to high levels of sunlight. This can be done by creating permanent screens or louver blades, a reinforced canopy or externally applied venetian blinds, or planting tall trees with thick leaves or shrubs. These are very effective when they shade the east and west walls of the building, which are exposed to the morning and evening low-level sunlight.

Shade is required not only against direct solar radiation but also against diffused radiation from the sky which, in tropical regions, may reach very high intensities (0.75 Kcal / cm^2 / day on a horizontal surface).

When horizontal adjustable louvers are used, they should be constructed so as to enable their opening at an angle of approximately 120°. Vertical shading devices consist of lower blades or projecting fins in a vertical position. Egg-crate shading devices are combinations of horizontal and vertical elements. The many types of grille-blocks and decorative screens may fall into this category. The construction of shading masks for moderately complex shapes is effective for any orientation depending on dimensions.

3.5. Design of Roofs and Walls

If a heavy-weight roof with an external layer of efficient insulating material, itself protected by a waterproof light coloured (whitewash) covering, is used, heat flow during the day from external layers is restricted by the insulation and reflection. Only a small portion of the potential heat is absorbed in the elements.

High heat capacity concrete walls externally insulated by rockwool or expanded plastic and covered by waterproofing materials are suitable for the purpose. All external surfaces should be as near to white as possible. The high thermal capacity of the concrete layer reduces the effect on internal temperatures of any heat, which thus penetrates.

The whole roof may be externally covered by polythene sheeting at a distance of 10-20 cm above the roof surface. Polythene (polyethylene) is transparent to restrict the radiative cooling of the roof at night. The disadvantage of the method is the deterioration of the polythene sheets due to exposure to the sun.

The alternative of double roofing at much less cost, especially in the factories in rural areas in hot climates, is to maintain vegetation on selected portions of the slanting roof.

3.6. Orientation and Design of Windows

In the equatorial location, the main windows should face north or south to avoid solar heat gain. At the higher latitude, though an orientation away from the Equator would receive the least sunshine, it may be desirable to have some solar heat gain in the winter when the sun is low, and so an orientation towards the Equator may be used where the workplace does not generate much heat. In both locations the minor openings at unimportant workplaces should be placed on the east and west sides. Solar heat gain in the west side can be particularly troublesome as its maximum intensity coincides with the hottest part of the day. If the wind to be captured or a pleasant view is to be utilised, etc., the opening of windows may at times override the solar consideration.

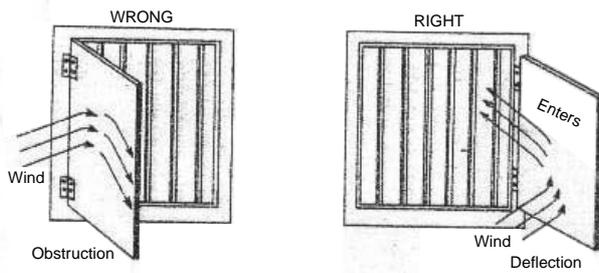
The air movement could be grossly influenced by the way the window blinds or sashes open. If the hinges on the windows are fitted properly depending on the direction of prevalence of the wind, the window blinds or sashes would act as deflectors to direct the wind through the windows, whereas if the hinges are fitted in the wrong way, the wind would be directed away from the room. In many of the factories in the tropical climates, just changing the hinges from one to the other side of the window frame may improve the climatic conditions greatly (fig. 2). This point has been overlooked in many factories in hot climates.


Figure 2. Correct method of fixing window blinds or sashes so as to facilitate entry of wind from the prevailing direction of wind.

The most effective height of the windows from the human comfort aspect is about 0.5 to 1.5 m above the floor. It is preferable to use horizontally pivoted windows with upper hinges which, when open, would direct the airflow downwards.

To raise the building on pillars is advantageous in a warm, wet climate because it enables better ventilation by locating the windows above the zone of maximum damping of wind by the surrounding vegetation, and also by enabling the cooling of the floor from below, which is particularly beneficial at night. In addition, the building is better protected from floods and from termites.

One of the basic needs of the human being is change and variation, a fact that has been ignored by early research workers. This point is particularly noticeable in mechanically controlled environments, such as in air conditioned buildings, where the environmental conditions can be and often are kept constant within very fine limits. What the designer should aim at is a range of comfort conditions within which considerable variations are permitted. It is quite interesting to observe that people enjoy natural, cool and fluctuating fresh breezes even when these stop for a few seconds at random, while people complain of the monotonous air movement at the same temperature and constant speed in an artificial climate. If these observations and causes are proved beyond doubt, in future the artificial climate may have to incorporate the random variation of air speed and air temperature within prescribed limits to provide the most comfortable conditions for workers.

The ordinary ventilation in the factories and workshops in hot climates should be at least 5.0 ft^3 (1.4 m^3) per person per minute. The air speed at the head level should be at least 100 cm / s (200 ft / min).

3.7. Design in Relation to Lighting, Colour and Noise

It is surprising that even today simple issues of heating, lighting and ventilation are too often inadequately considered and acoustic problems are not properly dealt with.

The effects of colour on people at work are to be considered for the scientific use of colours in the rooms and shop floors. In hot areas the "cool" blue or green colours, as against "warm" red should be used to give subjective sensations of coolness or impressions of reduced temperature.

The ceiling of a factory building plays an important role, particularly in reducing reverberant noise. Though people,

furniture, wall linings, soft flooring, etc., all act to absorb noise to some extent, a considerable proportion of any noise travels upwards to the ceiling. There are a wide variety of acoustically absorbent materials suitable for use in ceiling. The so-called "false" ceiling with sound absorbing material not only reduces noise but also helps to insulate and thus minimise transfer of heat from a hot roof to the shop floor.

3.8. Design in Relation to Safety, Health, Pollution and Welfare

Normally, factories should be so designed that the use of personal protective equipment against heat, dust, smoke, fumes, noise, accidental injuries, etc., is eliminated or at least minimal. If the hazards cannot be reduced at the source, then personal protective equipment has to be used, but one has to foresee that it might be impossible for the workers to wear protective equipment in hot conditions.

The normal psycho-physiological conditions of activity and rest with recovery from stresses are impeded by unfavourable climatic conditions and the resulting stress on body and mind causes discomfort, loss of efficiency and may eventually lead to a breakdown of health or even cause accidents. It is a challenge for the designer of the factory building to strive towards the optimum of total comfort, and health i.e. complete physical and mental well being.

A well designed working environment includes not only suitable physical conditions of ample ventilation, heat dissipation, illumination and other comfort standards, but also the tangible and intangible amenities that can transform discontent and boredom into interest and a sense of participation by the workers, as for example, the availability and use of shower facilities in hot climates, which are very much favoured.

For minimising accidents, the design criteria should take into consideration the major causes and frequency of different types of accidents from the record of similar industries in hot climates.

In hot, dry conditions, the chances of fire are much greater than in cold conditions, and hence greater precaution should be taken and better facilities provided for fire exists, structural fire barriers, safe internal and external access, especially in multistoried buildings. Industry has to count the cost of necessary precaution and control measures and the cost will in the long run have to be related to the total benefits to be expected from the process. The costs should be regarded as an essential parts of the process and not simply as an added burden to be carried on the back of the manufacturer.

4. FACTORIES

4.1. Air Pollution

The recent planning policy of most of the countries has been to encourage siting of industrial zones on the outskirts of new towns, or siting State or Government-sponsored industrial estates outside townships, mainly to reduce the effects of pollution on the people living in the towns. With the ever-increasing number of factories or industries, the threat of air, water and land pollution greatly increases.

To deal with the aspects of pollution directly related to the design and landscape and buildings for industries, one has to consider the effects of waste materials or surplus energy generated by various forms of human activity in industry threatening damage

to man's health, possessions, food supply, recreation and also to plants, animals and wildlife. In addition, there is pollution due to noise and other environmental nuisances generated from the factory buildings.

Air pollution arises from smoke, fumes and other gaseous emissions, dust and grit from the factory processes directly discharged into the atmosphere. Obviously, the design of the factory building, including the ventilation system, chimneys, insulation of furnaces in the shop-floor etc., must be done properly to cope with the maximum interference and pollution of the air by toxic and other substances and by heat. These ambient thermal pollution problems are enhanced by tropical climates. It is, therefore, very important that industrial plants and buildings be built to help in the effective control of pollution and its reduction.

The effect of a temperature inversion in trapping smoke and fumes near the ground is obvious. It is important to find out the height at which temperature inversion occurs. Very tall chimney stacks with correct height are able to penetrate the inversion layer to discharge their fumes in the rising air and thus avoid pollution. (Figure 2)

4.2. Factories and Water Pollution

Water pollution may occur from the falling rain passing through smoky and polluted air, by ways of ditches, ponds, streams, rivers, estuaries, etc. to the direct polluting of the sea itself. Many of the wastes of the factory are directly discharged into rivers, except in countries where there is strict enforcement of control measures to avoid pollution. Pollution of water may not necessarily render it toxic but often the effect is to deprive the water of oxygen and thus reduce its capacity to support life. The effects of thermal pollution are similar. The design of the factory buildings to avoid such pollution is an important necessity.

4.3. Factories and Land Pollution

Polluting of land arises from the solid wastes. Industrial chemicals destructive to insects and bacterial life may be leaked into the soil from the waste dumped upon it. The toxic and caustic effluents from chemical plants usually involve great risk. The disposal of this must be done properly and the design of the factory building helps this greatly.

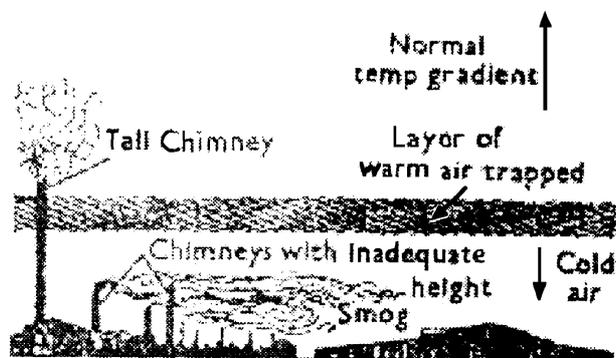

Figure 3. The effects of a temperature inversion in trapping fine dusts, smoke and fumes near to ground level. Very tall chimneys or stacks only are able to penetrate the inversion layer and discharge their fumes in the rising air.

4.4. Design in relation to Storage, Cleanliness and Maintenance

In tropical countries, the prevalence of hot and dry conditions leads to a lot of dusts. The factory should be so designed that the routine storage and maintenance of cleanliness are made easy. Hence, either the glass window should be at the lower level, or the glass windows near the top of a "saw-tooth roof" factory, for example, should have at least a low-cost bay with safety guardrails for safe, easy and regular cleaning. An ergonomically designed broom brush / wiper fitted on rollers so that the windows can be cleaned from the outside by pulling from one end to the other is also useful.

Easy accessibility for regular and proper maintenance of machinery must be considered in the design of the factory shop floor.

5. DESIGN OF INDUSTRIAL ESTATES

It is essential to have ergonomic considerations in designing industrial estates to reduce the cluster of small buildings and to improve the layout by various methods. A logical and scientific flow diagram for intake of raw materials and for output of finished products should be worked out for all the factories in the group. Efficient road, rail and conveyor systems should be made so that common points for packaging, loading and unloading, and common facilities for maintenance, security, safety, medical clinics, canteen, recreation, sports and other organisations, and common services for electricity, fuel, gas, water, steam, compressed air, refrigeration medium, telephone, modem, inter and intranets and a ring circuit of refuse and waste disposal could be ergonomically viable and useful. According to the suitability, any one of the different types of layout or plans such as linear or radial or ring types (figure 4) may be used.

5.1. Control of Factory Design

Unless the planning, location and design of the factory buildings are properly controlled from the very beginning, it will be extremely difficult to avoid grave situations in the years to come. In many countries, national laws, acts and local rules, regulations and restrictions determine location, construction and material usage in factory buildings. These acts, rules, regulations and restrictions should also be based on the principles of ergonomics and on appropriate guidelines so that the effective control can be established to humanise the environment and make for the proper development of the area and the progress of society as a whole.

An application to build giving an outline of the proposed factory should be made to the local planning authority. Permission to build should only be given with the condition that a detailed plan be submitted within a stated period. The local authority, through its appointed offices, should have the right of inspecting the work to ensure that the building is constructed according to the approved plan.

The factory inspectorate, like a "watchdog", should make good use of its loud bark and its nose for trouble, but should reserve the use of its sharp teeth for those rare occasions when they might be required to ensure the effective control of properly designed factories suitable for the climate.

Ergonomic Product Design

L. Bandini Buti

Società di Ergonomia Applicata, Milan, Italy

1. INTRODUCTION

Ergonomic design has as an objective the realization of quality products adapted to their user. Manufacturers tend to consider that a product is high quality if it respects a certain set of technical specifications; there seems to be little distinction between purely commercial needs and those of the end-user. Ergonomics counters this way of thinking by bringing into consideration the concept of ergonomic quality, which is concerned with the reaction or response of a product to the functional needs of user in everyday life and to his or her psycho-physiological characteristics.

Ergonomic design is based upon the active definition of a product by means of analysis of use and of its characteristics and its other needs.

In recent years the debate over industrial design and ergonomics has revealed a tendency to attribute a growing importance to the integration of ergonomics with design and innovation. At the Financial Times Conference "Product Strategies for the '90s", London, 15–16 October, 1990, T. H. Thomsen, for example, argues that, among other things, good design renders a product useful, self-explanatory and in tune with its environment. He also cites other important design factors which emphasize the psychological aspects of the product/user relationship; the need for study from the ergonomic viewpoint, giving a feeling of uniqueness, easy identification on the part of the consumer, generating trust in the product itself, creating an ideal user–machine interface, taking psychological factors into consideration. Thomsen also considers certain practical qualities (properties of handling, ease of cleaning, noise produced, clarity of the instruction manual) as being of importance.

Umberto Eco illustrates another aspect linked to a correct usability of products when he writes "the product must also demonstrate its purpose and the way in which it is to be used … this is a fundamental aspect of design which is not always given due consideration …". He also states that "These phenomena must also form part of the panorama of Italian design, otherwise one understands neither that which constitutes Italy nor that which constitutes design" (Sartogo 1982). The need for a product to communicate its use is clearly indicated by the author in this extract

> the product must also demonstrate its purpose and the way in which it is to be used. Thus, we see that there is a communicative aspect to a product, which is an important part of its design. Scissors are a perfect example of this: their form clearly indicates where the fingers should be inserted to operate them, even to someone who has never seen them before. Scissors are rightly considered a masterpiece of design: not only do they cut, but also they tell one how they are to be handled and used.

> This fundamental aspect of design is not always taken into consideration. Indeed, it should be recognized that quite often "unconscious" or "uncivilized" design from other, more primitive times, was actually much more masterly than that

produced by well-known names in the field of design in our own time. This stems, perhaps, from the fact that often (for "aesthetic" reasons) new forms are invented which say little or nothing to those who must use the product. … There is, here, a certain element of paradox in that, in their attempts to realize functional products, designers have been apt to design products which communicate little more than some design philosophy. In other words, the design doesn't say "I may be used in this or that way" as much as "I am a perfect example of good design"….

Ergonomic design must be considered as a way of confronting the themes of planning, by placing man at the center of the process. It is developed using various types of research, planning projects, and checks which all interact to form a unified process geared towards the definition of products and systems adapted for human use. Form is an essential part of the relationship between man and the object, and is thus a field of ergonomic analysis and intervention.

2. ERGONOMICS, DESIGN AND INNOVATION

The field of ergonomics has been involved with the theme of the integration of ergonomics and design, providing specific contributions which propose a couple of peculiar concepts in this area, namely those of *participation* and *globality*.

In its relationship with industrial design and with innovation, the concept of *participation* means paying attention to the needs of the user, attention which must be given through all the various phases of a project. It is particularly important to make an analysis of the user's possible behavior patterns in relation to the product, whether these be proper or improper, so that information may be gathered on any possible difficulties they may encounter. In this way one is able to work from a number of interesting "starting points" which stimulate the introduction into projects both of technical innovations and design innovations capable of resolving such problems.

The concept of *globality*, on the other hand, signifies the need to single out the minimum level of material and logical dimensions to be taken into consideration when working on project research, below which the control of the effects which the intervention shall bring about in the entire system becomes impossible. In the context of such a hypothesis it is necessary to investigate the complex technological and use relationships of the system (made up of the product and its immediate logical environment) before carrying out any analysis of the product being researched.

Ergonomic methodology is particularly effective in the carrying out of analyses of products and complex systems where aspects linked to use are prevalent (e.g. an ashtray or a tray are minimally complex in terms of use but have maximum aesthetic impact).

2.1. Integrating Ergonomics into the Design Process

The principles outlined above may be considered as forming part of the "culture" of a project, where they make clear that the product and the systems have to be planned in such a way as to cater for the needs of the user. To apply these principles it is necessary to develop a specific operative methodology and to become more familiar with some basic concepts which allow for prediction, innovation and systemization in the approach taken.

In the planning of products and systems, applied ergonomics makes use of means which are based on the analysis of individual test subjects, an efficient way of investigating the individual response to a product in everyday use.

Obviously, in the early stages of a project, when work is still at a conceptual or non-material planning level, tests cannot be carried out with users. It is, however, both possible and important to gain information using subject samples with other, similar products, experimental products and prototypes, and virtual reality simulations, in order to understand, observe, predict, visualize, communicate, and only then implement (Wasserman and Moggridge (1990), in Learning for experience — An approach to design strategies for product success, from the Financial Times Conference "Product Strategies for the '90s").

The feedback, be it positive or negative, which a product receives from the user is a fundamental part of the process from which innovative ideas may drawn. As soon as models and prototypes are available (even if only partially functional) it is important to carry out tests using product samples with subjects in order to ascertain whether innovative ideas introduced solve problems identified at the beginning of the process effectively, or if indeed they introduce any new problems. Thus, it is also possible to quantify and evaluate any possible benefits obtained. From such evidence it is also possible to ascertain criteria which may be used successively in the design process of other products.

Following this tests may be carried out using fully functional prototypes which have been conceived giving due consideration to the entire sphere of planning aspects (ergonomics, design, technology, manufacture, ecology, costs), tests which, however, allow one to intervene only in the case of particularly grave circumstances, as, generally by this stage, significant investment has already been made and any changes are likely to be regarded as too much effort in terms of time and costs.

2.2. Ergonomics and Form

Those working in the field of ergonomics often feel that the form of a product, and any connotations thereof, can be disregarded. Rationalism maintained that "that which is right is beautiful" with the intention of confirming the priority of functional aspects over formal ones and that beauty is essential to the correctness of the solution.

This paradigm, which compares form and function may be translated as the conviction that the image of a product is a negligible entity in terms of its evaluation and, still more, that a product which is ergonomically correct is probably anti-aesthetic.

The world of science makes use of methodologies based upon the comparability of data and on the universality of assertions. It cannot in any way use these for the evaluation of formal aspects which it thus tends to ignore as being uninfluential. While it is true that beauty is beyond measurement and also that analyses of form and color always refer to the significance of these aspects in relation to the culture and history of those who perceive them, we cannot be simply permitted to maintain that the problem does not exist. It will be necessary to create rigorous investigative methods even if these are not "scientific" in the sense defined by the exact sciences.

2.3. Industrial Products

An industrial product may be considered ergonomic if, during the various phases of its life, conception, realization, use, disposal or recycling, it not only does not cause damage but also generates beneficial psycho-physical conditions in all those who enter into contact with it; thus, if a product is only or principally capable of not causing damage or illness, it may be said that it fulfils the objectives of hygiene and medicine in the work place, but not those of ergonomics.

The performance area relates principally to the dimensional aspects of the product, the safe-guarding of health and safety of all those who enter, for whatever reason, into contact with the product, and to respect for its surroundings during manufacture, use and disposal. A peculiar characteristic of the assembled topics in the performance area is that the parameters used to describe these are valid for the population as a whole regardless of the characteristics of the individual. In fact the need to respect the electric safety of a product, not to cause pollution during or after use or for dimensional correspondence to a large population, are not factors that depend on who uses the product or where and how it is used.

The area of well-being, on the other hand, is principally concerned with the usability and agreeability of the product. These aspects are variable depending on the psycho-socio-cultural characteristics of the user, and must, therefore, be evaluated in relation to the particular characteristics of the individual and in reference to a precise physical, social and cultural space. It is, in fact, very likely that that which may be pleasing to an Oriental may not be so to a European, just as those sounds which today are considered pleasing and harmonious to the ear, were considered, when first created, as unharmonious since they hadn't yet entered the collective consciousness.

3. ERGONOMICS PROJECT ANALYSIS

To render industrial products more ergonomic one needs to carry out an objective evaluation (using techniques for the definition of quantifiable data) and the collection and comparing of the subjective experiences of potential users (which provide information on trends).

3.1. Objective Data

Objective evaluation techniques refer to objective and quantifiable data (dimensional aspects, anthropometric data, noise levels, illumination, strain, etc.). These enable us to measure many parameters, to compare products in production, both with one another and with models and prototypes, and to formulate new/future projects from objective data. They permit the evaluation of quantifiable aspects and are indispensable for the definition of guidelines and regulations and for the verification of their compliance with such.

3.2. Subjective Aspects

Objective data are of little use when analyzing individual behavior. The evaluation of factors such as the significance people give to messages and signals, the efficiency of tactile and visual perception of control units and displays, strategies of use, the effect of more than one stimulus being simultaneously present in the sensory receptors, is linked to a large number of aspects which vary greatly according to the user (aspects such as their perceptive abilities, their psycho-physical characteristics at the moment of use, their habits, their knowledge of and familiarity with the product or system, etc.). These factors, when considered together, indicate that in order to integrate ergonomics into the projection of products and systems, one must apply methods based on the analysis of significant subjects, which is an effective way of finding out what the individual response is under real conditions of use. Ergonomic intervention is characterized, for the greater part, by subjective aspects, as it means adapting environments and products to the person, not in an abstract manner but with respect to the specificity of each individual.

4. ERGONOMIC DESIGN

The various phases and activities involved in the development of a product, from the first ideas to the final prototype and production, may differ depending on the nature of the product being designed, on the dimensions of the series produced, on the level of technology and automation of the industrial process, on the dimensions of the proposed market, on the size and diversification of the population for whom the product is intended and on its degree of formation and knowledge of the product category, but a number of phases are both typical and indispensable in all cases:

4.1. Non-material Phase

In the initial phase the product to be designed is presented as an idea only, in as much as it is constituted of written material, images and graphic or virtual representations. During this phase there is little opportunity to study the idea with ordinary people in order to obtain their thoughts on the use of a product which has not yet been realized materially.

4.2. Make-up Phase

During the next phase the idea may be represented with three-dimensional models. These represent well the dimensional aspects of the product but tell one little or nothing about finishes and functioning. They do allow one to effect verifications of use on subjects, but the non-functional characteristics of the model does not allow for an experience of complete use (e.g. activities of use which require a complete model, handling qualities linked to the finish of materials and to the qualities of grip of materials, qualities of noise and strain which may only be evaluated from finished products and those assembled and fitted to the appropriate structures). A sample of interviewees cannot, in this case, be made up of members of the general public, as it is necessary to choose subjects who are able mentally to simulate real conditions of use, in other words to able to think and perform in the abstract.

4.3. Prototype Phase

During the third phase pre-series or functional prototypes may be created with which analyses may be carried out making use of real subject under real conditions of use. Experience has shown, however, that even when functional prototypes are available it may not easy to conduct trials with members of the public, for reasons of product security and confidentiality (for products not

yet on the market) or for safety reasons (with products not yet approvable or approved).

One should note here that a correct process of ergonomic planning is not effected from the beginning of the project, in as much as one waits until prototypes are available for carrying out verifications with subjects. Thus, the possibility of making changes to the product conception is greatly limited, if not altogether irrelevant. Subjective investigations therefore require the application of specific and differentiated techniques depending on the actual phase of project development.

5. THE USER

The principles of ergonomics applied to a project affirm that environments, products and systems have to be adapted to the psychophysical characteristics of the individual. This would seem to assert that every environment, product and system has to be conceived and realized specifically for one single person in so far as every person is unique. Such procedures do in fact take place in the sphere of artisan production, personal tailoring, or in the making of seats for Formula One drivers.

Such principles seem to be in clear contradiction of fixed, repeatable references and the standardization required by industrial production of environments, products and systems.

While remaining faithful to the general principle which affirms that an ergonomic product has to adhere to the needs of the single user, ergonomics recognizes that the aspects that characterize an individual can be studied and rationalized in that many of these are common to all people, others being common to large sections of the population, still others being linked exclusively to a person's individuality.

5.1. Characteristics Common to All

These consist of the characteristics that denote someone as human rather than any other living form, such as a capacity for vision, touch, hearing, walking, and emitting articulated sounds. The biological and psychosocial disciplines provide infinite data that can and must be used during planning.

5.2. Cross-sectional Characteristics

Other characteristics are, on the other hand, specific to large cross-sections of humanity. These regard, for example, the thermoregulation mechanisms of the body which vary in relation to skin color or cultural characteristics, so that sounds perceived as harmonious by certain populations are not perceived as so by others. One should note that such aspects also vary over time. The pictorial representations of the Impressionists, when first shown to the world, were judged as an offence to good taste, so much so that the adherents to that school were always excluded from official exhibitions, whereas today they are considered among the greatest painters of all time.

5.3. Individual Characteristics

Within this framework, which refers to all humanity or its large categories, more specifically individual variables (which may be cultural, biological or pathological) must be researched.

Individual anthropometric characteristics tell us that nobody corresponds perfectly to the anthropometric data assumed to characterize individuals of his or her size; the capacity for performing physical tasks which is linked to one's state of health, musculature and diet; problems of vision often related to age etc. These aspects may still be measured and statistically analyzed.

Other parameters in the areas of cognitive psychology and cultural background regard more properly subjective aspects such as habits, posture, ways of dealing with aggression from others and in general a person's attitude to life which leads to different modes of behavior when faced with the same stimulus depending on deeply rooted factors or momentary states such as anxiety, haste, the desire for self-affirmation, etc.

Individual aspects cannot easily be reduced to universal numeric values, and so their introduction into the framework of the project requires specific techniques based on specialist analysis and tests and verifications carried out on significant samples of the likely users of the product.

products and systems	ALREADY PRODUCED	BEING DEVELOPED
OBJECTIVES	- verify ergonomic quality - certify ergonomic quality	- introduce ergonomic quality into the design phase
PRODUCTS (material or computer simulated)	- existing and functional	- non-material idea (on paper or computer) - non-functional models - partially functional prototypes
OBJECTIVE ASPECTS	- data drawn from analysis and laboratory tests	- data drawn from analyses and partial tests on models and ptototypes - data drawn from analyses and tests on similar products
SUBJECTIVE ASPECTS	- expert evaluation for comparison with standards and regulations - use analysis with subjects	- use analysis of partial aspects on models and prototypes - extrapolation of use analyses on similar products
EMOTIONAL ASPECTS	- analysis of product agreeability with subjects, for comparison with other products of the same category	- analysis of product agreeability with subjects for the definition, description and evaluation of relevant parameters

Figure 3. Comparison of methods of analysis for products already realized and those in the planning phase -

5.4. Methods of Analysis

To be able to introduce ergonomic concepts into product and systems design, it is necessary to intervene right from the beginning of a project, before it becomes impossible to reverse any choices made. Analyses have, therefore, to be programmed in all stages of the project:

1. *General research of "needs"* and their evolution over time (projection for when the product will be on the market), carried out through market research and by consulting scientific literature.

2. *Specific research* carried out on a significant sample of potential users, employing plans, models and/or prototypes.

3. *Research into similarities* carried out on a significant sample of potential users, with products already on the market, which in various ways are significant of the intended product (through similarity, in various parts, etc.).

While there are no relevant conceptual differences in the analysis of products at the design phase and that of products already realized, there are many in the methods of such analysis. In the case of existing and functional products analyses may be carried out using the product under real conditions of use. One may evaluate both parameters measurable by physical means and those measurable by cognitive ones. With an adequate methodology it is possible to arrive at the ergonomic certification of a product. In the case of products which have not yet been realized, the analyses necessary for guiding the development of the project in an ergonomic sense, may be executed on parts of the product, on single aspects taken out of the product context, or on products similar to that being developed. In this case the analyses differ from those carried out on similar products, not as regards the ends sought, but as regards a different planning of the research and the need to develop an analysis concentrating on data.

Ergonomic Workstation Design

B. Das

Department of Industrial Engineering, Dalhousie University, Halifax, Nova Scotia NS B3 J 2X4, Canada

1. INTRODUCTION

Ergonomic workstation design based on engineering anthropometry and occupational biomechanics can play a major role in the reduction of many risk factors of occupational injury (Grandjean 1982). Anthropometry and biomechanics are closely related, because occupational biomechanics provide the bases for the use of engineering anthropometry to the problems of workstation design (Pheasant 1989).

Anthropometry is the technology of measuring various human physical straits, primarily such factors as size, mobility, and strength. Engineering anthropometry is the effort in applying such data to workstations, equipment, tools and clothing design to enhance the efficiency, safety and comfort of the worker. In the context of the workstation design, engineering anthropometry is employed to develop design parameters or dimensions for such a design.

Biomechanics deals with various aspects of physical movements of the human body and body members. The human body is considered as a linked body segments subjected to the internal forces generated within the musculoskeletal system and external forces imposed by the work situation (Karwowski 1992). Biomechanics uses law of physics and engineering concepts to describe various body parts and the forces acting on these parts during work activities (Frankel and Nordin 1980). The biomechanics or anatomy applied to the work situations is often considered the scientific basis of ergonomics (Tichauer 1978). Occupational biomechanics is defined as the physical interaction of workers with their tools, machines, and materials so as to enhance the workers' performance while minimizing the risk of musculoskeletal disorders (Chaffin and Andersson 1984).

An ergonomically designed workstation attempts to obtain an adequate balance between worker capabilities and work requirements. The objective is to optimize worker productivity and the total system and at the same time enhance worker physical and mental well being, job satisfaction, and safety. Often workstation in industry is designed in an arbitrary manner with little attention to anthropometric measurements and biomechanical considerations of the anticipated user. The situation is aggravated by the lack of usable design parameters or dimensions (Das and Grady 1983a). It is essential to understand the conditions under which biomechanics can be used for the assessment of a workstation (Marras 1997). When the magnitude of loads imposed upon the body is believed to be exceeding the tolerance of a structure, a biomechanical analysis is considered most helpful.

2. WORKSTATION DESIGN BASED ON ENGINEERING ANTHROPOMETRY

In a workstation design an attempt is made to achieve an optimum compromise between the variable anthropometry of the targeted operator population, and the physical size and the layout of the workstation components. An ergonomic analysis for a workstation design is concerned with spatial accommodation, posture, reaching abilities, clearance and interference of the body segments, field of vision, available strength of the operator, and biomechanical stress. The appropriate anthropometric data regarding body size, strength, segment masses and inertial properties from the established databases are typically used in the analysis.

Das and Grady (1983a, b) determined workstation design dimensions through the use of the existing anthropometric data, so that these dimensions can be readily employed by a designer. Workspace design dimensions were determined for industrial tasks in sitting, standing and sit–stand positions. Worker populations consisted of a combination of male and female workers and the individual male and female workers for the 5th, 50th and 95th percentiles based on existing anthropometric data. The normal and maximum reach dimensions were based on the most commonly used industrial operations, which require a grasping movement or thumb and forefinger manipulations. However, appropriate allowances were provided to adjust reach dimensions for other types of industrial operations. The normal and maximum horizontal and vertical clearances and reference points for the horizontal and vertical clearances were established to facilitate the design. The concepts developed by Farley (1955) and Squires (1956) were used to describe the workspace envelope for the individual worker. The dimensions of smaller (5th percentile) and larger (95th percentile) workers were used to determine the limits of reach and clearance requirements respectively.

2.1. Anthropometric Data Adjustment

The existing anthropometric data were derived on the basis of the measurements from nude subjects. Therefore the data were adjusted for clothing and shoe allowances. Since the data for the standing, sitting and eye heights were based on erect positions at work or rest, the data were adjusted to account for the 'slump' posture involved in the "normal" standing and sitting positions. Also, necessary adjustments were made for the reach dimensions used for performing various industrial operations (Hertzberg 1972). The corrected or adjusted anthropometric measurements to account for clothing, shoe and slump posture are presented in Table 1 (Das and Grady 1983a).

2.2. Workstation Design Parameters

To design a workstation, it is necessary to obtain relevant information or data on task performance, equipment, working posture and environment. In the case of a new workstation design, it is advantageous to obtain such information from a similar task/equipment situation. Before redesigning an existing workstation in industry, often it is desirable to conduct a worker survey through appropriate questionnaires to determine the effect of the equipment or system design on employee comfort, health and ease of use (of the equipment). However, frequently it is necessary to design a new industrial workstation. Even then, it may still be desirable to obtain feedback from the operators, who are engaged in performing a similar type of industrial task. The feedback may generate heightened awareness of workstation design problems and issues.

Table 1. Corrected anthropometric measurements to account for clothing, shoe and slump posture (Das and Grady 1983a).

Sex	Body Feature	Percentiles (cm)		
		5th	50th	95th
Male	Total height (slump)	166.2	176.1	186.3
	Body height (sitting, slump)	82.1	87.6	92.7
	Eye height (slump)	160.0	164.9	174.8
	Eye height (sitting, slump)	70.9	76.2	81.3
	Shoulder height	138.0	147.7	156.8
	Shoulder height (sitting)	54.7	59.8	64.4
	Body depth	26.7	30.2	34.0
	Elbow-to-elbow	40.0	45.1	51.7
	Thigh clearance	14.2	16.2	18.5
	Forearm length	37.1	40.4	43.7
	Arm length	68.3	75.2	82.0
	Elbow height	105.6	113.0	120.4
	Elbow height (sitting)	18.8	23.1	27.4
	Popliteal height (sitting)	42.4	45.7	48.7
Female	Total height (slump)	153.8	163.2	173.8
	Body height (sitting, slump)	78.5	82.8	87.1
	Eye height (slump)	143.6	153.5	163.4
	Eye height (sitting, slump)	68.6	72.4	76.5
	Shoulder height	127.9	137.5	146.6
	Shoulder height (sitting)	52.2	57.2	61.8
	Body depth	21.8	24.6	27.6
	Elbow-to-elbow	35.7	38.2	43.8
	Thigh clearance	12.4	14.4	16.5
	Forearm length	32.5	36.6	40.7
	Arm length	60.2	66.0	72.4
	Elbow height	99.0	105.1	111.2
	Elbow height (sitting)	18.8	23.1	27.4
	Popliteal height (sitting)	37.3	40.6	43.6

In the beginning, decisions are formalized regarding the task sequence, available space, equipment and tools. Work method needs to be established before embarking on the design of the workstation. Determination of the workstation dimensions usually proceeds according to the steps outlined in Table 2 (Das and Sengupta 1996).

The workstation design procedure commences with the collection of relevant data through direct observation, video taping and input from experienced operators and supervisors (step 1, Table 2). It is necessary to identify the appropriate user population based on such factors as ethnic origin, gender and age (step 2). The necessary anthropometric dimensions of the population are obtained or approximated from the results of the available anthropometric surveys that reasonably represent the user group. As these dimensions are taken from nude subjects in erect posture, they need to be corrected appropriately for the effect of clothing, shoe and normal slump posture during work (Das and Grady 1983a).

In developing an industrial workstation, a designer should take into account the workstation height (step 3). The work table height must be compatible with worker height, whether standing or sitting. The best working height is ~2.5 cm below the elbow. However, the working height can vary several centimeters up or down without any significant effect on performance. The nature of the work to be performed must be taken into consideration in

Table 2: A systematic approach for the determination of workstation design parameters (Das and Sengupta 1996).

1. Obtain relevant information on the task performance, equipment, working posture and environment through direct observation, video recording, and/or input from experienced personnel.

2. Identify the appropriate user population and obtain the relevant anthropometric measurements or use the available statistical data from anthropometric surveys.

3. Determine the range of work height based on the type of the work to be performed. Provide an adjustable chair and a foot rest for a seated operator and an adjustable work surface or platform for a standing operator.

4. Layout the frequently used hand tools, controls, and bins within the normal reach space. Failing that, they may be placed within the maximum reach space. Locate control or handle in the most advantageous position, if strength is required to operate it.

5. Provide adequate elbow room and clearance at waist level for free movement.

6. Locate the displays within the normal line of sight.

7. Consider the material and information flow requirements from other functional units or employees.

8. Make a scaled layout drawing of the proposed workstation to check the placement of individual components.

9. Develop a mock-up of the design and conduct trials with live subjects to ascertain operator-workstation fit. Obtain feedback from the interest groups.

10. Construct a prototype workstation based on the final design.

determining work height. For seated operators, provide adjustable chair and foot rests; for standing operators, provide an adjustable work surface or platform.

The hand tools, controls and bins that are frequently used need to be located within the normal reach spaces (step 4). The items used occasionally may be placed beyond the normal reach, but they should be placed within the maximum reach space. For locating a control that requires strength, give consideration to the human strength profile in the workspace. Extreme reach space, involving twisting of trunk, ought to be avoided at all times. Adequate lateral clearance must be provided for the large (95th percentile) operator for ease of entry and exit at the workstation and also to provide ample elbow room for ease of work (step 5).

The placement of the displays should not impose frequent head and/or eye movement. The optimum display height for the normal (slump) eye height is 15° downward gaze (step 6). Appropriate personnel from other functional units or departments should be consulted regarding material and information flow requirements (step 7). It is beneficial to consider the physical size of the individual components and make a scaled layout drawing of the proposed workstation to check the placement of the individual components within the available space (step 8). The operator–workstation fit should be evaluated with a workstation mock-up and through an appropriate user population (step 9). This will ensure that the task demand and layout do not impose an undesirable working posture. It is desirable to check the interference of body members with the workstation components. If necessary, the design should be modified. Finally, it is beneficial to construct a prototype workstation based on the final design. All the 10 steps shown in Table 2 may not be applicable in every industrial workstation design situation.

2.3. Workstation Dimensions

For the physical design of industrial workstations, the four essential design dimensions are: (1) work height, (2) normal and maximum reaches, (3) lateral clearance and (4) angle of vision and eye height.

2.3.1. Work height

Height of the working surface should maintain a definite relationship with the operator's elbow height, depending upon the type of work. The standing work heights for the 5th, 50th and 95th percentile female operators for performing different types of work for US population are presented in Table 3. The table provides guidelines especially for the design of delicate, manual and forceful work. Similar data for males can be obtained from Ayoub (1973), and Das and Grady (1983a).

2.3.2. Normal and maximum reaches

The tip of the thumb defines the normal reach while the forearm moves in a circular motion on the table surface. During this motion, the upper arm is kept in a relaxed downward position. The "maximum" reach can be considered as the boundary on the work surface in front of an operator to which s/he can reach without flexing his/her torso. For performing repetitive tasks, the hand movement should preferably be confined within the normal working area. The controls and items of occasional use may be placed beyond the normal working area. Nevertheless, they should be placed within the maximum working area.

The concept of normal and maximum working areas (Das and Grady 1983b, Das and Behara 1995) describes the working area in front of the worker in a horizontal plane at the elbow level; the areas are expressed in the form of mathematical models. The most frequently used area of the workstation preferably should be within the normal reach of the operator. The reach requirements should not exceed the maximum reach limit, to avoid leaning forward and bad posture. The maximum working area at the elbow level is determined from the data provided in Table 4. The adjusted anthropometric measurements for the arm length (K), shoulder height (E), elbow height (L), which are used to calculate arm radii (R) for the 5th, 50th and 95th percentiles for females.

Table 3. Standing work surface height for female operators in cm parameters (Das and Sengupta 1996).

Type of work	Population percentile		
	5th	50th	95th
Delicate work with close visual requirement	99-104	110-115	116-121
Manual Work	84-89	90-95	96-101
Forceful work aided by upper body weight	59-84	65-90	71-96

Table 4. Anthropometric measures for females and maximum reach in cm parameters (Das and Sengupta 1996).

Population percentile	Arm length (K)	Shoulder height (E)	Elbow height (L)	Maximum reach (R)
5th	60	128	99	53
50th	66	138	105	58
95th	72	147	111	63

Table 5. Anthropometric measurements for females for lateral clearances in cm parameters (Das and Sengupta 1996).

Population percentile	Hip breadth	Elbow to elbow	Body depth	Clearance waist level C1=W+10	Clearance elbow level C2=H+G+10
5th	40	36	22	50	68
50th	45	38	25	55	73
95th	52	44	28	62	81

2.3.3. Lateral clearance

A well known approach is to design the reach requirements of the workstation corresponding to the measurements of the 5th percentile of the representative group and the clearance corresponding to the 95th percentile measurements, so as to make the workstation compatible for both small and large persons. The minimum lateral clearances at waist level are determined by adding 5 cm on both sides or 10 cm to hip breadth (standing). Considering the elbow to elbow distance and the sweep of both the elbows within the normal horizontal working area and adding 5 cm on both sides, minimum lateral clearance at elbow level is determined. The values for lateral clearances are shown in Table 5.

2.3.4. Angle of vision and eye height

Das and Grady (1983a, b) have provided the eye height for the standing female operators: 143.6 cm for 5th percentile, 153.5 cm for 50th percentile and 163.4 cm for 95th percentile. For males, similar eye height data can be obtained from the source stated above. Using trigonometry, the angle of sight can be calculated from the horizontal distance of the display from the operator's eye position.

3. SUPERMARKET CHECKSTAND WORKSTATION: A CASE STUDY

The steps outlined in Table 2 were applied to design a supermarket checkstand workstation. The working posture and work methods of the cashiers were recorded through direct observation (step 1, Table 2). Based on the direct observation, the major shortcomings in the design of the supermarket checkstand workstation were identified.

An operator (cashier, all female) survey was conducted in 3 superstores, through questionnaires to determine the effect of (1) environmental factors, (2) general fatigue induced by the task, (3) physical demand of tasks, and (4) the postural discomfort of the operators during the course of a regular working day (step 2). The dimensional compatibility between the cashiers structural anthropometry and the workspace dimensions was evaluated using a scaled drawing of the existing checkstand which was prepared from the actual measurements taken at the site.

By employing an engineering anthropometry approach, the supermarket checkstand workstation design parameters or dimensions were determined for: (1) optimum work height, (2) normal and maximum reaches, (3) lateral clearance, and (4) angle of vision and eye height (steps 3–6). The appropriate data were used subsequently for the design of the checkstand workstation (Figure 1; Das and Sengupta 1996). The superimposition of the normal and maximum horizontal and vertical working areas on the supermarket checkstand drawing facilitated the design or

placement of the checkstand components. This procedure enabled placement of the components within the normal working area when possible and, failing that, within the maximum working area. Several alternative checkstand layout drawings were considered using a CAD package with human modeling capability. An adjustable and padded floor platform was provided for the cashiers. The platform height could be lowered by 6 cm at a time to accommodate taller cashiers. The padding was provided to reduce foot fatigue from prolonged standing.

The components that needed frequent operation were placed, as far as possible in the front of the cashier to reduce the twisting of the torso and neck. The width and depth of the laser scanner was reduced to accommodate the printer and code catalogue right in front of the cashiers. The reduced width scanner improved the cashiers' reach over both conveyor belt and the bag handling area. A deflector was provided on the conveyor belt to ensure that the products are within the maximum reach of the cashiers. The original product bin handling requirements at the left of the cashiers was eliminated and was replaced by plastic bag hangers at appropriate height and location. The superimposition of the normal and maximum horizontal and vertical working areas on the checkstand drawing facilitated the determination of the size and the placement of the checkstand components (step 8).

A time study of the simulated cashiers' task in the laboratory showed a 15% improvement in worker productivity. The main improvements in the proposed design were: (1) forward facing work posture and elimination of the requirement of twisting the torso (forward facing location of laser scanner, weigh scale, bag hangers, keyboard and printer/code catalogue), (2) increased area on the conveyor belt within the normal working area, (3)

placement of the visual display (item price) within the normal line of sight of the operator, and (4) adjustable height platforms to accommodate 5th, 50th and 95th percentile female operators. The proposed design would improve working posture, provide flexible work height, reduce reach requirements, improve visual display requirements and enhance productivity of the cashiers.

4. HUMAN MODELING PROGRAMS FOR WORKSTATION DESIGN

The computerized human modeling programs for an industrial workstation design provide a convenient computer interface for the user to interactively generate and manipulate true-to-scale, three-dimensional (3D) image of human and the workstation graphically on the video display terminal (VDT). Through the use of the programs, the designer can construct a large number of anthropometric combinations to represent the human. The programs give a complete control to the user over the development of the human model and provide a comprehensive package to evaluate human–machine interaction through easy to understand programmed commands. The user need not be a computer specialist to use such programs.

To illustrate the current state of development, Das and Sengupta (1995) had selected six representative programs: CYBERMAN, COMBIMAN, CREN CHIEF, JACK, SAMMIE and MANNEQIN. The individual programs were compared under four broad criteria: (1) usability in terms of hardware and software: (2) anthropometry and structure of the human model; (3) model manipulation, reach and visual analysis functions: and (4) other ergonomic evaluative functions (Das and Sengupta 1995). The programs differ considerably in terms of system requirement,

operating characteristics, applicability and the various ergonomic evaluation functions available in the human modeling programs. For the purpose of illustration two representative models are presented (Figures 2 and 3).

4.1. Recent Developments in Workstation Design Based on Engineering Anthropometry

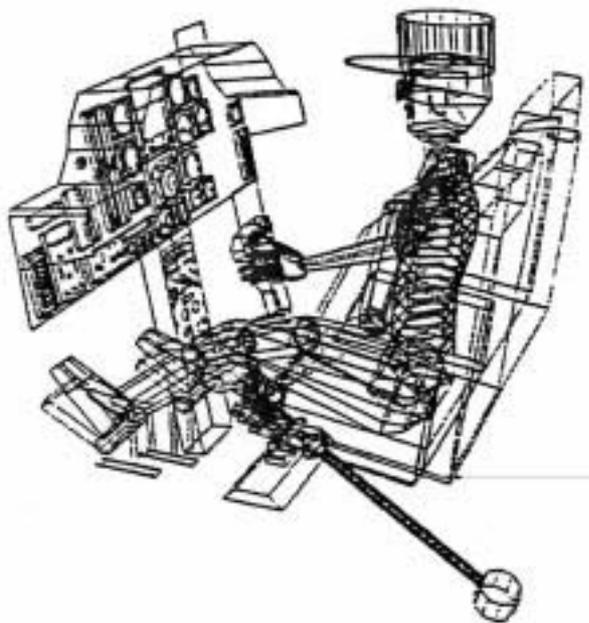
A computerized potentiometric measurement system (CPMS) was recently developed for anthropometric measurements of the three-dimensional maximum reach envelope (MRE) (Das *et al.* 1994). The system uses four potentiometric units, a power supply unit, a computer with analogue/digital (A/D) converter to measure the position of a movable stylus in three (S, Y, and Z) dimensions (Figure 4). This system took only 15 min for reach data collection


Figure 2. JACK human model seated within a workstation (Badler 1991).

of a participant in seated and standing positions. It recorded arm reaches while the arm was in motion, thus reflected the true dynamic nature of functional reach. The previous mechanical measurement systems recorded maximum reach envelope in terms of static arm reaches and took 3 h to collect data for the seated maximum reach envelope. The CPMS was successfully used to determine MRE for the 5th, 50th and 95th percentile males and females in seated and standing work positions (Sengupta and Das 1999).

An improved anthropometric model of three-dimensional maximum reach envelope (MRE) was recently developed (Sengupta and Das 1998). The characteristics of the model included: application of nonlinear optimization, use of relevant structural body dimensions, use of direct measurement of dynamic reach profiles and location of the spherically shaped MRE near the shoulder joint (acronium point).

4.2. Workstation Design Based on Occupational Biomechanics

A biomechanical approach to workstation design deals with the effects of exertion-related forces and awkward postures in a work situation that may cause pain or injury. For the design of a workstation it is necessary to know what a person can or cannot do. A person's physical capabilities, especially those that allow on individual to exert force or sustain external loading without causing personal injury can be determined by measuring human strengths (Mital and Das 1987). It is necessary to conduct a biomechanical evaluation of a workstation design when a worker is believed to be exposed to excessive physical stress or risk in a workstation. Through redesign of a workstation, it is possible to

minimize or eliminate work-related injuries to musculoskeletal system. The low back pain is considered to be the most costly and prevalent work related musculoskeletal disorder. According the National Council on Compensation Insurance (USA), 33% of all workers' Compensation payments are due to low back pain. The total cost estimates range from US$27 to 56 billion in the USA when indirect costs are taken into consideration (Andersson *et al.* 1991).

4.3. Determination of Human Strength for Workstation Design

Human strengths are classified as isometric or static and dynamic. The dynamic strengths are further subdivided into: (1) isokinetic, (2) isotonic and (3) iso-intertial. In the case of isometric or static muscle exertions, the body segment involved and the object held remain stationary, while in the case of dynamic muscular exertions both the body segment and object move. Because there is no effective limb–object–muscle movement in the case of isometric strengths, such strengths do not account for the inertial forces. Consequently, isometric strengths cannot be used for the determination of an individual's capability to perform dynamic tasks, such as materials handling. Thus, for the determination of a person's physical capabilities, dynamic strengths measurement is more appropriate than isometric or static strengths measurement. For designing industrial jobs and workstations, dynamic strengths should be used even though they are difficult to measure compared to static strengths. Table 6 shows isometric and isokinetic strengths of males in different postures (Mital *et al.* 1986).

Industrial workers should not generally exceed one-third of their isometric strength on a sustained basis in task performance (Putz-Anderson 1994). Overloading of muscles should be avoided to minimize fatigue. Dynamic forces should be kept < 30% of the maximum force that the muscle can exert; up to 50% is all right for up to 5 min. Static muscular load should be kept < 15% of maximum force that the muscle can exert. General guidelines suggest that hand forces should not exceed 45 Newtons. On the other hand, it is possible to handle a force of 4 kg for 10 s, 2 kg for 1 min and one-third of maximum force for 4 min.

For optimum design of a workstation, it is important to determine human strength profiles in the workspace. The ideal

Table 6. Isometric and isokinetic lifting strengths of males in different postures (Mital *et al.* 1986).

Posture	Exertion	Mean	Strength (kg) Standard deviation
Standing erect, fore arms horizontal, upper arms vertical	Isometric	40.4	6.7
Standing erect, upper arms horizontal, fore arms vertical	Isometric	52.6	8.5
Lifting floor to 81 cm height in free style	Isokinetic	110.4	30.2
Lifting from 81 cm to 152 cm in free style	Isokinetic	75.5	33.4
Pulling at 81 cm height from left to right	Isominetic	35.1	9.5

industrial workstation should be compatible with not only systems performance requirements but also with the user. The most obvious criteria are comfort and ease of use, but other equally important design criteria include work performance, safety and health (Das and Sengupta 1996). Several factors impinge upon the creation of the ideal workstation, one of which is *reach capability*, as discussed earlier under workstation design based on engineering anthropometry. Accurate reach capability data are essential to ensure that all hand-operated controls or tasks are located where they can be reached and operated efficiently. Another factor that impinges upon the creation of the ideal workstation is user *strength capability*. To ensure optimal workplace layout, it is imperative that operators strength profile be determined. The *strength profile* of a person under specified conditions is essential for the design of tools (e.g. their weight, ease of use), controls (e.g. type of grip required, spatial placement), and equipment – in other words, the workstation. Furthermore, for the selection or job placement of workers requiring strength exertion in task performance, the measurement of strength profiles of such individuals can be useful.

Studies have shown that horizontal distance and vertical height of exertion significantly affect the force exertable both in static and dynamic strength tests (Chaffin and Park 1973, Davis and Stubbs 1977). However these studies have not attempted to relate anthropometric reach space envelopes to the strength data obtained. Researchers have measured strength at varying elbow angles (Hunsicker 1955), fractions of mean reach for the population (Davis and Stubbs 1977, Kumar 1991), or fixed distances (Mital and Faard 1990). Individual functional reach regions have not determined measurement locations. For optimum workstation design a link must be established between an individual's ability to reach and exert force at functional reach regions. Recently isometric push and strength profiles were determined for the able-bodied population in the normal, maximum and extreme workspace reach envelopes (Das and Wang 1995). Also, isometric push, pull, push-up and pull-down strength profiles were determined for the paraplegics in the similar workspace (Das and Black 1999, Das and Forde 1999). Research is in progress at Dalhousie University, Canada to determine a comprehensive database for both static (isometric) and dynamic strength profiles in the workspace.

Insufficient physical capability while performing manual materials handling activities and tasks requiring hand tool usage can lead to overloading the muscle–tendon–bone–joint system and possible injury (Ayoub and Mital 1989). These two activities account for ~45% of all industrial overexertion injuries. It accounts for billions of dollars in worker's compensation cost (Waters and Putz-Anderson 1996).

4.4. Posture Analysis for Workstation Design

A common manifestation of back injury is low back pain (LBP). Epidemiological studies show a positive correlation between the exposure to mechanical overload at work and the incidence rate of LBP (Chaffin and Park 1973). However, except for traumatic and acute cases, the cause of the LBP still remains unclear (Kroemer *et al.* 1996). For the manual material handling (MMH) tasks, it is believed that the source of LBP can be traced back to the repetitive over-exertion at the lower back. This produces microtrauma at the lower spine structure over a prolonged period

of time. The microtrauma ultimately results in a permanent or temporary damage to the fibrocartilegnious disks and its surround structures and can cause LBP.

An important predictor of such structural failure is the mechanical forces acting at the lumber spine which depend on the interaction of the worker anthropometry and work characteristics. In the evaluation of workstation and work method, it is important to determine the stresses at lower back due to work performed at different trunk postures. From a biomechanical perspective, the compressive force generated at lower back (L5/S1) is believed to be the most significant factor in the development of LBP.

Safe limits of work related to heavy exertion have been well established for lifting and lowering type of manual material handling (Waters and Putz-Anderson 1996) and push–pull type of exertion (Snook and Ciriello 1991). But limits for work-related lower back stresses for postural loads are not well defined. Awkward postures are of major concern for workers who are performing repetitive jobs due to the frequency and cumulative effects of exposure. Non-neutral back postures such as flexion, lateral bending, and/or twisting increase the level of muscle fatigue and intradiscal pressures in the lumbar spine (Andersson *et al.* 1977, Chaffin 1973). Severe trunk postures can elevate the compressive force at low back, even though a load in the hands does not exist or is relatively light in weight (Chaffin and Andersson 1991).

Several whole body posture-recording schemes have been developed (Juul-Kristensen *et al.* 1997) to estimate the postural stress for various types of industrial work. Their effectiveness in quantifying the postural stress has been validated by extensive field studies (Genaidy *et al.* 1994). Primarily the posture recording schemes provide a means to estimate the level of postural stress based on the severity and duration of the work postures. However, most of them do not provide the safe limits of the postural stresses and thus, they are basically useful for comparison of postural stresses before and after modification of a work-site. The Ovako Working Posture Analysis System (OWAS) (Karhu *et al.* 1977) is a widely used postural recording scheme and has been applied to various types of industries (Pinzke 1992). A significant relationship between the back postures as defined by OWAS and prevalence in lower back pain has been established by epidemiological analysis (Heinsalmi 1986, Burdorf *et al.* 1991).

4.5. Use of Biomechanical Methods for Workstation Design

Occupation biomechanics provide a logical basis for providing data for human performance and human tissue tolerance. Biomechanical models of lower back with varied level of anatomical details and modeling capabilities have been developed to predict the compressive force in the low back due to external loads. The complex models have dealt with passive force generation and load sharing by muscles and ligaments, asymmetric postures, and inertial effects of dynamic motions. However, at the present state of development of the models, the model outputs are still not reliable enough for judging the absolute acceptability of a work situation, rather they are more suitable for comparing back loading in different work situation (Delleman *et al.* 1992). This is because of a the inherent difficulty in substantiating the validation of the model outputs and the uncertainties of the living tissue strength values against which the model predictions would be compared. Traditionally, the strength values were based on the failure strength of postmortem pine segments under axial strength values were based on the failure strength of postmortem spine segments under axial load. Lately, spine segments were tested under cyclic load, and fatigue failure data of spine segments are made available (Brinckmann *et al.* 1987). Often a computerized biomechanical model of the human musculoskeletal system is used to predict human capabilities for a particular task performance (Chaffin 1997). To predict whole-body exertion capabilities for a given population, Chaffin (1997) presents example logic for a model (Figure 5). Specific muscle group strength data and spinal vertebrae failure data are used in this model as the limiting values for the reactive movement at various body joints when a operator of particular stature and body weight attempts an exertion, such as lifts, pushes or pulls in a specific direction with one or both hands while maintaining a predicted stature. For comparing task exertions where specific localized muscle actions exist, it is possible to use electromyography (EMG) for the assessment of the active muscles and/or a subjective discomfort rating method.

Several guideline and design evaluation methods are available for the initial design of a workstation. The selection of an appropriate method will depend of the objective in terms of solving a specific problem, and whether a single exertion or multiple exertions are involved (Figure 6; Chaffin 1997). A

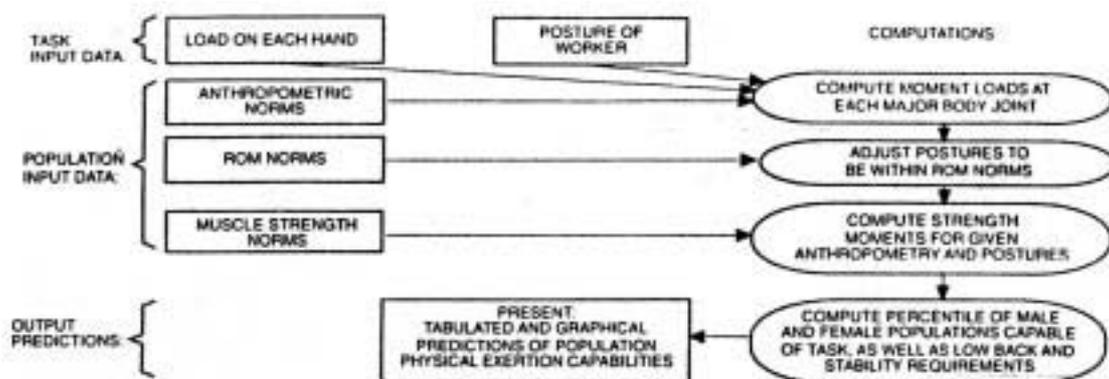

Figure 5. Biomechanical logic used to predict whole-body static exertion capabilities for given postures, hand force directions and anthropometric groups (Chaffin 1997).

prototype workstation design can be evaluated by employing a suitable method or several methods presented in Figure 7; Chaffin 1997). A representative worker(s) can be used to further refine the initial design.

4.6. Workstation Design for Manual Materials Handling

From a biomechanical viewpoint, package size can be of problem, especially when the package is located on or near the floor (Chaffin 1997). If the load is of a size that cannot be easily handled between the knees at the start of the lift, then an operator must lean the torso forward. Using the 3D Static Strength Prediction Program, Chaffin (1994) had demonstrated the effect of lifting two different size boxes of the same weight. The combination of a forward torso angle and large horizontal distance between the large box and low back caused about a 30–38% increase in predicted L5/S1 disc compression force compared to small box lifting close to the body. A significant risk of low back injury would result, if the object weighed > 35 lb.

From the viewpoint of workstation design, when large packages are involved they should never be presented to an operator at a height lower than about mid-thigh (or ~30 inches). This would allow the operator to stand erect and bring the object against (or near) the torso, thus minimizing lower back bending movements and resulting spinal compression forces. When large bulky objects are involved, adjustable lift tables should be used (Chaffin 1997).

The orientation of the package when presented to the operator must be taken into consideration. If the shape of the package is not like a cube but rather one small dimension, it should be presented in a more vertical direction. This will permit the operator to list the object closer to the body by straddling the narrow dimension, or if a handle is provided on the top, by lifting close to the side of the body.

5. SUMMARY AND CONCLUSIONS

For the design of an ergonomic workstation, it is essential to give utmost consideration to engineering anthropometry and occupational biomechanics. This will ensure a reduction of many risk factors of occupational injury and contribute towards enhancing worker productivity, worker physical and mental well being and job satisfaction.

In a workstation design, an ergonomic analysis is performed to deal adequately with spatial accommodation, posture, reaching abilities, clearance and interference of the body segments, field of vision, available strength of the operator, and biomechanical stress. Typically used in the analysis are the appropriate anthropometric masses and inertial properties from the established databases. It is necessary to make anthropometric data adjustment to account for clothing, shoe and slump posture. A systematic ergonomics approach is provided for the determination of workstation design parameters. The four essential design dimensions are: (1) work height, (2) normal and maximum reaches, (3) lateral clearance, and (4) angle of vision

and eye height. A case study of a supermarket checkstand workstation is provided to illustrate the systematic manner by which design parameters can be determined. To evaluate human–machine interaction for the design of a workstation, the use of computerized human modeling programs is illustrated by presenting two representative models: JACK and MANNEQIN. The recent developments in workstation design include: (1) a computerized potentiometric system for structural and functional anthropometric measurements, and (2) an improved anthropometric model of three-dimensional maximum reach envelope.

A biomechanical evaluation of a workstation is necessary, when a worker is believed to be exposed to excessive physical stress or risk in a workstation. It is possible to minimize or eliminate work-related injuries to musculoskeletal system through redesign of a workstation. For the determination of a person's physical capabilities, dynamic strengths measurement is more appropriate than isometric or static strengths measurement. Guidelines are provided so that industrial workers do not overload muscles to avoid or minimize fatigue. It is important to determine human strength profiles in the workspace for optimum design of a workstation. Since back injury often causes low back pain, it is necessary to determine the stresses at lower back due to work performed at different trunk postures. The compressive force generated at lower back (L5/S1) is believed to be the most significant cause for low back pain. To predict human capabilities for a particular task performance, a computerized biomechanical model of the human musculoskeletal system is often used. For the initial design of a workstation, several guideline and design evaluation methods are available. The effect of lifting two different size boxes of the same weight was demonstrated by using a 3D Static Strength Prediction Program. Guidelines are provided for manual materials handling especially when large packages are involved.

Evaluation of Work Chairs

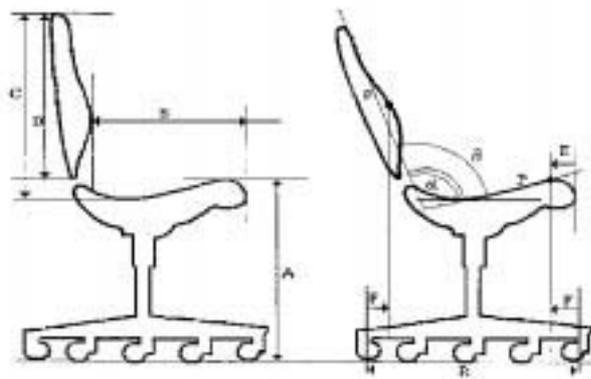
D. Colombini, E. Occhipinti, G. Molteni and A. Grieco
Research Unit "Ergonomics of Posture and Movement" EPM – Milano, I-20145 Milan, Italy

1. INTRODUCTION

Recently, changes have been introduced in the manufacture and marketing of work chairs, leading to an widespread use of the concept of "ergonomic quality" of chairs. Nevertheless, this subject once again poses a question: what are the circumstances and requirements based on which a work chair can be truly defined as ergonomic and can these features be identified?

It is well known that technical standards and regulations, however not dissimilar, are in force in different European countries. They define the wide range of manufacturing, dimensional and performance rules of work chairs. Many rules and regulations are still being discussed by European Community Standards Authorities (CEN). Therefore, the literature as well as the regulations have produced a series of criteria, though not as yet uniformly organized. The purpose of this chapter is to illustrate an organized approach for objectively evaluating the ergonomic features of a work chair.

2. BASIC ERGONOMIC REQUIREMENTS FOR WORK CHAIRS

All aspects should be taken into account when carrying out the ergonomic evaluation of work chairs to promote the psychophysical well-being of users. On the basis of this consideration, the following are the principal requirements that a work chair should meet to be defined as ergonomic:


A : SEAT HEIGHT
B : SEAT DEPTH
C : BACKREST SEAT PLANE HEIGHT
D : BACKREST HEIGHT

Figure 1. Lay-out of some of the measurements used for assessing safety, adjustability and comfort of the work chair (lateral view).

- Safety: the chair should never be the cause or the means of accidents.
- Adaptability: the chair and its components should have dimensions or be adjustable to meet the anthropometric needs of a wide range of users, and of at least 90% of the population.
- Comfort: the chair and its components (i.e. especially the seat and the backrest) should be upholstered, body contoured and reciprocally adjustable so as to meet the physiological needs and characteristics of many different "body shapes, curves and sizes."
- Practicality: the chair and its components should be easy to adjust by the user. The covering materials should favor hygienic conditions.
- Solidity: the chair, its components and adjustment controls should be sturdy, offering good wear and durability without changing performance over time.
- Suitability for the intended use: the chair should be appropriately designed for the intended type of and working environment: a standard chair that fits all types of jobs does not exist.

Each intrinsic factor described here requires the collection of many variables, both qualitative and quantitative, according to which specific criteria were set to determine whether or not a variable is acceptable, and if found acceptable, whether it is optimal or only sufficient.

In particular, reference was made to the criterion that 90% of the users' needs had to be met when evaluating the chair's dimensional and/or adjustment features. To this end, most appropriate, anthropometric parameters were established, and minimum and/or maximum values were set corresponding to the 5th and 95th percentile of the overall population (men and women) distribution. The anthropometric distributions referred to in this study were those of adult western populations as described by Pheasant (1986).

As far as the "shape" of the backrest is concerned, some data collected by the authors were used. These data were obtained by studying a sample of ~350 subjects (men and women) relative to the "shape" of the thoracic and lumbar spine, with the subject standing and sitting.

With regard to safety and performance, reference was made to the European Countries technical regulations in force, particularly German DIN 4551 and Italian UNI 7498.

2.1. Safety

When evaluating safety requirements the following characteristics and variables should be checked:

- Stability of the chair: the supporting base in projection should contain the surface area of the seat plane; in particular, the chair-to-ground projection of vertical force application points, placed 5 cm apart respectively should be contained within the extremity joining the two adjacent spokes. Moreover, the backrest-to-ground projection, with maximum retro-inclination, should fall within the area defined by the supporting base. While taking measurements, castors should be positioned in the most unfavorable position (Figure 1).
- Pressurized gas springs for adjusting the height of the seat plane and the slope of the backrest should be approved and tested by qualified standards authorities.

- Chair adjustment controls, especially if mechanical, should not be activated unintentionally.
- Chair components should be made of non-flammable material, especially the padding, covering materials or a combination of both.
- The chair should come in a choice of castors for different types of floors; it is better to equip chairs with anti-skid castors.
- Absence of sharp edges.
- Armrests should never pinch. In particular, they should not be open at the back.

2.2. Adaptability

The study of this requirement entails the analysis of a range of dimensional or adjustment variables of the chair components, mostly as a function of the variability of corresponding anthropometric parameters. These parameters include:

- Height of the seat plane (Figure 1): this corresponds to the anthropometric parameter known as "popliteal height." The height of the seat plane is measured from the ground to the highest point on the front edge of the chair when a weight or compression is placed on the seat plane (e.g. 50 kg). To meet fully the variability of the corresponding anthropometric parameter, this height should be adjustable between 35 cm (= 5th percentile in women) and 50 cm (= 95th percentile in men). It is surprising to note that current European regulations suggest a minimum height of 42 cm (UNI and DIN regulations): these values correspond to the mean value of the popliteal height of the general European adult population (men plus women). It is worth pointing out that part of the shorter population shall be expected to use a footrest. Therefore, bearing in mind the growth tendency of the popliteal height parameter in the population and the thickness of footwear (2–3 cm), much effort is still needed to lower the minimum height of the seat plane to at least 40 cm. The maximum height of the seat plane should be left unchanged (50 cm) or even increased to 53 cm or more (= 95th percentile in men wearing shoes).
- The usable width of the seat plane (Figure 2): this corresponds to the anthropometric parameter "hip breadth" in sitting position. In this case, aside from unrealistic adjustment mechanisms, the first step is to meet the needs of the widest subjects (= 95th percentile in women). Once this parameter is set, it becomes easier to meet the needs of other subjects. This parameter, however, becomes even more critical in the case of chairs with armrests. The suggested distance between the armrests should be equal to or greater than 49 cm.
- Depth of the seat plane (Figure 1): this corresponds to the anthropometric parameter "buttock–popliteal length." It is obtained by measuring the distance between the front edge of the seat plane and the most protruding point on the front of the backrest (i.e. lumbar support). This depth may vary in cases where the backrest is adjustable in depth or merely in slope; conversely it is fixed, with the chairs whose backrest and seat plane are joined into one body. With respect to this parameter, the most important issue is aimed at favoring the 5th percentile subjects of the buttock–popliteal length by considering measurements suitable for the proper placement of the thighs and at the same time supporting the lower back. This is particularly important in chairs without an adjustable depth, where the parameter involved should be < 41–42 cm.

- Backrest height (Figure 1): the backrest is intended to support the trunk. There are different types of backrests. Some chairs come with the backrest and seat plane all in one piece (single body). Other chairs have backrests not adjustable in height, and in other backrest adjustment in height is possible. In the best of cases, the backrest should at least support the trunk starting from the low back curvature (L5–S1) up to maximum thoracic kyphosis. Obviously, the correspondent values of the 95th percentile in men should be taken into account. An acceptable height is capable of supporting at least the entire low back segment. Generally, backrests (whether adjustable or not in height) that support only the low back are defined low. Backrests supporting the trunk up to maximum thoracic kyphosis are considered medium, while those which exceed this height are considered high. In the case of backrests with adjustable height, the backrest should be at least 32 cm high and its upper edge from the seat plane should adjusted to at least 48 cm from the seat plane. In fixed backrests the "upper edge-seat plane" distance should be at least 48 cm. Backrests with height < 32 cm (but > 22 cm) are acceptable if the measurements from the upper edge vary between 37 and 47 cm: support is only provided in the low back segment and, therefore, the chair is not advised for prolonged sitting positions.
- Backrest width (Figure 2): these measurements define minimum widths at the level of maximum lumbar lordosis and maximum thoracic kyphosis. To meet adequately the anthropometric parameters (values corresponding to the 95th percentile in men), these widths should be at least equal to 33 cm in the low back segment and 38 cm in the thoracic segment. For reference, lumbar width is measured by taking the maximum protruding point of lumbar support; thoracic width is measured ~19 cm above this point.
- Height, depth and width of the armrests: armrests are useful for supporting upper limbs while work is not being carried out, for getting into and out of the chair, especially people with functional motor disabilities, and also for keeping balance. On the contrary, armrests are not recommended for tasks involving the use of a high keyboard (especially mechanical), or when a fixed table is used under which the armrests cannot be inserted because the table is too low.

To determine the proper height of the armrest from the seat plane, it is worth recalling the anthropometric parameter "elbow–seat plane height" (obtained by measuring the distance between the elbow-to-ground height and the popliteal height, both taken in sitting position). It is better to refer to the low range of the parameter (small–medium, 5th to 50th percentile).

If the armrest is adjustable in height, its height from the seat plane should range between 15 and 23 cm (variations > 23 cm are possible); but if the armrest has a fixed height, it is better to choose a height measuring between 16 and 23 cm.

The recommended depth of the armrest is defined according to the anthropometric parameter known as "elbow-to-wrist length" in the 95th percentile of men. Since this parameter

measures ~30 cm and ideally at least two-thirds of the forearm should be properly supported, then the recommended depth for resting the arms should measure at least 20 cm or more, provided that the armrest is located in the right position for this function.

As for the width of the armrest, its dimension should be wide enough to allow for the forearms to be comfortably supported. Armrests with a width of 4 cm or more are recommended.

Table 1 (see end of article) gives a summary of the principal parameters dealt with in this study to assess adaptability. Each parameter was rated optimal, acceptable or unacceptable respectively.

2.3. Comfort

With respect to the other requirements, comfort is certainly the most difficult to assess from an analytical standpoint. The idea of comfort is easily influenced by the subjective evaluations of the users, and in literature this subject is still being widely discussed. The following reflections can shed some new light on the basic approach to the problem.

A work chair should always come equipped with a backrest to support the trunk. A backrest permits the relaxation of paravertebral muscles, and leads to less pressure overloading the intervertebral disks as compared with chairs without a backrest, even when these kinds of chairs come with a forward sloping seat plane.

A backrest also allows the trunk to alternate periods of support with periods of no support, thereby obtaining a variation in

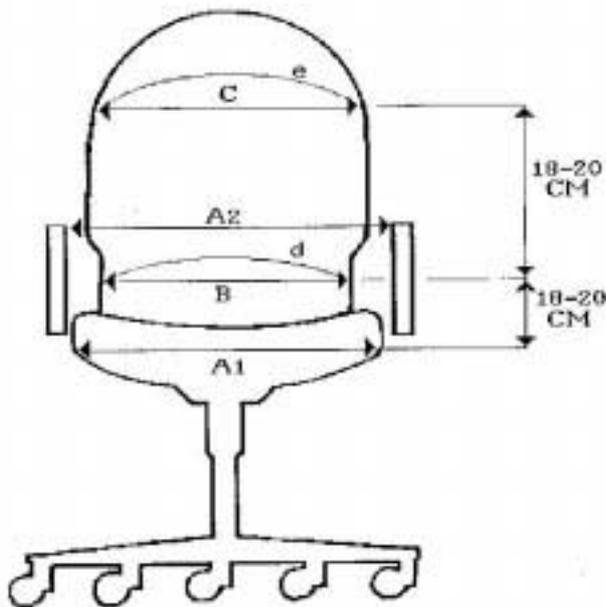
pressure load (otherwise impossible to achieve without a backrest), which is essential to the good nourishing mechanism of intervertebral disks.

A forward sloping seat plane, which is useful only in a limited number of workplaces with specific needs (i.e. work carried out at a drawing table), may indeed contribute to maintaining the physiological curvature of the lumbar lordosis, but nonetheless it tends to overload the lower limbs, particularly the knees. In cases of extreme seat plane inclination, a knee block has compensated for this overloading, but this solution is the cause of another problem, i.e. menisci disorders.

Proper support of the lower back is achieved using a sufficiently reclinable backrest with respect of a correct profile of the lumbar lordosis. Both conditions are vital to reducing muscle and articular overloading of the spine.

Therefore, in terms of comfort, a clear choice was made in favor of chairs with backrests reclinable, autonomous from seat plane, suitably contoured with a lumbar support and ideally adjustable in height and with a slightly retro-inclined seat plane. The backrest and the seat plane should also be shaped according to the details described in this paper. It is now possible to give the analytical details of each aspect characterizing a chair's comfort.

- Inclination of the backrest (Figure 1): its adjustability is aimed to meet the needs of different people, both subjectively and task-related, bearing in mind the relationship with the overall layout of the workplace. Too much inclination tends to interfere with work tasks and it may be the cause of a man/chair imbalance with respect to the supporting base. Inclinations of < 90° with respect to the horizontal plane is ineffective for supporting the trunk. The possibility of varying the angle between the trunk and the thigh, obtained by adjusting the inclination of the backrest, is also useful during different work tasks. From this standpoint, a good synchronous balance mechanism of this opening depending on the inclination angle presents an advantage, but it is not a necessary condition. Hence, backrests equipped with an inclination ranging between 90 and 115° (with respect to the horizontal plane) are preferable (120° for high backrests). The backrest should be adjustable to the desired inclination for whatever position or range of inclinations (i.e. almost 5°). The net angle between the backrest and the seat plane should be less than these values depending on the slight retro-inclination of the seat plane or the presence of synchronous opening devices between the backrest and seat plane. As for comfort, the chairs with a backrest, albeit reclinable, that is one piece with the seat plane (single body) are less effective. Likewise, in the absence of blocking devices for desired inclinations, backrests with inclinations obtained only by putting pressure on them (even with adjustable resistance) are less advisable.
- Contours of the seat plane (Figure 3): to avoid compressing the neurovascular structures at the popliteal level, the front edge of the seat should be rounded and possibly made of non-rigid material. The correspondent curvature should have a radius contained within 4–12 cm, and the height of the rounded area should measure ~4 cm. From front to back, the seat plane should be sloped slightly backwards in order to favor the placement of the thighs and stop the buttocks


from sliding forward. A slope ranging between 3 and 10° respect to the horizontal plane with the seat in normal position is recommended. These values may be slightly increased if synchronous opening devices of the seat plane — backrest angle are present. Towards the back of the seat plane, a concavity should be designed for housing the buttocks. The center of this concavity, from back to front, should be placed within 10 cm of the most protruding point of the lumbar support with the backrest in vertical position.

- Lumbar support (Figure 3): with regard to this basic element, the height of maximum protrusion from the seat plane, the depth and the length of its extension along the backrest should be taken into consideration. The height of maximum protrusion can be defined by considering the anthropometric parameter "lumbar lordosis–seat plane height." In optimum cases, this height should be adjustable between 17 and 28 cm. In cases of chairs where the backrest is not adjustable in height, maximum protrusion is fixed between 20 and 24 cm from the seat plane. The depth of the lumbar support at maximum protrusion should be set according to data in literature and original data on the anthropometry of low back curvature. To meet anthropometric requirements and different postural choices, depth should be adjustable between 2 and 5 cm. If it is not adjustable, then the depth should be set between 2 and 4 cm. The length of lumbar support extension along the low-back padded area of the backrest is determined by using such anthropometric parameters as: "distance between 1° sacral vertebra and 1° lumbar vertebra" and "distance between 1° sacral and maximum thoracic kyphosis." Generally speaking, extension ranging between 20 and 30 cm are suggested for medium-sized backrests and 13–16 cm for low ones. As for vertical contour of the backrest padding, it is important to notice that in the case of medium or tall backrests the curvature between the 1° sacral vertebra and the maximum thoracic kyphosis is not symmetric with respect to maximum lumbar lordosis, but rather is somewhat slight on top and more accentuated at the bottom.

- Padding: the aim of a good seat plane and backrest conformation, as well as eventually the contours of the padding, is to establish the right interface between the user's body and the seat itself, avoiding the undesirable effects of compressing any protruding bones and providing an appropriate distribution of body pressure. For most office workplaces, chairs should be manufactured using semi-rigid upholstery (with a deformation due to the weight of a person < 2.0–2.5 cm), sufficiently thick (4–5 cm) and preferably applied onto a well-shaped body of the chair. In industrial environments, where chairs often come in contact with dust and liquids, it would be inappropriate to use padded and/or upholstered chairs. Therefore, other kinds of materials are preferred (i.e. wood). In this case, a good profiling of the seat plane and backrest is highly recommended.

- Covering materials: the surface that comes in contact with the user should not create any thermal undesirable sensation. In particular, these materials should allow the skin to breathe but avoid creating cold sensations. Therefore, the suggested covering materials for seats and backrests should be made of porous material (placed over the padding) or in wood,

whereas plastic, rubber and metal chair coverings are not recommended. The armrests should be covered with plastic or padded material to avoid creating undesirable thermal sensations or hitting the nerve structures of the elbow on rigid parts of the chair. The covering material, particularly of the seat plane, should be rough enough to counter the buttock's tendency to slip forward.

Table 2 (see end of article) gives a summary of the principal parameters dealt with in this study to assess comfort. Each parameter was rated optimum, acceptable or unacceptable respectively.

2.4. Practicality

Adjusting the various chair components should be made as easy as possible for the user. If adjustments have to be made using controls that are difficult to maneuver or hard to reach, ultimately they will never be used.

The adjustment controls, particularly of the seat height and the different functions of the backrest, should be easy to reach from a seated or semi-seated position, without the need for use of force or additional equipment. Any knobs or handles should not be easily removable, and, if necessary, they should be fitted with guide stops.

The covering material of the chair should also be washable in order to guarantee the minimum hygienic requirements. This aspect is particularly important in industrial or in very dirty environments, or in cases where the chair is intended for multiple users. In these cases, the chair can be covered in fabric protected with easily removable covers or made of wood.

2.5. Solidity

Resistance to wear of the chair and its components is a prerequisite not only from a marketing standpoint, but also for ensuring the durability of ergonomic performance.

The sturdiness and resistance to wear of the seat and its components can be evaluated using the specific tests and interpretation criteria developed by National Standards Authorities, with validity in each of the countries respectively. Therefore, the results of such tests are important for making an overall ergonomic evaluation of a chair. The type of warranty and customer assistance provided by the manufacturer or distribution organization is another important aspect of this evaluation.

2.6. Suitability for the Workplace and Intended Use

As mentioned earlier, every workplace has its peculiarities and special needs from an ergonomic standpoint.

The chair is a separate working instrument and, therefore, it can have different characteristics and features that make it suitable (or unsuitable) for certain job settings, work environments or potential users. In other words, on the basis of a few characteristics, it is possible to define the general areas of potential chair use.

The "intrinsic" characteristics orientating the chair towards a specific job destination were examined in this study; then a summary is presented of all the necessary characteristics of chairs intended for wide areas of utilization.

- Castors: they should be buffed according to the type of floor

F : ROUNDED FRONT EDGE
```

Figure 3. Lay-out of some of the measurements used for assessing comfort of the work chair (lateral view).

used (smooth, carpeting, etc.). Chairs with castors for carpeting should not be used on smooth surfaces.

- Armrests: sometimes compatibility problems arise between the height (lower edge) of the worktable and the armrests.
- Covering materials and padding: in chairs intended for use in crowded areas, or areas with flames and sparks, both materials should be flameproof. In workplaces involving prolonged seated positions, a chair with semi-rigid padding is preferred. In working environments where the seat is easily dirtied, washable chair covers or upholstery should be used.
- Characteristics of the backrest: low, single body and non-adjustable backrests are not recommended for jobs involving prolonged seated positions. For these kinds of jobs, medium-to-high backrests that are separate from the seat plane are

suggested; backrest should be adjustable almost in inclination and fixable in the chosen position.

With regard to VDT workstations, it is worth recalling that EEC Directive no. 270/90 establishes that seat plane should be adjustable in height and backrests should be adjustable in inclination and in height.

For jobs involving prolonged seated positions, it is worth stressing that medium-to-high backrests with both kinds of adjustability and proper backrest profiling, especially in the low back area, are preferable. Chairs with low backrests should be restricted to jobs that do not entail prolonged sitting positions, provided they come equipped with the same two adjustments for the backrest.

1. INTRODUCTION

Ergonomics design of the workspace and that of many workstations requires making decisions regarding placement (layout) of a great number of objects (machinery, devices, tools) utilized by workers. Such a layout should allow for effective functioning of the human–machine systems. The placement of objects (layout design) is, therefore, an important ergonomic design problem for simple and complex systems and structures. Ergonomic layouts should be based on optimalization of specific ergonomic criteria. For this purpose, one must formulate measurable functions, i.e. the criteria appropriate to a given design situation. Such functions must allow one to distinguish between the better and worse projects. The formal layout algorithms and optimization methods in many cases allow to find solutions which are the best or close to it.

The essence of the problem can be illustrated based on a simple example. Let us assume that in an office building there is a need to deliver different types of documents among three different types of organizational cells or company units (ABC). Daily, on average, a messenger delivering paper documents needs to travel ten times between A and B (either way), five times between B and C, and 20 times between A and C. Figure 1 illustrates a layout of the corridor linking the three rooms (offices 1–3) containing cells ABC. Assuming the first layout from Figure 1 (layout A), during an entire working day one needs to travel 165 m (10 _ 3 + 5 _ 3 + 20 _ 6). Assuming layout B, the same activity requires travel over 120 m (10 _ 3 + 5 _ 6 + 20 _ 3). It can be seen that in the second case, the messenger can perform the same task with less effort.

The above example of office work illustrates the problem of document flow between different units of the organization. In a similar way, one can analyze a single human–machine system, even though the physical layout related to the required travel is not the only way to evaluate the quality of placement of controls and displays in such a system.

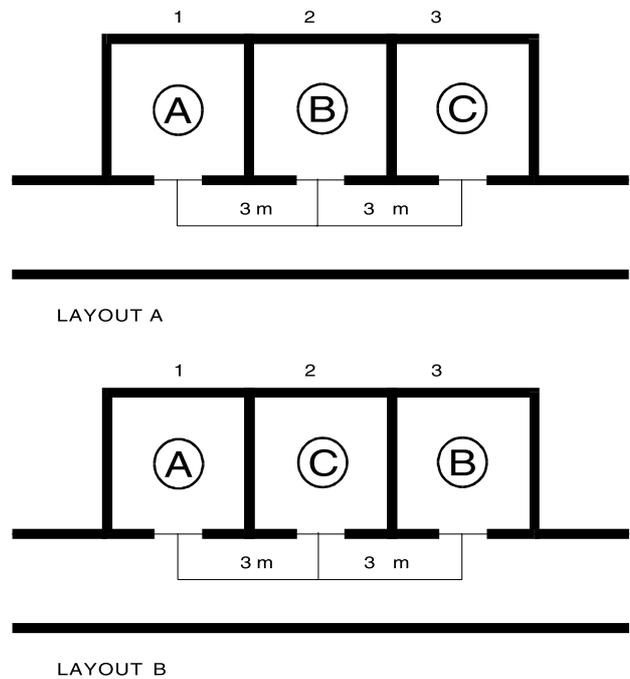
The classical example of the ergonomics problem of space-related layout is discussed in the book by McCormick (1976), that refers to design problem of an aircraft cockpit. One of the tasks in this a design is placement of the controls, which must be used blindly. In such a case, a reasonable approach would be to use a layout that would guarantee maximum reliability of reaching for and grasping the correct controls. The theoretical basis for such a layout is given by Fitts (1947), who studied the accuracy of blind motions, which can be quantified, depending upon location of the target with respect to the human operator, by


Figure 1.

considering the mean error in reaching the target. Having the information about frequency of use for the particular controls, one can calculate the overall mean error of reaching a target for a given layout. This can be done by summing over each control device the product of frequency of use and the mean error for its placement.

Traditionally, one can use many different concepts and criteria as the basis for evaluation of the layout of machines and evices in the human–work (human–machine) systems. For example, Bonney and Williams (1977), discussed the following layout criteria: (1) the type of user population, (2) comfort of use, (3) safety, (4) aesthetics, (5) closeness of devices, (6) easing their utilization, (7) appropriate distance (separation) between the devices to reduce potential error, (8) division of work between upper and lower extremities, (9) anthropometric dimensions and (10) functional relationships between devices. Proctor and van Zandt (1994), focus their attention main on the functional grouping of devices with respect to frequency and order of their use. Consideration of such issues by the designer working in a traditional way is often based on intuition, and can be improved with knowledge and experience. The attempts to formalize and use objectives methods for decision-making in this case, have also been undertaken in the past (McCormick 1976).

Owing to the very nature of many of the discussed aspects of design, it is often not possible to incorporate all of them into mathematical models, which are based on measurable quantities. In many cases, the formal models can only be used as tools that aid the design process. There are, however, in the ergonomic literature many examples where formal models are sufficiently robust and can generate final layout decisions with acceptable quality.

2. ERGONOMIC MODELS FOR LAYOUT DESIGN

The informal rules for placement of devices, tools, or machines in the workspace have been known in the ergonomics field for a

number of years. The most often cited rules recommend utilization of the following design criteria (McCormick 1976):

- Importance: the devices that are most important from the design objective point of view should be located in most important places (that is, those which are most convenient from their use) point of view.
- Frequency of use: the most frequently used elements/devices should be located in the most convenient places with respect to the ease of use.
- Order of use: the devices that are used one after another should be located close to each other.
- Functional use: the devices related to the same design function of the system should be grouped into blocks.

It should be noted that the specific design criteria could lead to contradictory solutions. For example, an important element (due to its safety connotation) can be used very infrequently. One can also imagine that there would be other set of rules applicable for some specific cases. It is difficult, however, to determine the hierarchy of different criteria, as such an attempt would lead to case-by-case (specific) classification. McCormick (1976) suggested that the design criteria A and B, discussed above, are particularly useful for layout of complex control panels (devices) in the workspace, while the criteria C and D are very useful for design of single control panels. This is because criteria A and B relate to the interrelationship between single devices and specific space locations, that is, the interrelationship between a specific point in space and the human operator. Criteria C and D are only related to mutual space relationships between different devices.

Wierwille (1980) developed formal models based on designating A and B as the criteria of the first-order (the relations measured by these criteria deal with single devices). Criteria C and D were classified as the second-order criteria, describing the relationships between pairs of devices. Given the above rules, the general problem of ergonomics placement of different elements (tools, devices, machines) at the workstation (workspace layout) can be formalized as follows: place several devices in the work space in such a way as to maximize the fulfillment of design criteria A, B, C and D.

The formal model of the above problem requires definition of an appropriate matrix that can be used to measure the degree to which criteria A–D are satisfied. This, in turn, leads to the need for defining a method for quantitative measurement for each of these criteria. Such a model is needed to distinguish between different design solutions.

A typical approach to satisfying criteria of the first-order is based on construction of the simple multipoint scales, which allow one to evaluate the location of various devices. Evaluation of the importance or frequency of use can be formulated by experts based on the knowledge about the tasks to be conducted on a given workstation. Evaluation of the quality of location for a particular workspace should be based on the ergonomics knowledge, and is often dependent upon the type of analyzed elements/system.

A given solution can be evaluated, for example, using:

$$Q_1 = \hat{A}_i W_i * I_{p(i)}, \qquad (1)$$

where W_i is importance of the device (i) in view of criterion A, or the frequency of use of the device (i) in view of criterion B;

$I_{p(i)}$ is importance (quality) for placement of the element (i) from the ergonomics point of view; and $p_{(i)}$ is an index for placement of the ith element.

If scale W is ordered in decreasing order (that is, the devices which are more important have higher values), and scale I is ordered in the increasing order, then a better design solution will have a smaller Q_1.

The criteria of second-order are most frequently being modeled using a sum of the products of indices of the length and distance:

$$Q_2 = \hat{A}_i \hat{A}_{j>i} L_{ij} * D_{p(i)p(j)}, \qquad (2)$$

where L_{ij} is the degree to which the devices (objects) i and j are linked together; and D_{pipj} is a distance between points and $p_{(i)}$ and $p_{(j)}$ in which the devices (i) and (j) have been placed.

According to criterion C, L illustrates how frequently the use of device (I) takes place before use of device (j) (or vice versa). For criterion D, the index L is the degree of functional linkage (with respect to the performed tasks) between the devices (i) and (j).

The double summation in the above equation means that in the evaluation process, one considers all pairs of devices: $j > i$, in the second sum is restricted to consideration of any given pair only one time.

L_{ij} can be put into a matrix, in which at the cross section of any row (i) and column (j) one can place the index of linkage (connections) between the devices (i) and (j). In such a case, typically one would fill out the matrix only above the main diagonal, as only these values are being considered by equation 2. For example, based on Figure 1, this can be shown:

Cell	A	B	C	
A	–	10	20	Linkage (L)
B		–	5	

In the above case, because the possible space for placement (layout) is restricted to specific rooms, one can represent the distances between such places:

Room	1	2	3	
1	–	3	6	Distance (m)
2		–	3	

Because evaluation according to equation 2 specifies, in general terms, a certain (important) distance, then it is natural that the linkage between each pair of devices will be derived in such a way so that the higher level of linkage will have the higher numerical value. In this case, the better layout solutions will have the lower overall values according to equation 2. Of course, the above evaluations are relevant for the situations that are similar to those presented in Figure 1, where equation 2 converts into simple length of travel that must be done by the messenger.

3. LINGUISTIC APPROACH

The equations 1 and 2 are not the only possible models of criteria for workspace layout design. For example, Grobelny *et al.* (1995) and Karwowski *et al.* (1999) have proposed an application of the fuzzy sets and systems theory for deriving a matrix for layout design. Such approaches have particular significance in

ergonomics analysis because they allow a consideration of the modeling process the element of imprecision, which often characterizes description of the human–artifact systems.

Linguistic problem description is more natural, especially when used to express the level of interrelationships or importance, as opposed to using the artificial scaling schemes. The layout design criteria of the first and second-order can be expressed using the language of logic in a way similar to the natural language.

For example, the design rule A can be restated:

IF Importance_level (of a given facility) is *GREAT*
THEN Location_place (of a given facility is *PROMINENT*. (3)

The rule C can be expressed as:

IF facilities pair *ij* is *USED IN SEQUENCE*   (4)
THEN *ij* are *ADJACENT* in the layout.

The underlined and capitalized words in the above equations are specific realizations of the linguistic variables, which values are words of natural language. In equation 3, such variables are the levels of importance and prominence of a location in the workplace. Equation 4 utilizes variables that can be named as the "sequential use" and "adjacency." Such equations express the idea of appropriate rules in a somewhat more formalized way, using the specific meaning. These are descriptions of the desired state for the specific model, which one can use to compare different design solutions. Utilization of equations 3 and 4 must be based on the specific evaluation mechanisms so that given rules 1 and 2, one could compare any pair of solutions, and choose the better one.

Because the above rules are logical expressions, the most natural way of evaluating then can be based on application of logical rules. The idea of linguistic patterns (Grobelny *et al.* 1995), is based on calculating the degree of satisfying such patterns (shown in equations 3 and 4), as defined by the specific solutions. This can be done by using one of generalizations for the classical implication table, which defines the truth of the sentence "IF a THEN b".

Depending on the truth (Tr) of its elements (a and b), one of such generalizations is the equation proposed by Lukasiewicz:

Tr(IF a THEN b) = min (1, 1 − Tr(a) + Tr(b)),   (5)

where (Tr) is the value of truth of the given expression (…).

It can be noted that equation 5 works in a way of a classical table of implication for truth, meaning that if Tr(a) and Tr(b) are 0 and/or 1, then the expressions are either *true* or *false*. The level of truth equals 0 (false) when a is true and b is false. In reality, the situations are more close to gradation of the value of truth. In such a case, equation 5 allows to define the level of truth of a given implication based on the level of truth for the parts a and b.

The level of truth can be defined on a scale from 0 to 1. A convenient mathematical apparatus that provides formal tools for evaluation of the level of truth is the theory of fuzzy sets (Zadeh 1968). The presented approach can also be used in a less formal way by utilizing subjective values (judgements) of truth based on the expert opinions.

For example, let us consider the situation presented in Figure

1. First one can note that in the problem of assigning specific rooms, one cannot directly apply the first-order evaluation rule because nothing is known about the value of the specific spaces for placement, or about the weight of the tasks. On the other hand, the problem of travel distance between the rooms can be evaluated by equation 4. Specifically, rule 4 can be modified slightly in order so that the expressions used are unambiguous. Given the above, one can propose the following expression:

IF the frequency of travel between the two cells, *i* and j, is BIG THEN the rooms which contain *i* and *j* are ADJACENT to each other   (6)

Cell	A	B	C	Degree of satisfaction for
A	–	0	1	the left side of rule (6)
B		–	0	

Cell	1	2	3	Degree of satisfaction for
1	–	1	0	the right side of rule (6)
2		–	1	

Let us also assume that we have the orthodox experts who only recognize a two-valued logic (true, false). If one can find data from matrices presented above, then using equation 6, and based on the knowledge and experience, one can, for example, say that frequency of travel equal to 20 is being BIG, while other frequencies are not BIG. Furthermore, the rooms that are adjacent to each other would be thought of as such rooms that have common walls between them (rooms 1 and 2; and 2 and 3). The above judgments can be set in matrices in the analogous ways as before.

Based on the above data (and Figure 1), one can perform the following evaluation for each pair of the organizational cells (units). The level of satisfying rule according to equation 5.

Cells	Layout (a)	Layout (b)
AB	min (1, 1 − 0 + 1) = 1	min (1, 1 − 0 + 1) = 1
AC	min (1, 1 − 1 + 0) = 0	min (1, 1 − 1 + 1) = 1
BC	min (1, 1 − 0 + 1) = 1	min (1, 1 − 0 + 1) = 1

As can be seen above, in the first layout solution (a), the pattern is not satisfied by a pair AC and its location. This assessment is logical also from the practical point of view, as the frequency of travel between cells A and C is BIG (according to the expert opinion), while the rooms containing cells A and C are not adjacent to each other.

In the second case, all pairs are satisfying the required pattern. Because the assessment according to the rule by Lukasiewicz expresses the level of truth, and 1.0 is the full truth, one cannot perform addition of such assessments for the specific layouts (as it is done in equation 2). Rather, the middle values of truth should be used. Therefore, such a layout satisfies the pattern according to equation 6 to the degree of 0.66, while layout B to the degree of 1 (fully).

4. CLASSIFICATION OF LAYOUT AND OPTIMIZATION ALGORITHMS

In the discussion above we have presented some methods for constructing the evaluation matrices for layout solutions. Such

matrices allow one to quantify, compare and select the best solution from a given set of solutions. A separate problem in this area of research is the rationale for selection of good solutions under different design situations. Because the above methods are very much dependent upon some characteristics of the design projects, one needs to develop a taxonomy of tasks, and then derive specific evaluation methods according to types of tasks to be solved.

The criteria for placement of objects and devices (layout) was discussed before. The first-order criteria indicate the way to place single objects in the workspace. The criteria of the second-order evaluate the mutual relationships between a pair of objects. In the example considered above, it was logical to utilize only the second-order design criteria. Such criteria are very useful in design of control panels, while the criteria of first-order are not applicable to this problem.

On the other hand, many design projects can only use the criteria of the first-order. Placement of the ready-to-use control panels in the workspace can be evaluated based on criteria on the first-order, especially when each panel serves to control different functions. There are also design situations, especially occurring in complex workstations, where one has to simultaneously seek a compromise between the rules specified by criteria of both orders. Therefore, design situations for placement of objects and devices can be classified as tasks of type 1, tasks of type 2, and the combined tasks (type 3), in which both evaluation criteria must be considered simultaneously.

The approaches to layout design problems (optimization of layout) in addition to the order of criteria also depend upon the way in which allowable places of localization (space) are restricted. An example considered above represents such restricted tasks, were space for placement of cells are predetermined. Therefore, only one cell can be placed in any given room. However, while designing a new control panel, designers may face a decision regarding placement of single elements on the panel, as well as consideration of the geometrical form and dimensions of the panel itself. Such a problem can be denoted as an "open problem".

Based on above discussion of the specific characteristics of layout design tasks, and the related design criteria, one can summarize the problem space as shown in Table 1. The above classification allows to assign to different types of tasks the specific methods and algorithms for their solutions, which can lead to either optimal or suboptimal layouts.

The restricted tasks of type 1 can be used to model common design projects, where the evaluation hierarchy for the objects to be placed, as well as an assessment of the usefulness of the predefined places are known. A typical example for this is placement of elements in the field of vision. Even though the

Table 1. Simplified classsification for layout design with respect to type of criteria and accessibility of space

	Type of design criteria		
	1st Order	2nd Order	Both simultaneously
Allowed places (pre-determined)	Restricted problems 1st Order	Restricted problems 2nd Order	Restricted problems-complex
Allowed places (any location)	Open problems 1st Order	Open problems 2nd Order	Open problems-complex

accessible places are not physically defined, one could determine the assessment values based on the knowledge of human field of vision. Therefore, the whole accessible space can be appropriately evaluated by, for example, assigning relative scores for visual acuity. Such a situation is very simple from the point of formalized optimization. The obvious solution would be to assign (consecutively) the most important objects to the most accessible places. This would lead to an optimal solution as discussed by Grobelny (1988).

McCormick (1976) also discussed the practical utilization of such an approach. Placement of control devices in an airplane cockpit was optimized by ordering devices with respect to the frequency of their use, while evaluation of the accessible space was done based on the research results of Fitts, regarding the precision of human motions under blind conditions. The presented solution called for consecutive placement of the most frequently used elements in the accessible areas, characterized by the highest precision of blind motions (based on a kinesthetic sense).

5. DESIGN ACCORDING TO CRITERIA OF THE SECOND ORDER

The placement of elements in the workstation based on criteria of the first-order are, in general, open, and can be solved in a similar way as the restricted tasks of the same type. That means that the basis for evaluation is the psychophysical characteristics of the human. If the accessible places are not determined physically, then the designer has much greater freedom to act. However, some areas with specific valuation can also be determined by objective characteristics of the human being, while the described method can give the optimal solution from the formal point of view.

Much more complex situation has to do with the tasks described by criteria of second-order. The classical optimization approaches allow seeking solutions only for tasks that are restricted (i.e. those with precisely specified placement spaces/location). These types of tasks can be defined as follows:

Place N devices in M accessible places ($M \geq N$), so that the value of the function of second-order is minimized (or the mean truth value calculated according to equation 4 is maximized).

The optimal solutions for the above can be reached by reviewing all possible layouts, and using the method of division and restriction as proposed by Gavett and Plytera (1966). Such an approach allows solving tasks with up to 20 elements. Therefore, for tasks with greater number of elements, it is necessary to use the heuristic algorithms.

Because classical algorithms require precise determination of the potential placement, the layout tasks which are open must be appropriately translated into the tasks which are restricted. Most often this is done through introduction of the modular nets, which restrict the accessible space given the specific patterns of the net. Sears (1993) proposed such an approach to optimization of the dialog windows for human–computer interface design purposes. The basis for optimization criterion was a road traveled by the cursor that is needed to accomplish basic tasks conducted using a given dialog window. The authors showed, based on empirical studies, that optimal solutions significantly improved the effectiveness of work with windows.

Drezner (1988) was first to propose a methodology for solving

the second-order layout tasks that are open on the surface, without any restrictions. A concept of the scattered plots was used for this purpose. An efficient heuristic algorithm is based on characteristics of the Eigen vectors and Eigen values of the relevant matrices, based on the following formula:

$$Q_2 = Â \, c_{ij} d_{ij}^{\,2} / Â d_{ij}^{\,2}, \quad (7)$$

where C is frequency of interactions (L) defined by equation 2; and D is distance between a given pair of objects.

The process of minimization is possible by analytical method. However, the objects must be placed on a straight line. The coordinates for such a solution (x and y) are the consecutive Eigen vector elements related to the second lowest value of matrix S, for which:

$$s_{ij} = -c_{ij} \text{ for } i \, \pi \, i, \text{ and } s_{ii} = Â_j c_{ij} \text{ for all } (i).$$

Good solutions (on the surface space) can be derived by taking as the coordinates of y, the elements of Eigen vector related to the third smallest value of an Eigen value of matrix S. This is because such coordinates represent the best solution on the orthogonal line with respect to the coordinate x.

Although theory of Eigen vectors and Eigen matrices is quite complicated, the algorithms which generate the solutions are very simple, and can be used without knowledge of such complex ideas. Given the relationship C_{ij} one needs to do the following:
- Develop matrix S.
- Calculate Eigen values and Eigen vectors.
- Select two vectors connected with the second and third smallest Eigen values, and take these as sets of consecutive for x and y solutions on the surface, respectively.

The second point of the above process must be realized using the computer program, for example, using the Mathematica.

Figure 2 illustrates the solution reached for an example where values of C were put in the form of 0,1, meaning that the elements are related to each other in the following way: the first place shows the number of the device, while the consecutive places show the number of devices related to the first device.

The scattered plot shows that, in most cases, the stars corresponding to the elements that are related to each other, are also located closely one to another. The flexible computerized

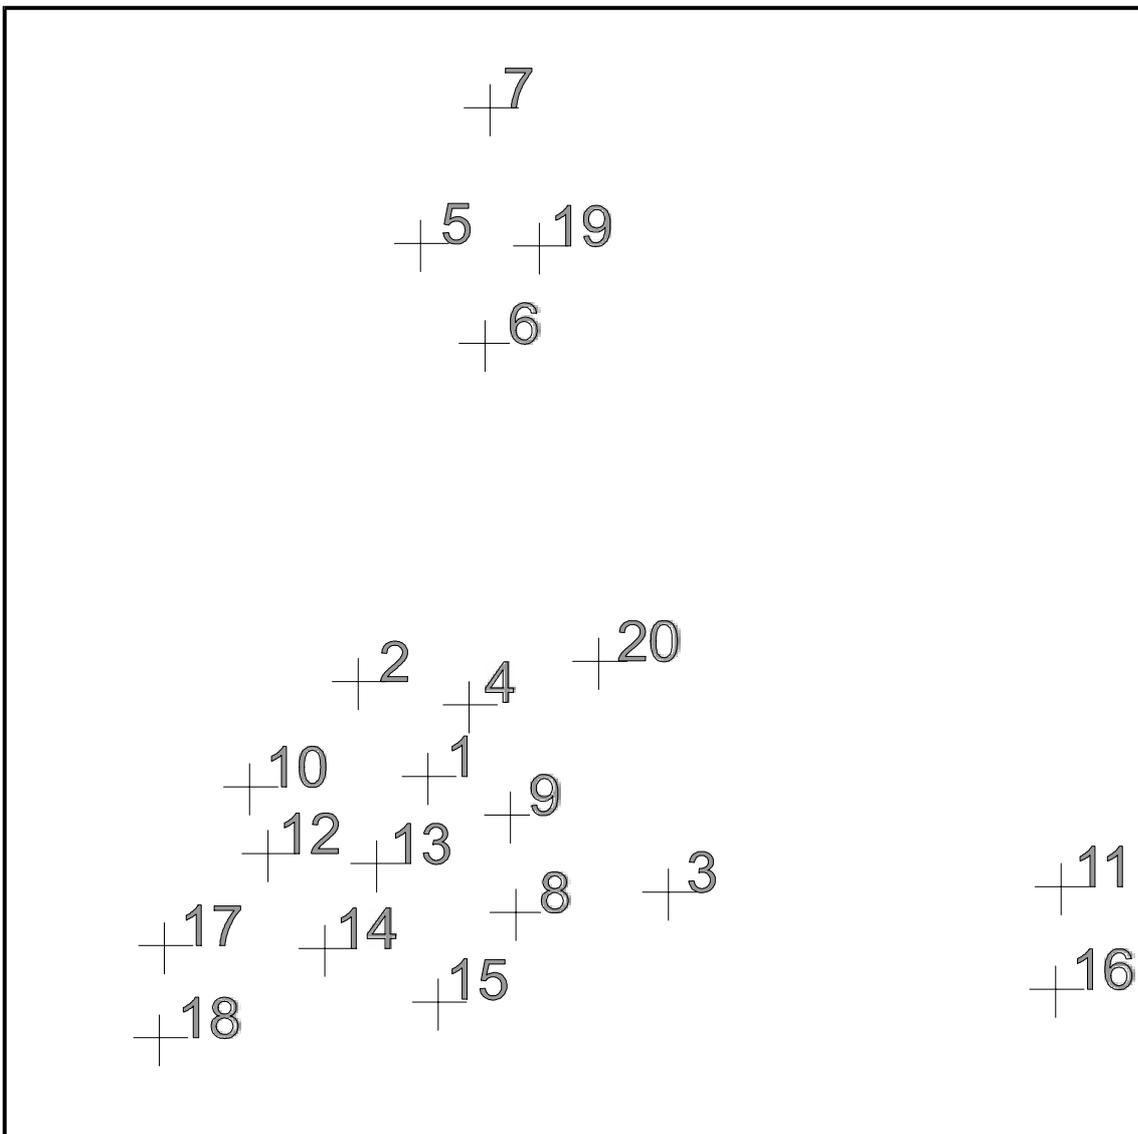

Figure 2.

method for generating the scattered plots using differential parameters was recently discussed by Grobelny (1999).

The scattered plots are the universal form for computer-aiding of layout design, especially when utilized as an aid to the designer, but one that does not replace his/her knowledge and intuition.

6. LAYOUT DESIGN FOR COMPLEX TASKS

The most complex problems in layout design are those that deal with situations requiring the use of both design criteria simultaneously, that is an assessment of design quality for complex tasks. The classical algorithm for solving these types of problems in industrial engineering is an algorithm proposed by Hillier and Connors (1966). This algorithm can only handle restricted tasks, where the number of places of localization is equal to the number of devices to be placed. The criteria of the first-order were interpreted by the authors as an assessment of the cost of placing machines/objects in given spaces. The criterion of second-order was defined as a matrix of transportation costs that are required for such placement. The algorithm progresses in the direction of minimization of the sum for both criteria.

Utilization of the above algorithm for ergonomics design purposes requires changing the task to one that is restricted, as well as developing a matrix for "installation cost", by determining the value of function 1 for each element at each place. It should be remembered that the assessment scales must be appropriately defined as the algorithm seeks a compromise that minimizes the sum of values for both criteria 1 and 2.

So far, no algorithms were proposed that would solve the combined complex tasks that are "open", in a way that is similar to the approach by Drezner, by allowing one to solve the task of second-order. Another problem that occurs in the practice of ergonomics design is the need for a consideration of the form and size of objects which are to compose the workstation. The discussion presented above simplifies classification of this problem. This is because the classical algorithmic approach described here is to a large degree independent of geometrical characteristics of the objects being placed. However, introduction of the modular nets brings the idea for defining dimensions and shapes of objects using the modular segments of the net. Such an approach was first used in industrial engineering (CORELAP). In the human–computer interaction area, the algorithm proposed by Sears (1983) utilizes modules for dividing places in a dialog window, and also for simulating functional contours of objects which are being placed in the windows.

7. CONCLUSIONS

The obvious question arises as to how such theoretical ergonomics solutions relate to practice. That is, whether the solutions developed by using methods discussed above allows one to improve the functioning of the real human–machine systems. Some of the solutions are obvious and do not require additional verification. Examples of those are related to problems with measurable, physical and economical functions of both orders. For example, the solution to the messenger travel problem considered in the beginning of this article shows that foot traffic in the office designed according to layout B will be smaller than the one designed using layout A.

Many ergonomics problems, however, do not have such uniquely defined and measurable indices, or such indices are not the only ones that determine the correctness of potential design solution. An example of such type of problems is the field of human–computer interaction. Appropriately designed dialog windows or manual structure does not necessarily improve the quality of such interface. This is because the factors that influence the subjective and objective evaluation of computer software (and the related interface) are very complex and not fully identifiable. Laboratory experiments by Sears (1993) and Grobelny (1998) indicate that optimized dialog windows (with respect to the road traveled by the cursor in the process of its use) are much more effective in real time. These are also being subjectively judged by the subjects to be better than those windows that are designed without any formal layout analysis of the objects placed on the computer screen.

Handtools

M. Braun and R. Schopp

Fraunhofer-Institute for Industrial Engineering (IAO), Stuttgart, Germany

1. INTRODUCTION

Handtools are used in all kinds of production processes, not only in the industrial production but also in the household, in medicine, arts, etc.; and particularly for the work on metals, textiles, rocks and food. The forces necessary arise from the human muscle strength. Thus, handtools are normally not used in long-term processes but they are needed for works which go beyond the human capacity (e.g. hammer drill).

In this context, *powered* handtools shall be discussed as well – although they are driven by an external source – because it is up to the human user to handle, hold and guide them differently according to the given task.

Within the ergonomic equipment design the designing of handtools plays an important role, because both the efficiency and the working process itself at the interface between user and his task are influenced. Within classification schemes handtools are distinguished from controls and machine tools.

It is the intention of this contribution to give an introduction into the handtool design process. Therefore, basic design dimensions, methodical approaches, and requirements of handedness are discussed, which are the basis of two case studies describing fundamental design dimensions by way of example.

2. DESIGN DIMENSIONS

In the ergonomic design process not only technical and formal–aesthetic aspects are of importance but also anthropometric, biomechanical, physiological criteria and aspects concerning occupational health and safety (see elsewhere in this volume).

To realize the efficient, comfortable and safe human use of handtools the design parameters are orientated to the characteristics and abilities of a specific user group (e.g. height, physical strength, freedom of movement, sensory perception and information processing). To avoid symptoms of fatigue or even occupational disease, the physical workload in its height and duration must be orientated to the user's strain limits.

Working with handtools can involve enormous risks of accidents, especially when they are not used at workstations with constant working conditions but in varying applications (e.g. at construction sites or in the food industry). Both the handtool and the object the user is working on can cause accidents. When a handtool is designed aspects of safety should be considered to protect the worker effectively from strain and risks (Hecker 1997).

The use of handtools can cause great strain on the hand because of impulsive work processes (e.g. the recoil of a hammer drill). Measures that reduce shock and vibration should already be taken when designing a handtool, e.g. concerning the minimization of production tolerances and diametrical clearances as well as of imbalances in rotating elements. Additionally, a spring-damper system is recommended to prevent shocks and vibration that affect the hand–arm system.

When handtools are used outdoors or under disadvantageous thermal conditions (e.g. in the construction industry or in forestry) a heat insulation is necessary.

Handtools can be differentiated into a hand side facing the user and a working side serving the direct work progress. The hand side as the interface to the user is of greater importance for the ergonomic design than the working side. The hand side of tools is normally represented by handles and control elements.

3. METHODICAL APPROACH

Each set of ergonomic equipment design requires the inclusion of methodical approaches, adequate instruments, and experience. In the ergonomic design process of handtools the following steps have proved successful:

- target and definition of the design task;
- analysis of the handtool to be designed;
- development of alternative design solutions;
- evaluation and selection of design alternatives; and
- realization of the selected design solution.

In the following the systematic proceeding will be described which leads to the conceptional design or corrective redesign of handtools. The aesthetic aspects like shape, size, material and surface have to be analyzed in detail before they can have an influence on the design (Bullinger and Solf 1979). Figure 1 illustrates the different steps when designing the hand side of tools. The proceeding will be described afterwards.

It is the aim of the *task analysis* to record all possible conditions of the task quantitatively. Either physical measurement or observations and interviews can provide the required data.

The next step is to examine and determine the *body's posture* of the user. Furthermore, the capable *motion range* of the hand–arm system as well as the *motion assignment* of the handtool and the hand–arm system within the task have to be taken into consideration. The best posture would be if the required movement direction corresponds with the anatomically favorable position or movement direction.

Then, the *posture of the hand* is examined, i.e. the position of the hand in relation to the forearm axis, as well as the *type of gripping*, i.e. the linkage between hand, fingers and hand side. When handtools are used static and dynamic forces have to be summoned up and transferred. Therefore, the designers of handtools have to focus on two problems: the static strain of muscles must be reduced and the transmission of great forces in the direction of the lateral and longitudinal hand axis should be prevented. For high force resistances the recommended type of gripping is steadily increasing within the types of coupling-contact (touch) to grasp.

The *type of coupling* chosen influences the strain that arises from the performed task. It would be best if the strength that is necessary to use the handtools originates from a direct, positive force transmission, for in the case of frictional transmission the strength that must be summoned up would always have to be greater. So if the optimal coupling is chosen the static physical strength can be reduced (Bullinger and Solf 1979).

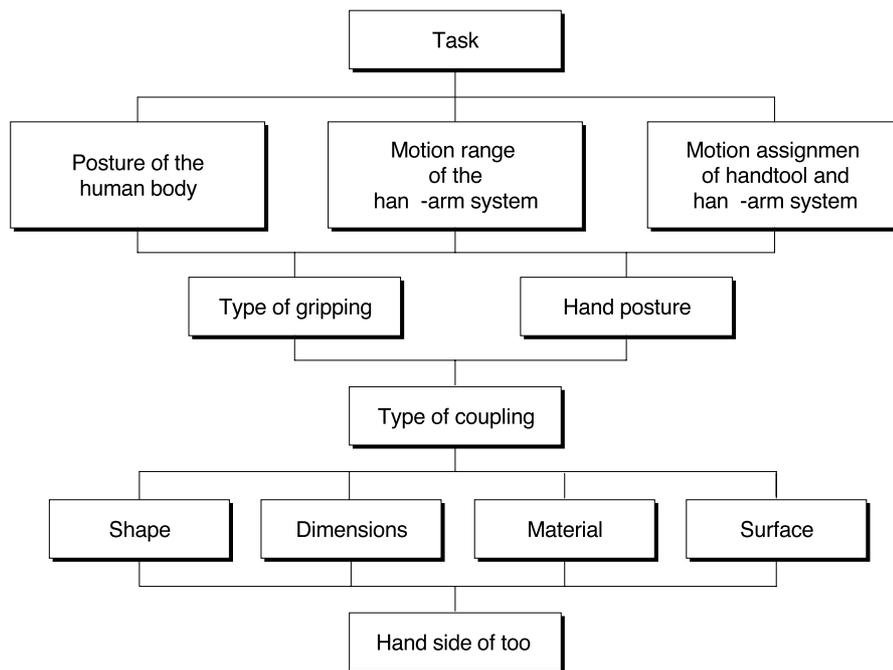
In the last step the formal–aesthetic design of the hand side is considered in the *form definition*. But only when the *shape* of the handside is fundamentally determined with regard to the handedness, it can be proceeded. Then, the next steps would be to discuss the *dimensions*, the *material* and the *surface* design.


Figure 1. **Proceeding levels of hand side design of tools (Bullinger 1994).**

4. HANDEDNESS

4.1. Situation

The handedness depends on the demands of the user and the work process. As far as the user is concerned one can differentiate between left- and right-handedness. Tools can be distinguished as follows: one-handed (e.g. pliers), one-handed with additional handle (e.g. hand drill), two-handed (e.g. spade), movable (e.g. scissors) and fixed (e.g. hacksaw) handles.

Society shows a preference for the right hand side. This is confirmed when looking on most of the symmetrical handtools designed for right-handers. There is a share of 10 to 15% of left-handers in our society – and this is expected to increase because of a more tolerant, that means not right-hand-orientated, education.

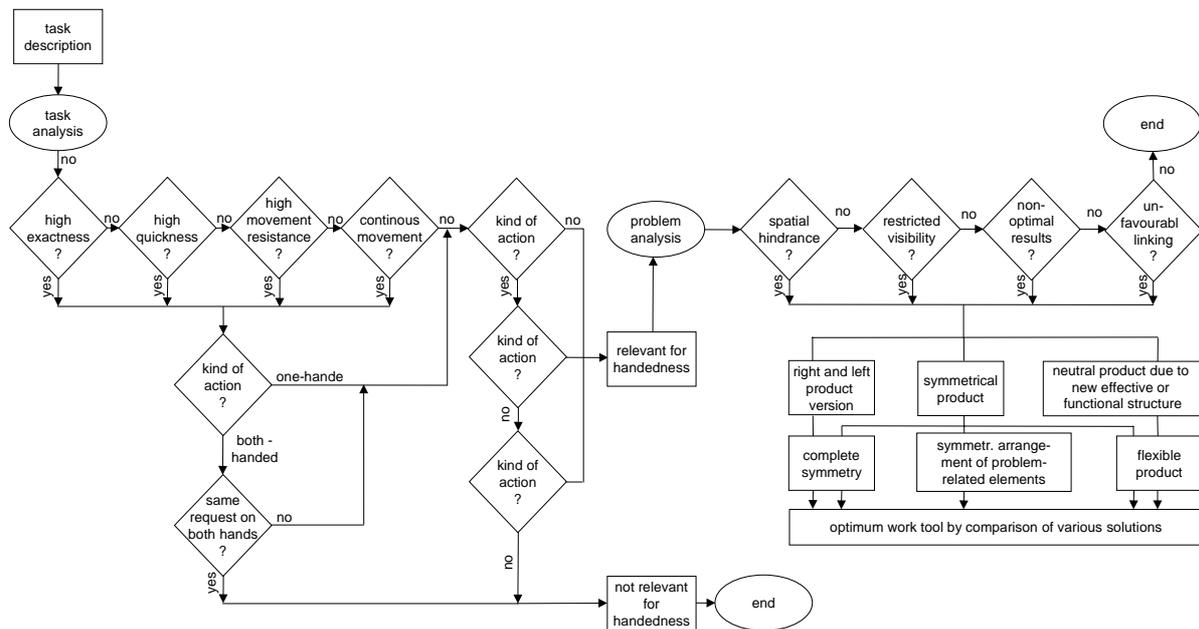
Only in a few cases two symmetrical handtools – one for right- and the other for left-handers – are an optimal solution, because often the working hand is defined by the working situation and not by the handedness of the single person. Nevertheless, in many working situations advantages can be seen when viewing on handtool design adjusted to handedness.

As a result of using handtools with the unsuited hand an increased accident risk can be stated. Possibilities for adaptions on the needs of left-handed persons are often unknown in practice and therefore rarely existing (Schmauder and Solf 1992).

4.2. Design Proceeding

Figure 2 is aimed at giving an idea how the handedness of humans can be taken into consideration when handtools are newly designed or redesigned. It was conceived as an addition to the prevailing rules and is meant to optimize existing proceedings. The course diagramme is divided into task analysis, problem analysis and new design (Schmauder and Solf 1992).

Within the analysis the task is characterized by answering the four questions: "Is high exactness demanded?," "Is high quickness demanded?," "Is there high movement resistance?," and "Is continuous movement necessary?" The demands on exactness and quickness correlate with the hand-performance and are therefore of importance for the task analysis. For tasks with low and both-handed equivalent demands on ability and aptitude of the hand–arm system it is not necessary to include handedness explicitly into handtool design.

If the task corresponding to the four questions is characterized as "demanding" or when the task must be performed one-handedly, it has to be proved in the problem analysis whether the user has free choice of hand-assignment; this is e.g. favorable in spatial hindrance. In case the performing hand is defined by the work process or by the existing design solution, the handedness must be considered, for the user has no choice of hand-assignment. Even when hand-assignment is not clearly defined it is principally possible to couple the preferred hand – which need not be necessarily the favorable hand – to the tool. The question on less- or non-optimal results is relevant when the user has free choice of the working hand and when the linking to the tool is not determined. Here it should be examined whether this determination causes non-optimal results (with consideration


IEEHF

Figure 2. From task analysis to problem analysis and new design.

on different shaping of performance). In a definite case there might be free choice of hand but a user-oriented handtool design makes it impossible to choose the unsuited one. Nevertheless, a non-optimal result might be achieved when different aptitudes are demanded, e.g. quickness and strength, which do not have their maximum constantly either in the right or left hand–arm system.

Handtools with high sensorimotor demands on the user should be designed so that they can be used with both the right and the left hand. This might be advantageous not only for left-handers but also for right-handers in case working with the left hand would be more favorable. This possibility of free hand choice should be realized in the handtool design – a left and right hand version should be an exception. Often it is sufficient to design the problem-relevant elements symmetrically or flexibly. Additionally the following design aspects should be taken into account:

- The visibility towards the working center should be good in any working position.
- Rotating handtools should – if possible – be designed for both clockwise-rotation and reverse action.
- Feed lines should be fixed symmetrically to the handtool, so that they cannot hinder the work in one direction.

5. DESIGN CASES

The two design cases described in the following are to be used as a basis for demonstrating the demands and design dimensions

in handtool design process by way of example. In doing so, it becomes obvious that a design process – considering the complex problems inherent in human and work – is dependent on the most varied factors.

5.1. Kitchen Knives

The knife is one of the most original tools of human. It is used in nearly all areas of everyday life when performing different work tasks in which material is to be cut or separated such as pricking, carving, splitting, peeling and scraping. In the course of automation the simple knife was replaced by new technologies; nevertheless, the hand-held knife cannot be replaced by machines or special-purpose tools in many areas still today. Above all in the area of the preparation of dishes and meals the knife has been the most frequently used tool now as before.

Professional users working in the kitchen frequently complain about pain in the shoulder/neck region. These complaints can above all be attributed to the cramped posture during cutting operations. On the other hand, pains in the hand–arm system and in the hand–finger system have their origins in the insufficient handle design of the used professional cutting tools.

The conventional styling of professional kitchen knives neglects ergonomic requirements that result from the handling of the tool by users with hands of different sizes and by application in different cutting tasks. A considerable ergonomic improvement of the kitchen knife can be achieved by a hand side (handle)

adapted to the working side (blade). The objective of designing a set of kitchen knives for professional use is to permit the optimal performance of all cutting tasks encountered with as few different types of knives as possible.

In an investigation of the human–knife–material system six typical cutting movements and six typical manners of gripping could be classified within the analyzed cutting operations. The cutting movements are dependent on the cutting task, i.e. from the work result achieved and from the spatial position of the cutting plane. The cutting tasks could be divided into the categories "cutting on a tabletop" and "free cutting in the room." The cutting movements are directly influenced by the possible movements of the hand–finger system and the hand–arm system. They can be regarded in dependence on the manners of gripping which are decisively influenced by the force to be exerted in performing the cutting task (Mangol and Eckert 1995).

There is a direct interrelation between cutting task, form of movement, manner of gripping and blade type. Based on this fact, seven different types of knives were defined, whose design requirements can be derived from a specific cutting task as well as from cutting movement and manner of gripping associated with it. The design requirements were worked out separately for each of the seven types of knives. In doing so, the requirements made on the blade geometry and on the handle geometry were detailed. This fact permitted seven different blade types and three different handle shape types to be defined (Mangol and Eckert 1995).

A comparison of the requirements regarding the handle geometry specific to the seven types of knives reveals correspondence for specific types. Therefore, all requirements made on the handle design can be satisfied with only three different forms of handles. These three forms of handles are not only different in an adaptation of the proportions of the handle to the blade length, but they have basic geometries that deviate from each other. The three forms of handles are each assigned to one of the seven blade types. Consequently, this knife set consists of seven different types of knives altogether, as shown in figure 3. Each of these knives has been optimized for a specific range of applications. All cutting tasks encountered in the professional kitchen will be covered by the application of the seven types of knives.

5.2. Powered Hand Drill

The second example deals with the design of a powered hand drill. Here, it is above all endeavored to improve the general handling of the tool for holding and guiding. A reduction in the total weight and a reduction of the tilting moment by displacing the tool's center of gravity near the handle or by arranging a supporting handle make a marked improvement in the handling conditions.

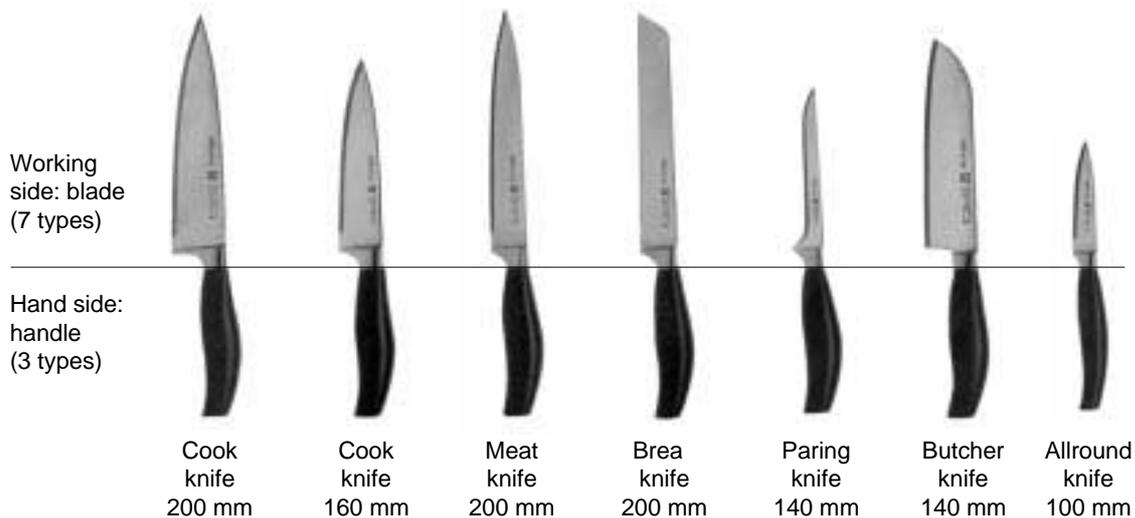
The handle of a powered hand drill should be arranged and shaped in such a way that a manual exertion of high feed forces is possible, at the same time as damping developing reaction forces and torques. In doing so, the feed force should be favorably generated by positive power transmission. The dimensional


Figure 3. Set of ergonomic designed kitchen knives for professional use.
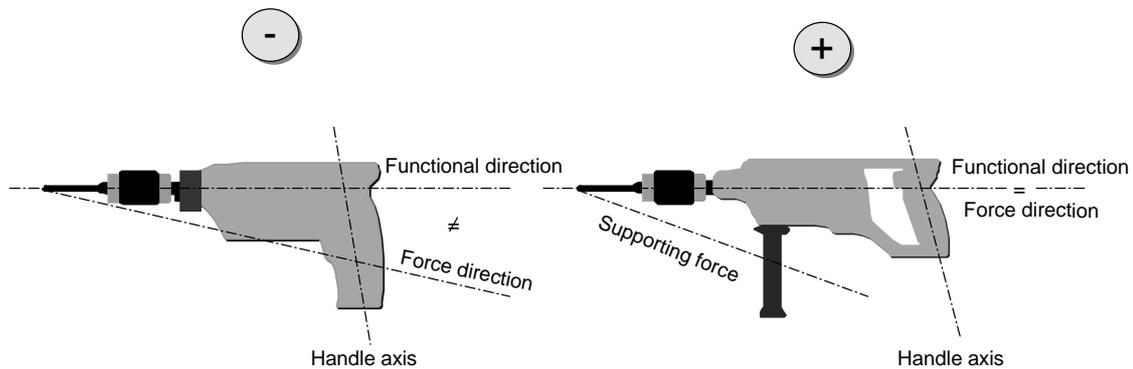

Figure 4. Design alternatives of a powered hand drill: suitable and unsuitable motion assignment.

design of the handle and the switches is oriented at the anthropometric and physiological properties of the hand–arm system.

It is the aim of the motion assignment that an agreement, as suited as possible, is achieved between the functional direction of the tool and the anatomically favorable movements of the user. The kinematics of anatomically suited modes of movement favors the exertion of force and prevents forced motions and postures. Figure 4 shows both the unsuitable and the suitable assignment of motion in a powered hand drill. By displacing the handle to the rear motor region, a direction of force will be obtained in the hand drill designed according to ergonomic criteria, with this force being in alignment with the functional direction resulting from the drilling axis.

Instruments and Design

P. Rabardel† and P. Béguin‡

†Psychologie, Université Paris 8, CNRS, 2 rue de la liberté, 93526 Saint Denis cedex 02, France

‡Laboratoire d'ergonomie, Cnam, 41 rue Gay Lussac, 75011 Paris, France

Today, the necessity of designing technical systems, products, machines and tools so that they are good instruments for users is more and more evident. This chapter formulates some theoretical proposals to contribute to anthropo-centered design, that is design organized around and for human beings, whether they be users of a product or professionals who use tools or machines. Proposed is a conceptualization of the instrument that design processes can be based on. We then develop the idea that design continues in use, and as a result, design processes need to consider this extension from the outset.

1. WHAT IS AN INSTRUMENT TO THE PERSON USING IT?

The literature proposes several definitions that vary depending on the disciplines and their aims. Norman (1991) distinguishes two perspectives: the "system view" and the "personal view":

- The system view is when the outside observer looks at how the man–artifact whole accomplishes a task. This is the traditional view of the man–machine system where the task is considered as unchanging and the instrument is seen as an amplifier of users' skill.
- The personal view is based on the analysis of modifications brought about by an artifact's use: what is transformed in the task, what must be learned, the processes that must be dropped.

The instrumental approach works within a personal view that we extend to activity. We think it necessary to:

- on one hand, analyze the influence of the artifact on the reconstruction of tasks, the appearance of new tasks and the disappearance of old ones.
- on the other hand, analyze the complete reconstruction of activity in the view opened up by Vygotsky (1931–78) with the concept of the instrumental act. This view is developed under various forms, particularly in current research on human–computer interaction and socially shared cognition (Bødker 1989, Caroll 1991, John-Steiner 1995, Kuutti 1996).

An essential precept of this work and that of the French-speaking school is that the instrument is a medium ground, half way between the subject and what needs to be transformed (matter or information) that we will call the "object". Between the three poles, subject, object and instrument, there are several interactions (direct subject–object interactions (dS-O) or interactions mediated by the instrument (mS-O); subject–instrument (S-I) and instrument–object interactions (I-O); Figure 1) where each type of interaction represents an analysis plan.

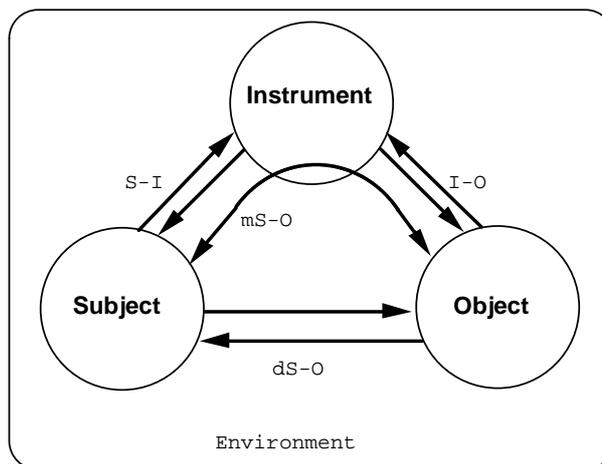
It is important to underline the fact that in this conceptualization, the instrument is distinguished from the artifact. Artifacts are built by humans with certain purposes in mind. Nonetheless, users do not always use artifacts as designers intended. This empirical fact has constituted, since the initial


Figure 1. I.A.S. model: the triad characteristics of Instrumentalized Activity Situations (Vérillon & Rabardel 1995).

work of Ombredane and Faverge (1955), one of the bases of French language ergonomics in which operator inventiveness is considered as an essential feature of work intelligence. In situations, operators explore, interpret, use and transform their technical, social and cultural environment.

It is within this activity that the artifact, whether material or symbolic, is instituted as an instrument by the user (Rabardel 1991, 1995). We propose that the instrument mobilized by the user in his/her activity be considered as a mixed entity, coming from both the subject and the object (in the philosophical sense). The mixed entity instrument includes both:

- a material or symbolic artifact produced by the subject or by others; and
- one or more associated utilization schemes resulting from a construction particular to the subject, or an appropriation of pre-existing social utilization schemes.

Schemes organize subjects' actions. They correspond to stabilized aspects of actions for known situations. It is because there are stable aspects in situations that actions also include stable aspects. An artifact is in itself a stable aspect within the situation in which it is used. This is why users construct utilization schemes which form the instrument once they are associated with the artifact. An example is the association between writing schemes and an artifact such as a pen which constitutes the instrument that allows the text to be written.

Utilization schemes have a private dimension particular to each individual. They also have a social dimension: they are common to all, or several members of a social group, a collectivity, a country, etc. This is why we speak of social utilization schemes.

Schemes assimilate. They can apply to several types of artifacts. The hammering scheme, usually associated with a hammer, can temporarily be associated with a spanner. This property, combined with the social nature of utilization schemes, is relevant to design because the designer is able to use a utilization scheme that exists within the collectivity in question to invent an artifact that can be easily assimilated into pre-existing utilization schemes. Schemes are also accommodating. They can change and develop with a changing situation. This characteristic is also

relevant to design because the designer can use a scheme that is merely a neighboring utilization scheme to the new artifact.

2. DESIGN CONTINUES IN USE ...

It has been seen that users establish the artifacts elaborated by designers as instruments. This activity can be almost instantaneous (like the transformation of the spanner into a hammer), or take place over long periods (like the constitution of writing schemes associated with the pen). Often there is an *instrumental genesis* (Rabardel 1991) that concerns both the artifact and the utilization schemes through two processes:

- The *instrumentalization* process concerns the emergence and evolution of the artifact and instrument components. It is based on the characteristics and properties specific to the artifact and gives them a status depending on the function of the action taking place and on the situation (in the example of the spanner replacing the hammer, the important properties are bulk, hardness and prehensibility). Beyond the action taking place, these properties can become, for the subject, a permanent characteristic of the artifact component of his/her instrument. Instrumentalization can go as far as transforming the artifact's behavior and in some cases, its material structure.
- The *instrumentation* process is relative to the emergence and evolution of utilization schemes: their constitution, their functioning and their evolution as well as the assimilation of new artifacts into already constituted schemes, etc.

These two dimensions of instrumental genesis are related to the subject and are different in their orientation. In the instrumentation process, the activity is oriented towards the subject himself and him managing his own activity. In the instrumentalization process it is oriented towards the instrument's artifact component and mastering the object of the action. The two processes work together to contribute to the constitution and evolution of instruments, even if, depending on the situations, one of them can be more developed, dominant or even the only one exercised (Rabardel 1995).

According to the traditional scheme, which temporally distinguishes design and use, the real use phase begins only after preparation, and possibly installation. The real use phase is supposedly nothing more than the functional use of the artifact. Our approach demonstrates that the design process does not stop with an instrument's use. It continues throughout its use in instrumental geneses. We think that users, as agents of these processes, are also agents of change in design as a whole. Of course they do this in a different manner to "institutional" designers. Users design for themselves. This self-designing can also result from work collectives (Béguin 1997).

3. TOWARDS DESIGN PRACTICES FROM AN INSTRUMENTAL VIEW

What are the consequences for design of this approach to instruments? Operator creativity and inventiveness constitutes an ontological characteristic of the design process and is not only an indicator of a deficit: needs change and use evolves following the changing dynamic of situations. Design continues in use and forms of exchange must be organized between the activity of one or more designers and the activity of one or more users. This is true before, after and throughout the design process (Béguin 1997, Rabardel 1997).

First we will look at before. We propose to undertake instrumental analyses preceding design with two objectives: to draw inspiration from artifacts born of previous instrumental geneses and to design around schemes (Rabardel 1997).

- on one hand, the analysis of instrumentalized artifacts by users reveals both perceived needs, accepted or rejected artifact functions and new created functions; the structural and behavioral solutions imagined by users;
- on the other hand, we have underlined the ability of utilization schemes to accommodate and assimilate. The analysis of utilization schemes appears as necessary given that the artifact's characteristics can lead to the mobilization of badly adapted schemes, or on the contrary, make difficult the application of schemes essential to reach the action's objectives.

Nonetheless, in our approach, the user's contribution is not limited to enriching data and ensuring the increased validity of technical choices. The analysis of instrumental geneses shows that while reducing effort and improving efficiency are definite motives, they can also come from the subject's sense of action (Minguy and Rabardel 1993).

Next we look at the post-design process in the designing of instrumentalizable artifacts. It is not only a question of designing artifacts that tolerate a range of uses. While a certain anticipation of uses and outcomes can be grounds for an artifact's design to an extent, only a small number of uses can be anticipated due to the contingencies that contribute to their appearance.

It should also not be imagined that artifacts adapt themselves to the user, even if this perspective seems interesting in certain cases. It is more a question of providing the user with artifacts that facilitate the process of instrumental genesis by bringing appropriate assistance to the elaboration of uses by novices, and by allowing users to act on the behavior and structure characteristics of the artifact. An artifact designed in this way must not only allow instrumentalization. It must also help the user to carry out an action and ensure that a coherent, collective use is maintained by making possible a shared construction between individuals. Shared is used to mean both "placed at everyone's disposal" and "true of everyone". As we can see, the instrumental approach opens up new perspectives to solve many questions. At the same time, it opens up new problems and we must be careful not to weaken users by leaving it up to them to find solutions to problems that are too complex given their resources and means, particularly when the solutions require them to go against directions.

Laptop Computer Use

L.M. Straker

Department of Physiotherapy, Curtin University of Technology, GPO Box U1987, Perth WA 6001, Australia

1. INTRODUCTION

Use of laptop computers has increased rapidly in the 1990s. More people are using laptop computers and each person is using them for more hours per day. This means that human-machine interaction is becoming more critical.

The rapid spread of laptops has outstripped the scientific community's research on the possible implications of their use. A few research reports have recently been published; together with the extensive research on desktops, they will be used to inform this article. What literature is available suggests laptops may be a problem for users; according to Harris and Straker (1999), 60% of laptop users report associated musculoskeletal discomfort.

This article considers some key issues and makes recommendations. The specifics are limited to the prevailing technologies of the late 1990s, but the principles should be valid for future technologies. However, this is one of the fastest areas of development, so the key features of the interaction could change quite rapidly. For example, the use of efficient speech recognition input and high quality displays may alleviate many of the postural and visual concerns.

Here are some brief definitions of the terms "laptop" and "desktop" as used in this article. And figure 1 shows a photograph of the different computers. Desktop computers are characterized by a screen (typically a cathode ray tube monitor but increasingly tubeless flat screens) that is separate from the keyboard and other input devices. It is often separate from the central processing unit (CPU) and disk drives, though the iMac is a notable exception. Desktop monitors and CPUs are typically rather heavy and are usually permanently located on a desk or other stationary work surface, though sometimes on a trolley. In the 1990s anyone asked to imagine a computer would typically imagine a desktop.

Laptop computers, sometimes called notebook computers, are smaller than desktop computers. Laptops were initially introduced to provide a portable computer, with 1990s laptops typically weighing about 4 kg (depending on battery size) and

Figure 1. Desktop, laptop and palmtop computers

being about the size of an A4 piece of paper and around 50 mm thick. With their processing power now equaling desktops, they are increasingly being used as replacements for desktops. Laptops can be characterized by a flat screen attached to a restricted keyboard which usually sits over the CPU and disk drives.

A third group of computers is also currently available. Palmtop computers are smaller still, around the size of an adult hand. They typically have liquid crystal display screens and small keys and/or stylus input. Palmtops currently have considerably less power than laptops, though still enough to run simple word processing, spreadsheet and database software. Their most common use is as "personal organizers" based on real-time diaries. However, their power can be expected to increase over the next decade, increasing their potential to be used as desktop replacements. Although not mentioned again here, palmtops raise similar issues to laptops.

2. POTENTIAL PROBLEMS WITH LAPTOP USE

Laptop computers are increasingly being used as replacements for desktop computers, and they are widely marketed as such. However, in the late 1990s they differ from desktop computers in at least four ways which have critical implications on the human-machine interaction: display device, input device, connection of screen and keyboard, and environs of use.

2.1 Display Device

Laptops use flat screen technology instead of cathode ray tubes. Originally they were simple liquid crystal displays but increasingly they are active matrix or thin film transistor displays. Some users report poorer screen clarity with laptops, even in ideal viewing conditions, whereas others find the flat screens more comfortable than cathode ray tubes. As newer technologies improve the clarity of flat screens, this may be less of an issue in ideal viewing conditions.

However, laptop viewing conditions are often far from ideal (section 2.4) and the possibly poorer screen clarity is compounded because flat screen technology is more susceptible to problems with viewing angle, lack of adjustability and reflections from the environs.

The result is common complaints of difficulty viewing laptop screens. The likely impact of this is a greater chance of visual discomfort and possibly visual disorders. Given the close linkage of visual and musculoskeletal systems, it is also likely that users will compromise their musculoskeletal system in an attempt to reduce visual discomfort. There is therefore also likely to be a contribution to increased risk of musculoskeletal discomfort and disorder.

2.2 Input Device

Current laptops typically use a smaller keyboard and a pointing device like a trackpad, trackball or mini-joystick (Batra *et al.* 1998). Keyboards usually have a reduced number of keys (number pads typical of desktop extended keyboards are usually missing) and often the size and spacing between keys is reduced. Digit and wrist postures are therefore likely to be more constrained and, especially for larger hands, more awkward.

Pointing devices are usually smaller than those associated with a desktop. The smaller and finer control movements required

may put greater strain on intrinsic hand muscles for movement control and forearm muscles for hand stabilization (Batra *et al.* 1998, Fernstrom and Ericson 1997).

Much of the common software of the late 1990s is written expecting a computer mouse as the main pointing device. Although laptop users sometimes attach a computer mouse, they often use the other built-in pointing devices. This is partially due to the environs of use; laptops are often used where a mousing surface is not available. Although there have been reports of musculoskeletal problems associated with mouse use (Cooper and Straker 1998), the finer movements associated with many laptop pointing devices may cause even more problems.

Different input devices have also been reported to affect performance speed and error in a variety of pointing and dragging tasks. Although the trackpad, trackball and mouse have usually provided better performance than other pointing devices, the assessments usually depend on the task undertaken.

The likely result of the more restrictive input devices normally used with laptops is a greater chance of musculoskeletal discomfort and disorder, with a potential effect on productivity.

2.3 Connection of Display and Input Devices

Nearly all laptops have their screen attached to their keyboard/pointing device. This connection limits the options available to the user for placement of screen and keyboard/pointing device.

Both the visual system and the hand movement system have zones of comfortable reach. Where the display and the control interfaces are separate, it is possible to try to optimize the position of each for the user. Thus two people working with desktop computers who have different visual accommodation and convergence and different arm lengths can vary the locations of screen and keyboard to suit their individual characteristics. But a laptop does not offer separate adjustability, so the user who prefers a larger eye-screen distance has to work with extended arms or compromise the screen distance to gain a comfortable arm posture.

There is considerable debate about the optimal positioning of computer interfaces, in particular the computer screen (see under VDU positioning). Recent research supports a keyboard position forward from the user, allowing nearly full forearm support on the desk surface. There is also considerable evidence that a low screen position results in less visual strain, although there is some concern that this comes at increased neck strain. When using a laptop on a desk, users typically adopt the flexed neck posture similar to a low desktop screen position (Harbison and Forrester 1995, Straker *et al.* 1997). The position for laptop use may therefore not be as problematic as first thought, though this is the subject of considerable debate. However, both sides would probably agree that it is desirable to have separate adjustability of screen and keyboard. Price and Dowell (1998) trialed "docking" a laptop with a desktop monitor and keyboard, but their results were inconclusive.

Straker *et al.* (1997) found no significant performance difference between desktop and laptop computers over short working periods, but there was a trend for faster word processing with the laptop. Several subjects who were not touch typists noted how it was quicker to move from viewing screen to keyboard with the laptop. The more restricted laptop posture probably has little short-term impact on productivity.

The likely result of reduced adjustability of screen and keyboard is a greater chance of musculoskeletal discomfort and disorder.

2.4 Environs of Use

Desktop computers are normally used at a single location, often dedicated to computer use. The desk, chair, foot support and associated documentation supports are often adjustable to obtain a comfortable posture. The lighting is often specifically designed for work with VDUs

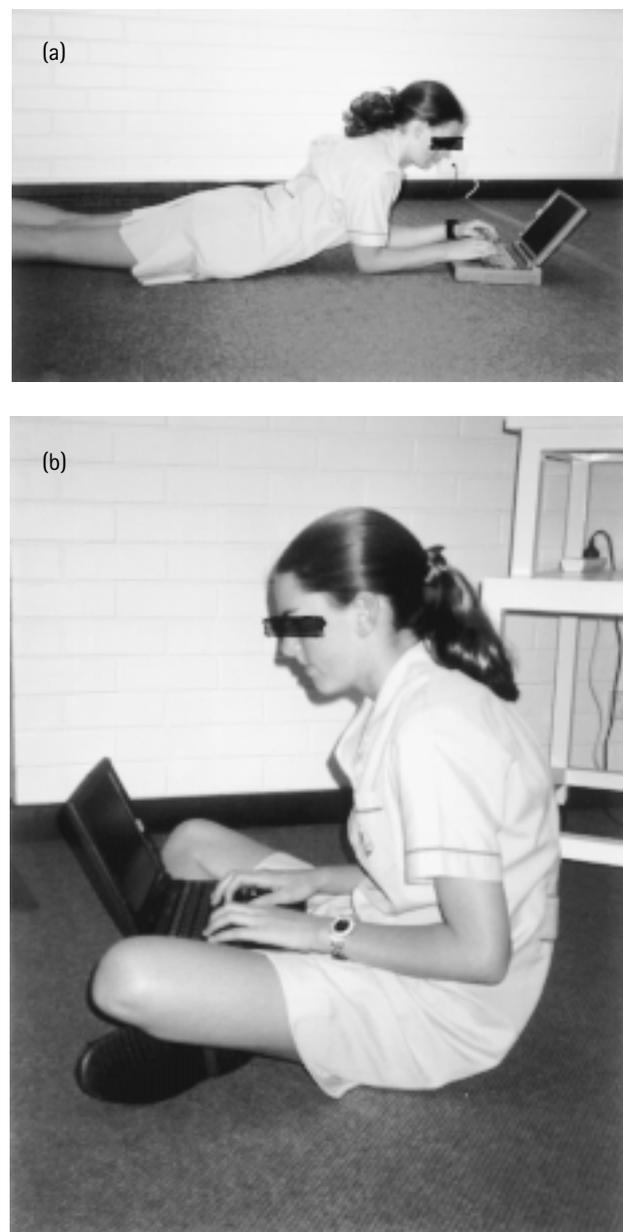
In contrast, laptops are used in a wide variety of situations: in a car, on the floor in a bedroom, between machinery on a factory floor, and in an airport terminal. Laptops are often used without furniture designed for computer use and in bright daylight or other unsuitable lighting conditions. A critical feature of the environs of laptop use is that the furniture and lighting designs are often uncontrolled by the user. This may be because it is a


Figure 2: Postures adopted for laptop computer use

client's home (e.g., for home sales) or because there are other design constraints (e.g., when using a laptop in a car).

Together with furniture constraints, the desire to minimize reflections and optimize viewing angle leads to a wide variety of postures being assumed. Although varying posture is an aim of physical ergonomics, the recommended variation is between "good" postures. Often postures adopted during laptop use are "poor"; that is, they involve extremes of range and sustained static muscle contraction (figure 2).

Even when a reasonable posture is used, e.g., upright sitting, there is usually limited opportunity for forearm support — important for reducing trapezius muscle loading (Aaras *et al.* 1998).

Laptops are also transported by users, and this creates a potential carrying problem which rarely occurs with desktops. Although current laptops usually weigh only about 4 kg, they are often carried with a power transformer, portable printer, mobile phone and paperwork. A survey of schoolchildren using laptop computers found 60% reported discomfort associated with carrying their laptops. Laptops may therefore add a critical mass to the load carried.

Again the likely result of the lack of control of environs of use and more frequent carrying is a greater chance of musculoskeletal discomfort and disorder.

2.5 Problem Summary

The design and use characteristics of laptops may result in increased potential for visual and musculoskeletal disorders compared with desktop computers. The small available literature on laptops supports these concerns, as do the implications from earlier research on desktops. The main problems are likely to be visual and musculoskeletal (mainly neck and upper limb) as a result of the poorer display clarity, more restricted input devices, lack of independent adjustability for screen and keyboard, and lack of control over environs of use.

3. RECOMMENDATIONS

It seems prudent to be cautious in the use of laptops. Pending further research, here are some tentative recommendations for acquisition and use:

- Preferably do not use laptops simply as replacements for desktops.

- Where laptops are used in office locations, use them in conjunction with a separate high clarity display and normal-sized keyboard — use docking.
- Buy one with the best quality screen (considering image clarity, angle of view, reflections).
- Buy one with full-sized keys.
- Use it for shorter periods of time between breaks (the poorer the posture, the shorter the work period); be guided by visual and musculoskeletal discomfort.
- Use a variety of supported postures in the middle of your joint range.
- Buy the least heavy laptop.
- Carry it in a comfortable backpack with two shoulder straps or use a wheeled "aircraft" case.

Performance Prosthetic Hands

I. Gilad

Faculty of Industrial Engineering and Management, Technion (Israel Institute of Technology), Haifa, Israel

1. INTRODUCTION

A primary goal in the design and provision of body-powered hand prostheses is to make them efficient and simple in operating. A hand prosthetic device should be designed along ergonomical principles to provide a good substitute for the missing organ. Obviously, the higher the efficiency the less energy is required to use or operate in daily life situations. It should be remembered that any prosthesis would always remain a secondary, artificial substitute hand and will be an inefficient device when compared to the real organ. The main contributor to the inefficiency is the prosthetic prehensor.

Arm amputees have a basic choice of a hook or a hand for the prosthetic prehensor. There are compromises between these two options. The hook is more functional, and the hand is more cosmetic. Some amputees solve the dilemma by having one of each and interchanging them as work and social situations dictate. Arm amputees prefer to have one acceptable prehensor and they want one which is functional and attractive, but it does not necessarily have to look like a hand. The study reports the findings about five mechanical prosthetic designs and one mechanical hand. These were examined in object-geometry handling and ADL (activities of daily living) tasks.

2. PREHENSOR DESIGN

The mechanical devices present four non-conventional designs for prosthetic prehensors, shown and compared to the traditional Hosmer/Dorrance hook and to a hand-like prosthesis. The various prehensor designs include two that incorporate different kinds of grasp and combine voluntary opening and closing features (LeBlanc 1988).

2.1 The Hosmer/Dorrance hook

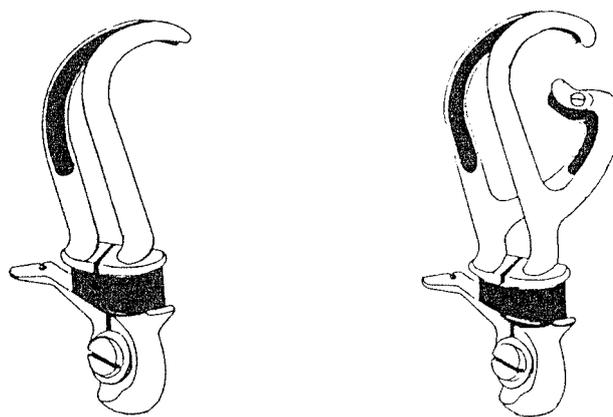
The first record of an artificial hand is an iron hand fitted to a Roman general who had lost his own hand in battle about 200 BC. In the later years of knights and armor, various prosthetic hands were fashioned out of metal, and at some point Captain Hook and other "pirates" were using hooks. In the 1890s, D.W. Dorrance developed the split hook. The Hosmer/Dorrance 5X hook (figure 1), which is made of stainless steel or aluminum, is the most common and is considered the "standard" for comparison with other prehensors. While many upper-limb amputees get used to the appearance of the hook, it is not what most people would consider an attractive looking device. For that reason, some amputees prefer the use of a prosthetic hand, although it may be less functional. In addition, some amputees try to have the best of both by having a hook and a hand and interchanging their use. Even then, sometimes the hand is relegated to the closet because of the inconvenience of switching prehensors and the superior function of the hook.


Figure 1. The Hosmer/Dorrance 5X hook (left) and the Gilad design (right)

2.2 The Gilad Design

This design (figure 1) is based on the lyre-shaped hook finger type "SS-555 Dorrance"; it features two additional "thumb fingers" which enhance the grasp performance. This device was introduced in Gilad (1985) after a time and motion study which advocated a design with greater ability to grasp various geometrical objects, but which still kept the simplicity of the popular two-finger design.

2.3 The Parker Design

This prehensor (Figure 2) is derived from study of the anatomy of the human hand. It is voluntary closing (VC), uses primarily three-jaw-chuck grasp, has curvatures for multi-point grasp of cylindrical objects, and has a cutout in the dorsum for use of pencils and utensils.

The operation of the Parker design is conceptualized as normally closed, thumb opening completely with a slight pull on the cable, and thumb closing with further pull on the cable. One unique feature being considered is cable take-up with thumb opening, which would allow a normally looser harness that would tighten for operation as the thumb opened for grasp.

2.4 The LeBlanc Design

This prehensor (Figure 2) is based mainly on functional considerations. It is voluntary opening (VO) in the normally closed position and is voluntary closing against the opposite finger. It has fingertip grasp in the VO position and palmar grasp in the VC position. The fingertips handle objects up to 1.5 inches in diameter, and the proximal area handles 1.5–3 inches in diameter. Prior work has indicated that 90% of activities can be handled with 1.5 inches opening or less.

2.5 The Nelson Design

This prehensor (Figure 2) is based mainly on esthetics. It is unique in that it has a rotary thumb which is normally closed in the VO position for finger tip grasp and then can be rotated around for palmar grasp in the VC position.

The LeBlanc and Nelson designs are unique in that they offer different grasping surfaces and the option of using VO or VC prehension. That is, one could hold objects in VO position with fixed prehension force and no harness pull, or hold objects in VC position with variable prehension proportional to harness pull.

Figure 2. The Parker design (left), the LeBlanc design (middle) and the Nelson design (right)

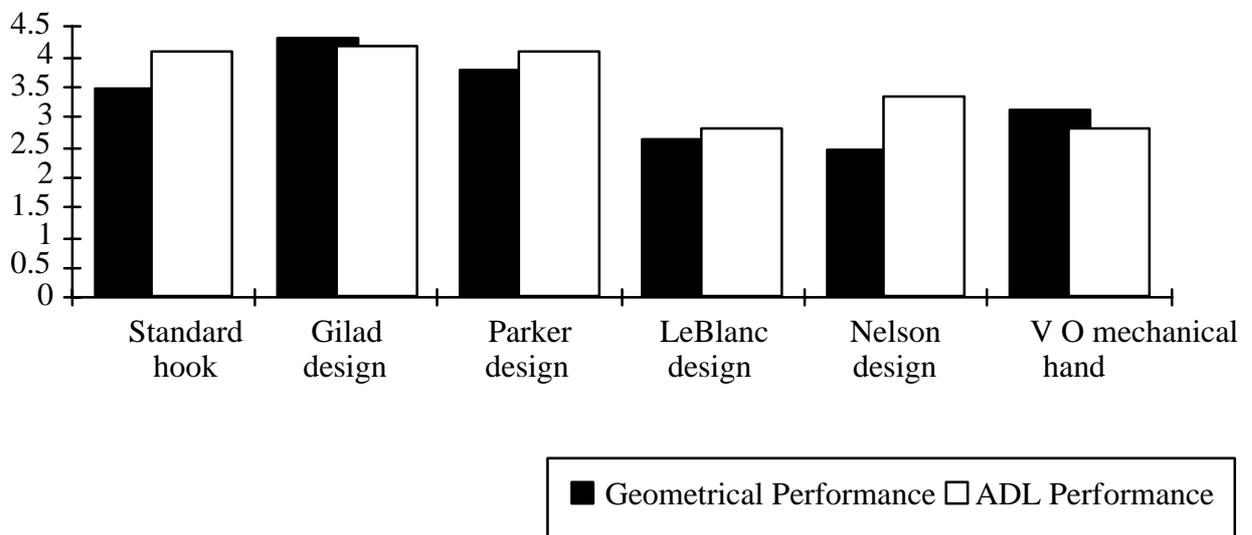
■ Geometrical Performance □ ADL Performance


Figure 3. Performance scores for five hook designs and the VO mechanical hand

Note: The challenge for the manufacturer is to design a prehensor which is functional as a hook and esthetically acceptable. The upper-limb amputee will prefer the functional design that provides an attractive-looking device. The ability to perform a set of 15 activities common to daily living was also tested. The scores from this performance analysis indicated that the Standard Hosmer/Dorrance hook, the Gilad design, and the Parker design were preferred. Of these, the two designs referred to as the Gilad and the Parker meet the challenge for good performance devices. Although the Gilad design got better scores in both geometrical and ADL tests, it is believed that the Parker design will be more suitable for users who seek the better esthetic appearance.

2.6 The Mechanical Hand

When appearance and body image are important to amputees, the cosmetic non-functional or the mechanical hand is preferred. The mechanical hand, like the Otto Bock which has a voluntary opening and spring closing mechanism, is then popular. These were not considered in this study.

3. COMPARATIVE STUDY

Subjects were asked to rank their preference after examining the use of the different prosthetic devices in two tests. The first test was the ability to grasp, maintain hold, transport and position four sets of geometrical objects differing in shape and size using time criterion (Gilad 1986). The second test was the ability to perform a set of 15 activities common to daily living.

From this performance check, it is clear that the Standard Hosmer/Dorrance hook, the Gilad design and the Parker design were preferred. The scores were presented in a 1–5 scale: 1 given when unable to perform the given task, through to 5 for excellent performance. Findings are presented in figure 3. From this performance check, it is clear that the improved hook of the Gilad and Parker designs were preferred.

4. DISCUSSION

The use of various types of prehensors varies significantly around the world. European countries have much the same technology available as in the USA but apply it differently. Cultural and psychological factors play a big role on the way technology is used in clinical practice.

Principles of Handtool Design

M. Aptel, L. Claudon and J. Marsot

Laboratoire d'Aide à la Conception d'Outils à Main Ergonomiques, Service de Physiologie, Environnementale, INRS Avenue de Bourgogne Bp 27, 54501 Vandoeuvre Cedex, France

The development of ergonomic tools responds, first, to health protection needs on the part of users. This is particularly the case in so far as MSD risks are concerned. Second, the development of ergonomic tools responds to the needs of the companies who use these tools and to their desire for better and more rapidly produced products. Only an ergonomic design process can enable tool manufacturers to meet these requirements. Three factors are involved: integration of ergonomics into the design process, definition of the different ergonomic stages involved in such processes and knowledge of the different factors involved in handtool design. The objective of this paper is to examine these three elements in more detail.

1. INTRODUCTION

For some years now, ergonomic handtool design has stimulated renewed interest among users, manufacturers and researchers. In the past, in fact since the Industrial Revolution at the beginning of the 19th century, emphasis was placed on handtool function to improve efficiency and to allow for standardization. The tool was required satisfactorily to fulfil the task for which it had been designed, to respond to the needs of the greatest possible number of users and to be as cheap as possible. Consequently, a given tool was designed to be used by all potential users. However, in recent years, approaches have changed and new notions of increased comfort and reduced biomechanical solicitation with regard to users' functional capacities have been introduced into tool design. There are several reasons for this development.

The rise of musculoskeletal disorders of the upper limbs (MSD) is the most important. These work-related disorders are found throughout the industrialized countries (USA, Sweden, France and Australia and are particularly widespread in industries that make use of handtools). As a result, the food-processing industry and car and household goods manufactures are production sectors in which the risk of MSD is particularly high. In a report published by the National Institute for Occupational Safety and Health (NIOSH) (Radwin and Smith 1993) it was estimated that MSD represents ~24% of all handtools injuries.

Second, the development of new technologies (artificial intelligence, robotics) and new forms of production process organization (just-in-time, ISO 9000 quality certification) have also had an impact. Such factors require a greater range of skills, greater know-how and deeper implication in the work process on the part of employees. New tool requirements have emerged from this background.

Finally competition between handtool manufacturers has led to widening of the skills and know-how required of manufacturers, including ergonomics, if they are to respond to market forces.

In practice, tool manufacturers must take three new types of need into account in the manufacture of handtools:

- Integration of ergonomics into the design process.
- Definition of the different ergonomic stages involved in the design process.
- Knowledge of the different factors involved in the design of handtools.

It is worth stressing, at this point, the relation between ergonomic design and the risk factors associated with MSD. Research into ways of improving ergonomic tool design dates from well before the systematic linking of tool design to MSD in the workplace.

The objectives that ergonomic study into handtools aims to achieve are constantly changing with technical progress, changes in the organization of work and the expectations of operators. Safety objectives, comfort and even considerations of style have been added to considerations of improved efficiency in tool design. To meet these new, interrelated requirements, researchers have resorted to a variety of methodological approaches derived from different disciplines (mechanics, physiology, psychology, sociology).

Hence, awareness that ergonomic design represents a means of preventing MSD leads to the addition of another objective to design specifications: the reduction of biomechanical and vibration risks. An "ergonomic tool" must be safe and efficient, and must also make fewer demands on upper limbs if risk of MSD is to be reduced.

The objective of this paper is to analyze these three requirements, first, to help manufacturers master ergonomic handtool design processes and, second, to help users develop specifications that will adequately express their particular needs in this field.

2. INTEGRATING ERGONOMICS INTO THE DESIGN PROCESS

The design process can be defined as a transformation of information allowing for movement from an initial concept to the final result. This process should be structured methodically. Indeed, it is generally accepted today that 75% of the total cost involved in the development and industrialization of a product is determined at the very outset of the design process.

Method in design process (Figure 1) involves an approach in which different "models" (language, technical experience, know-how. etc.), on the one hand, and different "tools", on the other, are brought together. By "tools", it is understood to be all the techniques involved in the analysis of the functioning of a part or the whole of the design process.

General design procedure involves a group of project participants (marketing, design, manufacturing) and a number of phases (definition of needs, specifications, general and detailed design). The approach adopted must achieve the highest possible integration of these different elements if the project is to run smoothly.

Traditional design process techniques have envisaged project participants and phases in a sequential manner. This sort of approach is characterized by:

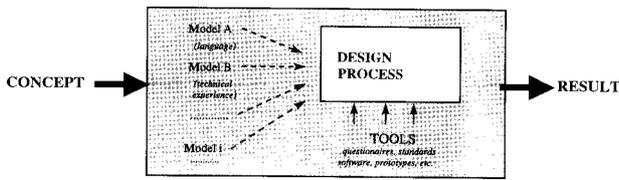
- the erroneous belief that needs and specifications can be fixed once and for all at the outset of the design process;
- a difficulty in integrating project participants other than those directly involved in the different phases (ergonomics, etc.); and


Figure 1. Method Structure.

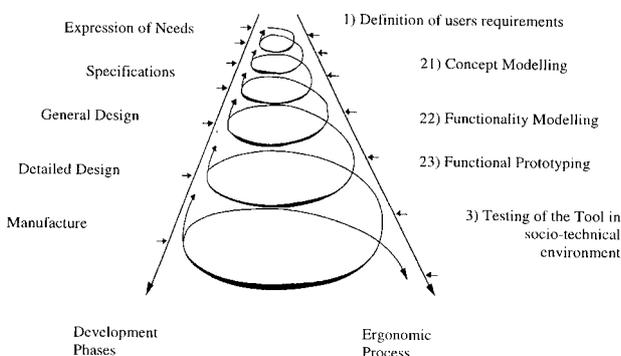
• a difficulty in, or even absence of, communication between the different participants involved in non-consecutive project phases. (Lack of communication of this sort is aggravated by the fact that protagonists in the process have difficulty in understanding all the intermediary objects involved: technical drawings, nomenclatures, technical sheets, specifications, etc. Lack of communication of this sort is one of the main reasons for the non-inclusion of ergonomic recommendations in the design process.)

The result of such an approach is that considerable difficulties are to be had in introducing ergonomics into the design process.

To overcome such difficulties, two approaches are to be recommended. On the one hand, iterative models, among which are to be found the spiral model for phase organization, should be adopted. On the other hand, concurrent engineering for the management of the different protagonists in the process is advisable.

The notion of "concurrent engineering" appeared at the beginning of the 1980s. Without going into detail, this concept aims to provide for the simultaneous integration of process management and the different phases in product development. It is essentially an organizational device allowing for improved communication between the different project participants (including ergonomics). Concurrent engineering has been defined by several authors (Evbuomwam *et al.* 1994), one of which is "A concurrent development of project design functions, with open and interactive communication existing among all team members for the purpose of reducing lead time from concept to production launch".

The spiral model (Figure 2) makes use of both functional analysis and prototyping techniques. It allows for the integration of all project participants before completion of each design phase. In addition, prototypes — which are intermediary objects that


each project participant readily understands — re-center attention on the product and improve communication in general.

3. DEFINITION OF THE DIFFERENT ERGONOMIC STAGES IN THE DESIGN PROCESS

Increasing awareness that (1) the user, (2) the tool and (3) the workplace, environment and task are inextricably linked has led to reconsideration of the content and meaning of the design process. Indeed, each of the three elements emphasized above interacts with the two others. Figure 3 gives this interaction.

Conventional study of tool function should be completed by inclusion of task and user characteristics (Figure 3). Only by using ergonomics can this objective be achieved. Three basic stages can be outlined:

• Stage 1. Definition of user requirements (Figure 2) and expectations after detailed observation of the work process and work context. Employee characteristics (training, anthropometric measurements, etc.) are also defined during this phase. Tool specifications finally emerge from the study of user needs and work processes.

• Stage 2. Design of a new tool prototype based on tool specifications and laboratory simulation and study of the biomechanical solicitation produced by the new tool by comparison with the tool previously used. This stage includes all other phases — that means, concept modeling, functionality modeling, functional prototyping (Figure 2) — relating to tool function, styling, etc.

• Stage 3. After formal completion of the second stage, test of prototypes by a large sample of users in real workplace situations. The trial should be conducted over a sufficiently long period (several weeks) and feedback on the user's perception of the new tool should be regularly sought according to a procedure similar to that used in the first phase. If satisfactory results are obtained, the tool can then be considered duly certified for those situations in which it has been tried and tested. Users must be trained and encouraged to use the prototypes over a sufficiently long period before final judgement is given.

Such an approach illustrates the extent to which final users are at the center of design preoccupations as they are the ones who do the work. Nevertheless, it is also likely that manufacturers will be keen to refer to the positive commercial advantages that ergonomic handtool design provides. Certain manufacturers already do this.

Figure 2. Spiral model for an ergonomic development process. (See Section 2 for the three stages of the ergonomic process.)

Figure 3. Relations between users/tool/workplace.

4. CRITERIA INVOLVED IN THE DESIGN OF HAND TOOLS

This section deals with a number, but not all, of the different elements making up Figure 3.

4.1. Tool Design

- Tool mass — tool mass is directly linked to the muscular effort expended by the user.
- Center of gravity — if the center of gravity is not situated on the grasp axe with regard to handle grasp, greater muscular effort on the part of the user is required.
- Handle form and dimensions — it is important that the form and dimensions of the tool handle are adapted to the form of the user's grip and allow for a satisfactory distribution of pressure in the user's hand.
- Handle length — the handle must be longer than the size of the user's hand to avoid points of excessive pressure on the palm.
- Handle material and texture — pressure distribution across the hand, shock and vibration absorption, electrical and thermal insulation, impermeability to certain chemical products and the possibility of allergic reactions to certain materials (chrome, nickel) should all be taken into account in choosing material. Handle texture determines the friction coefficient between the hand and the handle. This should be high to guarantee a firm grip when necessary and low when functions requiring a less firm grip are to be undertaken.
- Trigger — according to the type of work task involved and tool use required, the trigger on a power tool might be activated by the thumb, by one or several fingers or by the palm of the hand. Generally, surface contact for the trigger must be large enough and the thickness of the trigger fine enough to avoid points of concentrated pressure.
- Guards — the presence of a guard on certain tool handles (such as knifes) prevents the hand from sliding towards the functional part of the tool and thus reduces the risk.
- Inclination of the tool handle in relation to the functional part of the tool — according to the type of work task involved, the inclination of the handle in relation to the machine's functional part prevents the bad postures of upper limb.
- Vibration and reaction torque — exposure to vibration involves both the length of time the tool is used and the intensity of the vibrations transmitted to the upper limbs. Reduction of this vibration is achieved by vibration attenuating handle design. Similarly, it is important to reduce the reaction torque generated by certain rotating tools by introducing, for example, reaction torque bars.
- Other factors — other factors should be taken into consideration, such as noise, handle temperature for tools in which compressed air passes through the handle, the positioning and direction of compressed air exhaust pipes, etc.

4.2. User Comfort

- Anthropometric considerations — the use of anthropometric data relating to, for example, hand length, width and circumference is recommended in determining handle dimensions.
- Age — during tool testing, users of different ages should be chosen to eliminate the risk that the reduced physical capacities of older users are unduly taxed.
- Sex — handtool design should take differences between male and female hand size and physical force into account.
- Right- and left-handed users — tool design should cater for both right-handed and left-handed users.
- Experience and technique — instruction and training should be given, on a regular, systematic basis, to users with regard to tool use, strain reduction and performance optimization.

4.3. Environmental Factors, Work Tasks and Work Stations

- The right tool for the job — certain tools are adapted to particular work tasks. Different screwdrivers, for instance, are required for different work tasks (pistol right angle, in-line).
- Posture — user posture may influence the ability to exert an effort. Generally, the greater the distance between the user and the workplace, the greater the likelihood that an awkward or uncomfortable posture will be adopted. This results in diminished capacity to exert an effort.
- Physical conditions — the environment (thermal, lightening, noise) in which a tool is used should be taken into account during the design phase so that the tool does not become uncomfortable or even dangerous for the user.
- Gloves — according to the material used in their making, gloves can increase the external dimensions of the hand, reduce hand flexibility and sensitivity to touch or modify the friction coefficient. These all influence tool grasp factors.
- Tool supports and reaction torque bars — the use of certain accessories such as tool holders, etc. and reaction torque bars allows for diminution in the effort expended by the user.
- Tool maintenance — a well-maintained tool reduces biomechanical solicitation and improves performance and work quality.

All these factors are described in detail in the literature.

5. CONCLUSIONS

Recent scientific work illustrates the importance of adopting a participatory ergonomic approach to the study of tool design in authentic work situations involving habitual tool users. Ergonomic field observation techniques should be applied to handtools to provide specifications that will guide choices made by designers. It is generally admitted that no tool can in be considered "ergonomic". It can only be considered as such if it is properly adapted to all the different uses to which a specific user puts it. Given that work situations are by nature diverse, it is difficult to design a universal tool that is adapted to all possible work situations.

Moreover, in certain work situations, it may well be more profitable and efficient, as much in terms of production quality as in terms of reduced risk of MSD, to modify certain parameters of the work situation (the object on which the tool is used or an element in the production process, for instance) than to modify

the tool. Consequently, tool design includes not only the tool, as previously defined, but also advice, training and above all the ability to study the specific details of a given work process.

1. INTRODUCTION

The main goal of human factors specialists, as part of the design team, is to help develop products and systems that are compatible with the users' logic, so they can use them easily and efficiently. As time goes on, the market for the majority of consumer products will become more competitive and therefore hard to penetrate because consumers have very high expectations: they want to choose the "perfect" product. To better comply with the expectations of the market, it is important for human factors specialists to go beyond the criteria of usability by taking into account other dimensions such as aesthetics (i.e., product appearance, style) and innovation. This requires a more active collaboration with all design partners and also a better preparation of students in human factors programs to face the realities of the industrial world.

2. PROBLEMS RELATED TO THE "TRADITIONAL" HUMAN FACTORS APPROACH

Human factors specialists are mainly faced with two types of problems that are connected:
- lack of consensus about important methodological parameters such as usability metrics and context specificity (is it possible to generalize results observed in one design context to other design contexts?) ;
- lack of credibility in the industry.

Because our discipline has not defined standard methods to measure usability, it is very hard for human factors specialists to argue with the quantitative-based logic used by design engineers. Also, the ambiguity in the context specificity limits the generalization of our results and recommendations. These methodological weaknesses convey a "fuzzy" image of human factors and therefore could lead to lack of credibility in the product development teams.

The lack of credibility is also sometimes due to the "conservative" attitude adopted by human factors specialists: engineers propose and initiate (active role), human factors specialists execute and follow (passive role). The usual approach of human factors specialists is to "wait" for the engineers to ask them to evaluate a given prototype or product. Such an attitude is perpetuated by opinions such as Perrow (1983) who suggests that upper management should make an effort to introduce human factors specialists to design engineers and publicize for them. However, I disagree with this premise. Why can't human factors specialists initiate discussion with engineers and other design partners to present and explain the usefulness of their methods in the product development process?

If we want to have credibility, not only should human factors specialists get to know directly all relevant design team members but we should also dare to become leaders and propose creative product ideas and concepts. Innovation is not the reserved domain of engineers. As Norman (1998) points out, human factors specialists are very good at criticizing products but are not very good at proposing good ones.

3. MARKET REQUIREMENTS FOR A "SUCCESSFUL" PRODUCT

The first attribute that attracts a buyer is the appearance of a product, its aesthetics, its style. The product should look "good". The other important criteria is usefulness: buyers look for products that are necessary or valuable for their everyday life. Of course, all users expect the product to be easy to use and reliable. These four aspects, aesthetics, usefulness, usability and reliability, in concert are strong determining factors in a purchase decision.

In the current market, many consumer products become more similar because previous ideas that worked are "copied" by everybody. Therefore, the market tends to become more "uniform". For example, electronic products such as cellular phones, televisions or VCRs have almost all the same functions and their reliability is comparable. Similarly, looking at compact or even medium size cars, even though their reliability has considerably improved in the few past years, they all offer basically the same features. Nowadays, in order to attract the customer, it is not enough to design a nice, useful, easy to use and reliable product; it becomes necessary to offer products that are different from others, products that are innovative. Innovation is an important key for a successful product in the market.

One of the best examples of successful and lasting innovation is the post-it, by 3M. It is a very simple concept that is flexible (different sizes) and that can be used by everybody and everywhere. Everybody in the product design team, including human factors specialists, can think of such concepts, it's just a matter of imagination!

4. MOVING TOWARD A MORE GLOBAL AND AGGRESSIVE APPROACH

Several steps are necessary for human factors specialists to become more efficient and persuasive in the product development process:

4.1. Being Known in their Companies

Human factors specialists should take the step to explain their purpose, methodology and approach to all the persons involved in the product development process by focusing on the positive impact that their input can have on the product. They should also be able to attract the upper management by making clear and convincing presentations with concrete examples of successful "ergonomic" products. Training could be set up to make everybody aware of the importance of human factors in the early stage of the product development.

4.2. Being Accepted by the Design Team

As Norman (1998) suggests, human factors specialists should be less self centered and more open to other disciplines. They should make more effort to understand engineers' "techno-centered" (focused on the technical performance of a product) approach. To deal more effectively with engineers, it is necessary to present quantitative and objective data whenever possible, and understand the value in an interaction between quantitative and qualitative approaches.

Human factors specialists should also develop very close relationships with the Marketing department. This can be achieved by learning the "business" language (Norman, 1998), and also by developing collaboratively tools such as questionnaires and focus groups to apprehend the customer preferences: a good product is one that is useful for the market and easy to use. Lund (1998) proposes to "measure" usability with three scales: ease of use, usability and satisfaction. Those evaluation scales are common to human factors and marketing. According to Caplan (1990), it is also useful for human factors specialists to borrow the focus group methodology from marketing and add quantitative techniques to it because their recommendations will be more likely to be understood and accepted by management. Interaction and collaboration with Marketing is critical to gain credibility within the company.

Aesthetics is a critical dimension of an attractive product. Human factors specialists should also be more sensitive to the stylists' approach and try to find a balanced compromise between usability and aesthetic dimensions.

To summarize, in order to be really accepted and appreciated by the product team, human factors specialists should take into account all design dimensions in their approach: their recommendations should go beyond the criteria of usability and reflect a balance between technical, aesthetic, marketing and usability parameters.

4.3. Being Innovative

Innovation is critical for a successful product in the current market. Therefore, Human factors specialists should include creativity in their approach. We should think more in terms of "unique" products and original ways to present a product to customers. In fact, we should combine expertise and imagination to propose innovative products to engineers (during brainstorming sessions, for example) and show them that we could also be pioneers and leaders in product development.

4.4. Being more efficient

Efficiency means doing the best job possible in a short period of time. In order for human factors to be perceived as efficient in the product team, it is necessary to:
- use shorter and less complex evaluation methodologies. Approximate methods (short and less detailed or rigorous evaluation methodologies) should be preferred to long and "precise" methods: "good enough is good enough" (Norman, 1998).
- Develop specific guidelines for different product domains (computers, cellular phones, cars) in order to avoid long user evaluations.
- Develop sharable databases of different methodologies, results and recommendations published in various human factors articles, for different products.

Building credibility in industry requires four factors:
1. being known by all relevant persons in the company (including upper management),
2. being accepted by the product team,
3. being innovative,
4. being efficient.

Formal education is the best place to prepare those interested in applied human factors to enter successfully into industry and deal adequately with product design partners.

5. TIME FOR A CHANGE IN TEACHING HUMAN FACTORS

Currently, most psychology oriented human factors programs prepare students to become good researchers and average practitioners. For example, students are required to know in details all the theories of information processing and master long and heavy methods of task analysis. Their "theoretical" preparation is excellent. However, after graduating, human factors students know very little about the realities that they have to deal with in the product team: the engineers' "techno-centered" approach, short product development timelines, management expectations, the importance of innovation and aesthetics etc.

It is important to balance theory courses with concrete and realistic examples of the role that a human factors specialist should adopt in the product team. It becomes crucial to "build" students' character in college in order for them to be able to defend themselves in the tough industrial world.

The following points would help students be integrated easier in the product team:
- the techno-centered approach should be explained with concrete examples of the "appropriate" ways to deal with it (e.g., correlate objective and subjective data);
- the "business" language (Norman 1998) should be taught with the help of marketing experts;
- product stylists should be invited to present their approach and the influence human factors has on it;
- experienced human factors specialists involved in product development should be invited to explain the short and "approximate" evaluation methods that they use to deal efficiently with the design partners;
- students should be put in situations where they have to propose an innovative product and defend it using marketing, aesthetics and usability criteria;
- students should be taught to "sell" their discipline to upper management by preparing clear and attractive slides demonstrating the importance of human factors in the early stages of product development;
- focus should be on proposing creative and original concepts and ideas rather than criticizing existing products;
- students should have "competitive" group exercises where they have to argue, justify and defend their recommendations for a given product against each other.

6. CONCLUSION

Unlike engineering or marketing, human factors is not considered as primordial for product development. In fact, in many companies, human factors is still considered as a "luxury". In order for human factors specialists to "survive" in product teams, the first criterion is to earn credibility by being proactive, innovative, efficient and persuasive. The survival of our discipline does not only depend on our methodological strength or the efficiency of our recommendations; it depends also on our character, on our ability to compromise, argument, justify and convince.

It is about time to "revolutionize" our mentalities and become leaders in product development. It is about time to prepare ourselves and future human factors experts to enter the twenty first century with more confidence, an aggressive approach and a broader knowledge of other disciplines involved in product development.

Safety in Public Offices in Italy

A. Baldacconi

INAIL (Italian State-Owned Workers' Compensation System), University of Urbino, Italy

1. INTRODUCTION

A novel approach to international organization and coordination has emerged with the Community Framework Directives 89/391/EEC, 89/655EEC, 89/656/EEC, 90/269/EEC, 90/270/EEC, 90/394/EEC, and 90/679/EEC aimed to extend health, safety, protection and prevention in working environments.

The emerging theme is one that applies not only to occupational health and safety but also to other areas of social regulation where command/control instruments have been used extensively to environmental health and safety regulation.

In Italy such a directives were accepted by two Acts of the Italian government: Legislative Decree of 19 September 1994, no. 626 and Legislative Decree of 18 March 1996, n. 242.

Even if the former laws had been applied in the past, the above EEC directives are going to give a "New Approach" as "New Frontiers in Occupational health and safety" dealing with a "Management System Approach according to the ISO Model".

The new approach represents a bridge between the past and the present to encourage active debate on the issues raised and to avoid the inefficiencies and the limited applicability by tying environmental health and safety performance to market participation and procurement contract language.

2. PUBLIC OFFICES

2.1. Development of Requirements

In public offices usually the importance of a high-quality workplace has never been more evident than in today's climate of rising real estate costs and increasing business competition to give comfort and safety.

To attract and retain high-caliber employees, an organization must be able to offer a safe, comfortable, and stimulating work environment. To support those employees in executing their responsibilities and to maximize their contribution to the organization, the office must be efficient, functional, and flexible. Meeting these objectives requires that an organization plans strategically and designs facilities to meet the needs of the organization both now and in the future.

It is necessary to identify the major technical and design issues related to office environment, and to communicate those issues in terms that can readily be understood by the manager who does not have training in the interior architectural professional but is responsible for the planning and design of organizational facilities.

The safety management system has to guide through:

- office planning end design: *the strategic facilities planning process to understand in detail how to lay the proper groundwork for a specific interiors project by identifying clear objectives and selecting a qualified team;*

- reference to specific issues: *the various planning components of the office, building support system, and elements of interior design to yield information about planning and design consideration such as general office areas, support areas, government requirements, mechanical and electrical engineering systems, furniture, ceiling systems, lighting, color, acoustics, and finishes.*

This is the way to promote better understanding of the factors that constitute a high-quality workplace and the elements that combine to ensure successful implementation in health and safety. The objective in the development of requirements is to determine the total occupiable space required for the organization currently and in the future.

To develop the organization's requirements, the strategy facilities planner collects both quantitative and qualitative needs through management and personnel interviews, questionnaires, and facility surveys. For example, programming during a design project would identify a specific number and type of file cabinets, the information necessary to plan and design the space, the characteristic that would be affected by the building architecture or building support system (mechanical and electrical systems). In this way the strategic facilities planner evaluates existing planning standards to determine their adequacy for use in the study of planning standards and furniture inventory — workstation planning standards identify configuration for administrative through executive levels, equipment standards identify space to accommodate equipment and stand space for operating the equipment/support area such as conference room. Once the strategic facilities planner has compiled the quantitative and qualitative requirements for the organization, the data are analyzed in the context of trends, sensitivities, and potential risks. The purpose of conducting this analysis is to test the assumptions made during the study and the validity of the information developed, and to investigate the potential risk associated with each alternative solution. Ultimately, the sensitivity and trend analysis will assist the strategic facilities planner in designing an appropriate amount of flexibility in to the plan to accommodate the potential risk.

The first step in the trend and sensitivity analysis is to review all organizational and industry trends to determine if the projected requirements for the organization are consistent with those trends. If any inconsistencies arise, the strategic facilities planner must identify the causes and their potential impact on future solutions.

The second step in conducting the trend and sensitivity analysis is to determine the sensitivity of the study's result. To accomplish this, the strategic facilities planner must identify all factors affecting the validity of information and decisions made during the strategic plan's overviewing.

The third step is to assign potential risk to each factor. For instance, the strategic facility planner has assumed that the program information obtained during the development of requirements is accurate. In an office the interaction between man-machinery-environment must take into proper account the workstation standards.

In fact, a workstation is the space allocated to house a person to execute a job or task on an ongoing basis. The term workstation refers both to a private office with full height partitions and a door, and to an open-plan "cubile" configured from systems furniture or low-height partitions. The term standard indicates

that the workstation size and configuration are assigned on a standard basis for all personnel performing a similar function or at a comparable organizational level or job classification. Ideally, the number or workstation standards are kept to a minimum to simplify planning, future inventory, and facility maintenance. Workstation standards are generated based on:

- functional requirements of each position,
- organizational culture,
- organizational status,
- industrial or professional standards.

To ensure that workstation standards are responsive to user needs, it is necessary to survey and interview representatives from each job classification or standards category to solicit detailed information that will affect workstation size, components, and configuration of those components. The workstation standard size is the space necessary to accommodate:

- tasks performed,
- surface area requirements,
- technology/equipment requirements,
- storage requirements,
- conference/meeting requirements.

To develop the workstation standards it has to be satisfied of the following requirements:

1. Job classification function: *workstation user and job function: executive, manager, supervisor, professional/ technical, clerical.*

2. Worksurface area: *number and sizes of worksurfaces — primary, secondary, tertiary.*

3. Machine use: *amount, types, and sizes of electronic equipment — VDT, PC, printer, typewriter, other.*

4. Workstation area: *amount of space to be allocated for individual or task.*

5. Workstation dimensions: *length and width that will comprise the area.*

6. Conference requirements: *number of guest chairs.*

7. Storage requirements: *amount and type or unit size of the material to be stored and storage locations: letters or legal files, computer printout, binder, bulk.*

8. Configuration: *configuration of the worksurfaces, primary orientation, and opening for the workstation.*

9. Wire management: *type and location of wire management related components: baseline wireway; beltline wireway; grommet locations; wire management clips or trays.*

10. Lighting: *quantity and location of any task or ambient lighting components.*

11. Accessories: *type and number of accessories: task surfaces; pencil drawers; other.*

Once the decision-making process is in place, the team can develop a project definition for use in assembling a project team of professionals and in developing a strategy for resolution of the requirement, including specifically the two Acts of Italian government. A comprehensive project definition addresses the following issues: (a) project need, (b)reason for the need, (c) goals for the project, (d) parameters for a solution, (e) predisposition to a solution. According to the above issues many public offices must be subjected to interior redesign because they were set up in historical sites before and after the Second World War.

3. ACTS NO. 626/94 AND NO. 242/96

3.1 Objectives and Scope of the Acts

The objectives of these Acts are:

- To secure a working environment which affords the employees full safety against harmful physical and mental influences and which has safety, occupational health, and welfare standards that correspond to the level of technological and social development of the society at large at any time;

- To provide a basis whereby the enterprises themselves or the public administrations can solve their working environment problems in cooperation with the organizations of employers and employees and under the supervision and guidance of the public authorities;

- To provide in any working environment a unit so named "Prevention and Protection Services" (working environment committee). The aim of this unit is to edit a paper on all sources of risk. According to Webster's Unabridged New International Dictionary, risk is ''hazard; danger; peril; exposure to loss, injury, disadvantage, or destruction''. It distinguishes risk from hazard by suggesting that a risk is more often voluntary, a hazard the product of chance. These definitions contain the essentials of risk, combining the idea of loss with that of chance or probability because we need to know the probability, the likely consequences, and the best ways to reduce the probability and the consequences. The probabilities come from probabilistic risk assessments (more later) with inevitable uncertainties, and the estimates are apt to generate disagreement and confusion. Multiplying the probability of the event by the amount of potential loss it comes out what is called the product of expectation of loss, used as a final measure of risk. The working environment committee shall work to establish a fully satisfactory working environment and shall participate in planning safety and environmental work and shall follow up developments closely in questions relating to safety, health, and welfare of employees.

- To organize and plan health and safety according to the above paper, especially regarding the Matrix of Risk, with the aim to control, reduce or to leave out the expectation of loss and the potential hazards.

- To organize and plan information, instruction, assistance, consultation, and training.

The main scope of these Acts are:

- Provided that it does not expressly state otherwise, these Acts apply to all enterprises that engages employees;

- For the purpose of these Acts "employee" shall mean any person who performs work in the service of another. If an enterprise is conducted by two or more persons jointly for their own account, only one of those persons shall be deemed an employer under these Acts, the others being regarded as employees.

- For the purpose of these Acts ''employer'' shall mean any person, physically or legally representative, who has engaged employee(s) to perform work in his service. The provisions of these Acts relating to the employer shall apply correspondingly to the person conducting the enterprise in the employer's stead.

- The working environment in the enterprise or in the public administrations shall be fully satisfactory when the factors in the working environment that may influence the mental and physical health and welfare of the workers are judged separately and collectively (matrix of risk).
- The workplace shall be arranged so that the working environment is fully satisfactory as regards the safety, health, and welfare of employees. In particular, it shall be ensured that: (a) workrooms, passageways, stairways, etc. are suitably dimensioned and equipped for the activities being conducted; (b) good lighting is provided, if possible with daylight and a view; (c) climatic conditions are fully satisfactory as regards volume of air, ventilation, humidity, draughts, temperature, etc.; (d) pollution in the form of dust, smoke, gas, vapours, unpleasant odors, and radiation is avoided, unless it is known that the pollution cannot lead to undesirable effects upon employees; (e) noise and vibration is avoided or reduced to prevent undesirable effects upon employees; (f) the necessary precautions are taken to prevent injury to employees from falls and falling or sliding objects or masses; (g) precautions are taken to prevent fire and explosions, and to provide adequate means of escape in the event of fire, explosions, and other emergencies; (h) sanitary installation and welfare rooms are satisfactory in size and design; (i) workrooms, sanitary, and welfare rooms, etc. are kept in good repair, clean, and tidy; (l) first-aid equipment is readily accessible.
- Technical apparatus, machinery, and equipment shall be designed and provided with safety devices so as to protect employees from injury and disease; when technical apparatus, machinery, and equipment are being installed and used, care shall be taken to ensure that the employees are not exposed to undesirable effects from noise, vibration, uncomfortable working position, etc.; technical apparatus, machinery, and equipment should be designed and installed so that it can be operated by or be adapted for use by employees of varying physique; technical apparatus, machinery, and equipment shall always be maintained and attended.
- Toxic and other noxious substances must not involve a health hazard and so working processes and other work shall be fully satisfactory in order that employees are protected against accidents, injury to health, and excessive discomfort. The employer shall keep a record of such substances showing the name of the substance, its composition, physical and chemical properties, as well as information concerning possible poisonous effects (toxicological data), elements of associated risk, preventive measure, and first aid treatment.
- Conditions shall be arranged so that employees are afforded reasonable opportunity for professional and personal development through their work; technology, organization of the work, working hours and wage systems shall be set up so that employees are not exposed to undesirable physical or mental strain and so that their possibilities of displaying caution and observing safety measures are not impaired.
- The employees and their elected representatives shall be kept informed about the systems employed for planning and effecting the work, and about planned changes in such systems. They shall be given the training necessary to enable them to learn these systems, and they shall take part in planning.
- If the work involves particular hazard to life and health, a special directive shall be issued prescribing how the work is to be done and the safety precautions to be observed, including any particular instruction and supervision.
- Employees shall take part in the creation of a sound, safe, working environment by carrying out the prescribed measures and participating in the organized safety and environmental work of the enterprise; employees shall perform their work in conformity with orders and instructions from superiors and shall use the prescribed protective equipment, display caution, and otherwise cooperate to prevent accidents and injury to health.

4. OCCUPATIONAL HEALTH IN AN OFFICE ENVIRONMENT

It has been estimated that in Italy more than 12 million people are now working in offices or in settings similar to offices. Like the industrial environment, there are also some potential health and safety hazards in offices, which, if unattended, may cause illness, injury, and discomfort. For this reason, INAIL — Italian State-Owned Workers' Compensation System — has published a guide entitled "Working in safety and comfort in an office environment" in accordance with the above Acts.

The office environment is usually considered comfortable and healthy, but there are various factors which could affect or influence the health of the staff. In mild cases, complaints usually involve tiredness, nose and throat discomfort, back pain, eyestrain, headaches, tiredness, repetitive strain injury; more rarely health factors may include respiratory diseases (extrinsic allergic alveolitis, humidifier fever, asthma, allergic rhinitis), sick-building syndrome, indoor air pollution (nitrogen oxides, mineral fibers, radon, formaldehyde, solvents, environmental tobacco smoke, contributions from outdoor pollutants — traffic and industrial pollution, etc.).

An office workstation is the specific area that includes desks, chairs, footrests, VDT, plan files, printer tables, copying machines, storage cabinets, lighting, air conditioning, noise, and other environmental risk factors. The design of the workstation must be related to the ergonomic principles that include layout, seating, clearances, and adjustments to accommodate individual differences in size and strength. Failure to do so may result in errors, reduced efficiency, discomfort, and sickness or even injury

The design of a comfortable working posture is important because most office work is sedentary and bad postures can cause musculoskeletal injury, discomfort, pain and/or strain of the back, neck, shoulders, upper arms, knees, and feet.

Lighting is another important factor because if it is not well-designed, workers are unable to see comfortably; good lighting also helps to reduce accidents, eye strain, and discomfort.

Efficient ventilation systems are necessary to control airborne pollutants (for example, gases, dust, fungal spores, viruses, bacteria, and mites).

Falls Church VA 22042

1. INTRODUCTION

One of the more important tools for the human factors analyst to design systems in terms of the capabilities and limitations of humans is a standardized, formalized, and comprehensive human factors design process. This process is comprised of the activities to be conducted by human factors specialists in the determination of requirements and concepts for (a) improving human performance and safety while reducing error potential, workloads and manning levels, and (b) designing and evaluating human-machine interfaces.

A generalized human factors and engineering design process is presented in Figure 1. The phases of the process correlate with the phases of ship design described in Malone and Baker (1996). This process is focused on specific human factors outputs for each process phase, as indicated in the figure.

The following sections address each phase of system design.

2. HUMAN FACTORS CONCEPTUAL DESIGN PROCESS

Human factors objectives in this phase are to develop concepts for the roles of humans vs automation in conducting system functions, and to assess concepts in tradeoffs and modeling and simulation. In the conceptual design of ships and maritime system design, the major activities are those involved in a top down requirements analysis (Bost *et al*, 1998, Bost *et al*, 1996, Anderson *et al*, 1998, Anderson *et al*, 1997, Malone *et al*, 1996), as depicted in Figure 2.

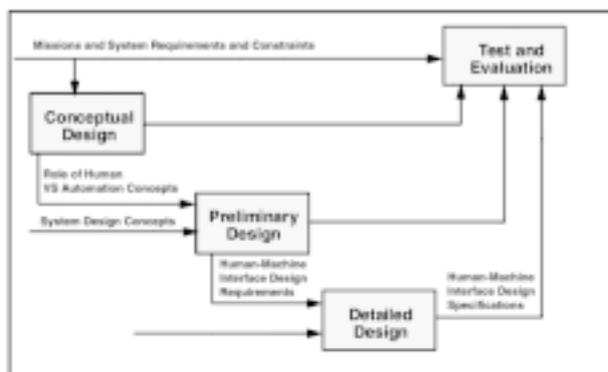
The activities shown in Figure 2 are described below.


Figure 1. Ship/maritime system development HFE design process.

2.1. Identify and Analyze Missions and Functions

The initial step is to identify missions, mission requirements, and mission scenarios. Scenarios will include the ships and maritime system requirements, system top level functions by mission, and conditions under which functions will be performed.

System functions constitute the major activities to be performed by the system. The ships and maritime system function analysis should, for each scenario, identify functions to be performed and provide a functional flow depicting the sequence of functions for the system completing a mission scenario. The functions will be decomposed to successively greater levels of detail in an iterative manner based on requirements associated with each function.

2.2. Conduct Function Allocations and Identify Roles of Humans

Through a reverse engineering process, functions and tasks in existing systems which impose heavy workloads on humans or which have performance or safety problems associated with them can be identified, and requirements for alternative allocations to humans or automation can be specified. The rationale for allocation decisions in the existing ships and maritime systems can be made explicit and opportunities for alternate allocations can be explored. Alternative role of the human concepts involve alternate approaches to automation, providing decision aiding to reduce human workload, leading to reduction in manning, and improved design of human–machine interfaces to simplify tasks and reduce workloads.

Figure 2. Human factors activities in the conceptual design phase.

2.3. Identify Human Factors Alternate Concepts and Technologies

The human factors approach to ships and maritime system design is focused on design requirements associated with automation, consolidation, simplification, and elimination of functions. Feasible concepts will be selected based on the results of simulation exercises assessing the workloads and performance problems associated with alternate human factors conceptual strategies. For these concepts, assessments will be made of how to reduce the manning required at functional duty stations, and the impact of manning reductions on readiness, performance effectiveness, and safety.

2.4. Conduct Simulations to Assess Workloads and Human Performance

The next step is to identify workloads and manning requirements associated with alternate function allocation schemes. The assigned roles of human vs automation for each function and task will be assessed in terms of impact on workloads and human performance through use of the task network simulation. The simulation identifies potential performance problems and quantifies the workload of operators for a simulated mission under the candidate function allocation strategies.

The net result of the application of the simulation is a first approximation of which roles of the human are feasible, what workloads are associated with these roles, what problems are to be expected in specific role of human models, and what human performance characteristics should be further investigated.

2.5. Assess Design and Readiness Requirements

Feasible manning reduction concepts will be selected based on the results of simulation exercises assessing the workloads and performance problems associated with alternate manning strategies. For these concepts, assessments will be made of how to reduce the manning required at functional duty stations, and how to enhance human performance, workload and safety.

3. HUMAN FACTORS PRELIMINARY DESIGN PROCESS

In the Preliminary Design Phase the details are defined for individual systems and subsystems necessary to meet system functions identified in the conceptual design phase. The major human factors activities in the Preliminary Design Phase are depicted in Figure 3 and are described below.

3.1. Conduct Task Analysis

A task analysis represents a model of human task sequences in the conduct of a series of functions, and identifies requirements associated with performance of each task. Task analysis provides the bases for making design decisions; e.g., determining, to the extent practicable and before hardware fabrication, whether system performance requirements can be met by combinations of anticipated equipment, software, and personnel, and assuring that human performance requirements do not exceed human capabilities. This analysis shall also be used as basic information for developing preliminary manning levels, equipment procedures, skill, training and communication requirements, and as logistic support analysis inputs, as applicable.

Figure 3. Preliminary design phase human factors activities.

3.2. Conduct of Human Factors Studies

Human factors studies are conducted in support of the identification of human-machine interfaces and requirements. Studies include additional analyses, (such as cognitive analysis, information handling analysis, timeline analysis, and workload analysis) and empirical (laboratory or simulation) investigations of human performance capabilities and limitations for specific interfaces.

3.3. Identify Human–Machine Interface Requirements

3.3.1. Analyze functional interfaces

The elements of functional interfaces include (a) the roles of humans versus automation in system operation, control, maintenance and management; (b) human functions and tasks; and (c) roles of system personnel in automated processes (e.g., monitoring, management, supervision, intervention, etc.).

3.3.2. Analyze informational interfaces

These interfaces constitute the information needed by a human to complete a function or task, required characteristics of the information (source, accuracy, currency, quantity), and protocols and dialogues for information access, entry, update, verification, dissemination and storage.

3.3.3. Analyze environmental interfaces

This class of interface is concerned with the system's physical environment (illumination, noise, temperature, vibration, ship motion, weather effects, etc.), workspace arrangement, facility layout and arrangement, and environmental controls. This class of human interfaces will be optimized by determining requirements for environments which are within performance, comfort and safety limits, designed in terms of task requirements with consideration for long term as well as short term exposures.

3.3.4. Analyze operational interfaces

Operational interfaces include operating, maintenance, and emergency procedures; workloads; personnel skill requirements; personnel manning levels; and system response time constraints.

The major impacts of operational interfaces are on human error probability, and safety. Design criteria for procedures address the extent to which required levels of human performance can be assured given time constraints. Human factors improves the accessibility, content, and organization of procedures by ensuring that the procedure is complete, correct, clear, concise, current, consistent, and compatible with the reading/language/skill levels of the users.

3.3.5. Analyze organizational interfaces

Organizational interfaces include the factors impacting the organization of system management functions, policies and practices, personnel jobs, and data. Criteria for optimization of organizational interfaces include determining that position descriptions are based on functions allocated to the position and include duties, jobs, responsibilities, levels of authority, tasks, and decisions appropriate for each position; that assignment of duties and tasks to each position is realistic; that duties and jobs are consistent with those found in existing systems; and that data required to perform functions and tasks are available, current, and identifiable.

3.3.6. Analyze cooperational interfaces

These interfaces are primarily concerned with communication, collaboration, and team performance. Human factors objectives in optimizing communications are directed at improving both the media and the message. Specific requirements for media design include speech intelligibility and communications device operability. human factors concerns for the message include message standardization, use of constrained language, controlled syntax, and restricted vocabulary, methods of coding message priority, and human error potential in message transmission.

3.3.7. Analyze cognitive interfaces

Components of cognitive human interfaces include decision rules, information integration, problem solving, instructional materials and systems, short term memory aids, cognitive maps, and situational awareness. Design requirements for cognitive interfaces focus on design for usability, and conceptual fidelity. A major cause for human error is the fact that the human is operating on the bases of erroneous cognitive expectancies concerning what the problem is, what the system is doing, and how it will respond. In attempting to diagnose a problem event, an operator relies on expectancies. These expectancies are developed based on information presented to the operator, his or her procedures and training, past experience, design conventions, and, when all else fails, intuition. Expectancies will support the diagnosis when the cognitive model that the operator has of the system is in close agreement with what is actually happening, i.e. has high conceptual fidelity.

3.3.8. Analyze physical interfaces

Physical interfaces include the physical, structural, and workstation elements with which the human interacts in performing tasks. Interfaces include: workstations, control panels and consoles, displays and display elements (screens, windows, icons, graphics), controls and data input and manipulation devices (keyboards, action buttons, switches, hand controllers), labels and markings, structural components (doors, ladders, hand holds, etc.), and maintenance design features.

3.4. Integration of Human–Machine Interface Requirements

Human-machine interface requirements are integrated through conduct of human factors studies and through requirements assessment. The assessment of interface requirements will focus on the extent to which interfaces will address human error potential of specific functions and tasks, and the extent to which interfaces will support the design of the system to be error-tolerant.

4. HUMAN FACTORS DETAILED DESIGN PROCESS

In the Detailed Design Phase of a ship or maritime system design and development, human factors issues of workspace design, control and display layouts, and environmental factors are addressed. In this phase the actual design features of human-machine interfaces are defined and developed. The steps to be achieved in this phase are presented in Figure 4. The activities to be conducted in this phase are described below.

4.1. Conduct of Human Factors Studies

Human factors studies are conducted in support of the development of design concepts and criteria. Studies include: Human-Error Likelihood Analysis; Tradeoff Analysis; and Modeling and Simulation.

4.1.1. Human-error likelihood analysis

The human-error likelihood analysis identifies tasks and task sequences which are critical from a systems effectiveness, and human and public safety point of view. For each task an identification will be made of the types of errors which have occurred in existing systems, or which could be postulated on the bases of human performance requirements.

4.1.2. Tradeoff analysis

Tradeoff studies will address the comparison of alternate design concepts, leading to a selection of an optimal concept.

4.1.3. Modeling and simulation

Modeling and simulation will enable conceptual or actual performance of human operators and maintainers with aspects of alternate design concepts. In this manner, the potential for human error can be assessed through observation of task performance.

4.2. Define Design Concepts and Criteria for the Design for Operability

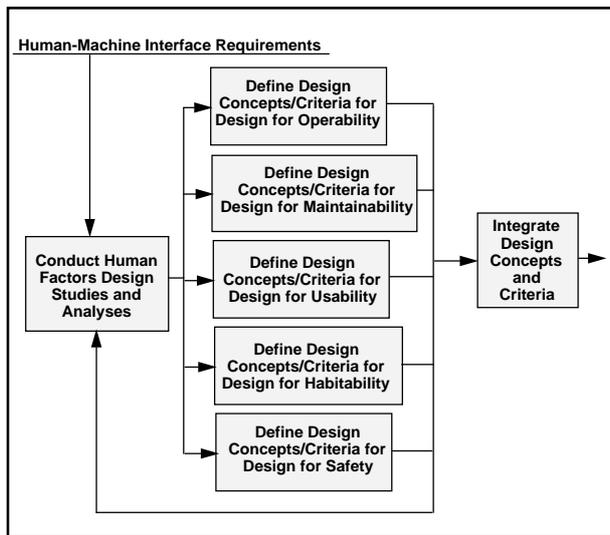
System elements which impact human-machine interface design for operability include workstations, I/O hardware, software, data bases, networks, computation systems, peripheral devices, communications systems, and software engineering environments. Human–machine interfaces include displays, displayed information, display characteristics, display formats, integration of displays, labels, instructions, alarms, symbology and graphics, decision aids, decision support systems, input devices, data designation and manipulation devices, controls and controllers, control systems, control and display arrangements, communications, workspace layout, workspace environment, help features, embedded training, intelligent tutoring systems, and procedures.


Figure 4. Human factors activities in the detailed design phase.

4.3. Define Design Concepts and Criteria for the Design for Maintainability

Maintainability design requirements include information requirements, design for accessibility, equipment arrangement to facilitate maintenance, procedures, troubleshooting diagnostics and decisions, skill levels and maintenance training, equipment design for maintainability, allocation of maintenance responsibility to man or machine, equipment installation requirements, requirements for special tools and support equipment, job aid requirements, communication requirements, facility design requirements, and safety design requirements.

4.4. Define Design Concepts and Criteria for the Design for Usability

The development of detailed HMI design for usability will focus on prototyping HMI concepts to assess and reduce the risks associated with integrating available and emerging human factors technologies into a system design approach to satisfy a validated mission need. Test and evaluation of prototypes will confirm the feasibility of specific design approaches relative to its ability to satisfy the mission need and achieve minimum acceptable operational performance requirements within affordability constraints. Prototyping will be used to assess cost and performance tradeoffs.

4.5. Define Design Concepts and Criteria for the Design for Habitability

Habitability design involves specifying workspace free volume, environmental effects, traffic patterns, workspace layout, facility compartmentalization, quality of life, and adequacy of the design for habitability. The human factors concepts to be developed will address the major user-machine and user-facility interface issues. Human factors concepts will either be developed or will reflect an assessment of architectural/engineering design concepts from a human factors point of view.

4.6. Define Design Concepts and Criteria for the Design for Safety

The development of human–machine interface design concepts and criteria as they relate to safety will be concerned with identifying, evaluating, and providing safety considerations or tradeoff studies to identify concepts for: guarding the hazard; labeling the hazard; alarming the hazard; training/procedures for avoiding the hazard; or designing out the hazard

The effort will entail the review of appropriate engineering documentation (drawings, specifications, etc.) to make sure safety considerations have been incorporated. These activities will extend to reviewing logistic support publications for adequate safety considerations, and ensuring the inclusion of applicable USCG, EPA, and OSHA requirements; verifying the adequacy of safety and warning devices, life support equipment, and personal protective equipment; and identifying the need for safety training.

4.7. Integrate Human Factors Design Concepts and Criteria

Design concepts and criteria will be integrated through modeling and simulation efforts which will produce prototypes of the interfaces for selected scenarios.

5. HUMAN FACTORS TEST AND EVALUATION PROCESS

The initial activity in human factors test and evaluation is to identify ship and marine equipment, systems and operations which are expected to be high risk from a human error point of view. High risk situations are those for which human error likelihood is relatively high and those for which human errors, whatever their likelihood, would produce results catastrophic to human or environmental safety.

Requirements and constraints for human factors T&E will then be specified. This will begin with an identification of constraints, including time limitations, legal barriers to evaluations, and availability of data. Requirements for evaluations include functional requirements, information requirements, performance requirements, decision requirements, support requirements, and interface requirements.

The next step will entail identification of human factors evaluation scenarios. When the requirements for evaluation of high risk equipment, systems, and operations have been identified, evaluation scenarios will be described. These scenarios include tasks and test conditions to be included in the evaluation.

The next step will be to identify human factors evaluation measures, criteria, and data requirements including the actual data required from the evaluation, and factors influencing the quality of these data.

The final steps in test and evaluation is to integrate the T&E requirements into a human factors test plan, conduct the tests and evaluations according to the plan, and analyze and interpret T&E data.

Ships and Maritime Systems: Requirements and Issues

C. C. Baker and T. B. Malone

Carlow International Incorporated, 3141 Fairview Park Drive, Suite 575, Falls Church, Virginia 22042, USA

1. INTRODUCTION

This article presents an overview of the performance requirements placed on humans in maritime systems and on many of the personnel issues associated with humans working at sea. Manned maritime systems are small floating and mobile societies that are, for varying lengths of time, entirely self supportive and autonomous. Nearly all human needs of land based society must be fulfilled by at-sea systems, including providing; sustenance, recreation, transportation, communication, waste disposal, socialization, shelter, warmth, sleep, hygiene, and medical needs.

The missions of the maritime platforms themselves are varied, but generally involve one of the following: transportation of goods (merchant ships for carrying varying cargo); projection of power (military and maritime law enforcement); or mining (fishing industry, oil and natural gas recovery). To meet it's mission, the marine system must: generate power, navigate, manage waste, provide environmental and self protection, and accommodate the human inhabitants. All of these requirements must be met under the extremely diverse and often harsh conditions of the sea (Anderson, et.al. 1998).

2. HUMAN FACTORS, SYSTEM MISSIONS AND FUNCTION REQUIREMENTS

2.1 Mission–Function Analysis

Missions of maritime systems are the goals, or objectives, of what is intended to be done or accomplished. A typical mission for a merchant container ship, for example, would be to load containers beginning at point A, transport them to Point B, and from point B, to pick up additional containers and transport them to other points. All of this cargo hauling would also happen within the constraints of shipping schedules, fuel costs, and so on. A mission then is what the system is expected to do within a set of constraints. Functions are mechanisms by which mission requirements are performed. For example, moving cargo from point A to point B suggests a need for motive power, and therefore, a system propulsion function exists. Mission-Function analysis is a technique for identifying and analyzing system functions that must be provided to meet system objectives. Functions are analyzed hierarchically, such that high level functions spawn lower level functions. For example, providing motive power can be broken down to sub-functions, such as: generation of mechanical power, providing cooling to mechanical processes, providing for equipment monitoring and control, and providing means to diagnose malfunctions. Table 1 shows a highly generalized top-level function breakdown for a notional military ship.

In summary, (1) mission statements identify *what* is to be accomplished by the system, and (2), functional analyses and

Table 1. Typical Total Ship Functional Breakdown (top-level)

Mission Operations (vary by mission)	Special Operations
Boat Handling/Boarding	Underway Replenishment
Area Surveillance	Electrical Failure
Communications – Internal	Extreme Weather
Communications – External	Fire – Large and Small
Weapon and /Combat Information	Flooding/Ballast control
Helicopter or other air operations	Collision/ Grounding/ Stranding
NOAA/Weather services	Internal Security
War fighting	Loss of Propulsion
Cargo Handling	Tug and Pilot interfaces
Oceanographic	Boarding/Law Enforcement
Search and Rescue	Anti-Terrorism
Deck Operations	Man Overboard/Rafters
Anchoring	Fuel Spills/Environment Hazards
Docking Undocking	Lifeboat
Helo Operations	**General Operations**
Boat operations	Bridge - Housekeeping
Line Handling/Mooring	Bunkering (Refueling)
Anchor	Deck Equip Maintenance
Towing Operations	Direct Shore Gangs
Underwater Lighting	Docking/Undocking
Navigation/Bridge	Line/wire Maintenance
Approach Berth	Medical
Berthing	Stores Breakdown
Collision Avoidance	Steering Gear Maintenance
Depart Berth	Stores Handling/Breakdown
Hull Performance/Station Keeping	Structure Maintenance
Maintenance	Wash down - Deck
Maneuver	Wash down - Engine
Lookouts	**Administration**
Signals	Reporting
Position Fixing	Health Care
Record/chart Keeping	LAN Maintenance
Track Keeping	Finance/Payroll
Voyage Planning	Ships Meetings
Weather Monitoring	Mission Planning
Hotel/Unit Support	Shore Operations
Catering/Messing	Stores loading
Laundry	Port Logs/Records
Provisioning	**Maintenance – Ship area**
Space Cleaning	Vital Systems Test
Waste Disposal	Equipment Surveillance
Maintenance – Overview	Computers
Maintenance Philosophy	Electric System
Depot/Shoreside	Evaporators
Intermediate	Fuel Oil
Hull	Fuel Transfer
Unit	Generators
Training and Personnel Support	Inert Gas
Off ship and Schools	Propulsion
OJT	Pumps/Valves
Cross training	Tools/Test Equipment
Engine and Auxiliaries Operations	Communications
Record Keeping	Boat Maintenance
Routine Operations	HVAC
Watch Standing	Housekeeping/Cleaning

statements begin to identify *how* elements of the mission are to be accomplished. HF requirements begin to emerge when decisions are made as to who or what (humans, machines, or a combination) is responsible to provide specific system functionality (Baker 1997).

2.2 Specifying the Role of the Human

A central HF issue in any system design is the allocation of

functions to man or machine, thereby establishing and defining the role of man in the system and allocating responsibility to maximize overall system performance. Function allocation is based on an assessment of the differential capabilities and limitations of men and machines in terms of the requirements of a specific function. Machines excel at generation of vast amounts of power, performance of highly repetitive tasks, and performance of tasks in noxious environments. Machines are also highly reliable, capable of performing their functions for months on end. Humans are resourceful, have marvelous sensory capabilities, can render decisions and generate plans with varying amounts of information, and can apply control and manipulate objects in moderately precise, but in a highly variable and adaptive, fashion. Humans are also much more variable, unpredictable, and error prone compared to machines. The general allocation of function that determines the relative roles of humans and machines stem from these relative differences in capability.

There is an increasing need for interactive dialogue between humans and computers in automated systems. It underlines a requirement to consider the interactions between man and machine because few operations are either purely manual or totally automated; most are "semi-automatic". The role of man in automated operations is as activator, monitor, manager, and under certain circumstances, as the intervening decision maker, taking over control from the automated process. The role of man is situationally dependent.

Highly generalized contributions of humans to maritime systems include:

- Sensory and perceptual functions - notably vision and hearing as sensory inputs, and highly adaptive and learned filtering and interpretation of sensory data as perceptual input.
- Decision making and planning - including surveillance and supervision of machine function, and intervention of machine function where deemed necessary.
- Object manipulation - generally those of very low force requirement, but that are of an unpredictable and variable nature. For example, manipulating and repairing electronics equipment.

2.3 The Problem of Human Error

Human error refers to any situation where an observer fails to perceive a stimulus, is incapable of discriminating among several stimuli, misinterprets the meaning of a stimulus, makes an incorrect decision, fails to select a correct response, or performs a response in an incorrect manner. A definition of human error states that it is an action that violates some tolerance limit of a system. Human errors have been classified as:

- errors of omission (tasks that are skipped)
- errors of commission (tasks performed incorrectly)
- sequential errors (tasks performed out of sequence)
- temporal errors (tasks performed too early, too late, or not within the required time).

While human error will always be with us, there are characteristics of people which have an influence on the frequency of errors. These include such factors as fatigue, disorientation, training, motivation, forgetting, confusion, incorrect expectancy or set, excessive stress, boredom, inadequate skills and knowledge, and

inadequate or impaired perceptual or cognitive ability. Such factors can certainly contribute to the occurrence of errors, and in some cases even cause errors (Malone, et.al., 1997).

It is also well established that factors external to the individual can influence the potential for human error. Elements of the job or task, design of equipment, operating procedures and training can affect the potential for error. These external factors can be classified as situational factors and design factors. Situational factors include those aspects of the operational setting, other than design, which influence human error incidence. These include: task difficulty, time constraints, interfering activities, poor communications, and excessive workloads. Design factors include aspects of the system hardware, software, procedures, environment and training which affect human error likelihood. Design factors encompass such aspects of the system as: man-machine interface design features; information characteristics (availability, access, readability, currency, accuracy and meaningfulness); workspace arrangement; procedures; environments; and training.

Human error has been cited as a causal or contributing factor in an increasing number of incidents and accidents. The GAO report quoted above reported that at least 50% of the failures of major weapon systems are due to human error. The GAO listed five "types" of human errors which cause the most failures. These include: 1) failure to follow procedures, 2) incorrect diagnosis, 3) miscommunications, 4) inadequate support, tools, equipment and environment, and 5) insufficient attention or caution.

A number of other sources have estimated the incidence of human error as a causal factor in a variety of accidents and incidents. These include the following (Malone, et. al.)

- an NTSB investigation of 82 major marine accidents in the 1970-80 timeframe revealed that 33 were collisions and that human error was the predominant cause of ship collisions;
- An American Nuclear Society (ANS) Report in 1986 stated that 90% of facility emergencies involve human error;
- A study of the role of human error in chemical plant safety in 1987 found that most accidents were due to human errors;
- The Office of Technology Assessment (OTA) estimated in 1986 that 62% of hazardous material spills were due to human error;
- A Boeing study attributed 65% of all airliner accidents from 1959 to 1986 to human error;
- The Navy Safety Center cited human error as the cause of 85% of ship accidents;
- The Nuclear Regulatory Commission attributed 50% of nuclear power plant accidents to human error;
- According to the US Department of Transportation, 90% of all automobile accidents involve human error.

3. HF ISSUES ASSOCIATED WITH HUMANS AT SEA

From the above discussion it is clear that many factors influence the occurrence of error. The questions that are presented from this are (1) what are the factors and issues associated with error and (2) what control can be exercised over these factors and associated issues. The following present samples of HF issues related to human performance, safety, and quality of life of people at sea.

3.1 Physiological Issues

These deal with factors influencing human performance such as work-rest cycles, environment, and fatigue. Life at sea is inherently fatiguing. Just living on a rolling, pitching platform increases the physical energy needed to walk, stand, and even sit. Further, few people aboard ship experience predictable sleep-wake cycles, and work-sleep cycles shift on a daily basis. Sleep deprivation is a chronic condition at sea.

The physical characteristics of ship design also tend to induce fatigue. Steep ladders, narrow passages, and cramped quarters increase the energy expenditures of crew in all aspects of living such as simple walking from space to space, accessing equipment, or carrying equipment and goods to workstations.

Other factors of the environment also challenge the human at sea, including extremes in weather ranging from arctic cold to tropical heat, job performance in the dead of night and in intense sunlight. Visual function is required under extremely diverse conditions, from display reading in darkened rooms (radar areas, for example) and under intense sunlight. Ships are also noisy, and the characteristics of ambient background noise (low to middle frequencies) tend to mask audible signals and speech.

3.2 Maintenance Design and Practices

This includes design and procedural issues related to conduct of maintenance activities. It also includes issues related to maintenance philosophy and distribution of functions to ship vs. shore-based support. Marine systems exist in harsh environments that adversely effect equipment reliability, further, constraints (such as ship size) impose limitations on the extent of redundancy that be provided for vital systems. Design of systems for ease of maintainability therefore become extremely important. The same constraints that limit the level of redundancy also tend to limit the physical space available to support corrective and preventive maintenance. Design for physical access to equipment is often sacrificed due to these space limitations.

3.3 Design and Arrangement Issues

This group of issues addresses the physical design of workspaces, operational and maintenance, to enhance human performance. Issues address physical access, safety, and communications supporting distributed task performance. Much of any marine systems arrangement is driven by it's mission and resulting functionality. Humans are integrated into this arrangement and often must contend with designs that are optimized to facilitate the physical functioning of the hardware. This can distribute job performance over large areas of a marine system (for example, logistics areas and machine shops that are distant from the hardware that they support). This increases the work requirements of the crew, and tends to induce fatigue and human error.

3.4 Training

The functional diversity of marine systems, in concert with limited numbers of people available to participate in the performance of functions, results in the need for people to provide many functions and to have diverse skills. Crew must be crossed trained to cover all the job requirements associated with human functions. Review of Table 1 shows over 100 functions at the very top level. If a ship with a functionality of Table 1 were to be manned at a level of 20 crew (as some ships are), then it becomes apparent how much cross training and specialization each crew member must posses in order to meet all the functional requirements of the system and it's mission.

3.5 Environmental and Safety Issues

These include issues such as damage control in optimally manned ships, effects on crew workload as a function of crew member disability, and manning implications of off-normal operations (such as engine failure, electronics failure, etc.). Special skills are required at sea to meet situations such as fire and flooding.

4. SUMMARY AND RECOMMENDATIONS

Marine systems place heavy demands on the performance of humans who operate and maintain them. Maritime systems (1) have a diverse set of mission requirements and systems functions, (2) operate in a often difficult environment, (3) must be self supportive and autonomous to succeed in their missions, and (4) often have a limited crew of humans to operate and maintain the hardware. In order to meet mission requirements of the systems while also meeting the needs of the human operator/maintainer, the following are recommended:

i. Develop and apply a process that guides HF analysis, design, and test and evaluation. The article in this document entitled 'Human Factors in Ships and Maritime Systems: Design Process' by Thomas B. Malone provides a foundation for an HF process.

ii. Apply Human Engineering (HE) standards and guidance to the design of major marine systems interfaces. Two good sources of HE design guidance are:

1. American Bureau of shipping (1998). Guidance Notes on the Application of Ergonomics to Marine Systems. ABS, Two World Trade Center, New York, New York.

2. American Society of Testing and Materials (1995). Standard Practice for Human Engineering Design for Marine Systems, Equipment and Facilities. Standard F 1166-95a. West Conshohocken, Pa.

§DERA, Farnborough, UK

1. INTRODUCTION

The interaction between machines and man is, and will continue to be, a pervasive technological challenge engaged by defense-related science and technology communities internationally. Optimal effectiveness of current and future weapon systems will only be achieved if the interactions between the operator, or group of operators, is efficient and intuitive. According to Leger *et al.* (1997), the tactical cockpit of the future will be influenced by both the future combat environment and technology affordances. This chapter provides a vision of the future combat environment and the human–system interface technology for tactical cockpits operating within that environment.

2. THE FUTURE COMBAT ENVIRONMENT

Aircraft present three unique and powerful advantages to the combat environment. They operate within an expansive three-dimensional volume, operate at higher speeds than do other combat vehicles and their operations are extremely flexible and unpredictable. Because of this, over the next 20 years it is unlikely that the basic operational roles that aircraft will be called on to complete will be significantly different from those laid down in the current air power doctrine. It is clear that in the future the highly dynamic and time-critical nature of the combat environment that currently exists for tactical aircraft will become more dynamic and require an increased pace of decision by the pilot.

There are four technology innovations that will dramatically affect the look and feel of future tactical cockpits. They are un-inhabited vehicles, directed-energy optical weapons, stealth and affordability. These technologies will affect the perceptual and cognitive workload of the pilot by manipulating the content and character of information availability. The portrayal of information to the pilot and the ability to control the acquisition and subsequent transmission of prioritized and synthesized information from the pilot are central themes of future tactical cockpit design.

The increased use of uninhabited vehicles for both reconnaissance and combat is gaining more acceptance within the military community. This will translate into concurrent operation of inhabited and uninhabited vehicles in the same airspace. In the future, the pilot of a tactical aircraft may be physically located inside the air vehicle or may be remotely located, either on the ground, at sea or in another air vehicle.

Directed optical energy weapons such as lasers will affect the look and feel of future tactical cockpits. Laser weapons have the ability temporarily or permanently to damage the human visual system. The speed of a laser weapon, calculated from when it is activated to when it reaches its target, is orders of magnitude greater than any projectile weapon, such as a gun or missile. In addition, the frequency of the laser can be modulated within the visible spectrum in ways that make it difficult, if not impossible, to counter without completely removing the pilot's view of the outside world.

Stealth technology renders an aircraft, or other vehicle, almost invisible to sensors used in military aircraft such as radar or infrared detectors. This invisibility, more precisely described as a reduced signature, allows the stealth user more freedom of movement within the combat environment at the expense of not operating active sensors. The use of stealth technology by an adversary makes targeting more difficult and the possibility of surprise by the adversary increases dramatically, potentially turning an offensive situation into a defensive situation in a matter of seconds.

A critical driver in the design of future tactical cockpits will be affordability. In fact, affordability will have a pervasive impact on every device and concept within the future tactical cockpit.

2.1. The Pilot's Job

In simple terms, the job of a flight crew is to aviate, navigate and communicate. The three functions are typically described as flying the aircraft. For the military flight crew, they must fly *and* fight. More specifically, the aircrew of a combat aircraft must fly the machine to a location, often via a predetermined routes, where the target, in the air or on the ground, can be found and attacked before returning to a friendly base.

Different aircraft, roles, locations, weather conditions, targets, defenses, equipment failures and interactions with other forces generate a plethora of specific demands and concerns that the crew must deal with to complete the mission satisfactorily. However, it is reasonable to describe the job as being composed of the following separable high-level tasks: aircraft control, navigating, managing the mission, managing aircraft systems, communicating, targeting, managing weapons, and countering threats.

Pilot's of current, as well as future, tactical aircraft must maintain situational awareness, which has been described by tactical pilots as knowing the following within a volume of space and time over which they can exert control:

- Knowing where the threats are and what they are doing.
- Knowing where the friendlies are and what they are doing.
- Knowing what my flight knows and options for offense and defense.
- Knowing what other flights know – to a lesser extent.
- Knowing what I do not know directly.

3. FUTURE COCKPIT TECHNOLOGY (NEXT 3–7 YEARS)

The cockpit technology of current tactical aircraft includes 6-inch monochrome and color head-in displays, 10–20° monochrome heads-up displays (HUD), analog intercom combined with auditory warning tones, and the control concept of hands-on stick and throttle (HOTAS). However, move advanced interface devices and concepts, such as helmet-mounted displays (HMD), digitized and localized auditory displays, wider field-of-view head-up displays, collimated head-level displays, large area liquid crystal displays, haptic displays, direct voice interaction, and touch screens/touch pads may be applied in future tactical

Figure 1. Within 7 years, the tactical cockpit will include a HUD, HMD, HLD, localized audio, DVI and haptic displays.

cockpits. Figure 1 depicts a tactical cockpit that could exist within the next 3–7 years.

3.1. Hands-on Stick and Throttle

Most modern aircraft have now adopted the HOTAS concept, initially implemented on the F-15 but generalized with the F-18 for sensor and weapons management. This concept is closely linked to the notion of *real-time command*, where the pilot can immediately operate a control, without the need to release the stick or throttle to reach a switch on a dedicated control panel. It is now well recognized that this concept greatly enhances pilot effectiveness during combat missions.

Although it was initially intended to control the weapon system in the final phase of the mission, the HOTAS concept has been progressively extended to other mission phases. The intent of this extension was to reduce pilot workload, such as the control of the aircraft system configuration during ingress. As a consequence of this extension, the number of real time commands available from HOTAS has sometimes increased considerably, heavily soliciting the pilot working memory. The problem is basically linked to the saturation of working memory, inducing the need for additional training hours, without totally suppressing the risk of high error rates and poor results.

3.2. Large Area, In-cockpit Displays

The notion of a large image was a key element in the origin of the *little picture–big picture* concept proposed by Adams (1995). Both head-in and head-out displays are likely to co-exist in the cockpit of the future. Besides redundancy, these display concepts bring different advantages in regard of building good situational awareness.

Integrating large field-of-view head-in displays in combat aircraft is technically challenging due to the cockpit environment and the lack of space. Currently, the largest image displayed in a tactical aircraft is found in the Rafale, with the color head-level display (HLD) concept. Using LCD valves and collimation optics the HLD offers a square field of view of 20 x 20°. At the normal distance of vision for the HLD, achieving an identical image size would require a 12 x 12-inch display.

While the HLD is intended to display complex tactical situation, the Rafale's HLD is also used for map presentation, more demanding in regard of display resolution. Recent studies indicate that numerous situations would require a simultaneous management of short-, mid- and long-term information, requiring a frequent swapping between different map scales. In contrast, and in an operational context, it may be of great interest to allow different information to be displayed contiguously with a variable window size. For the future, such considerations are leading to concepts of large, re-configurable and interactive displays. The size of such a display could be, as an example, in the range of 20 x 15-inch. Some of the expected benefits would be:

- Increased flexibility, as the displays windows size or location could rapidly be reconfigured following mission type, phase or even user experience or cognitive style. On request, most adapted size for a given situation could be rapidly obtained, from full screen to iconic.
- Capacity to display complex tactical situations with an always appropriate size and resolution.
- Allow in-flight mission planning and rehearsal.

3.3. Head-up and Helmet-mounted Displays

A HUD is a cockpit-mounted virtual visual display in which the pilot views symbology or imagery overlaid on the real-world scenery as viewed through the display. A HMD is similar in concept except that it is mounted on the pilot's head, is much smaller and lighter, and takes advantage of a sensor that measures head position and attitude to spatially stabilized symbology and/or imagery.

It is quite likely that the HUD, if they remain in the cockpit, will see very little evolution from their current status for military aircraft application. Progress has continued on color HUD development. In fact, a color HUD has been tested on a Mirage 2000 test-bed aircraft at the French Flight Test Center at Brétigny sur Orge. Nevertheless, with cost effectiveness consideration becoming a crucial factor, further development of such equipment is very unlikely. It can also be expected, based upon progress in HMD technology that helmet mounted equipment could supersede HUD in the cockpit.

The first generation of helmet-mounted equipment (sight only, using a head-tracker) is already in service on fighter aircraft as the Mig-29. Second-generation HMD (symbology only) or even third-generation (symbology and sensor imagery) are now quite close to application on fighter aircraft. Interest in third generation HMD for helicopters, as an important part of the aircraft system during night operations, is now well recognized and clearly established for both mono- or binocular designs. Testing of second generation HMD has convinced tactical pilots, who had the opportunity to use such equipment in flight, about the great potential it has for close in air-to-air combat superiority. Advantages, in terms of radar or seeker lock on, reverse cueing and off-boresight missile launch have been reported in many places. Several human factors and system integration issues need to be rapidly clarified to accelerate the introduction of the helmet-mounted technology.

3.4. Auditory Displays

After the visual channel, the audio channel has always been an important display in aeronautics and essentially based on voice

communication. More recently, attempts have been made to investigate the use of acoustic orientation cues. What is new with the current trend is the expansion of *audio symbology* far beyond the current status of auditory warnings.

Synthesized voice messages are now a classical feature of commercial and military cockpit. the advantages and disadvantages of such communication mode have been widely reviewed. Recently, the use of iconic and metaphoric representations associated with comprehensive understanding of sound signal characteristics were used to build a set of auditory threat warning symbology in the UK.

Over the past 10 years laboratory work and some flight-testing has been devoted to the investigation of 3D localized sound. Results obtained in-flight, and within flight simulation, have confirmed the interest of localized auditory information, especially when coupled to HMD. Applications include following areas:

- Threat or waypoint spatial localization.
- Spatial separation of audio communication.
- Warnings and alarm.

3.5. Haptic Displays

The use of tactile interface to convey spatial orientation information has been suggested. Application of such techniques could also be advocated in the context of a synthetic environment. The first application of haptic display is certainly to restore feedback cues for aircraft control, which were lost with the introduction of fly-by-wire controls. Such techniques may also prove to be useful in synthetic environments.

3.6. Direct Voice Interaction (DVI)

Numerous studies and test flights have been devoted to voice control in the first half of the 1980s. Results obtained at that time were quite mitigated and the general feeling was that substantial progress had to be made in this area before direct voice interaction (DVI) can really be used in a cockpit. Nevertheless, DVI was included very early in the EFA program. It is currently considered as an option on the Rafale. Significant progress has been made in the early 1990s, which now makes DVI quite attractive for complex cockpit environments.

The UK and France have independently flight-tested voice recognition systems currently under development in their respective countries. Despite the fact that different test-bed aircraft and methodologies were used, there is a striking convergence of results obtained in UK and France. Recognition rates reach, in both cases, 98% for short sentences in stable flight conditions and remain between 85 and 89% under G-load. The effects of stress, acceleration, noise reduction and modeled dialogue are current subjects of research.

3.7. Touch Screen–Touch Pads

Strictly speaking, touch screens and touch pads belong to the manual control category. The use of touch screens is now well established in civil applications such as in terminals for banking operations. Touch pads can replace joysticks, to move a cursor as an example, and allow input validation. Both technologies have been flying for quite a long time on the Rafale. They are now used routinely by pilots, with very positive results so far. They may rapidly become a common feature for other cockpits.

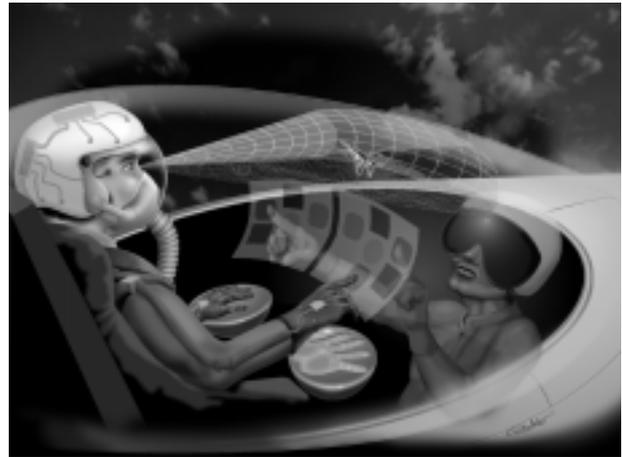

Figure 2. Advances in pilot state measurement and modeling, combined with advanced control and display technology, will revolutionize the tactical cockpit within the next 15 years.

4. FUTURE COCKPIT TECHNOLOGY (NEXT 7–15 YEARS)

These interface concepts include control using eye line-of-sight and gestures, interfaces that measure pilot state and adapt in real-time, and potentially totally enclosing the cockpit. Figure 2 depicts a tactical cockpit that could exist within the next 15 years.

Eye tracking, or gaze control, measures the eye line-of-sight and uses it to select and activate discrete or analog controls, or to orient symbology. Gesture-based control recognizes static postures of the hands and fingers as well as dynamic movements of the hands and fingers as a control or communications device.

4.1. Windowless Cockpit

The windowless cockpit, which is probably the greatest change in cockpit configuration to future tactical aircraft, will come about from the need to protect aircrew against optical/directed energy weapons. A reliable counter to the optical threat is essential, and this will be in the form of protection for the pilot's eyes. Both operational requirements and peacetime considerations suggest that a close-able solution, protection deployed as required under aircrew control, is an acceptable solution when current protection, the use of helmet visors with single or multi- become ineffective against variable-frequency lasers. Reactive dyes or other elements may well provide a longer-term solution against agile lasers, but the density of the visor is liable to leave a pilot, in a crucial part of the mission, with a partial or fully restricted vision of the world outside of the cockpit. Full closure may be achieved either on the helmet visor, or the cockpit canopy, but, in either case, the direct view of the outside world would be obstructed, and the information needed would have to be presented either from the range of sensors, or synthetically from aircraft data bases, or both.

4.2. Adaptive Interfaces

Adaptive interfaces will utilize knowledge of the operator's state, both measured and modeled, to enable automated, real-time decisions regarding information management and display characteristics. These characteristics include information modality, spatial arrangement, temporal organization and control

utilization. The adaptation of the interface to operator state can occur across two different domains, the first being dynamic function allocation and the second being information portrayal characteristics. The adaptation is enabled by the availability of three technologies: (1) highly flexible display and control devices, (2) computational models of situation awareness, workload and operator performance, and (3) direct real-time physiologic and behavioral measurement of the operator.

Virtual Workplace Design

G. Andreoni and A. Pedotti

Dipartimento di Bioingegneria, Politecnico di Milano, via C. Golgi, 39, I-20133 Milan, Italy

1. INTRODUCTION

In society, with the increasing role of machines in everyday life, the topics concerning the man–machine interface are becoming a major subject in designing home and job environments, production systems, transportation, and education tools.

In particular, ergonomic design based on a deep knowledge of the human psycho-physiological capabilities and limitations in relation to the requirements of machines and environments can be very incisive and effective. But it is very difficult to make ergonomics participate also in the earliest phases of the design. In general, the work and the role of the ergonomist begins when the physical mock-up of the product (tool, environment, workplace, etc.) is built and ready to be tested. In that way they can intervene only in a second time, even if we have to remember the general ergonomic guidelines that should be followed by designers.

Nowadays the virtual design (also called *virtual prototyping*) of workplaces and the simulation of the man–machine interface is going to have more and more importance to save time, money and risks during the design phase of manufacturing lines and cockpits (Haslegrave and Holmes 1994, Miller 1997). Therefore, to make a real intervention of ergonomics possible in this phase, one of the arising problems in this field is the realization of a virtual manikin able to move in a human like way inside the virtual environment. This will allow for testing the man–machine interactions before the mock-up is built cooperating directly in the early CAD design (Wilson 1997).

For this reason, the manikin has to represent a fundamental part of the whole system for design, since the virtual environment has usually a very good CAD description and is thus well identified. Nowadays the manikins can simulate a lot of possible movements but it can be seen how this movement can be far from the movement humans are likely to perform.

2. ANALYSIS OF THE POSTURE IN THE CAR

2.1 Car Seat

In general manikins are controlled by kinematics or inverse kinematics or a mixture (Badler *et al.* 1993, Das and Sengupta 1995). These methods produce reliable solutions to the motion generation problem, but observing the moving manikin it is easy to detect an "artificial" motor task. So we can say that they are reliable but not realistic approaches.

In fact, we can say that there are two ways to generate the movement of the manikin. One is the use of *deterministic mechanical models*. For these models some kind of criterion of optimization (energy, power, trajectory's length) must be introduced in order to deal with the overdetermination of the inverse kinematics problem (Uno *et al.* 1989). The other is to use *neural networks* to drive the model starting from examples acquired on humans (Massone and Bizzi 1989).

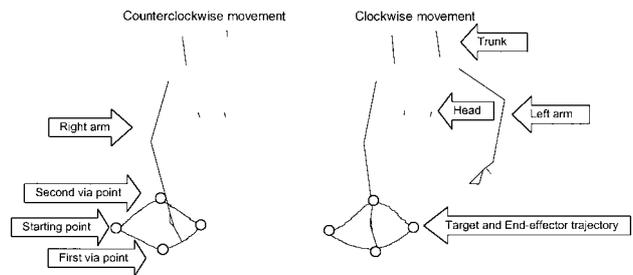

Figure 1. CAD representation of the environmental condition (left) where the subject performs reaching movements: the stick diagram of the moving subject (right) shows the body segments considered in the biomechanical model.

Some examples of this second solution regard the studies on the analysis and the simulation of working tasks in a seated position. A mock-up represents a working bench on which a seated operator assembles some parts or he has to perform reaching and grasping movements like pushing buttons or handling car commands: this representation of the experimental setup is shown in Figure 1. This CAD design is also a virtual working environment where the movements are to be performed. In this case the aim of the research is to investigate the motor strategies and the coordination of the movements of the upper limbs with the head–trunk complex. A 29 degrees of freedom model was defined for the upper trunk including both arms and the head. The ELITE system was used to collect kinematic data. This automatic motion analysis system uses small passive retro-reflective markers to highlight the body landmarks. The designed model was implemented by using 24 markers. The computer vision techniques for obtaining coordinate data on human motion have many potential advantages because they use optical (non-contacting) principles and can be automated to work rapidly and accurately without human intervention.

The kinematic patterns of the variables are computed from this markers distribution applying to the data set the biomechanical model; they are also needed for the *neural network training*.

In fact the data to be provided to the neural network are the angles of the various joints acting in the movement, and the trajectory of the end-effector (the index fingertip since the hand was modeled as a single rigid body). A campaign of acquisitions was conducted with different modalities on three population percentiles (5% female, 50% male and 95% male). Reaching movements, point to point and including via-points, were performed both on the bench and on the vertical direction. In the case of trajectories with via-points, the typical bird-eye pattern was observed (see in Figure 2 the stick diagram of the model as well as the trajectory of the end-effector during a clockwise and counter clockwise movement including via points). This behavior reinforces the need of the use of real data, in this case processed through neural networks, instead of deterministic models that can not account for these strongly human features.

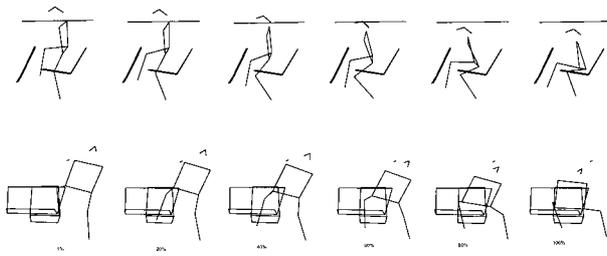
Neural networks need many training examples, and the number of examples is directly proportional to the level of complexity of the motor task to be simulated. Therefore, for very


Figure 2. Typical non-linear human behavior: reaching target and return to the starting point passing through two via points with the right upper limb: counter-clockwise (left) and clockwise (right) movements.

complex task, involving the whole body (this means to consider a biomechanical model with a high number of degrees of freedom) and eventually performed in a complex environment (i.e. an environment with many objects inside it to be considered in the collision avoidance) both the number of examples to be given and the experimental set-up to be adopted could represent a severe problem. For this reason another approach for the simulation (that is also based on actual data) was developed and applied in studies of the movements of man–machine interface in car related tasks.

The car is the most common transportation mean and, therefore, the most lived environment for millions of humans. Therefore, the study of man–machine interface is very relevant both for the evaluation of the comfort related to a given car set-up and in relation to muscular fatigue and load distribution associated to long-term tasks involving car driving and usage.

Among these, tasks accessibility movements, driving movements can be identified at a high level of priority.

For accessibility movements we mean the set of motor tasks performed to enter and to take the seated position inside the car and to get out from the car considering the various situations: anterior seat, driver seat, posterior seat (a typical example is shown in Figure 3).

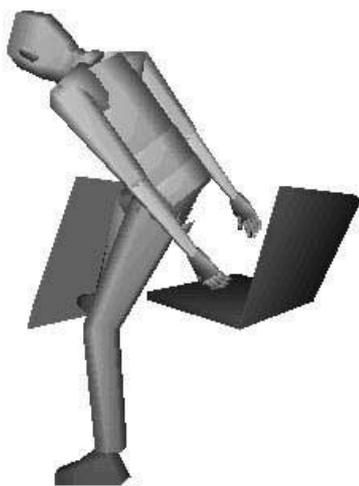

Figure 3. Stick diagram sequence of the entry movement in a car cockpit for one subject adopting the most common motor strategy (the lateral sliding) in the sagittal (up) and frontal (down) plane.

The performance depends on the anthropometric characteristics of the subject and on the shape, structure and dimensions of the car and can be of great discomfort.

Driving movements refer to the motor performance requiring coordination between upper limbs and trunk to reach and manipulate various commands: steering wheel, lights, switches, air conditioning commands, shift on the floor, seat-belt, etc. They refer also to the lower limbs and foot movements performed while acting on the brake, acceleration and clutch pedals. Therefore, the analysis of driving movements and the optimal design in order to facilitate their execution is strictly related to the general optimization of driving improving also safety.

Optimal design of cars should optimize accessibility movements and driving movements execution to improve comfort, safety and to prevent the long-term pathologies related to unsuitable loads and movements.

Up to now these problems have been faced by using simulation programs on computer or an approach based on dummies. Moreover the traditional procedure followed in developing a new vehicle begins with the exterior styling: in a second time man is "fitted" inside this volume. That is what is called an "outside-in" approach. All these methods and computer tools are very useful for designing an acceptable structure in terms of dimension and shape. However, they are based on the concept of the human being as a *passive load* and are not considering the real execution of movements in term of control strategies adopted: kinematics and coordination among the various body segments, dynamics, muscle forces and loads on the major joints. Therefore, this simulation approach leads to the definition of a stereotyped man–machine interface in which the concept of comfort is related to several parameters in a deterministic way.

Future design of MMI could greatly take advantage from these observations by considering the "real" behavior of a statistically significant population performing the required motor task. This means to reverse the idea into an "inside-out" approach to the new vehicle design (Porter and Porter 1997). The development of new technologies makes possible the analysis in three dimensions with the required level of precision of complex movements performed in car usage. It becomes, therefore, possible to investigate the different motor strategies involved in such interactions and to identify in a quantitative way several factors that are important for the most ergonomic solution in the design of the machine (Andreoni *et al.* 1997). In this way it is absolutely necessary to begin from the real human behavior properly to model all the different modalities that can be used to carry out a specific movement. This means to have a set of movements described in their kinematic variables that represent the *grammars of the movement*. If the complete movement can be divided in different phases it is possible also to extract specific and elementary tasks.

The experimented application is oriented to the design of cars and takes into account primarily the complex interaction between the user and the vehicle in terms of movement required for accessing and driving the car. This approach is based on the direct and dynamic evaluation of such interaction, on the identification of the motor strategies in relation to the structure of the car, on the relative constraints and the specific features of the human neuromotor system. Also in this case the three-dimensional measurement of human movement is reduced to

the detection of the trajectories of several points that identify the positions of the body segments in space. In the first stage the protocols, the models and experimental setups were fully implemented and applied on a small sample population.

The first outcome was the identification of the main motor strategies (Pedotti and Crenna 1990) used by different subjects in entering the car. Despite the great complexity of the movement involved in this task, each considered subject showed a high level of repeatability (invariant individual motor strategy which represents the grammar of the movement) as presented in Figure 3 for the most common and used motor strategy. At the same time we observed a constant energetic characteristic among such different strategies: the vertical center of gravity displacement, i.e. the potential energy is the most correlated parameter with the lowering of the door height. The flexion of the left hip demonstrated to be another correlated parameter: in fact the values increased during the lowering of the doorway. This is very important from an ergonomic point of view because this angle is related to the limb entirely supporting the body weight while the subject is entering and we could assume it as an indicator of the postural status, or also of the effort spent in the task (the movement corresponds to a muscular work done). This result points out a quantitative relationship between the dimension of the door and some kinematic variables independently form the motor strategy used by the subjects. The outstanding consistency and sensitivity of these data validate the method and confirm its reliability as a feasible and innovative tool to evaluate and classify car set-ups in terms of energetic accessibility cost (measure of comfort).

The approach developed for the simulation of the movement consists in the modulation of the real movement in response to a varying parameter of the set-up; it means to modify through a mathematical function the non-linear component of the temporal numerical series of the degrees of freedom of the movement beginning from a grammar of movement extracted from an observed movement. To extract a grammar of movement means to calculate the temporal numerical series of the kinematic variables defined with respect to the biomechanical model.

The biomechanical model has an identical general structure for all the subjects (same body segments of the kinematic chain and constant number of degrees of freedom) but it is customized on the single subject through a procedure of matching (minimizing the sum of the square distances of the points of the biomechanical model from the real anatomical points of the subject acquired in the standing posture).

Starting from the actual data the movement is modulated to adapt it to the new environmental conditions. The real kinematic data corresponded to the mathematical model of the motor strategy referred to a particular set-up. The first step of the procedure was the separation of the movement in two components: a linear function which was obtained by connecting the starting point and the ending points defined by the first and last frames by a line for each kinematic parameter (or degree of freedom of the biomechanical model), and a non-linear component which represented the modulation of the movement. We then reconstructed the virtual kinematic data of the simulated movement by an algorithm which minimized a target function. This target function was designed to:

- minimize the joint movement with respect to the standing posture;
- respect a collision avoidance function;
- ideally reach the same modulation for the non-linear component of each anatomical angle (e.g. to have a same coefficient of the non-linear component for each degree of freedom: it means to distribute the modification along the body districts);
- respect particular constraints (such as keep in touch ground and left foot until the subject is not seated); and
- respect joint constraints (such as physiological limits or joint ranges of motion).

The initial value of the target function for each joint angle and for each frame of the movement was given by the linear function value at that time.

The algorithm computed the new joint angles in the virtual movement and then re-calculated the 3D coordinates of the

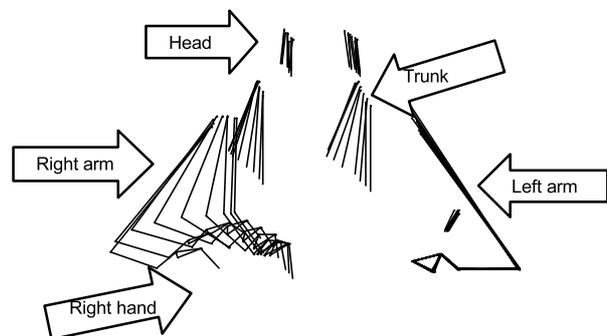

Figure 4. Simulated frame of the entire entry to the left posterior seat in VRML. This allows for CAD importing and testing different environmental conditions (e.g. the height of the doorway from the floor or the distance between the seats).

anatomical marker on the basis of the biomechanical model previously defined.

In this way the kinematic data of a simulated or synthetic or virtual movement are computed: they correspond to a subject whose anthropometric dimensions were known and adopting a precise motor strategy to enter a vehicle of given (virtual or real) dimensions. A frame of the simulated movement is presented in Figure 4 in VRML environment.

The comparison between the simulated and the real kinematics in a test movement demonstrated the reliability of the method with statistical significance.

3. CONCLUSIONS

In conclusion, we said that a good simulation tool is fundamental for correct the design of workplaces. In this way also specific and proper algorithms for the ergonomic evaluation can be included to compute an assessment of the ergonomic condition and give the information of how to improve the working conditions.

Many common methods for the ergonomic evaluation are used in these programs: for example static and dynamic biomechanical calculations, reaching zones, RULA index, OWAS, NIOSH lifting equation. Also databanks with information about comfort joint range and zones, field of vision and the computation of strength under different conditions can be used as reference.

So it is possible to integrate ergonomics and engineering in the technical design with all the benefits of a more effective collaboration between ergonomists and designers for a better product design and manufacturing organization (Haslegrave and Holmes 1994). This is the realization of the "inside-out" approach for ergonomic design, with a human-centered philosophy applied to the design itself.

Visual Display Units: Positioning for Human Use

L.M. Straker

Department of Physiotherapy, Curtin University of Technology, Perth WA 6001, Australia

1. INTRODUCTION

As an increasing proportion of the workforce spends a greater proportion of their work (and leisure) time interacting with computers, the object of the visual interaction, the visual display unit (VDU), becomes a critical component in the interaction.

This chapter will review the options for the optimal placement of a VDU in terms of vertical height, lateral location, eye–screen distance and VDU tilt. The discussion is focussed on a single computer screen office workstation, although the principles may be applicable to other workstations.

2. VERTICAL HEIGHT

2.1. Vertical Placement Options

VDU for office work are usually placed in one of three vertical locations, as described below.

2.1.1. "High" — top of screen level with sitting eye height

The traditional recommendation for VDU placement has been to locate the top of the screen at sitting eye height (Figure 1). With a typical 13-inch monitor at 750 mm from the user's eye this results in viewing angles (angle between horizontal and a line from the eye to the visual target) from 0 to 15°.

2.1.2. "Mid-" — bottom of screen level with desk surface

Recently, more researchers have advocated a lower VDU position, with the bottom of the screen at desk height (Figure 1). For a user of average height sitting upright at a desk just above elbow height and viewing a 13-inch monitor at 750 mm, this would give viewing angles from 15 to 30°.

2.1.3. "Low" — bottom of screen just visible over keyboard

The third option for VDU vertical placement is as low as possible given cathode ray tube monitor and keyboard input device (Figure 1). Using current desktop computer and keyboard technology, the lower limit is probably formed by the viewing angle to the far edge of the keyboard. For the same situation as described in Section 2.1.2, where the user has full forearm support on the desk with the keyboard furthest edge ~500 mm from the user's abdomen, the lowest possible viewing angle is ~45°. Thus, with a 13-inch screen the viewing angle range could be 30–45°.

2.1.4. "Ultra-high" and "ultra-low" positions

"Ultra-high" positions are above sitting eye height. For example, de Wall *et al.* (1992) recommended a VDU position that would result in viewing angles of 5–25° above the horizontal.

"Ultra-low" positions would also be possible with flat-screen technology by placing the screen on the desk just in front of the user's abdomen. This would be comparable with reading a book

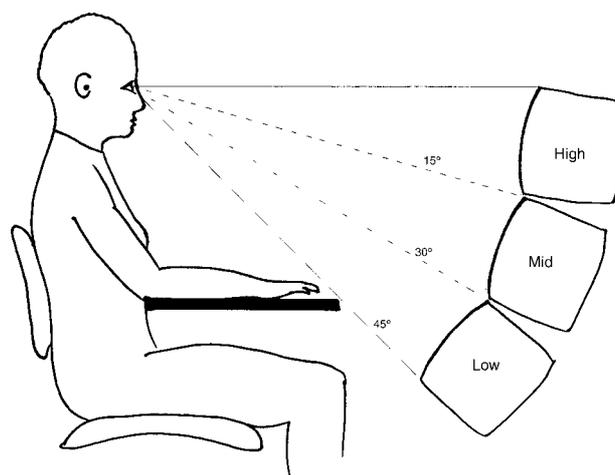

Figure 1. Vertical VDU placement options: (a) "high," (b) "mid-," (c) "low."

placed flat on the desk and result in viewing angles from 45 to > 65°.

2.2. Evidence for a "High" VDU Position

The main argument for the "high" position is to reduce musculoskeletal strain on the neck by keeping the head in the "normal" upright standing position.

A "high" VDU position is likely to result in less neck flexion, and to a lesser extent less thoracic flexion. Based on modeling of neck muscle forces de Wall *et al.* (1992) suggest neck extensor muscle forces are minimized by a head position with 30° *extension* relative to "normal" standing head posture. At the other extreme, excessive neck flexion results in increased neck muscle loads and discomfort. There is general agreement that extremes of neck extension and flexion should be avoided, however the optimal neck position is debated. "High" VDU placement will result in less flexion than lower positions, but may result in undesirable neck extension.

Research in the author's laboratory has found reduced cervical and thoracic erector spinae muscle activity in the "high" position compared with the "mid-position", with a similar trend in upper trapezius (Mekhora 1996). Turville *et al.* (1998) also found a reduction in cervical and thoracic erector spinae activity in the higher position, although they found an increase in trapezius activity on one side. Aaras *et al.* (1997) found no difference in trapezius activity between a higher and lower VDU position when there was no forearm support. As neck flexion becomes near end-of-range, one would expect extensor muscle activity to reduce due to increased passive tissue tension. Whether or not this is desirable is not known.

In summary, there is reasonable evidence that when users work in an upright sitting posture, a "high" VDU position is associated with reduced neck flexion and reduced cervical and thoracic erector spinae activity. Most researchers consider the trapezius to be a critical muscle (due to its prevalence in reports of work related symptoms), but the current evidence for whether one VDU height is preferable for trapezius is conflicting. Further, it is not known whether the increased neck flexion with lower VDU placement is a problem.

2.3. Evidence for a "Mid-" to "Low" VDU Position

The two main arguments for the lower positions are to reduce visual strain by locating the VDU where it is easier to accommodate and converge for close visual work (Lie *et al*. 1997) and to reduce musculoskeletal strain.

Visual accommodation is the change in the shape of the eye lens capsule to achieve focus. Insufficient accommodation results in blurred images. Convergence is inward turning of the eyes to keep a single binocular visual image. Inaccurate convergence results in double images. Muscles control both accommodation and convergence. The eyes have natural resting points for accommodation and convergence, and as a visual target moves in closer from these points more eye muscle activity is required. Thus, just as there is a convenient reach zone for touching, there is a similar zone for visual "touching." However, unlike the tactile reach zone, an arc around the shoulder does not define the visual reach zone. Rather, the visual "reach" zone extends out from the resting points and comes closer to the user with increasing downward viewing angle. The resting point of accommodation averages ~800 mm with young people and shifts farther with increasing age (Krueger 1984). The resting point of vergence averages 1120 mm with a horizontal viewing angle and comes in to 900 mm with a 30° downward viewing angle (Heuer and Owens 1989). A lower monitor position will allow for closer viewing distances without an increase in visual strain.

Aside from less strain on eye muscles, with lower gaze angles the eyelid covers more of the eyeball that helps reduce the likelihood of dry eyes (Villanueva *et al*. 1996).

The support for a lower VDU position being less straining visually comes from the general knowledge of human visual performance but also from laboratory and field studies. There is little doubt that from a visual system point of view, lower VDU placement is preferable (assuming suitable non-reflective environmental lighting).

The second argument for the lower monitor positions is to reduce neck musculoskeletal strain by reducing head–neck extension (Ankrum 1997), lengthening neck muscles (Burgess-Limerick *et al*. 1998) and allowing a greater variety of appropriate neck postures (Ankrum and Nemeth 1995).

Proponents of lower VDU positions argue that users typically flex their lower cervical spine and extend their upper cervical spine (to give the chin jutting forward posture) when working with "high" VDU monitors. Upper cervical spine and head–neck extension is maintained by static muscle activity, probably by small, deep neck muscles in particular. The sustained activity may result in discomfort and disorder.

Fatigue in the muscles supporting head–neck extension is more likely as the muscles would be working in shortened positions. (There is a relationship between the length of a muscle — compared with its resting length — and the tension or force it can generate such that the more shortened a muscle is the less force it is able to generate. In essence a shorter muscle equals a weaker muscle.)

Ankrum and Nemeth (1995) suggest that lower VDU positions allow a range of neck flexion postures while keeping appropriate gaze angles. Turville *et al*. (1998) attempted to determine whether users do vary their neck posture more when working with a lower VDU, however their measure was not adequate.

While the preference for lower VDU positions from a visual point of view is in little doubt, the preference from a neck musculoskeletal point of view is still contentious.

2.4. Issues Complicating Recommendations for VDU Height

Several limitations in the available research literature make weighing the evidence for various VDU height options difficult. Different definitions of postural and visual angles make comparison of research difficult. This is further complicated by inadequate descriptions of working postures, and by different postures being used (upright with unsupported forearms and forward tilt with supported forearms) and different equipment (some studies have used what are now considered old monitors with poor clarity; this may have affected vision and therefore posture).

Current technology in office furniture and lighting design often restricts the option of "low" VDU height as a separate support surface below desk height is required and office luminaries may not be designed to reduce reflections on "low" VDU. A further example of possibly important interactions between VDU height and posture is that the "low" position may restrict the use of the backward tilting sitting posture. This posture has some research support and is probably a useful alternative sitting posture. In contrast, the "low" VDU position may encourage a forward tilting posture, which is also probably a useful sitting posture.

Technological changes are tending to merge the options as large screen sizes usually mean an overlap of positions. For example, with a 21-inch screen (vertical screen dimension of 300 mm, compared with 240 mm for a 13-inch screen), the viewing angle range at 750 mm is nearly 25°. Thus the "high" position would be 0–25° and the "mid-" position would be 5–30° and the "low" position 20–45°. Further, flat screen technology may provide the option of using a VDU like a book, at an even greater viewing angle (the "ultra-low" option described above).

Individual variation may also mean one position is not suitable for all users. For example, a user who has played a piano regularly since childhood may be musculoskeletally adapted to an upright sitting posture and "high" to "low" visual target.

3. LATERAL LOCATION

The lateral location of a VDU is less contentious than the vertical placement. After only ~7° (100 mm at 750 mm) of eye lateral movement the head responds by postural change (Fisher 1925, cited in von Noorden 1985).

Sustained head and neck rotation is likely to result in musculoskeletal discomfort. Therefore, if the visual task is largely screen based the screen should be directly in front of the user. If the visual task entails a mix of screen and paper, or multiple screens, then a compromise position should be selected while trying to avoid sustained neck rotation to one side.

4. EYE–SCREEN DISTANCE PLACEMENT

Appropriate eye–screen distance interacts with height, so that as the VDU is placed lower, it can be placed closer to the user. Lower gaze angles bring the resting point of vergence closer, and

sustained viewing of visual targets closer than the resting point of vergence has been found to increase eyestrain (Owens and Wolf-Kelly 1987). Therefore, at any one VDU height, users will tend to find viewing more fatiguing at closer eye–screen distances. Optimal eye–screen distances are also dependent on the user's visual capacity (which is age related) and the clarity and size of the visual image. While recommendations have varied from less than 500 mm to near 1000 mm, when the VDU is in the "mid-" vertical position somewhere ~750 mm is likely to be comfortable for many users. Greater eye–screen distances are probably also suitable, as long as screen font sizes are increased. However office space and increased costs for large screens may constrain more distant VDU placement.

5. VDU TILT

It is generally recommended that VDU should be tilted to maintain an approximate 90° between line of sight to center of screen and screen surface.

Ankrum *et al.* (1995) found vertical monitor tilt influenced postural and visual discomfort. Tipping the monitor forward so that the top of the monitor was closer to the eyes increased neck, upper back, and visual discomfort when compared with a monitor tipped backward at the same gaze angle. They attributed the results to a visual phenomena called the vertical horopter (the locus of points in space that stimulate binocular singularity in peripheral vision) The vertical horopter tips away from the viewer at much the same angle that a person would read a magazine.

Optimal tilt may need to be compromised in work places where luminaries are poorly designed and thus cause screen reflections.

6. RECOMMENDATIONS

VDU workstations should allow for considerable adjustability in VDU position to allow for individual visual and musculoskeletal system differences, task differences and environment differences (especially lighting).

VDU workstations should preferably be adjustable enough to allow the VDU to be:
1. directly in front of the user;
2. at 600–1000 mm distance;
3. tilted slightly back from a right angle to the line of sight;
4. with the top of the screen to be as high as a 5° viewing angle; and
5. with the bottom of the screen to be as low as 50° viewing angle.

A single height desk surface can not provide this adjustability.

When allowing a user to determine a comfortable VDU location the starting point could be with the VDU directly in front, at 1000 mm, tilted slightly back from at right angles to the line of sight and with a viewing angle of 30° to the bottom of the screen.

Wearable Computers

W. Barfield and E. B. Nash

Virtual Environment Laboratory, Department of Industrial and Systems
Engineering, Virginia Tech, Blacksburg, VA 24060, USA

1. INTRODUCTION

Over the past few years, developments in a new information technology known as wearable computers have been rapidly taking shape. Wearable computers are fully functional, self-powered, self-contained computers that allow users access to information anywhere and at any time. A wearable computer is designed for hands-free mobile computing and is a battery-powered system worn on the user's body. Wearable computers may be configured in many different forms from see-through head-mounted displays (HMD) with speech input, to wearable computers with input devices worn on the wrist or body. This chapter reviews the components of wearable computers, addresses developments and design issues, and summarizes application areas.

2. COMPONENTS OF WEARABLE COMPUTERS

One of the main goals of wearable computers is to allow users to access computational resources whenever and wherever they are in the environment. Compared to virtual and augmented reality display systems, in which users are confined to the range of motion associated with the length of the cable connecting the display hardware and rendering platform, wearable computers allow complete freedom of motion within the real world. This mobility generally requires three standard system components, each worn on the user's body. These are the computer unit, the power supply, and the input devices. The computer unit functions to store, retrieve, and process information. Typically belt or wrist worn, it houses the CPU, motherboard, hard drive, and memory.

In terms of computational resources, the processing power and storage capability of PC-based wearable computers are generally comparable to those of current laptop technology. The power supplies usually consist of lithium-ion-based battery packs that are worn on the body and connected to the computer. They can generally last for 2-4 hours before recharging is necessary. But other developments are also being investigated, such as lithium ion polymer batteries (which may allow 11 hours of usage before recharging), and harnessing human motion as a power source (Starner 1997). Output may be viewed using either a flat panel display (FPD), which is typically worn on the wrist, or a head-mounted display (HMD) connected to the computer unit.

Head-mounted displays for wearable computers may be characterized as opaque or see-through. Each type may be viewed in monocular or binocular mode. Monocular displays require the user to integrate the display viewed using one eye with real-world scenes viewed using the uncovered eye (Figure 1).

When worn over both eyes, opaque head-mounted displays still allow real-world scenes to be perceived, in this case by using

Figure 1. Picture of a user with a wirelessly networked "Mobile Assistant" wearable computer accessing a map of Virginia Tech through the World Wide Web (Picture courtesy of Virtual Environment Laboratory, Virginia Tech).

video captured via a camera mounted on the HMD (or some other location). In contrast to opaque HMDs, see-through HMDs admit light from the outside environment, allowing users to directly view the real world with the naked eye. Half-silvered mirror systems fixed in front of the user's eyes reflect light from computer-generated graphic images. The resulting image is an optically combined view of the real world superimposed with graphical images.

Because the user is often using one or both hands to perform a task in the real-world environment, input devices used with wearable computers need to be designed to allow the user efficient manipulation and interaction with both the displayed information and objects in the real world. The input devices that have evolved for use with wearable computers are diverse and ever changing to accommodate user needs. For data entry or text input tasks where hands-free operation is not needed, body-mounted keyboards, wrist keyboards, and hand-held keyboards are often used. Cursor movements used to select options or manipulate data formerly using mice are being substituted by other devices such as track pads. When real-world tasks require the use of both hands, hands-free operation can be provided through speech recognition along with gesture- based, EMG-based, and EEG-based input device technology.

3. WEARABLE COMPUTERS AND AUGMENTED REALITY

One important application for wearable computers is use with augmented reality display technologies. Augmented reality in the context of display design refers to the ability to project or merge graphics or text with real-world imagery (Barfield *et al.* 1995). Feiner *et al.* (1993) refer to this ability as "knowledge enhancement" of the world.

There are different types of wearable display technologies that can be used to combine real-world objects with computer-generated imagery to form an augmented scene. Optical-based wearable computers allow the observer to view the real world directly with computer graphics or text overlaid using a head-mounted display (HMD) which is worn like glasses. Video-based wearable computers use cameras mounted near the user's eyes to present live video with overlaid computer graphics or text. Both types of display can present stereoscopic images if two slightly offset cameras are used.

4. EXTENSIONS OF WEARABLE COMPUTERS

4.1. Network Applications

Due to the advent of wireless technology, wearable computers are now permitted to be wirelessly connected to local area networks (LANs) or wide area networks (WANs). This has important applications for users of wearable computers. Namely, users may now access databases from shared networks such as the World Wide Web at any time or place.

4.2. Integration of Sensor Technology

Another interesting extension is the integration of sensor technology with wearable computers for the creation of "smart spaces." We define smart spaces as environments in which objects have associated with them (1) a CPU allowing some minimal level of intelligence to exist in the object or environment, and (2) sensors that detect the presence of other objects within the environment

or the state of the object itself. In order for any digital system to react to events in its environment, it must be able to sense the state of the environment. This can be accomplished by incorporating sensors, or arrays of various sensors into systems. Sensors are devices that are able to take an analog signal or stimulus from the environment and convert it into electrical signals that can be interpreted by a digital device with a microprocessor. The stimulus can be a wide variety of energy types but most generally it is any quantity, property, or condition that can be sensed and converted into an electrical signal (Fraden 1996).

In general, there are two kinds of sensors: active and passive. The characteristics of these two types of sensors will affect their potential use as components of a wearable computer system. Active sensors require an external power source or excitation signal in order to generate their own signal to operate. The excitation signal is then modified by the sensor to produce the output signal. Therefore, active sensors consist of both a transmitting and receiving system. A thermistor is an example of an active sensor. By itself it does not generate a signal, but by passing an electric current through it, temperature can be measured by the variation in the amount of resistance (Fraden 1996). In contrast, passive sensors directly convert stimulus energy from the environment into an electrical output signal without an external power source. Passive sensors consist only of a receiver. An infrared motion detector is a passive sensor; it uses radiant heat energy from the objects as its source of detection energy.

When building and employing sensors into intelligent environments (including wearable computers), designers should consider the application of the intelligent environment and select the sensor technology which best complements it. Among these considerations are the sensor's accuracy, range, calibration error, power consumption, physical dimension, saturation, reliability, sample rate, and noise filtering.

5. WEARABLE COMPUTERS AS ACCESSORIES TO THE HUMAN

Wearable computers can also be thought of as personal information devices (Starner *et al.* 1997). With experience, the user can personalize the system to ensure appropriate responses to everyday tasks. As a result, the user's wearable computer system becomes a mediator for other computers and interfaces in the environment, providing a familiar, dependable interface.

Effective provision of this type of "intelligent assistant" depends on several considerations. For one, it is easy to cross the boundary between information that is actually useful and clutter that is overwhelming. Thus, in order to assist the user more effectively, a wearable computer might model its user's actions, goals, and even emotions. Systems have been developed to track the user's position, visual field, and current interests as revealed by what is being typed (Starner *et. al.* 1997). This type of interaction is well suited to wearable computers because continual close contact with their user allows a unique opportunity for sensing the user's actions. In practice, such a system using bio-sensors to measure physiological states might allow a wearable computer to track the state and actions of its user and react accordingly.

A more personal and striking interface may be possible if the user's emotional affect can be sensed as well (Picard 1995). It is well known that emotional affect plays a large part in everyday

life (Damasio 1994). Picard (1995) discusses ways in which computers might recognize affect as well as a number of potential applications of affect-sensitive wearable computers. Specifically, by combining a wearable computer with biosensors that can sample a user's temperature, blood pressure, galvanic skin response, and electromyogram, it is possible to create an "affect model" of the user. Using these sensor data and the user model, a wearable computer can track the state and actions of its user, and react accordingly.

Finally, user models implemented within a wearable computer system should be able to predict future actions. In turn, this information can be used to allocate resources preemptively. For example, if a user enjoys hard rock music when working on a late night project to keep alert, but prefers classical music during the day to lower stress, the wearable computer can predict what the user may want to listen to next and can download potential selections over a wireless network.

Human interaction with the real world can provide the dimensions by which wearable computers can be evaluated. Two of these dimensions include the level of mobility provided by the computing system and the level of scene fidelity. The level of scene fidelity refers to the quality of the image provided by either the virtual reality display, the real world, or the augmented world. Not surprisingly, real-world experiences result in high levels of mobility and scene fidelity. Essentially, this is because humans have developed the capacity to carry their sensors with them as they move around the environment, and they experience the world with the resolution provided by these biological sensors.

Wearable computers also allow a high degree of mobility, but current limitations in the technology do not permit as wide a range relative to our human bodies. For example, currently we cannot swim with wearable computers although our biological sensors easily allow for this. And mobility is further inhibited by the extra weight that must be tolerated. On the other hand, wearable computers using see-through optics or live video for output allow a high degree of scene fidelity. Wearable computers using computer-generated images may suffer in the area of scene fidelity because currently they do not have the rendering capa-

bility of workstations that are often used (e.g., SGIs) to render high resolution graphics for augmented reality environments.

6. CONCLUSIONS

Present advances in microelectronics and wireless networking are making truly ubiquitous computing a reality. However, as the number and complexity of wearable computers continue to grow, there will be increasing needs for systems that are faster, lighter, and have higher resolution displays. In addition, wearable computer systems must become unobtrusive and socially acceptable. Thus, components of the wearable computer (CPU housing unit, input devices, and output devices) will have to look far more like clothing or clothing accessories than the commercial wearable computer systems available now. Lastly, with wearable computers and with appropriate sensors integrated into objects within the environment, it is possible to create "smart spaces", in which users will interact with each other and with networked objects within the environment to gain information, solve problems, and "think together".

Wheelchairs

I. Gilad

Faculty of Industrial Engineering and Management, Technion–Israel Institute of Technology, Technion City, Haifa 32000, Israel

1. INTRODUCTION

Mobility aids are the basic social needs for individual that suffer from limitations in gait abilities. Henceforth mobility must be viewed as being essential to the outcome of rehabilitation for wheelchair-dependent persons and to their successful integration into society and active life. In the case of the disabled, a wheelchair is more than simply a mobile aid to transport an individual from one place to another. For the young disabled a wheelchair is essential to socialization, education, and employment; for the older disabled it is an around-the-house moving device. Young and old use wheelchairs in very different ways, but both groups need them to satisfy a set of subjective physical comfort requirements, fit individual anthropometry, relate to their age group, and comply with any other special needs.

Today's wheelchairs propose a variety of mechanical bodies and supporting equipment to stabilize the user's body. To best fulfill technical requirements and address the needs of different users to match the appropriate wheelchair, a systematic approach should be introduced. The match between the appropriate wheelchair and the needs of an individual is usually provided by professional social and medical systems or agencies, acting as local or federal authorities. But these systems use different procedures and policies when providing the right wheelchair. To learn about selection of wheelchairs, two surveys were conducted in Israel; they indicated that much work remains to be done in optimizing the selection procedures for mobility aids.

The number of actual wheelchair users is difficult to determine. An estimated number for Europe is 2.5 million wheelchair-dependent individuals (Van der Woude 1999). For the USA two numbers are quoted in the literature: Gaal *et al.* (1996) gives a figure of 1.4 million wheelchair riders, and nearly half of them live outside of institutions. Kopardekar and Mital (1994) estimate 0.7 million regular users of wheelchairs; an additional 1.0 million Americans are using wheelchairs, while suffering from cardiovascular, nervous system, or related diseases until they become mobile. A study conducted in Israel by Gilad (1997) found that about 1% of the population use wheelchairs permanently or in a temporary mode of mobility.

These groups are large enough to allow research on effectiveness of use and effectiveness of rehabilitation programs. The number of wheelchair users is high in the three estimates cited here and in many other estimates. It is therefore costly to provide mobility aids, and in the light of this expenditure some people are now concerned about the low level of satisfaction expressed by the average wheelchair user.

Wheelchairs are generally used by three sectors: young people, adult people, and elderly people. Advances in medical treatment have helped children and the younger generation (ages 3 to 18) to survive diseases of the nervous system and the musculoskeletal system (e.g., multiple sclerosis and cerebral palsy). The children and young handicapped use manual and semipowered wheelchairs fitted with special seating supports. The adult sector (ages 18 to 64) is three times as big as the young sector; it is divided into three groups:

- People handicapped from birth or through childhood diseases of the nervous system or the musculoskeletal system.
- Individuals in middle age who survive a traumatic accident related mainly to the spine or cervical regions. Their handicaps result from work, car crash, military, sports, and other physical activities.
- Individuals suffering from progressive physical malfunctions, due to diabetes or cardiovascular problems. This sector is the most active: 55% use motorized or powered wheelchairs, 45% use manual wheelchairs.

The number of people in the elderly sector (ages 65+) is increasing at a rate of about 15% annually. In my survey, 46% of them are stationed in adult homes and geriatric facilities; this population uses basic manual wheelchairs.

A cross-handicapped population survey was conducted to analyze the mechanical fit and personal satisfaction between wheelchair users and their actual wheelchair. Another survey was conducted in parallel to examine the procedures used by the different agencies while assigning wheelchairs to the handicapped. Two kinds of questionnaire were designed: (1) a questionnaire for wheelchair users, and (2) a questionnaire for professionals who choose the wheelchairs and allocate them to users; among the professionals are occupational and physical therapists, nurses, administrative personnel, and sales executives.

The user questionnaire was so designed that every wheelchair user can easily answer it. It was distributed to war-disabled, car and work accident victims, musculoskeletal injury patients, and elderly users, people who use wheelchairs in their own home or in a nursing home. Its questions cover physical fitting, level of mobile activity, purpose of use, chair features, ease of use, and safe use, limitations imposed by the wheelchair, moving ability in a range of given activities, ease of ingress and egress, and personal experience of the social and medical services.

The professional questionnaire was distributed to rehabilitation agencies. Its aim was to analyze procedural topics and to learn about the fit of the wheelchair and common needs of the users. The answers provided information on wheelchair design, such as seat height, length, width, slope, shape, backrest, clearance for feet and calves, armrest, required force to operate, and cushions. It contained questions on safety, because about two-thirds of wheelchair injuries require medical attention.

The overall figures on wheelchair users are 74% male and 26% female; these figures differ in each category. About 60% of the users reported that they were appropriately fitted for seat height, width, length, and slope measures. About 50% of the wheelchairs were adjustable for adaptability and comfort. Some 70% of users were satisfied with their current wheelchair. Many safety incidents and injuries are reported among wheelchair riders. A recent study reported in the USA showed that incidents among wheelchair users break down like this: 42% due to tip and fall, 33% due to component failures, and 25% due to other events. Statistics derived from the Israeli survey show similar figures. In the 77% that are not the result of component failure,

many of the underlying causes arise because the wheelchair does not fit the user's needs.

2. SELECTION ALGORITHMS

It was found that the various financing authorities pursue very different policies when assigning a wheelchair to an individual. The majority of the individuals who participated in the study have criticized this. Findings indicate that, when design is considered, there is low correlation between the human needs, the mechanical supporting aid, and the maneuvering solution. In many cases the device is uncomfortable and therefore is not used in the proper way. The users were not informed about their optional needs and the available solutions. In providing an inappropriate tool to the needed person, the policy makers unfortunately failed to optimize the efforts and the heavy costs involved.

Neither of the above policies has a computerized information base from which a wheelchair user can find out how to choose a wheelchair, or what is available from manufacturers. Most of the information is transformed via verbal communication, in nonformalized venues. No formal guide is used on educational issues or selection of the proper solution for nonstandard personal requirements. Older people require escorts and help in folding their wheelchair; these aspects should receive adequate attention. These needs were reported by 36% of the Health Ministry population and 25% of the Ministry of Defence population. When these needs are reported, it is important to assess the capabilities of the handicapped person and their spouse. Very little attention is given to the type of wheelchair or the technical solution to be used.

The financial aspects for purchasing a new wheelchair differ among the financing agencies. It is obvious that financing agencies aim to lower their expenses, and this conflicts with the decision on which components and which design of wheelchair will be recommended to an individual. This causes arguments between the authorities and the wheelchair user. The budget involved in supporting the wheelchair population is enormous. I could not get access to the real figures, but my estimates are high compared to what I used when accumulating the cost per wheelchair and the cost of solving any problems. The handicapped popula-

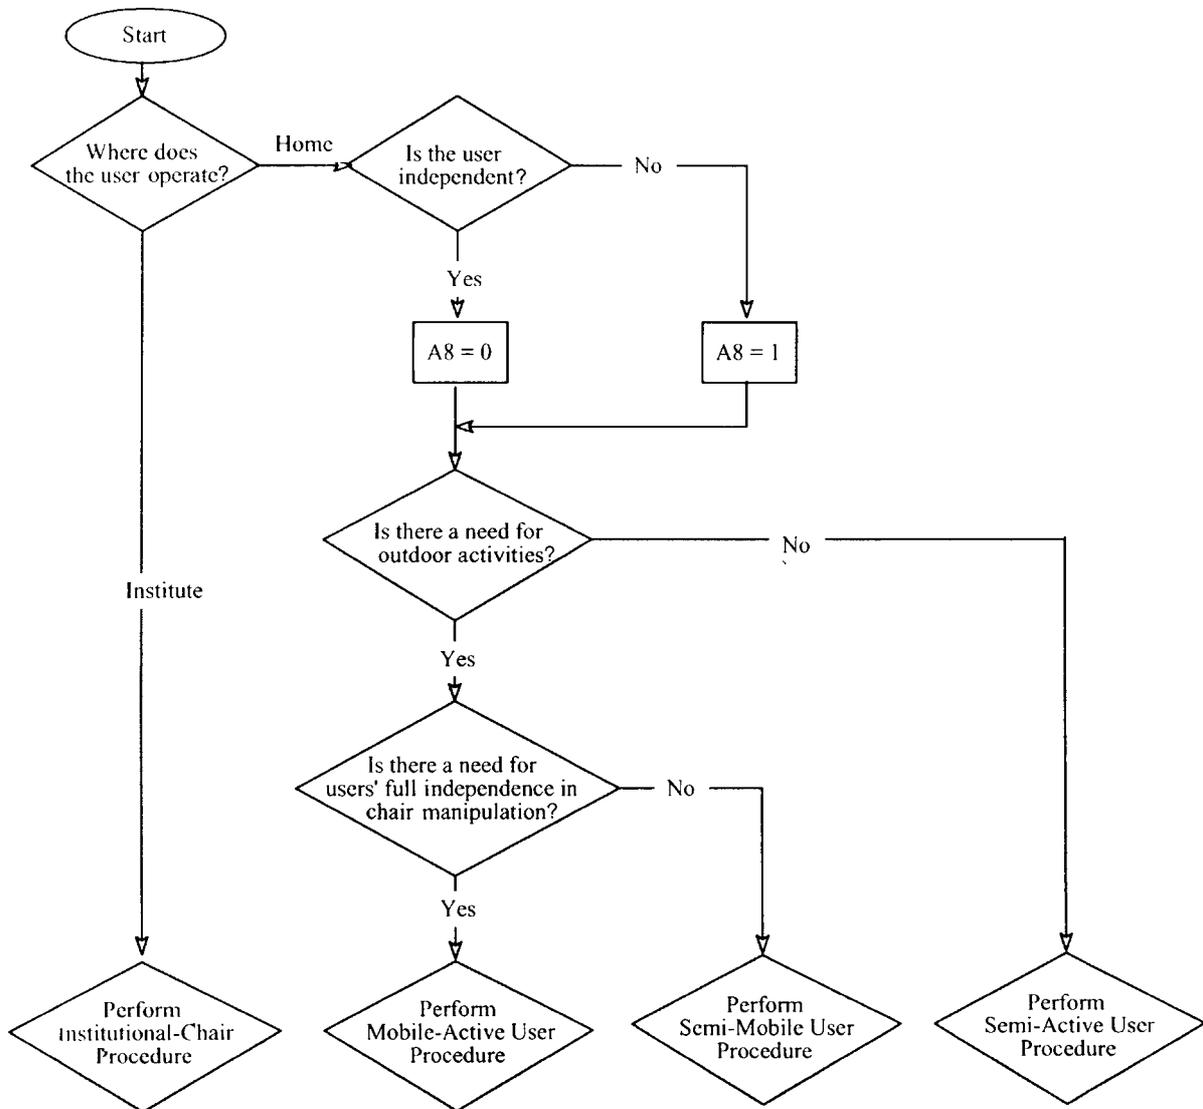

Figure 1. First-step algorithm for wheelchair selection and definition of user's need
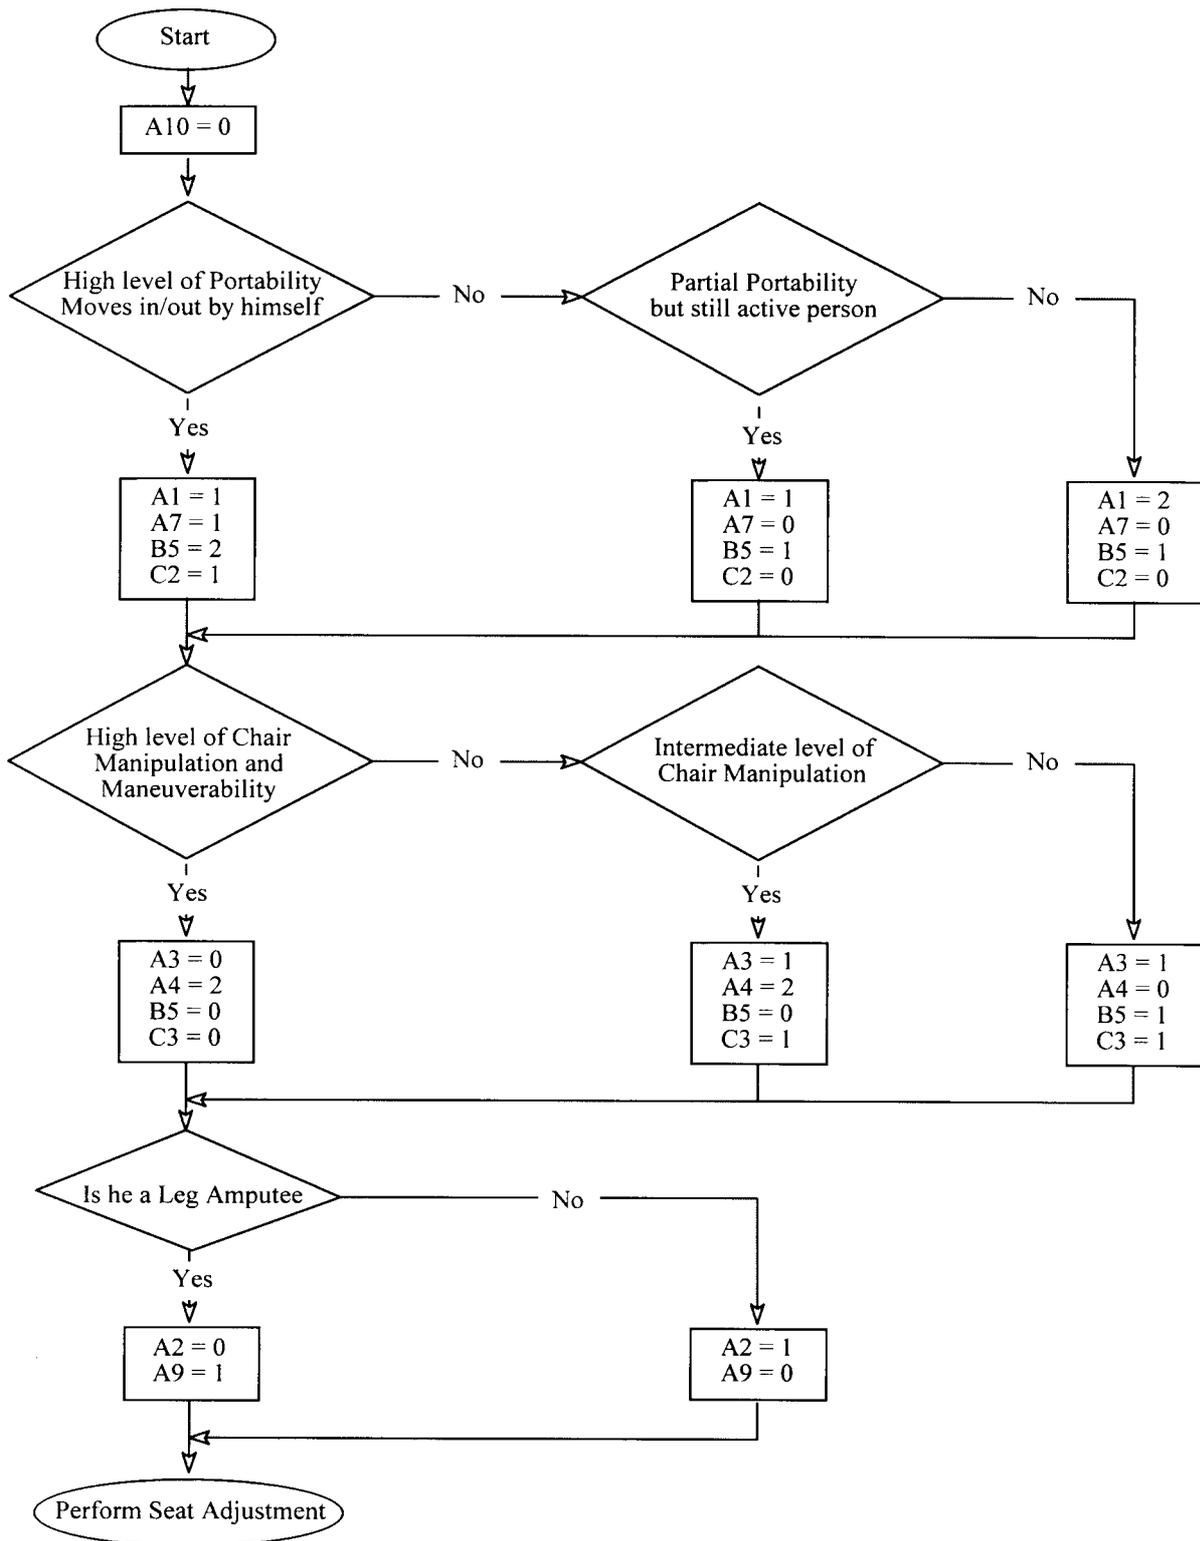

Figure 2. Algorithm to select a wheelchair for an active user

tion is very diverse and there is no way to organize its sectors to improve their current status, as a healthy society will do. Trying to work out a better system, I have suggested an algorithm that provides a good policy for the social and medical authorities. It is divided the into three categories: chair frame, chair seat, accessories and special aids.

Each category is then divided into components or adjusting features that have an impact on the fitting procedure. Figure 1 shows how to define a user's need as the first-step algorithm for wheelchair selection; the categories used in this algorithm are given in Table 1. Wheelchair selection is then performed in four steps:

1. Define the type of chair user, according to the actual user's needs: institutional chair, mobile active user, semimobile user, and semiactive user.
2. Perform chair selection for each type of user, observing the definitions and required components for each user's specific needs.
3. Perform the seat adjustments.
4. Perform the accessory adjustments.

Figure 2 shows the selection algorithm for an active user who is a self-operator, commonly known as a free person; the categories used in this algorithm are given in Table 2.

Workstations Organization

E. Górska

Institute for Organization of Production Systems, Warsaw University of Technology, ul. Narbutta 85, 02-524 Warsaw, Poland

1. INTRODUCTION

An ensemble of enterprises is best visible on workstations. First of all the defects, which are the consequence of the organization of production process and the work of sections directing the process, are seen.

Organizing the workstations is a very complicated problem. It is a result of workstations functioning in production process, which focuses all technical, organizational and ergonomical elements relative to the needs and wants in the work process.

Organization of the workstation should connect all these components and create a harmonic entirety. It will provide optimal realization of the planned goal. The growth of the workstation organization level can have an important influence on production effects. Thanks to rationalizations in the organization range, it is possible to have an increase of works' efficiency with relatively little investment in circulation.

2. DIFFERENCE BETWEEN WORKPOST AND – STATION

In organization theory the notion of "a workpost" and of "a workstation" is usually used. In general, a workpost denotes a room or a part of a room that is at the same time a spatial unity and a separate place, and it serves for some purposes to a specific working team consisting of a few people who do the same job and use the same set of tools.

The notion of a workpost can be understood as *a place occupied by an employee in some system or organization*. In this case a specific partial activity done by a given employee and resulting from the work division is taken into consideration.

This term also suggests a basic organization unit where human work is carried out. Its main characteristics are: static system of components, dynamics of human work, operation of machines and influence of environmental factors.

A workstation is generally understood as the smallest production unit.

Thus, "a workpost" refers to every post where work is carried out (including the work of a manager of a big company or the work of a usual factory worker). The starting point of this analysis does not constitute a production process or a part of production space but the functions to be fulfilled and which have been assigned to an employee. Therefore, the notion of "a post" also includes an employee. According to the definition, both types — a workpost and a workstation — have the same logical structure of their notions. It enables one to analyze the organization of these two types using the same methods. It also enables one to transform some rules of the organization of workposts to workstations. The complexity of this division (workposts and -stations) and the problems connected with clear logical naming result in the mixing and exchanging of these two types in the literature of the subject.

Furthermore, it must be stated that every workstation is necessarily a workpost but not every workpost is a workstation.

3. WORKSTATION

The notion of a workstation both in the literature and in practice is defined in many different ways. In general it can be said that a workstation is the smallest production unit in which a man acts in a deliberate way, using machines and necessary tools, working with material and carrying out some stage of the production process. Putting it in a more detailed way, "a workstation" can be defined as the smallest production unit whose main characteristics are: necessary instrumentation for the given work, the personnel employed and the relevant work standards and safety regulations.

Thus, it is the smallest basic unit capable of production in which there occurs, in the precisely determined space, an organic unification of the three main factors of this process: producers (people), the means of work and the work objects.

A workstation can be a stationary or a movable means of production (in buildings, at machines or work facilities, in the means of transport, vehicles) that is operated by an employee to carry out all the preparatory and production activities or to control and monitor the production (in the case of the high-tech automatic machines).

A workstation is therefore an object that fulfills strictly determined basic production tasks with the help of human and technological means constituting a part of production process. This kind of object is functionally connected with other objects of the same kind. In other words, there is a workpost when there is a man performing his assigned production duties. The conclusion is obvious: one workstation can be equipped with a few machines or instruments, with one machine or with a part of a machine. Apart from a machine (or its part) and instruments being the basic technical component of a workpost, a workpost includes also some indispensable space necessary for man to move at his work and to store the material before and after the treatment.

Many specialists analyze a workstation from the functional point of view and consider it "the smallest subsystem of the company, its smallest so-called work system." It is an often heard definition that a workstation constitutes "a set of relevant components, factors of production process interconnected and functioning as a homogenous production element which performs some specific tasks."

Taking system theory as a starting point, a workstation can be described as "the smallest system (subsystem) of work, separated from a superior system and integrally connected with it by fulfilling the partial target (task) which necessarily refers to the main target of the superior system."

If one treats a workstation as a system, it should involve not only a working space and instruments, but also a human and his relations with the environment.

In the descriptions of workstations, a technical and organizational point of view usually prevails, which is connected with the work division and specialization of a station. Unfortunately the problems about worker's needs, social status in the structure of the company, rights and prestige are left behind. Describing the fragmentary structure of a workstation involves the loss of information about the worker's motivation, attitude to duties and responsibility.

The desirable behavior of a worker can be achieved only when

the process of planning the work system takes into consideration psychosocial determinations of a worker's behavior and the technical and organizational requirements of a workstation.

While analyzing the scope of commonly accepted definitions, one often comes across the statement that a workstation is "a part of a production or industrial space," "a part of a machine and production space," "a place of work, an employee, an instrument and machines," "space, equipment and energy," "the smallest production units, "space, machines, object of work and performers," etc.

Some indispensable components of a workstation necessary for the production process to take place include:

- Production tasks.
- An employee (group, team).
- Equipment (machines, instruments, subsidiary equipment, tables, chairs, containers).
- A product or a service which is the object of the work.
- Size and shape of the production space occupied.

Designing a modern workstation involves not only tasks connected with the performance of the production process, but also adjusting a workstation to the human needs and determinations. It is the issue that concentrates the efforts and interests of many specialists from different fields: machines designers, technologists, economists, and the representatives of the humanities and other sciences like anthropologists, psychologists, physiologists, etc. It not only demonstrates the contribution of sciences dealing with technology, economics and organization, but also it emphasizes the significance of medical and social sciences.

This is a good example of tendencies which opt for a greater humanization of work and adjusting it to the psychophysical characteristics of humans. In regard to this problem, a workstation at every stage of its design, analysis, evaluation or improvement should be recognized as a coherent system integrating three main elements: the human–machine–material environment.

The relations between these elements change with the modernization and mechanization of a workstation and show the evolution of links, which become more and more complex as the level of mechanization and automatization increases. In this case the significance of human duties decrease and other functions become of greater significance, which is in turn conditional on a machine's work.

The human–machine system is shown as a separate system to make the interpretation more clear. A workstation as a human–machine system not only must meet the modern requirements of production, but also above all it must fulfill the needs of human.

Thus, one must aim at such technical and ergonomic designs and solutions that would guarantee the best harmonization of the two elements of human–machine system or human–technical instrument system.

The human–technical instrument system, defined and described in a proper manner, and reflecting a given workstation, is a basis of an analysis and evaluation of the phenomena which occur within this system.

The human–technical instrument system has a dynamic character: it changes in time, it interacts with physical, chemical, biological and social environment and this environment also influences it. During its operation it can interact with different systems, which can even result in modifying its own previously arranged plan of action.

The name of a basic human–technical instrument system has been adopted for a system consisting of a man and a determined kind and number of technical means which are used to carry out a planned task in the specific time and in the specific way. The elementary character of the system — as a feature of its structure — consists in the fact that depriving the system of whichever element violates its ability to carry out the planned tasks. The basic human–technical instrument systems can differ greatly from each other in many following ways:

- The degree of complexity of tasks.
- The intensity of environmental influence (above all physical, chemical and biological factors of the environment).
- The strength of relations between other basic systems.
- Significance for the subsystem operation.

There are three types of the basic human–technical instrument systems that depend on technology and the level of modernization:

- Systems consisting of a man and a machine (instrument), e.g. a turner and his turning lathe, a blacksmith and his hammer, a driver in his vehicle.
- Systems consisting of a man and a fragment of a larger technical instrument, e.g. a worker working at a streamline or at a lathe.
- Systems consisting of a man and a larger number of single machines that work at the same time, e.g. a worker inspecting the work of lathe machines.

4. ORGANIZATION OF WORKSTATIONS

The organization of a workstation aims at such collection of means and their use (and the application of these means and methods) which makes it possible for a performer to carry out his task in the proper manner.

The proper organization of workstations and production processes aim at achieving most favorable economic results by increasing the productivity and better work quality — using the least effort on the part of the workers — and providing safe and comfortable work conditions.

The organization of a workstation depends on the organization system of the group of workstations consisting of the individual stations. Some claim that the organization of a workstation is a system made of properly applied elements, which interact to achieve a given target. The aim of the accepted organization of a workstation is to provide an effective fulfillment of tasks in the situation of some inner disturbances and mutable influence of the environment.

Nowadays the development of sciences concerning work like the organization of work, the analysis of work and, particularly, ergonomics has changed in the significant way the attitude towards the organization of work. The organizers leave behind the traditional methods and become more and more interested in the system solutions. They treat a workstation as a system separated from the environment — a subject to changes due to the influence of the environment and a subject interacting with the environment. The system approach in the organization practice is very effective.

The main components of the organization system at a workstation are:

- Methods of work.
- Organization of work.
- The spatial organization of a workstation.
- Service.
- Material environment of work.

The organization of a workstation can be analyzed from the three points of view, i.e. space, time and relations to other workstations.

While adopting the spatial point of view, some elements taken from the entire analysis of the three main factors of a workstation find their reflection in the specialized fields of scientific research, e.g.

- Human adaptation to work (the physiology of work, psychotechnology, etc.); it involves the analysis of the performer's features — a man in his working space — in a static manner, separated from the other main factors of a workstation.
- Work adaptation to human (ergonomics); it involves the analysis of the means and conditions of work in the working space. This set of problems is most often the object of research that results from the common understanding of a workstation where the equipment is the richest and the most important source of changes and improvements.
- Human adaptation to human (sociology and psychology of work); it involves the analysis of a human–performer in his relations with other performers working at workstations and managers.

Analyzing the main factors of a workstation (performer, means and objects of work) in time, i.e. the harmonization of the work time of the individual factors, which is usually analyzed separately and then analyzed in their mutual relations.

The main object of analysis of this approach is human (performer), which is also an object of interest of many specialized institutions with a whole spectrum of methods, techniques and means.

Analyzing the work time of a worker and looking for the ways of increasing his efficiency is not always a right and effective approach. While operating unique and high-tech machines, the main problem is to provide work continuity of these machines and not the problem of work pauses for the workers, engineers or technicians who operate the machines (e.g. operating electronic code machines, energy systems, etc.)

When no main factor of a workstation is engaged in the production process, there is a pause in the work of a workstation.

While analyzing the organization of workstations, some special attention should be paid to the individual factors during the work pauses. These pauses are described as technological breaks.

The analysis of workstations is from the third above-mentioned point of view: in their relation to other workstations — apart from the analyzed problems of the psychology and sociology of work — it brings into view some work means indispensable to a workstation like transport machines, communication and signaling means, etc.; and particularly work objects in their production course starting from a stock (in the form of the initial material) through all the production and inspection stations (in the form of semiproducts) to the store and market (in the form of ready products). The time of the material course in the production process together with

expectations determines the length of the production cycle, which in many cases can be a measure of the level of the organization of production.

With the higher types of production (of an average and large series mass production) the relations between workstations are more and more straight.

While analyzing the organization of a workstation, it cannot be identified exclusively with the work organization and the organization of production. The humanocentric approach must be taken into consideration, that is ergonomic aspects, and also a classical human–machine system must be connected with the environmental factors and the technological problems whose degree of modernization determines the organization of a workstation.

Concluding the organization of a workstation must involve elements of work organization, production, technology and ergonomics.

Taking for granted that a workstation is a human–technical object system, one can define the organization of a workstation as a purposely designed system of organizational, technical and ergonomic elements that are included in the system of interaction with the environment and which will allow one achieve this goal/target. While designing as well as analyzing the organization of a workstation, the role of the environment must be considered and its significance must be revealed, i.e. the influence on the human–technical object must be analyzed if its disturbing, stimulating or neutral/indifferent impact is to be proved.

The organization of a workstation therefore must be a result of three factors from the field of the organization of work and production (O), technology (T), science about human being, his psychophysical abilities, the motivation of his actions (E) and his behavior in the working team:

$$O = f\{(T_1 \ldots T_n), (O_1 \ldots O_n), (E_1 \ldots E_n)\},$$

where T is technological factors — technology and properly chosen machine determines a type and form of a workstation; O is organizational factors (of production and work) — a workstation is under a constant influence of the organization of material supplies and receipt/collection of the product (the pace of work, the means of transport, the means of mutual synchronization and spatial relations of instruments and the objects of work during the following operations, methods of work, etc.); and E is ergonomic factors — adaptation of a workstation to the psychophysical features of a working subject/human and the shape of the occupational environment.

Some of these factors are interconnected, which means that the change of one of them involves disturbances in the system of the others and requires their change. Ergonomic factors are connected with both other groups of factors.

The changes in the first two groups of factors often influence the form of a workstation when one considers its adaptation to a human being. Technology and the organization of production very often become invariable determinants to which the entire body of ergonomic designs must be adjusted (so-called corrective ergonomics). When analyzing and evaluating a workstation one must bear in mind a most favorable model, which means that one must know in advance what the aims are and if they can be achieved.

Environment

Environmental Ergonomics

A. Hedge

Department of Design and Environmental Analysis, NYS College of Human Ecology, Cornell University, Ithaca, NY 14853-4401, USA

1. INTRODUCTION

Environmental ergonomics studies our physiological and behavioral reactions to the ambient environment, and the design of effective barriers that allow us to survive in otherwise inhospitable settings. Research on physiological and behavioral reactions includes studying topics such as responses to cold and heat stress, our capacity to perform work in extreme climates, and acclimatization processes. Research also focuses on requirements for clothing and enclosures that allow us to live in extreme terrestrial climates that range from deserts to Polar regions, or that allow us to venture into extremely harsh environments, such as the ocean floor or outer space. Effective barrier design encompasses the following:

- Clothing — the primary barrier that functions as our second skin and provides for thermal comfort and protection from adverse conditions (personal protective equipment), such as extremes of cold, heat, wind, wetness, air pressure, chemical contaminants, etc., as well as providing adornment and modesty values.
- Enclosures — two types of secondary barrier function as our third skin to provide safe and comfortable conditions:

1. Vehicles — most types of vehicles function as a protective barrier against climate conditions. Everyday transportation vehicles (cars, buses, trains, etc.) provide internal conditions within the vehicle that are regulated for human comfort. Specialized transportation vehicles (planes, submarines, space shuttle, etc.) provide a comfortable climate that allows human survival in otherwise fatal conditions.
2. Structures — climate conditions within buildings are designed to provide us with appropriate ambient environmental conditions (thermal comfort, ventilation and indoor air quality, lighting, acoustics, etc.) in even the most inhospitable terrestrial locations. Buildings regulate daily and seasonal variations in climate and this allows people to populate a much wider range of environmental niches, well beyond those in which the clothed body alone is capable of surviving.

2. AMBIENT ENVIRONMENT CONDITIONS

2.1. Thermal Conditions

Being warm-blooded creatures, we strive to maintain a thermal balance with our environment within relatively narrow limits ($37 \pm 1°C$). For survival, acceptable limits for the deep body core temperature are between 35.5 and 39.5°C. The skin can tolerate a much wider temperature range with limits between –0.6°C (skin freezes) and 45°C (skin begins to burn). Thermal balance occurs whenever net body heat production matches the rate of heat gain or loss via physiological processes. The body generates heat through metabolism and muscle activity not related to external work, and it exchanges heat with the environment via several processes. We can lose or gain heat by:

- *Radiation* between skin or clothing surface and surrounding surfaces, e.g. windows, sun.
- *Conductance* to the surfaces by direct contact with skin or clothing, e.g. sitting on a warm or cold surface.
- *Convection* — a form of heat conductance where the surrounding air close to body absorbs heat. Natural convection occurs as air warmed by body heat rises. Forced convection occurs when air is moved past the body, such as by a fan, or by loose clothing (bellows effect).
- *Evaporation* of water through the outer layers of skin (insensible perspiration) or from the skin surface when this is wetted by sweat (perspiration) or some other external agency affects heat exchange. At maximum sweating, evaporation accounts for 15% of heat loss. Heat is also lost through warming and wetting of air that is inhaled and then exhaled and by excretion of feces and urine.
- *Storage* of heat in the body. Ideally the rate of heat storage should equal 0 when the body is in heat balance i.e. heat production = heat loss with no storage.

In practice the body rarely attains or maintains heat balance and environmental ergonomists study the many factors influence the effectiveness of the heat exchange processes.

2.2. Heat Exchange Mechanisms

Three physiological mechanisms for heat exchange allow us to adapt to variations in thermal conditions. These are:

- *Vasomotor* — the skin needs a minimal blood supply to keep it alive. For thermoregulation this blood flow can be increased many times. Increasing skin blood flow raises skin temperature, which increases heat transfer to the environment, and cools the body core. Decreasing skin blood flow cools the skin, reduces heat transfer to the environment and warms the body core. Changes in skin blood flow are most marked at the extremities of limbs (hands and feet) and less marked in the trunk and head.
- *Sweating* — transferring heat from the core to the skin becomes increasingly difficult as skin temperature approaches the body core temperature. In hot environments sweat evaporation cools the skin surface allowing heat transfer from the core. Sweat rate varies from a minimum of ~650 ml/day, to a daily maximum continued total sweat rate of ~1 liter/h. Over shorter periods of up to 6 h the maximum short-term sweat rate may be as much as 2.5 liter/h. Sweat is secreted by two types gland:

1. *apocrine* — forehead, back, palms of hands, armpits — produce protein-containing sweat; and
2. *eccrine* — produce dilute salty and watery sweat from all other skin areas.

- *Shivering* — when skin blood flow is minimal there may be excessive heat loss from the body core by conduction through the skin. Maintenance of body core temperature requires an increase in heat production and shivering is disorganized muscular activity that has this effect, and increases heat production 300–400%.

2.3. Effects of Heat and Cold on the Body

Our ability successfully to thermoregulate depends on individual factors, such as age, alcohol consumption, general health and acclimatization to thermal conditions. For a normal adult, when

the body core becomes too warm, blood flows from the body core to the skin, and sensible perspiration starts, which dissipates additional body heat by sweat evaporation. *Hyperthermia* occurs if heating of the body continues beyond its ability to lose heat through perspiration (i.e. the upper critical temperature). Hyperthermia risks are greater in hot industries, such as steel or glass making factories, and in hot climates. Hyperthermia can be fatal, with between 240 and 1700 deaths per year in the USA depending on heatwave conditions.

When cold, skin vasoconstriction occurs to shunt blood to the body core, *piloerection* (i.e. the hairs of the skin stand up) helps trap an insulating layer of air over the skin, and shivering starts. *Hypothermia* occurs if body cooling continues beyond our ability to generate and conserve heat (i.e. the lower critical temperature). Hypothermia risks can occur in cold industries, such as refrigerated cold storage, arctic or antarctic settings, mountain climbing, deep sea fishing or diving, outer space, etc., or in cold climates. Hypothermia can be fatal with 600–1000 deaths per year in the USA, depending on the severity of the winter.

2.4. Thermal Comfort

Thermal comfort is a psychological concept that is affected by at least six variables:

- *Air temperature* — temperature (°C) of the ambient air.
- *Mean radiant temperature* — average temperature (°C) of radiant sources, such as a fire. Radiant asymmetries (warm front, cold back; warm head, cold feet) can produce thermal discomfort.
- *Air speed* in meters per second past the body. Air moving over the skin cools this.
- *Humidity* — percent relative humidity. (Percent relative humidity is the ratio of the moisture content of the air divided by the maximum moisture content of that air at the same air temperature and barometric pressure, _ 100.) Sweat evaporation is less effective as humidity rises.
- *Activity* — muscular activity generates heat.
- *Clothing insulation* — different clothing designs and materials have different thermal insulation properties (clo units; 1 clo = 58 W/m²). Summer attire is ~0.6 clo and a winter ensemble ~1.0 clo. A well-padded high-back office chair insulates the body at ~0.3 clo. Clothing insulation is reduced by wind or body movements that disrupt the air layer between the skin and the clothing, or by wetting the clothing.

2.5. Thermal Comfort Standards

For most indoor spaces we attempt to construct settings that provide for thermal comfort. Two thermal comfort standards apply to indoor environments.

2.5.1. Thermal comfort zone (ASHRAE [American Society for Heating, Refrigerating, and Air-conditioning Engineers] 55-1981)

Thermal comfort conditions are defined as those for which > 80% of the people will not report thermal dissatisfaction. These conditions are specified as a zone on a psychrometric chart representing various combinations of air temperature and relative humidity for particular air velocities, clothing ensembles, and seasons (winter and summer). Air temperature and mean radiant

temperature are assumed to be equivalent, and activity levels are assumed to be typical for indoor settings.

2.5.2. Fanger's comfort equation (ISO 7730)

Thermal comfort is defined by the physical state of the body rather than environmental conditions (Fangor 1970, ISO 1984). A comfort equation is computed that predicts comfort temperature (°C), the average thermal comfort votes for any group of people (predicted mean vote, PMV), and the percentage of people who will be dissatisfied with the thermal environment (predicted percentage dissatisfied, PPD). Several experiments show that for sedentary work and light clothing, the preferred temperature is close to the 25.6°C predicted by Fanger's equation. Preferred temperatures appear to be uninfluenced by age, race, or individual differences (Fangor 1970). Studies of sex differences in thermal comfort have produced conflicting results. Recently, computer programs and portable thermal comfort instruments based on ISO 7730 have been developed. However, in some laboratory and field research the PMV does not always give good predictions of thermal comfort ratings (McIntyre 1980, Bensel and Santee 1997, Konz 1997).

2.6. Temperature and Performance

Many studies show how changes in thermal conditions can affect human performance (Konz 1997, Parson 1998). Extremes of heat or cold can decrease work performance. The effects of heat on task performance may depend upon the cognitive complexity of the task and the level of heat exposure that occurs. Changes in thermal conditions can affect worker performance in office buildings, for example, typists with no incentives or knowledge of results produce more work at 20°C than at 24°C. Students' *t*-test scores generally are better with 22–23°C than > 26°C. Cold conditions can impair manual dexterity when hand skin temperatures are between 13 and 18°C. Cold conditions can also affect psychomotor task performance.

2.7. Ventilation and Indoor Air Quality

Indoor air quality focuses on the nature and concentrations of air pollutants (particles, fibers, gases or bio-aerosols) inside of enclosures that can adversely affect comfort, performance and health. Ever since the energy crisis of the early 1970s, which resulted in reductions in the design standard for mechanical ventilation rates, there has been a growing awareness of the impact of indoor air quality on comfort, health and performance.

2.7.1. ASHRAE Standard 62-1989

In the USA the ASHRAE Standard 62-1989 sets minimum ventilation rates for occupant comfort. Acceptable indoor air quality as "air in which there are no known contaminants at harmful concentrations as determined by cognizant authorities and with which a substantial majority (80% or more) of the people exposed do not express dissatisfaction." Occupants of modern, sealed, air conditioned buildings, may experience symptoms of the sick building syndrome that may be caused by poor indoor air quality (O'Reilly *et al*. 1998). (Sick building syndrome describes complaints of non-specific symptoms among building occupants, such as headaches, sore and irritated eyes, sore throats, and flu-like symptoms.) Indoor air pollutants can affect cognitive performance, cause eye, nose, throat, and lower respiratory tract

irritation, elicit acute and chronic health symptoms, provoke allergic reactions and fatal illnesses. Many factors affect indoor air quality, including outdoor air quality, ventilation system design and performance, and emissions from building materials, technology, workers, and their activities. Indoor air quality studies typically investigate a wide array of contaminants that include:

- *Combustion gases* — exhaust emissions of combustion gases can include:

1. *carbon monoxide* — a colorless, odorless gas. It affects psychomotor task performance and is toxic at high concentrations;

2. *carbon dioxide* — a colorless, odorless gas that we exhale. High carbon dioxide levels promote drowsiness, and ultimately asphyxiation;

3. *nitrogen oxides* — several gases that can cause mucus membrane irritation and provoke bronchospasms; and

4. *sulfur oxides* — several gases that can cause mucus membrane irritation and affect lung function.

- *Ozone* — a colorless, pungent gas that causes mucus membrane irritation, provokes asthmatic reactions, and has toxic effects. A major component of photochemical smog that occurs in may cities.

- *Volatile organic chemicals (VOC)* — a wide variety of carbon chain or ring compounds. Indoors they may be emitted from construction materials, paints, adhesives, furniture, office technology, cleaning agents, smoking, etc. Studies of building products emissions report ~80% of indoor VOC may cause eye irritation, and ~30% are suspected carcinogens. Exposure to low level mixtures of VOC adversely affects health and performance. Chamber studies show that exposure to a mixture of 22 VOC, typical of indoor settings, produces detectable neurotoxic symptoms within 2 h of exposure to a concentration of 25 mg/m^3 (O'Reilly *et al*. 1998).

- *Formaldehyde* — a colorless gas with a pungent odor. Toxicity occurs through contact with skin and mucous membranes (eyes, nose, throat). Some people can become sensitized to formaldehyde. Exposure can induce fatigue, memory lapse, headache, difficulty sleeping, respiratory problems (including asthma), and eventually chronic respiratory disease and possibly nasal and respiratory tract cancers.

- *Radon* — a colorless, odorless radioactive gas that emits radiation as it decays into its progeny through a decay chain. Radon is thought to cause some 20 000 deaths per year among non-smokers.

- *Bioaerosols* — In the USA, respiratory tract infections (mainly viral illnesses) account for 75 million visits to physicians, 1.25 million hospitalizations, $15 billion direct medical costs, 150 million lost workdays and $59 billion in indirect costs (lost income, absenteeism). Three groups of microorganisms, viruses, bacteria and fungi, are responsible for many of the bio-aerosol illnesses associated with indoor exposures. Bio-aerosol exposure can be fatal, such as those deaths from Legionnaire's disease. The relationship between the risk of respiratory tract infections and the spatial design of buildings and ventilation system performance is only poorly understood. Research shows increased risk of infection in shared offices and in air-conditioned spaces (O'Reilly *et al*. 1998).

2.8. Lighting

Visible light is electromagnetic radiation that is emitted by a source. Since ancient times people have used artificial light sources, such as oil lamps or candles, to supplement or replace daylight. Today, electric lighting provides a wide array of options for creating artificial lighting conditions 24 h a day that support diverse kinds of visual work, irrespective of natural light levels.

Environmental ergonomists studying lighting pay particular attention to six factors that determine appropriate lighting for visual tasks (Boyce 1997):

- *Contrast* — the difference between the luminance (brightness) of an object and the luminance of the background. It is easier to see high contrast targets than low contrast targets. Contrast is affected by several factors, including the type and amount of light sources, by surface reflectance, by viewing angle and by target size.

- *Size* — the larger an object, the easier it is to see. The size of the image on the retina is important, not the size of the object, and this is affected by viewing distance. As we bring an object into closer focus we can see finer details.

- *Time* — seeing takes time. The retinal biochemical processes take time to occur, visual processing and recognition also takes time, especially for unfamiliar objects. Consequently viewing time is important. We need bright light if objects are to be briefly seen.

- *Luminance* — the quantity of incident light arriving from a source. This determines *illuminance* (i.e. the amount of light falling over a unit area) which affects the luminance of the task.

- *Color* — this affects both to contrast and luminance factors because the eye is not equally sensitive to all wavelengths, and ~8% of men and 0.5% of women have color vision deficiency (Boyce 1981).

- *Visual acuity* — the resolving power of the eye is affected by anatomical factors. The shape of the cornea produces ~70% of its refracting (light bending) capabilities, with the crystalline lens providing ~30%. Changes in lens curvature (accommodation) alter refraction and focus light onto the photoreceptive retina.

2.9. Visual Processes

Light is detected by photoreceptors in the retina of each eye. Each retina has ~130 million rods (monochromatic vision), and ~7 million cones (color vision) concentrated in the fovea, the region of greatest sensitivity and acuity. Plentiful light allows high visual acuity and color vision (photopic vision). Low light levels reduce visual acuity and impair our ability to see colors (scotopic vision). The eyes adapt slowly when moving between light and dark spaces, and visual recovery can take up to 1 h. The eyes adapt more rapidly when moving between dark and light spaces, but immediate visual function can be impaired for a short while. Partial adaptation can occur if visual field contains adjacent dark and bright areas. This is why ergonomists do not recommend placing a VDU screen either facing or backing against a bright background, such as a window.

2.9.1. Aging on visual performance

With age, especially > 40 years of age, the lens loses flexibility and presbyopia occurs. The lens also becomes increasing opaque

with age, which reduces light transmission and can result in a cataract. Fluid filled compartments of the eye, the aqueous humor and vitreous humor, function to provide nutrients to the non-vascular structures within the eye and maintain the shape of the eye. With age, more light scattering occurs, especially at the shorter wavelengths. Retinal sensitivity decreases with age, especially at low luminance levels. Sensitivity to glare increase with age (Anshel 1990).

2.9.2. Lighting, computer work and eyestrain

Workers, especially computer users, may experience glare in their workplace. *Disability glare* is direct glare from a bright light source, such as bright sunlight through a window. *Discomfort glare* is indirect glare from uncomfortably bright reflections, such as ceiling light reflections in a computer screen. Screen reflections can be distracting, and cause visual discomfort and eyestrain. Surveys of computer users find that inadequate lighting is frequently reported, and eyestrain afflicts almost half of all workers. Field studies testing different lighting have found that computer workers report fewer complaints of eyestrain and eye focusing problems, greater satisfaction, and express strong preferences for lensed-indirect uplighting compared with parabolic lensed downlighting (Hedge *et al.* 1995).

2.10. Acoustic Environment

Sounds are an integral part of human communication for most people. Sound is the result of pressure changes in the air, and its intensity is measured in decibels (dB). A very quiet room would have a sound level at ~40 dB, conversations are mostly between 55 and 65 dB, and a jet taking off may emit sound > 130 dB. Sounds > 120 dB usually feel painful to the ears. Brief exposure to high intensity sounds can produce a transient impairment in hearing, called a temporary threshold shift. Prolonged exposure to loud noise can cause a permanent threshold shift and permanent hearing damage.

When sounds are intense, annoying or otherwise unwanted they become noise and that can adversely affect our performance and health. The noisiness of a sound often results from the subjective impression of how annoying it is. Noise can be unwanted sound that carries unpleasant information about the sound source (e.g. a crying baby), or it can be loud, annoying unwanted sound (e.g. a jackhammer outside one's window late at night). The ear is least sensitive to lower sound frequencies, and most sensitive to frequencies in the speech range, especially ~3 kHz. Lower frequency sounds generally are less annoying than higher frequency sounds of the same subjective loudness (Kryter 1985).

2.10.1. Occupational noise

Sources of occupational noise include the vibrations of structures, machines, or their components, and also aerodynamic turbulence (e.g. high-pressure air jet). Occupational noise exposure assessed by quantifying a permissible noise dose that is based on daily exposures. Permissible noise dose is regulated by OSHA (Sanders and McCormick 1993).

Industrial plants typically transmit noise to the external environment via certain sources or routes (e.g. open windows, roof ventilators, steam injectors, compressors, diesel engines).

Planning regulations have reduced the impact of noise generating industries on many residential areas. However, indoors in manufacturing industries 80% of noise levels > 80 dB and 20% > 95 dB. Exposure to noise this loud can cause hearing loss (i.e. physiological deterioration of hearing due to destruction of hair cells in the organ of Corti, and decreased number of associated nerve fibers). Exposure to uncontrollable and unpredictable noises can also have stressful aftereffects on behavior. Studies of occupational noise show that this is associated with annoyance, health problems, accidents and reduced efficiency of performance (Crocker 1997).

2.10.2. Speech privacy

In many modern open-plan offices worker performance is impaired by inadequate speech privacy and distracting noise from computers, telephones, printers, photocopiers, air conditioning and conversations. Speech privacy increases as the intelligibility of encroaching sounds decrease. Solutions to office noise problems include increasing the sound absorptance of room surfaces, especially the ceiling, and reducing source strength (e.g. choosing quieter equipment, encouraging workers to speak more quietly). Sound masking systems can also be effective because they add background "white" noise to the office that lowers the signal-to-noise ratio.

2.11. Electromagnetic Fields

Electric and magnetic fields (EMF) emanate from power lines and from office equipment, such as cathode ray tube computer screens and system units with power transformers. There are concerns about prolonged EMF exposures and health effects, such as nervous system cancers and leukemia. Research findings are conflicting. Most modern computer monitors are low-emission designs and with older computers EMF issues can be minimize by putting the computer monitor and system unit at arms length on a non-conductive surface.

2.12. Vibration and Motion

Oscillating motions can cause vibrations that can adversely affect the body and performance in several ways (Griffen 1997). Whole-body vibration occurs when the body is supported by an oscillating surface, such as a vibrating truck seat or a boat moving up and down on water. Very low frequency whole-body oscillations, usually < 1 Hz can cause *motion sickness*. Whole-body vibration also reduces efficiency for manual tasks such as tracking, typing or writing. Segmental vibration occurs when only a part of the body is in contact with an oscillating surface. Sometimes this is useful, for example, a vibrating pager silently signals a call. Often the segmental vibration is associated with hand-transmission from a tool, such as a chain saw, weed trimmer or jackhammer. In extreme cases hand-transmitted vibration can lead to a disease caused *vibration white finger*.

2.13. Gravity

Riding a roller coaster subjects the body to high rates of motion brief fluctuations in gravity. For some people this is a thrill, for others a fright, and for some a cause of motion sickness. These transient changes are magnified for people in other high-speed settings, for example, a pilot flying a high-G turn, an astronaut during lift-off. High-G situations affect the body in many ways,

increasing loads on the musculoskeletal system and modifying blood distribution, which sometimes causes symptoms ranging from elbow pain to loss of consciousness. At the other gravitational extreme our continued exploration of long-term effects of space requires knowledge about the effects of microgravity on the body and on performance (Albery and Woolford 1997).

3. CONCLUSIONS: WORK–ENVIRONMENT DESIGN — A PROCESS OF INTEGRATION

Environmental ergonomics is making an increasingly important contribution to improving the design of environments. Poorly designed workplaces can create many problems for occupants that affect their attitudes and motivation (e.g. satisfaction with work), their health and stress level, and reduce their efficiency. Well-designed work environments provide good ambient conditions that satisfy the physiological and personal requirements of workers. Environmental ergonomists typically use a systems approach to analyze the interactions between users, technology, the organization, and the ambient environment. They also work as members of a design team that includes other professionals, such as architects, interior designers, and engineers (ventilation, illumination, acoustics). In many respects environmental ergonomics is still in its infancy, yet as human influence spreads into remote and hazardous places on and beyond the earth, environmental ergonomics has an increasingly important role to play.

Flight Motion Effects on Human Performance

F. H. Previc

Flight Motion Effects Branch, Air Force Research Laboratory, Brooks Air Force Base, Texas, USA

1. INTRODUCTION

The aerial environment can be very dangerous and unforgiving to humans because of its abnormal accelerations, excessive motions and G-forces, and frequently distorted visual cues. Several "sensory" syndromes occur during flight are known to severely impact aircraft control and mission performance, the most prominent of these being spatial disorientation (SD) and motion sickness (MS). These syndromes and other physiological stressors such as high G-forces may compromise perceptual judgments (for example the perceived direction of gravity), cognitive skills (for example temporal estimation), motor function (for example inability to control or initiate eye or arm movements), and overall psychological functions (for example motivation). The remainder of this chapter will describe in greater detail the problems associated with SD and, to a lesser extent, MS and high G-forces. Finally, implications for human factors research and design of information displays in the aerial environment will be discussed.

2. FLIGHT MOTION SYNDROMES

2.1. Spatial Disorientation

A commonly accepted definition of SD is "an erroneous sense of one's position and motion relative to the plane of the earth's surface" (Gillingham 1992). This definition encompasses all erroneous perceptions of aircraft attitude (pitch and bank) and altitude above ground. In its mildest form, SD is almost universally experienced by pilots and other aircrew during their flight careers, but it can also lead to serious safety risks and even mishaps in its severe manifestations. For example, it is estimated that 30% of all fighter pilots have experienced at least one serious SD episode (Kuipers *et al.* 1990), with an actual SD mishap occurring once every 300,000 flying hours. During the 1980s, the United States Air Force suffered 81 Class A mishaps due to SD at an annual cost of over $100M (Gillingham 1992), while a similar percentage of mishaps (~15% of the total) was reported by the United States Navy during this period (Bellenkes, Bason and Yacavone 1992). Although the percentage of general aviation accidents attributable to SD is less than 5%, the percentage of fatal mishaps in this flying community is also estimated at about 15% (Kirkham *et al.* 1978).

Spatial disorientation is typically categorised into three major types: Type I (unrecognised), Type II (recognised), and Type III (incapacitating) (Gillingham 1992). Type I involves a situation in which the pilot feels the aircraft is properly oriented when it is not; information from the primary flight instrument displays that could contradict the pilot's erroneous percept may not be registered if he or she suffers from distraction, task-saturation, or merely negligence in his or her instrument cross-check. Type I SD contributes to over 50% of all SD mishaps, often in the form

of "controlled flight into terrain". Type II SD involves a recognized conflict between the pilot's "natural" orientational percept and his or her "synthetic" orientational percept derived from the instrument readings. The pilot does not always recognise that an SD episode is occurring is such an instance, but may instead attribute the discrepancy to instrument malfunction (which almost never is the case). In Type III SD, the pilot may recognise the SD episode but may be too incapacitated to make the appropriate control response due to vestibulo-ocular disorganisation (for example uncontrollable ocular nystagmus in a spin) or to an inability to establish voluntary motor control (for example the "giant hand" phenomenon). Although Types II and III are less likely to result in an actual SD mishap than is Type I, Type II SD is extremely common and even Type III SD has been reported in about 10–15% of fighter pilots.

The causes of SD are multifold and involve several sensory and perceptual systems as well as cognitive and motor factors. As will be discusssed later in this article, erroneous visual and vestibular inputs are the source of most SD illusions. Cognitive impairments, mainly in the form of loss of situation awareness, can precipitate an SD episode, whereas motor-control problems in the form of a conflict between the voluntary cortical (lateral) and primitive reflexive (ventromedial) motor systems can exacerbate an SD episode to the point of Type III.

2.1.1 Visual aspects of SD

Visual interactions in 3-D space

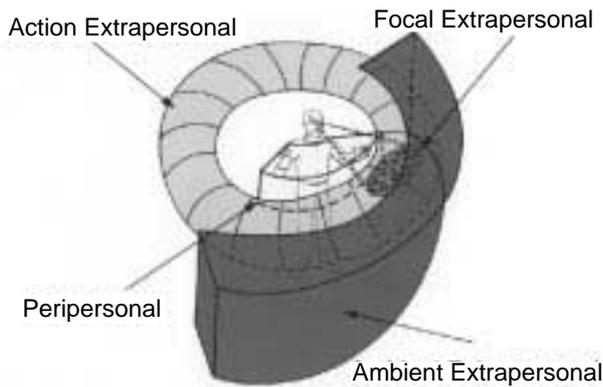
Various visual illusions and other aspects of SD have traditionally been interpreted using the distinction between focal and ambient vision (Gillingham and Previc 1993), but this dichotomy has recently been incorporated into a more general model of 3-D space that includes four major realms of visual processing (Previc 1998). The four realms, shown in Figure 1, are the 1. *peripersonal*, used for reaching and manipulation of objects, 2. *focal extrapersonal*, in which visual search and object recognition occur, 3. *action extrapersonal*, devoted mainly to navigation and orientation within topographically defined space, and 4. *ambient extrapersonal*, in which postural control and orientation within earth-fixed space occurs. The ambient extrapersonal system, which extends over the entire visual field and represents the most radially distant portion of our visual world, provides the framework that allows us to maintain our spatial orientation on earth preconsciously. Through a combination of perceptual, oculomotor, and postural mechanisms, ambient vision helps to maintain a stable, vertically oriented world despite the constant movement of the visual field during various types of self-motion. By contrast, the focal extrapersonal system maintains a high-resolution but attentionally demanding visual processing realm limited to the central 30° or so of the visual field. From the standpoint of SD, the fundamental visual problem is the loss or distortion during degraded visual conditions of the "natural" ambient visual reference frame with its wide field-of-view (FOV), which must be supplanted by a mental representation of the aircraft's orientation in space derived from aircraft instrument displays using spatially limited focal-extrapersonal vision. Such a "synthetic" orientational percept usually consumes considerable attentional resources and is frequently unable to achieve "visual dominance" over nonvisual (for example vestibular) orientational inputs.


Figure 1. The four regions of interactions in 3-D space: peripersonal, focal extrapersonal, action extrapersonal, and ambient extrapersonal. From Previc (1998, Fig. 3).

Visual SD illusions

The most prominent types of visual illusions are those derived from distorted or absent ambient vision, especially involving terrain or horizon information (Gillingham and Previc 1993). False horizons and/or surface planes can be especially dangerous, leading to illusions of pitch, bank, and altitude above ground. Some of the most dangerous ambient visual distortions in bank are sloping cloud decks (as when a moving weather-front expands the cloud deck on one side), sloping terrain, and tilted sky formations such as the Northern Lights. A well-known example of a false horizon in pitch occurs when flying over a shoreline at night, which recedes beneath the aircraft during level flight in the same manner as an actual horizon does while the aircraft pitches upward and can, therefore, lead to an illusion of pitching-up if the lights of the shoreline are misperceived as the horizon. The sloping walls of canyons, if sufficiently large, can also lead to a misperceived slope of the canyon floor and a misjudgment of terrain elevation. Finally, distorted illumination gradients can induce powerful inversion and other orientational illusions, if the normal tendency for the lighter regions of the visual field to be on top is violated; two of the best-known illumination illusions involve 1. flying over water at low sun-angles toward an incoming cloud-front that darkens the sky relative to the water, and 2. flying in clouds when the sun angle is low, which can severely tilt the ambient illumination gradient.

An absent ambient visual reference frame can also be very dangerous to pilots. In daylight conditions blowing sand and snow can create situations known as "brownout" and "whiteout" respectively. A sparse and irregular terrain can destroy the beneficial effects of many monocular depth cues such as texture gradients and perspectival splay in judging altitude and distance, especially in the case of foreground ridges obscured by direct sun angles. Night-time conditions can also destroy the ambient reference frame by blending ground lights and starlights or removing the horizon and terrain features altogether. This can lead to SD during aerial refueling, formation, deployment of flares, and many other situations containing only limited visual references that move independently of the horizon and ground planes. Night-time landings are especially difficult, giving rise to the "black-hole" illusion in which an isolated runway appears be more distant than it is, leading to a short approach on landing. The "black-hole" illusion is especially dangerous when combined

with a narrow or upsloping runway, upsloping terrain beyond the runway, or weather conditions such as rain or fog, all of which create the illusion of a runway being further away than is actually the case.

Generally, focal extrapersonal processing is used to help us orient only when ambient vision fails us, as in the above situations. However, sometimes focal-mode vision can dominate our orientational percepts even when an ambient reference frame is available, as in the case of "known size". Because of size-constancy mechanisms, ground features become smaller as our distance to them increases, but narrow runways or forests composed of atypically small trees can contradict this information.

2.1.2 Vestibular aspects of SD

Vestibular processing and its limitations

The vestibular system contains two major sets of organs: the six semicircular canals (one pair for each of three orthogonal planes of motion) and the four otolith organs (the utricle and saccule on each side). The cardinal principle of vestibular processing is that 1) the semicircular canals act as angular accelerometers in sensing, by means of the hair cells attached to a gelatinous structure known as the cupula, the inertial lag of the endolymph inside them as the head moves, and 2) the otolith organs, by virtue of the relatively dense calcium-carbonate crystals located on their membranes, respond to the shearing forces produced by linear acceleration or head movements relative to gravity. The vestibular system is a diffusely projecting system that is closely linked to the ambient extrapersonal visual system in its cortical projections; hence, it complements the earth-referenced ambient system in providing an gravitational frame for our perceptual-motor activity (Previc 1998).

The vestibular system is ideally designed to detect transient motions on earth, such as horizontal head movements and walking (which typically occur in a frequency range above 1 Hz). Unlike the ambient visual system, it is not designed to detect *sustained* head rotations or linear accelerations. For example, during an angular rotation lasting only a second or so (see left portion of Fig. 2), the canals effectively integrate the angular acceleration signal to accurately sense head-velocity in space; because the inertial lag of the endolymph dissipates after ~5–10 sec, however, the canals may signal a turning in the opposite direction if a slowing of a sustained constant-rate turn occurs (see right portion of Figure 2b). Similarly, the otoliths correctly sense the velocity of the head in space if the linear-acceleration signal is less than a second or two, whereas the movement of the otolithic membrane during a more sustained acceleration is interpreted as a shift of the head relative to gravity (which produces the same hair-cell shearing motion in the otoliths, as shown in Figure 3). The difficulties in interpreting vestibular inputs during the sustained angular and linear accelerations found in the aerial environment constitute the major source of vestibularly generated SD illusions in flight.

Vestibular SD illusions

There are two basic types of vestibular SD illusions: those caused by angular motion and those caused by linear motion (Gillingham and Previc 1993). In many situations, both angular and linear motion illusions are present, often in conjunction with visual SD illusions as well.

One of the historically most dangerous of the angular (or

Figure 2. The different response of the semicircular canals to a transient acceleration and deceleration (left panel) versus a sustained acceleration and deceleration (right panel). As shown at right, the output of the cupula (as well as the subject's perceived turning velocity) is underestimated after the first second or so of the constant-acceleration, increasing-velocity rotation (part a). No cupular response or perceived velocity occurs after the acceleratory stimulus ceases and the rotation attains a constant velocity (part b). The cupula responds to the deceleration in part c and the subject's perception is of rotating in the direction opposite to the original turn, although the actual rotation remains in the same direction as before but with decreasing velocity. From Gillingham and Previc (1993, Fig. 25).

"somatogyral") illusions is the "graveyard spin", whose underlying mechanism is the inability of the canals to relay correct velocity information during a sustained turn. For example, a pilot may attempt to use his right rudder in recovering from a prolonged left flat spin, but even though this effort may successfully stop the spin momentarily it gives rise to a perceived spin to the right because the horizontal canals now sense the rightward deceleration. Another angular illusion is the Coriolis or "cross-coupled" illusion, in which a head movement during a continuous turn stops the motion in a canal that is no longer in the plane of motion and produces an illusion of motion in an orthogonal plane (for example a 90-deg pitch of the head while yawing can lead to a rolling percept because the horizontal canals, now in the roll plane, receive a deceleratory stimulus once they are removed from the plane of yaw motion. The angular SD illusions still contribute to a large number of mishaps in general aviation, but they are considered less of a danger in modern high-performance military aircraft because of the generally smaller turning rates in these aircraft.

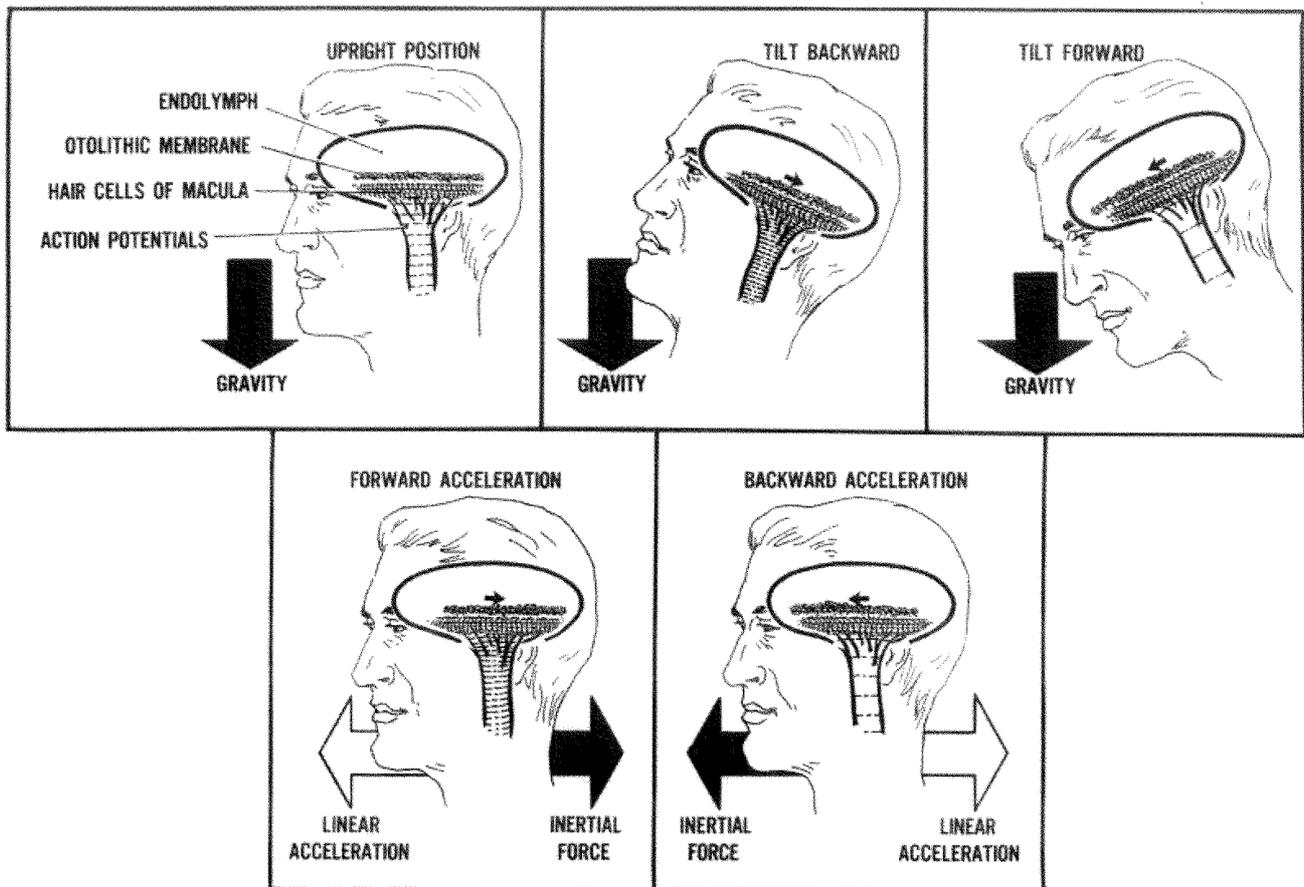
The most prominent linear SD illusions are caused by 1. a deviation of the resultant gravitoinertial force vector away from the true vertical or 2. a change in the magnitude of the gravitoinertial force vector. These changes can be produced by sustained accelerations (as during takeoff) or by centrifugal forces that emanate from the inside of turns or level-offs. One of the most dangerous linear SD illusions is the "somatogravic" illusion, which gives rise to a pitch-up illusion during sustained forward acceleration at takeoff and a pitch-down illusion during deceleration on approach (see Figure 3). If a pilot is climbing during the former situation, a lowering of the nose of the aircraft may create a level-off whose centrifugal force is directed through the bottom of the aircraft and leads to a feeling of inversion. The "graveyard spiral" is another dangerous SD illusion caused by a resultant gravitoinertial force that deviates substantially from the gravitational vertical. This illusion, which is manifested in an erroneous perception of being level while banked in a sustained turn, is caused by two main factors: 1. a failure to sense a continued turning after being in a coordinated turn for several seconds, as occurs during several types of maneuvers; and 2. the imposition upon the force of gravity of a centrifugal force emanating from the inside of the turn, which leads to a resultant gravitoinertial vector that is directed through the top of the aircraft. As the pilot rolls out of the turn to level flight, a misperception of banking in the opposite direction (an example of the "leans") will occur. If the pilot follows his or her "natural" orientational percept rather than that indicated by the cockpit instruments, then an unintended return to the original bank may ensue. Finally, a head movement in an excessive-G environment can result in


Figure 3. The ambiguity between the otolithic response to a sustained linear acceleration (top part) and a head tilt relative to gravity (bottom panels). From Gillingham and Previc (1993, Fig. 11).

an illusion of aircraft motion in pitch or roll, because greater shearing motion of the otolithic membrane occurs at higher G-levels for the same angle of actual head tilt. This "G-excess" illusion is believed to especially dangerous when a pilot looks upward from the inside of a turn, because the excessive otolithic shearing may be interpreted as a rolling out of the bank by the aircraft; hence, the pilot may inadvertently overbank the aircraft to maintain the coordinated turn percept.

Although a good ambient visual reference such as the horizon can usually overcome illusions caused by erroneous vestibular and other nonvisual orientational percepts, this may be less true of more impoversihed visual stimuli that are perceived as lying with the frame of motion of the aicraft. Under the latter conditions, the visual world may tend to move in concert with the vestibular SD illusions (as in the "oculogyral" and "oculogravic" illusions) rather than break them.

2.2. Motion Sickness

Motion sickness refers to a general autonomic syndrome produced by certain types of motions or conflicts between different sensory inputs during simulated or actual motion. The most prominent symptoms of MS are pallor, cold sweating, nausea, and vomiting, but a host of other cardiovascular, gastrointestinal, respiratory, thermal, ocular, and mental (for example drowsiness) symptoms are all associated with this syndrome (Money 1970). Both parasympathetic and sympathetic activity are altered in MS, although the most dramatic manifestation of MS—vomiting—is

believed to be mainly a parasympathetic response. A combination of drugs that block parasympathetic activity (for example scopolamine) or increase sympathetic (for example amphetamine) activity appears to be the most successful method of preventing MS (Money 1970).

The etiology of MS is not entirely understood, but evidence from a number of sources suggest that certain types or combinations of motion are extremely provocative, as are certain types of sensory conflicts. The types of motion that appear to be most likely to lead to MS include low-frequency vertical oscillations and cross-coupled (Coriolis) angular motions created by head movements in a rotating vehicle. Exposure to 0-G environments also generally leads to MS, as in the space adaptation syndrome experienced by about 75% of astronauts; head movements relative to gravity (for example pitch and roll movements) appear to be the most provocative stimulus for such "space sickness". The role of sensory conflict in MS is well-documented while wearing prismatic lenses that distort or invert the visual scene; a similar mechanism may underlie what has been termed "simulator sickness", which is experienced while flying wide-FOV simulators whose actual motion (or lack thereof) does not always match that expected from the motion of the visual scene. Although the relationships of the various types of MS to each other are not entirely clear, it has been confirmed that an intact vestibular system is necessary to experience MS—i.e., persons with deficient labyrinths are not susceptible to any form of MS (Money, 1970). Even when distorted or asynchronous wide-FOV visual inputs

contribute to MS, the conflicts they engender may ultimately rely on interactions occurring at the level of the vestibular nuclei or the vestibularly responsive portion of the cerebellum (Henn, Young and Finley 1974), especially given that distorted visual inputs do not create MS in labyrinth-defective subjects (Money 1970).

Motion sickness is not considered a serious problem in commercial aviation, as the incidence of "airsickness" among commercial airline passengers is only about 0.5%. The incidence of MS among military pilots is much greater, presumably due to the more stressful motions encountered in military aviation. About 10–15% of military pilots suffer from MS during the early stages of training, but only 1% of all pilots are ultimately eliminated because of a failure to adapt to MS (Money 1970). However, even in those cases where frank MS is no longer a problem, more subtle signs of MS such as drowsiness may be manifested at times.

2.3. High–G Stress

Although high G-stress exerts its most profound effects on human performance by diminishing the oxygen supply to the brain and restricting the motions of skeletal motor systems with large inertial masses such as the head and limbs (see Albery, this volume), there are also specific visual and vestibular effects that can affect performance. For example, retinal vascular insufficiency can result in shrinkage of the peripheral visual field and changes in color perception, while vestibular effects include abnormal vestibulo-ocular reflexes (for example upbeating nystagmus) and the previously described G-excess SD illusion. The precise consequences of these G-related visual and vestibular effects are not known, although it can be assumed that they pose a much more serious problem for pilots of high-performance aircraft than for general and commercial aviation pilots.

3. IMPLICATIONS FOR HUMAN FACTORS

The sensory problems created by the abnormal acceleratory environment of flight can, if not properly understood and combated, seriously degrade pilot performance. The best defense against such threats are effective information displays that are vigilantly monitored by pilots who are highly trained in instrument procedures. However, human factors engineers must design displays, switches, and other human-interface elements for worst-case scenarios, rather than ideal ones. They must take into account the fact that, while disoriented or in some other form of visual–vestibular conflict, pilots may suffer from a disorganised cognitive state in which attention resources are reduced, temporal perception is distorted, voluntary motor

commands are difficult to execute, etc. Whereas, for example, recovery from an unusual attitude in a laboratory may require approximately 1 s on average, pilots during actual flight may require up to 5-10 s to clearly determine the attitude of their aircraft using their HUD or other current display. Even highly overtrained responses may fail to be executed under such circumstances, as the pilot may behave more like a novice than an experienced aviator. It is, therefore, important to present primary flight and other control information in a highly effective and intuitive manner, consistent with how the brain naturally processes such information (Previc in press). Greater use should be made of nonvisual (for example tactile and auditory) sensory systems and motor systems that are less affected by G-forces and visual–vestibular conflict (for example the fingers).

It is ultimately through improved design of aircraft control stations that the consequences of SD and related "sensory"-induced flight syndromes can be most effectively counteracted.

1. INTRODUCTION

After almost 100 years of service, commercial air travel can look back with some satisfaction on an excellent safety record. Nonetheless, rapid growth in air traffic is threatening the ability of air traffic control (ATC) systems worldwide to handle traffic efficiently and safely. Moreover, even if the airline accident rate remains at its current low value, it is estimated that on average one major commercial airline accident will occur somewhere in the world *every week* simply because of the increased volume of traffic. The recent call for a fivefold improvement in safety by the Gore Commission in the US was clearly motivated by the need to avoid the public outcry that would result from such an outcome.

1.1. What is Free Flight?

To meet this challenge, several proposals to change the ATC system have been put forward. In the US there has been much interest in free flight (FF), which has been promoted by the Radio and Technical Commission for Aeronautics (RTCA) advisory group. FF represents a radical departure from the current method of controlling air traffic, which is based on radar surveillance and ground control of aircraft movements along well-specified paths in the sky. Under FF, aircraft could fly preferred routes and have greater flexibility in maneuvering, including "self separation" from other aircraft. As stated by the RTCA in 1995, the goal of FF is to allow aircraft under instrument flight rules (IFR) the ability to choose, in real time, optimum routes, speeds, and altitudes, in a manner similar to the flexibility now given only to aircraft operating under visual flight rules (VFR). In theory, FF will result in the utilization of more fuel-efficient routes and a reduction in the delays imposed by ATC. To achieve this goal, traditional strategic (i.e. flight-path based) separation will be replaced by tactical separation based on flight position and speed. The responsibility for separation will gradually shift from the current ground-based system to a more co-operative mix between the air and ground.

An alternative approach to FF is to extend the current system of ground-based ATC. Responsibility for separation would remain firmly on the ground, but there would be greater use of automation to support air traffic controllers (ATCos) in the management of an increasingly dense airspace (Wickens *et al.* 1998).

The US Federal Aviation Administration (FAA) Free flight Phase I Plan includes elements of both these proposals. Current views of FF are less ambitious than those initially proposed by the RTCA in 1995, and do not include removal of separation authority from ATCos. Moreover, European proposals for future ATC differ from those in the US, but also include some elements of FF.

1.2. Human Factors in Free Flight

Developing future ATC systems that allow for increased capacity while improving safety levels will pose considerable technical and human factors challenges. For convenience we divide the human factors issues in FF into three categories: (1) air (pilots); (2) ground (controllers and dispatchers); and (3) air—ground (pilot—controller—dispatcher communications, and collaborative decision-making). It should be noted, however, that all three are highly interrelated. In a systems view they should be considered simultaneously, along with the automated systems and technologies (such as the Global Positioning System (GPS) and Automatic Dependent Surveillance-Broadcast (ADS-B)) that will support FF.

2. AIRCRAFT AND PILOT FACTORS

According to a vision of mature FF as espoused by the RTCA, aircraft would generally be free to fly user-preferred routes, modify their trajectories en route, and self-separate with minimal intervention by ATC. By shifting much of the responsibility for these tasks to the flight deck, it is thought that airlines can derive significant economic benefits through increased use of direct routes. FF could also lead to a dramatic increase in airspace capacity, especially over oceanic areas in which only a limited number of flight tracks are currently available.

Although the advent of FF assumes certain enabling technologies, it would represent as much an operational (or procedural), as a technological, evolution. From a human factors perspective, there are many critical flight-deck issues that must be addressed. Two are briefly addressed here:

- Will pilot workload be increased with the use of a cockpit display of traffic information (CDTI)?
- Will pilots be able to use CDTI and other systems to achieve self-separation from other aircraft safely and efficiently?

2.1. Cockpit Display of Traffic Information (CDTI)

Work is beginning on examining these issues in a systematic manner. The most research has been done on CDTI display design, because the concept of presenting traffic information in the cockpit is an old one that was extensively examined by NASA during the 1980s. A primary area of concern is whether a CDTI will negatively impact pilot visual workload, by increasing heads-down time in the cockpit. The early studies established the feasibility of the CDTI concept, but also found some evidence for an increase in pilot workload associated with use of the CDTI. More recent studies have shown that when predictive information is added to the CDTI display (e.g. a threat vector indicating the approach of an intruder aircraft), pilot workload is reduced, although the heads-down problem remains (Morphew and Wickens 1998).

2.2. Airborne Self-separation

Can pilots use CDTI and other cockpit systems to maintain self-separation from other aircraft, with minimal ATC intervention? This is an ultimate goal of FF, and a recent study indicates that it is feasible, at least in a simulated environment (Van Gent *et al.* 1998). These investigators modified an algorithm developed at the MIT Lincoln Laboratory for airborne conflict resolution that would not involve any communication between pilots. The algorithm assumes that aircraft and the destinations to which they fly to can be modeled as positive and negative electrical

charges, respectively. Simplistically speaking, aircraft therefore "repel" one another and are attracted to their destination. Combining these forces creates an avoidance vector for maintaining minimum separation standards (e.g. 5 nm and 1000 ft) between two aircraft. Van Gent *et al.* (1998) tested eight flight crews in an advanced cockpit simulator under varying levels of traffic density. The highest level of traffic represented three times the current normal density of traffic in Europe. All eight crews flew successfully, with no separation losses, and participants rated the system quite favorably. Van Gent *et al.* (1998) concluded that a FF concept of automated airborne separation with no ATC involvement "could not be refuted."

2.3. Other Airborne Human Factors Issues

Several other human factors issues need additional work or are still to be addressed. These include:

- How to display a complex four-dimensional problem when a conflict is predicted?
- How much of the conflict detection and resolution process can be automated?
- How to present a resolution advisory: as a flight plan change or as a more short-term solution such as a heading or altitude change?
- Will the required cooperative behavior still occur in a competitive situation, or will competing airlines abuse the system for economic gains?
- How robust and safe can such a human–machine system be?

3. GROUND FACTORS: AIR TRAFFIC CONTROLLERS AND DISPATCHERS UNDER FREE FLIGHT

The work described so far suggests that pilots could use CDTI to maneuver to avoid conflicts with other aircraft, particularly if predictive information is provided. Airborne self-separation has also been shown to be feasible in simulation studies. Before FF can be implemented safely, many other human factors problems on the airborne side will have to be resolved. However, their resolution alone will not be sufficient: ground and air–ground issues will also have to be addressed.

What are the most important ground issues? To begin with, note that the ground side includes not only ATCos but also airline dispatchers. The role of dispatchers will expand dramatically under FF (Smith *et al.* 1997). Currently, airline dispatchers possess the best information on global weather patterns that can be passed on to pilots seeking to fly fuel-efficient routes. How will competition between airlines impact the role of dispatchers under FF? Will the best route suggested by the dispatcher for one airline also be selected by other airlines? This might lead to congestion and delay, and possible cancellation of FF by controllers due to impending loss of separation, thereby negating any potential benefits of FF. Recent studies of the National Route Program (NRP) suggest that this might occur. The NRP allows aircraft to file direct routes above specified altitudes and at certain distances from major airports. The idea of the program is to lessen cruise flight time en route between airports. However, a study by Smith *et al.* (1997) revealed that many aircraft participating in the NRP requested the same routing, creating heavy traffic on a single preferred route that resulted in delays and in some cases re-routing

back to the original non-preferred route. Such unanticipated effects may also occur under FF and may not be predictable prior to operational tests.

How will FF impact the ATCo? First, it must be recognized that an advanced FF system that implemented airborne self-separation would nevertheless require ATCo intervention under four general cases identified by the RTCA: (1) to ensure separation, (2) to preclude exceeding airport capacity, (3) to prohibit unauthorized flight through special use airspace, and (4) to ensure safety. Two of these exceptions specifically involve cases in which the ATCo may be called upon to resolve a conflict (e.g. if there is an outage in a GPS satellite, or a failure in the conflict detection system). The question thus arises, can the ATCo "step in" and do this effectively if he or she has ceded all or some separation responsibility to the air side?

3.1. The Changed Role of the Controller

FF, if implemented to its fullest extent, will dramatically change the role of the controller. Strategic air traffic management will change to tactical control, and active management to management by exception. The airspace will become relatively less structured, thereby introducing a degree of uncertainty. Responsibility for separation and maneuvering, now firmly under ground control, will move to the air, and surveillance will be shared between the air and the ground. Finally, under advanced FF, the controller will become more of a passive monitor of the airspace rather than an active participant in control.

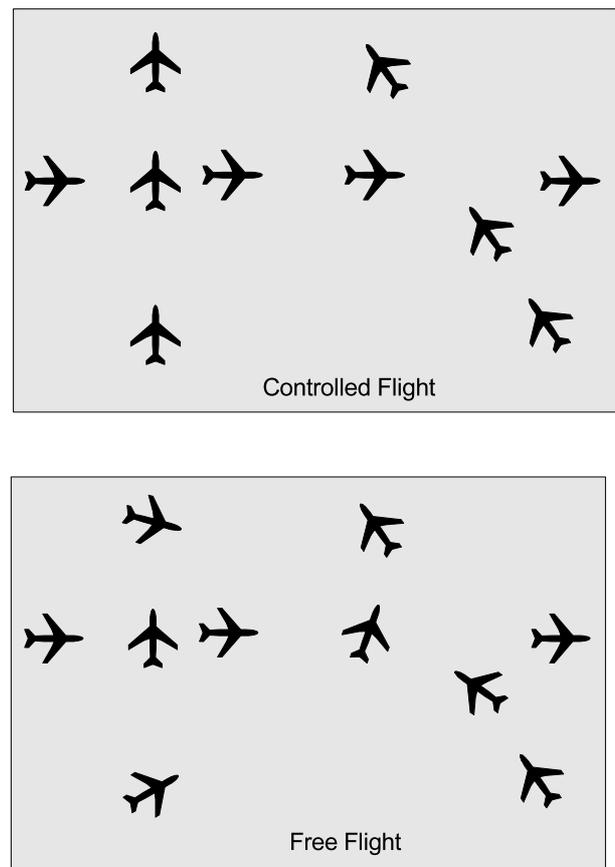

Figure 1. Representation of aircraft movements under controlled flight (top) and free flight (bottom). Potential conflicts are more difficult to predict under FF.

To understand how profoundly the change to FF could influence controller workload and monitoring, consider the simple diagram of figure 1, which depicts the principles of controlled flight and FF in the en-route phase. The diagrams are identical, except that the angle of four of the ten aircraft has been changed under FF. Notice how much more difficult this makes the task of anticipating traffic conflicts. Under controlled flight (top), there are a limited number of areas at which conflicts are likely to occur. Indeed, the historical reasons behind the current-day fixed route structure have to do more with human limitations than with technical or procedural concerns. Under FF (bottom), on the other hand, assuring separation of the same number of aircraft is now a daunting task for the controller.

3.2. Monitoring, Situation Awareness, and Failure Recovery

While relinquishing active responsibility for separation, the ATCo will become more of a monitor as FF moves towards a mature level. A recent report by a National Research Council panel on future ATC raised some concerns regarding this development (Wickens *et al.* 1998). One concern is how effective a controller can be in a purely monitoring role. Human monitoring of automated systems can be poor, especially if the operator has little active control over the automated process and is engaged in other tasks (Parasuraman and Riley 1997).

Recent simulator studies have examined how FF may influence controller performance, situation awareness, and workload (Endsley, *et al.* 1997; Hilburn *et al.* 1997). The studies disagree on the effect of FF on controller workload, with one finding an increase and the other a decrease. The discrepancy may be related to the use of civilian ATCos in one study and military ATCos in the other (cf. Hilburn and Parasuraman 1997), as well as other methodological differences. However, there is agreement that in FF conditions in which the controller is given no information about the aircraft's intent, controller workload is increased. Thus, the provision of intent information will likely be a key issue in FF implementation.

These studies suggest some caution in implementing high levels of FF in which authority for separation is increasingly given to the air side. In the ultimate extension of this trend, *all* authority is ceded to the aircraft. This is the so-called *mature* stage of FF. Such a stage will have been reached when the technologies and procedures are in place for full aircraft self-separation, with ATC in a monitoring role. The end result will be an airspace that is considerably more dense and complex than it is today. As noted previously, Van Gent *et al.* (1998) found that pilots could self separate without ATC involvement in traffic with three times current density in Europe. Will the controller of the future still be able to monitor such a saturated airspace and intervene effectively if, for example, the pilots cannot resolve a conflict, there is a GPS outage, bad weather encroaches into the FF airspace, or there is some other system failure? To examine this issue, a recent study investigated how well controllers could detect conflicts and aircraft self-separating events when all separation decision-making authority was removed from them, as it would be under advanced FF (Galster, *et al.* 1999). Controllers missed a very high proportion of the conflicts, especially under high traffic. Self-separating events went unreported even more

frequently. When conflicts and self-separations *were* identified, they were reported at very short times prior to their occurrence.

These studies suggest that although FF may or not increase ATCo workload, situation awareness and monitoring performance may be adversely affected. This might make ATCo-based recovery from failure in a timely manner nearly impossible (Wickens *et al.* 1998). Requiring ATCos to "step in" to assure separation might therefore put them in a very difficult position. Furthermore, if controllers are to be held legally liable in such a situation, they may legitimately demand a greater controlling role than envisaged by FF advocates to be commensurate with this responsibility.

4. AIR–GROUND COMMUNICATION AND INTEGRATION

Both pilots and controllers will be affected by the technological and procedural changes brought by FF. In addition, as mentioned earlier, airline dispatchers represent another group of agents involved in the airspace system whose role will be changed by FF (Smith *et al.* 1997). Over and above the domain-specific human factors issues that arise for pilots in the cockpit and for controllers and dispatchers on the ground, effective air–ground communication and integration will be necessary for FF to be implemented safely. In commenting on the change from the current system of centralized control and clear-cut division of responsibilities to a distributed system under FF with sharing of responsibilities, Smith *et al.* (1997) have questioned whether effective cooperative decision-making is possible when the different agents have different information sources and differing local goals.

Cockpit studies of FF have focused on pilots' use of CDTI for navigation and for self separation. Ground ATC studies of FF have examined the effects of different FF scenarios on controllers' ability to monitor the airspace and to resolve conflicts if called upon to do so. Since all versions of FF envision a role for controllers (though that role will be different), it would therefore be appropriate to include both pilots and controllers in a single study of FF. This was done in a recent study in which a flight crew flew a 747-400 simulator in a FF airspace that was also monitored by air traffic controllers (Mackintosh *et al.* 1998). As in the study by Van Gent *et al.* (1998), pilots were able to use CDTI to detect and resolve conflicts with intruder aircraft. Under such self-separation conditions, there was greater air–ground communication, usually by pilots informing controllers of the maneuvers they had taken. However, there was a much greater rate of air–air communication between pilots, which has consequences for such issues as pilot workload and frequency congestion.

5. DISCUSSION AND CONCLUSIONS

Human factors studies of FF have just begun. There are several system-level issues that must also be addressed, in addition to the more local human factors problems that we have discussed. These include reconciling the different and sometimes competing goals (e.g. vis-à-vis efficiency and safety) of airlines, dispatchers, pilots, controllers, and regulatory agencies. Predicting the implications of various FF concepts for safety and efficiency also raises significant challenges. Moreover, several research methodologies may need to be used to evaluate the safety impact of FF, in addition to the traditional human factors methods

(Wickens *et al.* 1998). Among these are large-scale simulations and modeling studies that make valid assumptions about the human agents involved in the airspace system; and extensive human-in-the-loop studies of the type that have already been conducted, but with the participation of *all* human and machine agents that would play a role in FF. Such studies may be beyond the capability of any one group or research center, thus necessitating cooperative projects between centers. They may be also quite expensive and time-consuming to conduct, but if the goal of *increased* safety (rather than level safety) is to be reached, the funds for such evaluation efforts should be procured, even as much larger sums of money are being devoted to develop the technologies needed for FF.

Human factors studies of FF are also of broader interest from the perspective of human–automation interaction in complex systems. This is because FF will require the development of several automation tools to aid both pilots and controllers (Parasuraman, Duley, and Smoker 1998). Over the past decade, human factors researchers have documented in some detail the system and human performance benefits as well as costs associated with certain forms of automation (Parasuraman and Riley 1997). Some of these automation tools will be designed to have relatively high levels of autonomy, which will raise significant issues of whether and how humans and "intelligent" agents can share decision-making responsibility in a distributed system (Smith *et al.* 1997).

Another reason why the study of FF should be of broad interest to human factors and ergonomics is that FF represents an emerging set of technologies and procedural changes that has not yet been fully implemented. There is recognition of the need for human factors evaluations of the concept and for such evaluations to continue through the stage of design, operational deployment, and field experience (Wickens *et al.* 1998). Human factors is often a reactive discipline, being considered well after the design of a system is fixed and at a time when only minor changes can be made. In the case of FF, there is some hope that human factors can play a more proactive role by providing results that can be easily translated into design guidelines. Whether this promise is realized, however, will depend not only upon the quality of the human factors input that is provided to the designers, manufacturers, and regulatory agencies, but also on political and economic factors that may fall outside the influence of the discipline

Human Exposure to Vibration

D. E. Wasserman

Human Vibration & Biomedical Engineering Consultant, Cincinnati, OH 45242, USA

1. INTRODUCTION

Worldwide there are millions of people who go to work each day who are exposed to mechanically induced vibration. These include truck, bus, heavy equipment, fork lift, farm vehicle operators, train engineers and conductors, miners, helicopter and fixed-wing aircraft, ship personnel and fixed plant sites. These people are exposed to head-to-toe whole-body vibration (WBV). Users of hand-held power tools such as chain saws, various electrical and air-driven pneumatic tools such as chippers, grinders, sanders, mining tools, drills, road rippers, etc. are exposed to segmental or hand–arm vibration (HAV).

2. VIBRATORY MOTION

Mechanical vibration can be oscillatory, impact or random and each is characterized as a vector quantity and thus consists of both an intensity or magnitude and a direction. Vibration measured at any one point consists of six vectors: three linear mutually perpendicular vectors and three rotational vectors called pitch, yaw and roll. Generally in human vibration work only linear measurements are obtained. Root-mean squared (RMS) acceleration is usually the intensity measurement quantity of choice and is expressed in either $m\ s^{-1}\ s^{-1}$ or gravitational g's, where $1\ g = 9.81\ m\ s^{-1}\ s^{-1}$. There are specific vibration frequencies (Hz) where WBV is measured (1–80 Hz) and where HAV is measured (5–1500 Hz). Finally, there is a undesirable phenomenon known as resonance or natural frequency where humans are optimally tuned to impinging vibration resulting in involuntary amplification and exacerbation its effects at these resonant frequencies; WBV resonance occurs at 4–8 Hz for vertical and 1–2 Hz for the side-to-side or front-to-back directions. For HAV resonance is thought to occur at 100–250 Hz (Wasserman 1987).

3. HUMAN EFFECTS OF VIBRATION EXPOSURE

The major human effects generally can be subdivided by either WBV or HAV exposure.

3.1. Major WBV Effects

At WBV frequencies < 1 Hz, sea sickness or kinetosis can occur which usually ceases when exposure stops. At frequencies > 1 Hz both acute and chronic WBV effects can occur. Generally, if acute exposure occurs at the 4–8 Hz resonance band there can be a potential safety issue, because, for example, a vehicle operator might not be able safely to control the steering wheel; there also can be discomfort due to WBV exposure (Griffin 1990).

The major medical effects of chronic WBV exposure are principally, but not limited to: (1) severe low back pain; (2) lumbar spine disc :degeneration, loss of moisture, buckling, slipping/prolapse, herniation, tearing, distortion, excessive pressure (Dupuis and Zerlett 1986, Wilder *et al*. 1994); and (3) spon-taneous abortions and related gynecological problems have been reported in female vehicle drivers chronically exposed to WBV (Abrams 1990).

3.2. Major HAV Effects

Chronic HAV exposure has been causally linked for > 80 years to a generally irreversible condition of the fingers and hands known as Hand–Arm Vibration Syndrome (HAVS); previously called Vibration White Fingers, and Raynaud's Phenomenon of Occupational Origin. HAVS (Pelmear and Wasserman 1998) is initially characterized by attacks of paresthesia (tingling and/or numbness in the fingers and hands). As HAV exposure continues, finger blanching attacks in one or more fingers, lasting 5–15 min, occur particularly in the presence of cold. With continued HAV exposure, this condition is cumulative and progressive, involving multiple fingers; in its terminal stage (rarely seen) gangrene of the fingers can occur requiring digit amputation. Medical treatment involves the use of so-called "calcium channel blocker" medications which are not curative, but are palliative (i.e. easing pain and suffering without curing). Thus both early detection of HAVS and the cessation of HAV exposure are essential for these hand power tool operators.

Typically HAVS prevalences as high as 50% have been found in pneumatic vibrating hand-tool workers in the USA. Finally, it is important to note that a physician's early and careful differential diagnosis is essential to distinguish HAVS from other similar conditions such as idiopathic Primary Raynaud's Disease and (non-vibration) Carpal Tunnel Syndrome.

4. VIBRATION HEALTH AND SAFETY STANDARDS

Numerous nations worldwide have participated in the development of consensus health and safety standards/guides in an effort to protect workers against the hazards of both WBV and HAV exposure. Initial standards efforts were begun by the International Standards Organization (ISO) in the late 1960s and continue to this day in cooperation with national standards setting organizations such as the American National Standards Institute in New York, British Standards Institute in London, and others including the European Union.

Examples of WBV standards/guides include ISO 2631, ANSI S3.18, BSI 6841. Examples of HAV standards/guides include ISO 5349, ANSI S3.34, BSI 6842. Worldwide virtually all WBV standards employ the same measurement coordinate system; the same is true for HAV standards. This permits easy comparison of vibration data made by various groups.

5. CONTROLLING VIBRATION EXPOSURE

The major engineering methods of vibration reduction include isolation (the intentional alteration of the pathway between the vibration source and the human receiver) and damping (vibration impinging upon a viscoelastic material, causes the material to deform thus converting mechanical energy into a small amount of heat).

5.1. Reducing WBV Exposure

Air-ride seats are commonly used in trucks, buses, farm and construction equipment, ships, fixed plants, etc. to isolate the operator's upper torso/spine from WBV, especially in the 4–8 Hz region. Also in use are isolated truck cabs and special vehi-

cle suspensions. In fixed plant locations, isolating machinery and the remote placing of controls all help to reduce WBV exposure. Administrative controls including regular rest breaks and not lifting cargo immediately after emerging from driving a vehicle.

5.2. Reducing HAV Exposure

First, workers are advised to use tools that are both anti-vibration (A/V) designed and ergonomically designed since an ergonomically designed tool may only represent the optimum interface between the worker and the tool (i.e. handle design, weight, etc.) but these tools do not necessarily have reduced vibration characteristics within the tool *per se*.

Second, do not as a rule use "tool wraps" that use a wade of vibration damping material merely wrapped around a conventional tool handle, because of both the increased handle diameter of the handle and the limited ability of the wrap to damp HAV from certain tools.

Third, use only full-finger, good fitting, A/V gloves that reduce vibration and keep the fingers and hands warm and dry. Do not use "exposed fingers" gloves that only protect the palm since HAVS nearly always begins at the fingertips.

Fourth, good work practices include: keeping the entire body warm and dry especially the hands; no smoking while using vibrating hand-tools since nicotine, cold and vibration all constrict blood flow. Let the tool do the work grasping it as lightly as possible consistent with safe work practices. If signs and symptoms of HAVS appear see a physician immediately. Keep the tool and implements in good working order; replace worn-out tools promptly.

Human Aspects of Lighting in Working Interiors

A. Wolska

Safety Engineering Department, Central Institute for Labour Protection,
ul. Czerniakowska 16, 00-701 Warsaw, Poland

1. INTRODUCTION

Lighting is one of the main environmental factors in the work area. Over 80% of information on the work stands is collected (received) by the eyes. We used to talk about lighting the workplace, but in fact we should talking about lighting for the people in the workplace. This is why, lighting design should provide an environment in which people, through the sense of vision, can function safety, effectively and comfortably (Rea 1993). Lighting of an interior should fulfil three functions (ISO 8995, 1989, prEN 12464 1996):

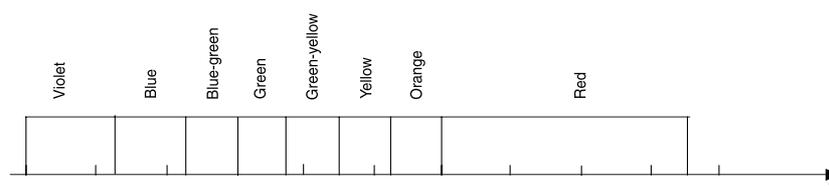
- Ensure maximum safety (making any hazards visible).
- Maintain an appropriate level of visual performance (workers should be able to perform their visual tasks, even under difficult circumstances and during extended periods).
- Provide acceptable visual comfort (interior appearance and good frame of mind).

Safety should be ensured in all circumstances but different emphasis is given to visual performance and the appearance of the interior depending on the nature of the interior. For example, lighting for a tool room in a factory should put much more emphasis on lighting the task than on visual comfort and on the pleasant appearance of the room, but in a restaurant or a hotel room the priorities should be reversed. In all cases, energy consumption and cost effectiveness of a lighting system should be considered.

Lighting of an interior by daylight and by electric lighting should provide optimum conditions for performing a task and an appropriate environment.

2. LIGHTING TERMINOLOGY (PARAMETERS)

2.1. Light (visible radiation)

The Illuminating Engineering Society of North America (IESNA) has defined as radiant energy that is capable of exciting the human retina and creating a visual sensation (Rea 1993). Light is visible radiation. The visible range (spectrum) is between 380 and 760 mm on the electromagnetic spectrum (some sources quote slightly different ranges like 380–780 or 380–770 mm). The visible spectrum can be divided into eight subranges, which correspond to the relevant color of light: violet, blue, blue-green, green, yellow-green, yellow, orange and red (Figure 1).


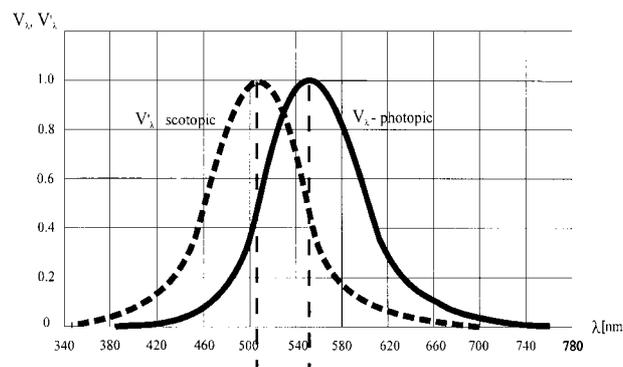


Figure 2. Luminous efficiency curves for photopic and scotopic vision

2.2. Spectral Luminous Efficiency Curves

Physical quantities describing the radiation (like radiant flux, irradiance, radiant intensity) are not sufficient to define (designate) efficiency of radiation to create a visual sensation. Sensitivity of human eye is different for particular wavelengths of visible radiation. It means that eye is more sensitive to some wavelengths than others. There are individual variations, and not everyone has the same sensitivity. In 1924 International Commission on Illumination (CIE) adopted and agreed on a standard response called the CIE standard observer and established luminous efficiency curves for photopic and scotopic vision (North 1993). As seen in Figure 2 the photopic function V_λ describes the spectral luminous efficiency function for photopic (cone) vision with maximum sensitivity at 555 nm (green-yellow) and scotopic function V describes the spectral luminous efficiency function for scotopic (rod) vision with maximum sensitivity at 507 nm (blue-green).

2.3. Photometric Quantities and Units

Photometric units (quantities) are the physical quantities, which are assessed on the basis of the visual sensation they create.

Luminous flux – Φ (unit 1m, lumen) – quantity of light emitted from a light source per time unit. The lumen is a unit relating radiant flux (in watts, W) visually to effective light for a CIE standard observer.

Luminous intensity – I (unit cd, candela) – angular density of the luminous flux in a given direction. It is luminous flux emitted in a very narrow (unit) solid angle containing the given direction. One candela is equal to one lumen per steradian (1 cd = 1 lmsr^{-1}).

Illuminance – E (unit lx, lux) – area density of a luminous flux incident at a point on a surface (luminous flux per unit area - lx = 1 mm^{-2}).

Figure 1. Subranges of visible radiation

Luminance – L (unit cdm^{-2}, candelas per m^2) – physical measure of brightness. It represents the luminous intensity emitted (or reflected) in a given direction per projected area of a luminous (or reflecting) surface.

Contrast – C, luminance difference of two objects, surfaces or parts of the objects in the visual field, which are adjacent to each other (viewed simultaneously) or observed one after the other (successively). Contrast is defined in several ways:

Luminance ratio – ratio between the luminances of any two areas in the visual field (usually observed successively):

$$C = \frac{L_1}{L_2} \qquad (2.1)$$

or:

Luminance contrast – relationship between the luminances of an object and its immediate background (for surfaces viewed simultaneously):

$$C = \frac{L_1 - L_2}{L_1} \qquad (2.2)$$

where $L_1 > L_2$.

or when the areas of different luminances are comparable in size, the following formula may be used (ISO 8995, 1989):

$$C = \frac{L_2 - L_1}{0.5(L_1 + L_2)} \qquad (2.3)$$

where
L_1 = luminance of background or the largest part of the visual field
L_2 = luminance of the object.

Reflectance – ρ, physical property of surface. It is the ratio of the luminous flux reflected from a given surface to the luminous flux incident on it. Reflectance values that approximately equal 1 correspond to bright (white) surfaces and values that almost equal 0 correspond to black surfaces. Depending on the type of texture of surface three main kinds of reflection can be distinguished: specular (mirror or polished surfaces), diffuse (matt surfaces) and mixed combination of polished and matt surfaces, i.e. polished scratch on matt surface). For matt surfaces the following relationship can be used:

$$L = \frac{\rho E}{\pi} \qquad (2.4)$$

where
L = luminance (cd/m2)
ρ = reflectance of the surface considered
E = illuminance (lx)
π = 3.14.

2.4. Visual Performance and Lighting

There are many different types of work stands in industry, offices and in other working interiors, which require specific visual conditions to perform visual tasks, often very complex. The goal of lighting design is to minimize strain of the visual system and to achieve efficient visual performance. Prolonged visual work in poor lighting conditions induces visual fatigue, which can manifest itself in a variety of asthenopic symptoms like headache, redness, tender, itchy, burning, dry, throbbing eyes, focusing problems and blurred or double vision. Visual fatigue symptoms are temporary and after a rest period those symptoms should disappear. On the other hand the term "visual performance" is used to indicate quantitatively how workers "perform" in terms of speed, accuracy and probability of detection in their visual field (ISO 8995, 1989). The optimum values of lighting parameters, from the human point of view, are determined on the basis of visual performance assessment. Thus effectiveness of the visual system is measured in terms of visual performance and it depends on visual and non-visual factors like visual capability of the individual, visibility of the task, and psychological and physiological variables (North 1993). Lighting engineering can influence only on the one group of factors, which are connected with the visibility of the task. The visibility of task depends on two groups of factors:
- Task attributes (size, distance, luminance, contrast, color, surface properties).
- Illumination (illuminance level, illuminance uniformity, luminance distribution, spectral content of light sources, glare).

Knowledge of the task attributes is essential that lighting designer should prepare an appropriate project of illumination from the point of view of visual performance.

3. LIGHTING CHARACTERISTICS

Interior lighting conditions are described by the following lighting parameters, which determine a satisfactory luminous environment:
- Illuminance level.
- Illuminance uniformity.
- Luminance distribution.
- Glare.
- Spectral characteristic of light.
- Flicker.

3.1. Illuminance Level

Illuminance and illuminance uniformity are determined and measured on the work plane. The work plane is a plane at which work is usually performed and it is usually a task surface (on a real height above the floor). When there is no information about the height of the task surface, a horizontal reference plane is assumed. Its height depends on particular national requirements. For example, in US standards it is 0.76 m above the floor; in Polish ones 0.85 m. For corridors, stairs, bathrooms, communication areas, etc. the floor is taken as work plane height.

Illuminance level, which is required for visual task performing depends on two parameters:
- Apparent target size (function of the smallest size of target and viewing distance).
- Degree of visual task difficulty (depends on task contrast and reflectance).

The degree of visual task difficulty increases when the task contrast and reflectance decreases. For very difficulty visual tasks and a small apparent target size the required illuminance level should be higher. In accordance with the Weber-Fechner Law and lighting practice (illuminance values increase by a factor of ~1.5, that is

the smallest increment needed to give a significant difference in the subjective lighting effect) the following scale of illuminances is recommended: 20–30–50–75–100–150–200–500–750–1000–1500–2000–3000–5000 lx.

In practice the required illuminance level for a given task (work plane) refers to the average illuminance on the task surface (work plane). Average illuminance on a given surface is calculated as an arithmetic average of at least three measured illuminances at evenly distributed points on that surface. This means that measured illuminances at each point of surface need not be equal or higher than required by standard illuminance values. Only average values of illuminance are compared with required values.

Most lighting standards for different areas, tasks or activities gives, as seen in Table 1, ranges of three illuminances. Higher values in the range can be used as follows:
- When unusually low reflectances and/or contrast are present.
- When visual performance is critical.
- When the visual capacities of the workers are below normal (e.g. most workers are 40 years old or more).
- When accuracy or higher productivity is important.

According to ISO (ISO 8995, 1989) the lower values in the range can be used as follows:
- When reflectance or contrasts are unusually high.
- When accuracy or higher productivity is not important.
- When the task is executed occasionally only.

Many working interiors are dim at illuminances lower than ~200 lx. That is why 200 lx is recommended as the minimum illuminance for workspace where work is executed for long periods.

3.2. Illuminance Uniformity

Variation of illuminance should be considered on two areas: on and around the visual task area and in the whole interior. Excessive changes of illuminance in the visual field can be distracting and cause changes in adaptation during the movement of the fixation point from a bright to a dark surface. Transient adaptation problems can reduce visual performance, so uniformity is important. Uniformity of illuminance is calculated as a ratio of minimum measured illuminance to the average illuminance of a given work plan (task surface). It should be pointed out that task area is not usually identical with the entire area of the workstation and during the measurement this should be taken into account.

Table 1. Illuminances ranges for typical areas, tasks or activities (from ISO 8995, 1989: 3)

Illuminance range, lx	Type of area, task or activity
20–30–50	Outdoor circulation and work areas
50–100–150	Circulation areas, simple orientation or short temporary visits
100–150–200	Rooms not used continuously for working purposes
200–300–500	Tasks with simple visual requirements
300–500–750	Tasks with medium visual requirements
500–750–1000	Tasks with demanding visual requirements
750–1000–1500	Tasks with difficult visual requirements
1000–1500–2000	Tasks with special visual requirements
above 2000	Performance of very exacting visual tasks

Recommended uniformity values differ in different countries. For example, British recommendations require the uniformity of illuminance over any task area and immediate surround be > 0.8 (that does not necessarily have to apply to the entire room). Polish recommendations are less restrictive and uniformity of illuminance on the work plane should be > 0.65 for prolonged work and 0.4 for casual work and communication areas.

In most work interiors there are different visual tasks with various degrees of difficulty, and some tasks require a higher level of illuminance. Often, especially when most tasks require a lower level of illuminance, it is waste to illuminate the whole interior to a higher level of illuminance. In those cases general lighting should ensure a lower level of illuminance and some workstation should be additionally lighted by localized or local lighting. However, in those cases it is important for the average illuminance difference between two adjacent interiors (corridor and room) and between different work planes in the same room to be < 1:5.

3.3. Luminance Distribution

The luminance distribution in the field of view controls the adaptation level of the eyes, which affects task visibility. The luminance distribution in the field of view also affects visual comfort. For a given lighting level, differences in luminance will be caused by differences in surface reflectance. It can happen that the illuminance is appropriate for the visual task but luminance balance in the whole interior is unacceptable. Luminance distribution can be described either by luminance ratios of adjacent surfaces and surfaces viewed in sequence or by reflectances of major interior surfaces. Too high luminance ratios (> 1:10) will cause fatigue and/or glare but too low luminance ratios result in a dull and non-stimulating working environment. To improve the visual performance of a task the luminance of the task surround should be lower than task luminance, but > 1:3.

3.4. Glare

The lighting system should provide a luminous environment that is free of the glare phenomenon. This phenomenon exists when parts of the visual field are excessively bright in relation to the brightness of the general surroundings to which eyes are adapted. From the psychophysiological point of view there are two kinds of glare: disability glare and discomfort glare. Glare is experienced when the excessive brightness of an object (light source) is in or close to the direction of the line of sight (direct glare) or when such light sources are reflected in glossy surfaces (reflected glare).

3.4.1. Disability glare

Disability glare impairs the vision of details or objects (visibility and visual performance are reduced) without necessarily causing discomfort. It occurs when a large source of low luminance or a small source of high luminance is seen close to the line of sight to the visual task. Disability glare is connected with a veiling luminance produced in the eye on the retina by scattered light in ocular media inhomogeneities. This luminance is superimposed over the well-focused image on the retina and, as a result, reduces its contrast that results in decreased visual performance and visibility. Veiling luminance, or in other words disability glare, depends on illuminance from the glare source at the eye and the angle between the primary object and the glare sources. It is largely independent of the luminance of the source.

3.4.2. Discomfort glare

Discomfort glare causes a feeling of discomfort without necessarily impairing the vision of details or objects. It is normally experienced as a feeling of discomfort, annoyance or pain, which increases with time, and it may contribute to fatigue. It has been found that discomfort glare depends on the luminances of the glare sources, the adaptation luminance level (background luminance), the number of glare sources, the source area and the angle between the primary object and the glare sources. But the degree of discomfort glare also depends on the kind of activity being performed. A more demanding visual task will result in a stronger feeling of discomfort. The limitation of discomfort glare is one of the major quality aspects of lighting because when discomfort glare is properly controlled disability glare does not exist. Discomfort glare must be controlled at the design level (stage) and in fact it is control of direct discomfort glare from lamps and luminaries by controlling the luminance of those in the direction of the observer's eyes. The degree of luminance control differs according to the type of task and activity. The CIE has classified task and activities into five groups (i.e. Quality Classes) according to the degree of the required luminance control. There are quality classes: A, B, C, D, E, where class A means the most restrictive glare limitation for very exacting visual tasks and class E means very low glare limitation for low visual tasks demands. There are various glare systems and different countries have adopted different design procedures to evaluate the degree of discomfort glare in a given situation.

Table 2. Lamp colour appearance group (from ISO 8995, 1989: 3)

Colour appearance groups	Colour appearance	Correlated colour temperature, K
1	Warm below	3 300
2	Intermediate	3 300 to 5 300
3	Cold	above 5 300

group 1: is appropriate for residential type areas

group 2: is most widely used in working interiors

group 3: should be used only for high lighting levels, for special tasks (like colour matching) or in warm climates

3.5. Color of Sources

The quality of the color of light emitted by lamps is characterized by two properties:
- color appearance
- color rendering capabilities.

Both properties of a light source are determined by the spectral composition of the light emitted. Different spectral compositions of light can result in a similar color appearance but they can produce different color rendering.

3.5.1. Color appearance

The color appearance of a lamp refers to the apparent color (chromaticity) of the light it emits. Its correlated color temperature in Kelvins (K) describes it. Lamps can be divided into three main groups according to their color temperature (Table 2).

The color appearance of an object depends on the spectral distribution of the light that illuminates it, the chromatic adaptation of the observer and the spectral reflection characteristics of the surface.

3.5.2. Color rendering

Color rendering describes the appearance of object colors under a given light source compared with their appearance under a reference source. A general color-rendering index R_a has been introduced for objective identification of color rendering properties. Its maximum of 100 corresponds with excellent color rendering (i.e. a test source gives exactly the same effects as the reference illuminant).

Color rendering of light sources depends on the spectral distribution of light. To simplify specifications of the color rendering indices, color rendering groups have been introduced (Table 3).

3.6. Flicker

The light emission of all AC lamps has a cyclic variation. It is small for filament lamps but more visible for fluorescent and discharge lamps. Flicker usually increases with the lamp's age (especially for fluorescent lamps) and can be avoided by replacing old lamps with new ones. Flicker from high-pressure lamps is more noticeable in lamps with transparent than in those with fluorescent coating on the bulb.

Rotating parts of rotating machinery which are lighted by

Table 3. Lamp color rendering groups (from ISO 8995, 1989: 3)

Colour rendering group	Colour rendering index range	Colour appearance	Example of use	
			Preferred	Acceptable
1A	$R_a \geq 90$	Warm Intermediate Cold	Colour matching, clinical examinations	
1B	$80 \leq Ra < 90$	Warm Intermediate	Offices, hospitals	
		Intermediate Cold	Printing, paint and textile industries, demanding industrial work	
2	$60 \leq Ra < 80$	Warm Intermediate Cold	Industrial work	Offices
3	$40 \leq Ra < 60$		Rough industries	Industrial work
4	$20 \leq Ra < 40$			Rough industries

fluroescent or discharge lamps can appear as stationary, or as reduced speed, or as in reverse rotation. This phenomenon is called the stroboscopic effect and it might be a potential risk factor at this type of workstation. It can be avoided by lighting the rotating part of machinery by incandescent lamps or by dividing the lamps between three phases.

Using lamps with high frequency supplies can more effectively reduce flicker and stroboscopic effects.

4. LIGHTING SYSTEMS

4.1. Classification According to Luminaries Layout

The visual field of a worker is different depending on whether worker is concentrating on a task or looking away for relaxation. For this reason a distinction between task lighting and the lighting of the environment should be made. According to the luminaries' layout in the interior, the following methods of electrical lighting can be distinguished:

- General lighting – lighting, which provides a uniform level of illumination on the work plane in the whole of an area without any provision for special local requirements;
- Localized lighting – lighting, which illuminates an interior and at the same time provide a higher illuminance over a particular part or parts of the interior (using luminaries above the visual task)
- Local lighting – additional lighting providing illuminance over a small area, for special task requirements, which does not contribute in general surrounding lighting and is controlled separately from general lighting

The method of lighting selection depends on the required illuminance level, room characteristics and work stands layout. General lighting provides the same required illuminance level at each workstation in the room. It is appropriate for small offices (small room, one workstation) or for rooms, where on all the workstation the required illuminance is at the same level and task lighting is inappropriate. Localized general lighting provides a required illuminance level at work stands (using task luminaries above the workstation) and a lower level of general illumination. It is desirable in open-plan arrangements. Local lighting provides a required level of illuminance only at that workstation, when additional task luminaire is mounted. Local lighting should be designed to use only for use with general lighting, because it illuminates only a small area of the workstation. The general lighting level should be at least 20% of the required illuminance level (i.e. 20% of total illuminance from general and local lighting). This method of lighting is appropriate in big interiors, where work stands differ considerably in illuminance requirements, and work stands are unstable.

4.2. Classification According to Light Distribution

- direct lighting – lighting by luminaries distributing 90–100% of the emitted light directly reaching the reference plane (i.e. surface to be illuminated) (Rea 1993). This term usually refers to light emitted downward.
- indirect lighting – lighting by luminaries distributing only 0–10% of the emitted light directly reaching the reference plane (i.e. surface to be illuminated). It means that 90–100% of emitted light is distributed upward.
- semidirect lighting – lighting by luminaries distributing 60–

90% of their emitted light downward and the other 40–10% upward.
- semi-indirect lighting – lighting by luminaries distributing 60–90% of their emitted light upward and the otehr 40–10% downward.
- general diffused lighting - lighting by luminaries distributing 40–60% of the emitted light downward and the other 60–40% upward.

A broad range of different possibilities of creating general lighting like direct lighting, indirect lighting and combinations of direct and indirect lighting gives lighting designers a lot of variants of lighting designs for specific interiors. Choosing one of those lighting systems has its consequences in the appearance of the luminous environment and in energy consumption. Direct lighting emphasizes horizontal planes like the work plane and the floor and also vertical surfaces (like walls) when the luminaries have wider light distribution or when they are placed near the wall. There is a wide range of direct-type luminaries with a variety of light distribution characteristics from very broad (using translucent diffusing shielding) to narrow concentrated (using specular reflectors and louvers). Special attention should be paid to glare limitation, especially in VDT rooms. This lighting system has the lowest energy consumption (appropriate illuminance level on the work plane at the lowest energy consumption).

Indirect lighting illuminates the ceiling. So the ceiling is the brightest surface in the visual field. The illuminationi of the ceiling should be evenly distributed to avoid too high values of luminance. Indirect lighting can provide diffuse lighting similar to the light of an overcast day without creating veiling reflections and shadows (incidence of light from many directions). This lighting system has the highest energy consumption (appropriate illuminance level on the work plane at higher energy consumption).

A combination of direct and indirect lighting can produce excellent results. The indirect portion should not create excessive luminances of the ceiling and the direct portion should not produce glare.

5. MAINTENANCE

Two main factors, that is a decrease of the lamp's light emission in time (lamp aging) and accumulation of dirt on lamps, luminaries and other surfaces in the interior, result in a progressively decreasing illuminance level in time. Good maintenance of the lighting system means periodical cleaning of luminaries, lamps replaced before the end of their lifetime and periodical cleaning or painting of the walls and ceiling. The lighting designer should plan appropriate intervals of clearning, with the frequency depending on the type of luminaire, the rate at which dirt accumulates in a given interior and the cost of cleaning. There are two kinds of lamp replacement, called individual and group replacement. Individual replacement (replacement of all lamps in a given interior) is preferred in large interiors and in busy areas (i.e. corridors).

Illumination: Basic Definition

P. R. Boyce

Lighting Research Center, Rensselaer Polytechnic Institute, Troy, NY 12189, USA

1. PHOTOMETRIC QUANTITIES

Illumination is the use of light to make an object visible. Light is electromagnetic radiation in the wavelength range 380 nm to 760 nm. Electromagnetic radiation within these wavelength limits produces a response from the human visual system. Electromagnetic radiation outside these wavelength limits does not.

The total electromagnetic radiation emitted by a source is quantified as the radiant flux. Radiant flux is the rate of flow of energy and is measured in watts. The total amount of light emitted by a light source in all directions is quantified as the luminous flux. Luminous flux is radiant flux multiplied by the relative spectral sensitivity of the human visual system and is measured in lumens. The relative spectral sensitivity conventionally used is the Standard Photopic Observer of the Commission Internationale de l'Eclairage (CIE).

While luminous flux is a useful term for describing the light output of a light source, it does not describe the distribution of light from a luminaire. To describe such a distribution a measure of the amount of light emitted in a specific direction is necessary. Luminous intensity is used for this purpose. Luminous intensity is the luminous flux emitted / unit solid angle, in a specified direction, and is measured in candelas.

Both luminous flux and luminous intensity have density measures associated with them. The luminous flux falling on unit area of a surface is called the illuminance and is measured in lumens / meter^2 or lux. The luminous intensity emitted per unit projected area in a given direction is the luminance and is measured in candelas / meter^2 . Table 1 summarizes these photometric quantities.

Table 1. The photometric quantities

Measure	Definition	Units
Luminous flux	That quantity of radiant flux which expresses its capacity to produce visual sensation	Lumens (1m)
Luminous intensity	The luminous flux emitted in a very narrow cone containing the given direction divided by the solid angle of the cone, i.e. luminous flux/unit solid angle	Candela (cd)
Illuminance	The luminous flux/unit area at a point on a surface	Lumens/meter^2
Luminance	The luminous flux emitted in a given direction divided by the product of the projected area of the source element perpendicular to the direction and the solid angle containing that direction, i.e. luminous flux/unit solid angle/unit area	Candela/meter^2
Reflectance	The ratio of the luminous flux reflected from a surface to the luminous flux incident on it	

For a matte surface: Luminance = (Illuminance x Reflectance) Π

2. COLORIMETRIC QUANTITIES

The photometric quantities do not differentiate between light made up of different wavelength combinations, i.e. light with different spectral distributions. The spectral distribution of the light reaching the eye is largely but not entirely responsible for what color is perceived. Two three-dimensional color spaces, L_{ab} and L_{uv}, have been developed by the CIE as maps of color. L_{ab} is generally used for object colors and L_{uv} for self-luminous colors. The position of an object in these color spaces is calculated from the spectral distribution of the light reflected from or emitted by the object. The coordinates of an object in color space indicate what color it will be perceived to be. Objects that have the same coordinates in color space will appear to be identical in color, even if they have different spectral distributions. Objects that have different coordinates in color space will be perceived as different in color.

Although the L_{ab} and L_{uv} color spaces are the most sophisticated maps of color, other simpler color systems are used by the lighting industry. The CIE 1964 uniform color space is used in the calculation of the CIE General Color Rendering Index, an index taken to classify the color rendering capabilities of light sources. The positions in the color space of eight test colors under a reference light source and under the light source of interest are calculated. The differences between the positions of each test color under the two sources are obtained, adjusted for chromatic adaptation, averaged and modified so that a maximum value of 100 is obtained when there are no differences.

The CIE General Color Rendering Index is a rather course measure of the ability of different light sources to render colors. Different light sources of interest have different reference light sources. Further, because of the averaging, two light sources that render colors differently can have the same CIE General Color Rendering Index. This means that the CIE General Color Rendering Index should only be used for separating light sources into broad classes of color rendering capabilities.

A two-dimensional color surface, the CIE 1931 chromaticity diagram, is used to characterize the color appearance of light sources and to define the acceptable color characteristics of light signals (figure 1). The boundary of the surface represents colors created from single wavelengths. The point at the center, called the equal energy point is where a spectrally neutral surface will be located. Any other color will be located somewhere between the equal energy point and the edge of the diagram. The closer the coordinates of the color are to the edge of the diagram, the greater the strength of the color. Figure 1 also contains two other pieces of information; the areas in which the chromaticity coordinates of signal lights need to fall if the signal is to be perceived as the specified color, and the full-radiator locus. This latter represents colors generated by a black-body radiator. The color appearance of a nominally-white light source is conventionally described by its correlated color temperature. This is the temperature of the black-body radiator which is closest to the coordinates of the light source on the CIE 1931 chromaticity diagram.

3. THE GENERATION OF LIGHT

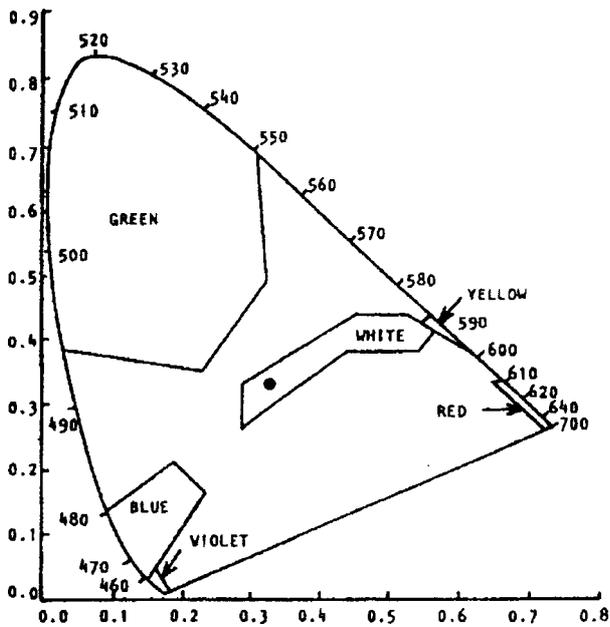
Light is generated naturally, in the form of daylight, and artificially, by converting various forms of energy into electricity and then into light. Natural light is primarily characterized by its variability.


Figure 1. The CIE 1931 Chromaticity Diagram. The filled circle is the equal energy point. The boundary curve is the spectrum locus with the individual wavelengths marked. The enclosed areas indicate the chromaticity coordinates of light signals that will be identified as the specified colors.

Depending on the meteorological conditions, time of year, time of day, and latitude, daylight will vary in amount, spatial distribution and spectrum. Daylight has two components, sunlight and skylight. Sunlight is light received directly from the sun. Skylight is light from the sun scattered in the atmosphere. The nature of the atmosphere and the distance that the light passes through it determine the balance between sunlight and skylight. The greater is the path length and the more scattering centers there are in the atmosphere, the higher is the proportion of skylight.

Electric light sources used for illumination can be divided into two classes; incandescent lamps and discharge lamps. Incandescent lamps produce light by emission from a hot wire. Discharge lamps produce light by emission from an electric discharge in a gas. Incandescent lamps do not require any other equipment to operate. Discharge lamps require additional equipment, called control gear, to operate because the electrical

conditions needed to initiate a discharge are different from those needed to sustain it.

Table 2 summarizes the performance characteristics of two incandescent lamp types and four discharge lamp types and gives the most common applications for each lamp type. The values in the table 2 should be treated as indicative only. Details about the characteristics of any specific lamp should be obtained from the manufacturer.

4. CONTROL OF LIGHT OUTPUT

To produce illumination it is necessary to both generate light and control its distribution. For daylight illumination, the distribution of light is determined by the size, shape, orientation, placement and shielding of windows and skylights. For electric illumination, light distribution is determined by the luminaire the light source is operated in and the arrangement of the luminaires in the space. A luminaire provides mechanical support for the light source, connects the light source to the electricity supply, houses any control gear necessary, and controls the light distribution by some combination of diffusing, reflecting or refracting elements.

As for the control of light output, daylight through a window can be limited by blinds. Wherever the sun, or a very bright sky, is likely to be directly visible through a window, blinds are desirable to avoid glare. The most acceptable form of blinds are those that shield the viewer from a direct view of the sun or bright sky while preserving some view out.

Switching or dimming is used to control the light output of electric light sources. Time switches are useful where the space is occupied on regular schedule. Occupancy sensors can be used to avoid waste of electricity by switching off lighting when there is nobody in the space. However, if such sensors are insufficiently sensitive they may be disliked because they switch lighting off when people are present. In addition, frequent switching may shorten lamp life. Manual switching is the most common form of switching. Manual switches are more likely to be used if the control panel is labeled so that the operator knows which luminaires are being switched.

Dimming systems exist for incandescent light sources and for tubular and compact fluorescent light sources. The factors to consider when assessing a dimming system are the range of light output over which dimming can be achieved; the extent to which the color properties of the lamp may change; and whether lamp

Table 2. Summary of characteristics of some common electric light sources

Light Source	Luminous Efficacy (1m/W)	Correlated Color Temperature (K)	CIE General Color Rendering Index	Lamp Life (hrs)	Applications
Tungsten	8–19	2700	100	750–2000	Domestic Retail
Tungsten-Halogen	8–20	2900	100	2000–4000	Display
Tubular Fluorescent	60–110	3000–5000	50–95	9000–20,000	Commercial
Compact Fluorescent	50–70	2700–4100	80–85	9000–20,000	Commercial Retail
Mercury Vapor	30–60	3200–7000	15–50	16,000–24,000	Agricultural Industrial
Metal Halide	50–110	3000–6500	65–95	3000–20,000	Industrial Commercial Exterior
High Pressure Sodium	60–140	2100–2500	20–70	10,000–24,000	Industrial Exterior
Low Pressure Sodium	100–180	1800	n.a	16,000–18,000	Exterior

life is altered. A common technique for dramatically increasing the life of an incandescent lamp is to operate it slightly below its rated voltage.

5. THE HUMAN VISUAL SYSTEM

The human visual system involves both eye and brain working together. An image of the world is formed on the retina of the eye. At the retina, the photons of light forming the image are absorbed and converted to electrical signals. Some image processing occurs at the retina, and at various stages up the optic nerves and in the visual cortex. The processed images produce perceptions based partly on past experience.

There are two types of photoreceptors in the retina, called rods and cones. Rods and cones differ in their sensitivity to different wavelengths and in their absolute sensitivities to light. Rods show a peak sensitivity to light at 507 nm while cones show a peak sensitivity at 555 nm. Rods are approximately 100 times more sensitive than cones. In simple terms, rods provide night vision while cones provide day vision. Further, rods and cones are distributed differently across the retina. Although there are cones spread across all of the retina, they are more dense in a small central area of the retina called the fovea. Rods are also spread throughout the retina apart from the fovea, where there are none. Rods reach their maximum concentration about 20∞ from the fovea. This difference between photoreceptor types in the fovea and the peripheral retina is magnified by the connections between photoreceptors and optic nerve fibers. The ratio of photoreceptors to optic nerve fibers is close to one in the fovea but increases rapidly as the deviation from the fovea increases. This pattern is reflected in the way in which the parts of the retina are used. Basically, the peripheral visual field is used to detect changes in the visual environment which are then examined by turning the head and eyes so that the location where the change occurred falls on the fovea. The fovea is the part of the retina where the finest visual acuity and contrast sensitivity occur. It is what we use when we look directly at something.

The human visual system can function to some degree from starlight to bright sunlight, a range of luminance of about 12 log units. But it cannot operate over the whole of this range simultaneously. To adjust the sensitivity of the visual system to different prevailing luminances, a process of adaptation occurs. Adaptation to a sudden change of about 2 to 3 log units of luminance is fast, a few seconds at most, but adaptation over a larger range can take much longer, of the order of minutes. While adaptation is in progress, visual capabilities are reduced. Even when completely adapted, the capabilities of the visual system depend on the luminance to which it is adapted. Three distinct ranges of luminance can be distinguished; the photopic, mesopic and scotopic. Table 3 summarizes these ranges and the associated visual capabilities.

Interior lighting and decor usually produce luminances which ensure the visual system is in the photopic state. Exterior lighting on roads and urban areas usually provides luminances high enough to ensure the visual system is operating around the photopic–mesopic boundary. It is only in areas completely without lighting that the scotopic state is reached.

Table 3. Summary of the operating states of the visual system

Operating State	Luminance Range Photoreceptor	Active Wavelength	Peak Sensitivity	Characteristics
Photopic	>3cd/m²	Cones	555 nm	Fine resolution Good color vision
Scotopic	<0.001cd/m²	Rods	507 nm	No color vision Poor resolution Fovea "blind"
Mesopic	>0.001 and <3cd/m²	Cones and Rods	Between 555 and 507 nm	Reduced color Reduced resolution relative to photopic

6. TASK PERFORMANCE AND VISUAL PERFORMANCE

Illumination is often provided to facilitate the performance of tasks. Visual tasks usually have three components; visual, cognitive and motor. The visual component uses the sense of sight to collect information from the visual environment. The cognitive component is carried out in the brain and ascribes meaning to the visual information collected. The motor component is the physical response to cognitive output. Of course, these three components interact to produce a complex pattern between stimulus and response. Further, every task is unique in its balance between visual, cognitive and motor components and hence in the effect illumination has on task performance. This makes it impossible to derive a single relationship between illumination and task performance that can be generalized to all tasks.

However, it is possible to establish a general relationship between illumination and visual performance. Figure 2 shows the relative visual performance of a task requiring the detection of a stimulus in a known position, for four different size stimuli, for a range of luminance contrasts and retinal illuminances. The form of the relationships shown in Figure 2 for each target size have been called the plateau and escarpment of visual performance. What this means is that visual performance changes only a little over a wide range of visual sizes, luminance contrasts and retinal illuminations (the plateau). However, if visual size or luminance contrast or retinal illumination is reduced sufficiently, visual performance deteriorates rapidly (the escarpment). The existence of a plateau of visual performance implies that for a wide range of task sizes and contrasts, visual performance is relatively insensitive to illumination but when conditions reach the edge of the plateau, performance declines rapidly. This pattern of performance has been found for many real tasks with a large visual component.

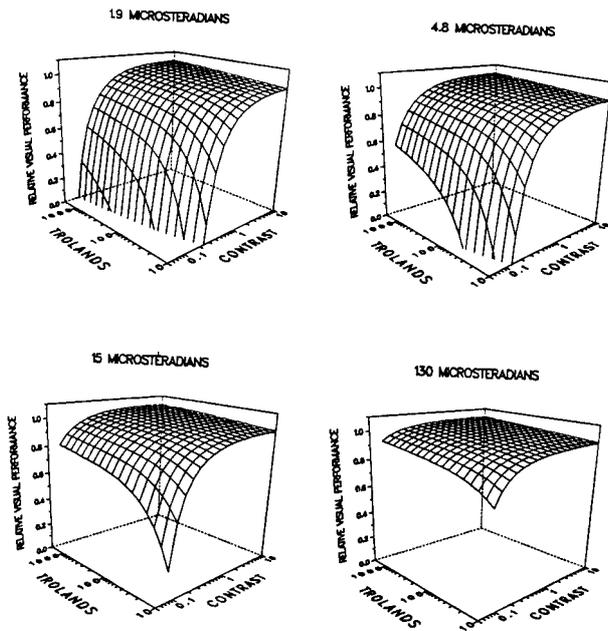
The relationships shown in Figure 2 are derived from tasks which are viewed directly, i.e. which are imaged on the fovea. However, there are a whole class of tasks that involve visual search because the location of the object to be found is not known. A visual search is made using a series of eye fixations, until the object to be found is detected and identified. Usually, the object, or something like it, is detected in the peripheral visual field and then identified after the fovea has been brought to bear on the object. The speed with which a visual search can be carried out is dependent on both the visibility and conspicuity of the object


Figure 2. Four relative visual performance surfaces for stimuli of four different sizes, measured in microsteradians. Each surface shows relative visual performance plotted against retinal illumination in trolands and luminance contrast. Retinal illumination in trolands is calculated as the product of the luminance of the surface being viewed and the associated pupil size. (After Rea, M.S., and Ouellette, M.J., Relative visual performance: A basis for application, Lighting Research and Technology, 23, 135, 1991)

being sought. The visibility of the object will be determined by its size, luminance contrast and color difference from the background. The conspicuity of the object is the extent to which it is different from all the other objects in the area being searched. It is possible to have an object which is highly visible but difficult to find because it is not conspicuous.

The level of visual performance that is achievable with a given task depends on the stimulus the task presents to the visual system and the operating state of the visual system. There are five characteristics of a task and its lighting which determine these conditions. These are its visual size, luminance contrast, color difference, retinal image quality and retinal illumination.

6.1. Visual Size
A large stimulus is the easier to detect than a small one. The size of a stimulus is always expressed in some form of angular measure. The visual size of a stimulus for detection is often expressed as the solid angle the stimulus subtends at the eye. For resolution of detail, the visual size is usually given as the angle the critical dimension of the stimulus subtends at the eye. For complex stimuli, the spatial frequency distribution is used to characterize the stimulus. Lighting can do little to change the visual size of two-dimensional objects but shadows can be used to enhance the visual size of some three dimensional objects.

6.2. Luminance Contrast
A stimulus with a high luminance contrast is easier to detect than a low luminance contrast stimulus. Luminance contrast is expressed in a number of ways. For stimuli which are seen against a uniform background, e.g. print, luminance contrast is defined as:

$$C = (L_t - L_b) / L_b$$

where
C = luminance contrast
L_b = Luminance of the background
L_t = Luminance of the detail

For stimuli which have a periodic pattern, e.g., a grating, the luminance contrast or modulation is given by:

$$C = (L_{max} - L_{min}) / (L_{max} + L_{min})$$

where

C = Luminance contrast
L_{max} = maximum luminance
L_{min} = minimum luminance

It should be noted that these definitions of luminance contrast have different ranges of possible values. The luminance contrast of a stimulus can be modified by lighting either because the distribution of light leads to veiling reflections occurring on specular surfaces, or because light is scattered inside the eye over the retinal image, or, where color stimuli are involved, because different light sources with different color rendering properties are used

6.3. Chromatic Difference
A stimulus can be discriminated from its background because it is different in color. Such color differences can be used for detection even when there is zero luminance contrast. Chromatic difference can be expressed in terms of positions on an equal-luminance plane of a color space. Light sources with different spectral emissions can alter chromatic differences.

6.4. Retinal Image Quality
The quality of the retinal image is influenced by the optical quality of the object being imaged, the amount of light scatter that occurs in the eye and the ability of the eye's optical system to focus the image on the retina. The choice of light source can influence pupil size and hence depth of field but having the correct optical refraction in the form of glasses or contact lenses is usually a better approach.

6.5. Retinal Illumination
The state of adaptation of the visual system is determined by the retinal illumination. The retinal illumination in turn is determined by the luminances in the visual field, the pupil size and the absorption of light in the eye.

By altering any or all of these characteristics, the achievable level of visual performance can be moved to the plateau. How effective making any of these changes will be depends on the initial condition. The closer the task is to threshold, the bigger

the effect of changing any of the characteristics will be. Above threshold, the most effective characteristic to change is the one which is limiting performance. For example, increasing the luminance contrast of a stimulus which is very small in size will help but increasing the visual size would be more effective. Similarly, enhancing color difference will have little effect if the task has a high luminance contrast unless the color can be used to distinguish the stimulus from other non-stimulus objects. Often it is not possible to change the characteristics of the task. In this situation, only the lighting can be changed but it is always desirable to match the lighting to the physical characteristics of the task. For example, if the task is two-dimensional and of matte reflectance located on a matte background, increasing the retinal illumination is about the only option. However, if the object is three-dimensional and is a specular reflector, the appropriate light distribution can increase the visual size by casting shadows, and increase the luminance contrast by producing highlights. If the object is distinguished from its background primarily by color, the light spectrum used is an important consideration

7. VISUAL COMFORT

Designing good illumination almost always involves a consideration of both visual performance and visual comfort. Illumination that is inadequate for the performance of a task will lead to visual discomfort, but visual discomfort can also occur when the lighting of the task is adequate. This is because visual discomfort can be produced from anywhere in the lit space but visual performance is usually only affected by the lighting in the immediate area of the task.

Red, sore, watering eyes; headaches and migraines, gastro-intestinal problems and muscular aches and pains can all be due to inappropriate illumination, although all can have other causes. There are several different aspects of illumination that can cause discomfort. They are:

- Flicker — Whether a regular, visible fluctuation in luminous flux will be considered uncomfortable depends on the context. In the entertainment industry flicker is often associated with an attempt to generate excitement. However, in functional spaces, flicker will almost certainly be strongly deprecated. Whether a fluctuation of luminous flux will be visible as flicker will depend on its frequency and modulation. The occurrence of flicker can be made less likely by using high-frequency control gear for discharge lamps and/or by the mixing of light from lamps powered from different phases of the electricity supply.
- Glare — Glare can be both absolute and relative. It is possible to have absolutely too much light. Too much light is rare indoors, although it can happen where there are many high-reflectance surfaces, but is common in full sunlight. Glare can also occur when the range of luminance in a visual environment is too large. Conventionally, this form of glare is divided into two types, disability glare and discomfort glare. Disability glare reduces visual performance because light scattered in the eye reduces the luminance contrast of the retinal image. Disability glare is most commonly experienced from oncoming headlights when driving at night. Most forms of disability glare also cause discomfort but it is possible to have disability glare without discomfort when the area of the source causing the disability is large.

- Discomfort glare causes discomfort without any effect on visual performance. Discomfort glare increases with increasing luminance and solid angle of the glare source increase and decreases with increasing luminance of the background and deviation from the glare source. Most luminaires are designed to limit the discomfort glare likely to occur for common directions of view.
- Shadows — Shadows can cause discomfort when they make task performance more difficult. How and if they make task performance more difficult depends on their size and location. If a large area is in shadow, the effect is the same as if the illumination has been reduced. If the reduction is sufficient to move visual performance off the plateau of visual performance, discomfort is likely to be experienced. If shadows are cast over and within parts of an object and those shadows hide important details, then again visual performance is likely to be reduced and visual discomfort experienced. However, shadows can also be valuable in revealing the form of three-dimensional objects. Shadows can be reduced by increasing the amount of interreflected light in the space or by providing local lighting which can be adjusted in position.
- Veiling reflections — When a source of high luminance, such as a luminaire, is reflected from a specular surface, such as a computer monitor, the luminance contrast of the display will be reduced. This reduction is said to be due to veiling reflections. The magnitude of veiling reflections are determined by the specularity of the material being viewed and the geometry between the observer, the object and the high-luminance source. Veiling reflections only occur when the object has specularly reflecting surfaces and when the geometry conforms to the laws of specular reflection. Veiling reflections can also be considered of benefit in some situations, e.g. when displaying silver plate, but in this situation the reflections are conventionally called highlights although physically they are the same phenomenon as veiling reflections.

8. LIGHT AND AGING

The human visual system deteriorates with age. Specifically, by forty the ability to focus at close distances is reduced; by sixty the amount of light reaching the retina is markedly reduced and the amount of light scattered in the eye is markedly increased; and by eighty the color of the light is distorted by increased absorption of the short wavelength light and a decline into partial sight is increasing likely. The ages given at which these changes occur are at best approximate but the trend is consistent. These changes in the optical characteristics of the eye with age diminish the visual capabilities of older people. Usually visual acuity, contrast sensitivity and color discrimination capabilities are reduced, the time taken to adapt to large and sudden changes in luminance is increased, and glare is perceived more frequently.

The detrimental effects on visual capabilities can be partially offset by the careful use of light. More light will help provided it is delivered without glare, shadows and veiling reflections. Adjacent areas should be lit to similar illuminances, or if this is not possible, there should be a transition zone lit to an intermediate illuminance. It should also be noted that the judicious use of decor to attach high luminance contrast to salient

detail in the visual environment can be make a space much easier for people with poor visual capabilities to understand.

9. TISSUE DAMAGE

Like all forms of electromagnetic radiation, exposure to light in sufficient quantities can cause tissue damage to both the eye and the skin. Tissue damage can be caused by either photochemical and thermal effects. Different types of damage to the eye and skin have different wavelength sensitivities The probability of different types of tissue damage occurring usually increases as the product of the spectral irradiance and the duration of exposure increases.

Tissue damage to the eye is minimized in many situations by the usual behavioral response to bright light exposure, that being to blink and look away. This involuntary response is only effective for light sources which appear bright. Sources which produce large amounts of ultraviolet or infrared radiation without much visible radiation are dangerous because they do not appear bright. Tissue damage to the skin takes one of two forms, photochemical damage caused by ultraviolet radiation and burns caused by visible and infrared radiation.

The sun is probably the light source with the greatest potential for tissue damage because it produces such large amounts of ultraviolet, visible and infrared radiation. Exposure to the sun commonly leads to skin reddening and sunburn and, if frequently indulged in, is associated with skin aging and skin cancer. Voluntary staring at the sun can also lead to retinal burns. Exposure to the sun clearly needs care but so does exposure to some powerful electric light sources. Such light sources are typically used in such applications as floodlighting large sports stadia while others are a source of optical radiation for industrial processes.

The hazard represented by a light source in a given situation can be evaluated by applying the recommendations given in publication RP 27 of the Illuminating Engineering Society of North America "Recommended Practice for Photobiological Safety for Lamps and Lamp Systems". Application of these standards to various commonly used electric light sources have shown that electric light sources used for conventional interior lighting do not usually represent a hazard.

1. LAMPS

There are two main lamp categories: incandescent and discharge lamps. Within each category there are some lamp groups with a range of lamps that differ in construction, wattage, luminous efficacy, color properties, etc.

1.1. Incandescent Lamps

The incandescent lamp group consists of two main subgroups: normal incandescent (or tungsten) lamps and tungsten halogen (or halogen) lamps.

1.1.1 The tungsten incandescent lamp

This is the oldest electric light source that produces light by electrical heating of a tungsten filament to high temperature (incandescence point). Visible radiation is emitted. The filament is sealed in a glass bulb (clear, opalizing, frosting, coloring or mirror coating), which is usually filled with an inert gas like argon or krypton. The most common types are known as general lighting service (GLS), decorative (e.g. candle lamps) and reflector (e.g. PAR, crown-silvered lamps). A normal incandescent lamp has a low color temperature of about 2700 K and emitted light is perceived by the eye as warm. It is almost yellow. The advantages of a filament lamp are:

- low initial costs,
- immediate full light output,
- continuous spectral emission,
- excellent color rendering (R_a = 100),
- simple operation,
- ease of dimming.
  The disadvantages are:
- low luminous efficacy (8 $\prod$ 21 lmW^{-1})
- short life (about 1000 hours)
- life sensitive to voltage fluctuation and vibration

Filament lamps are mainly used for domestic and display lighting.

1.1.2 Tungsten halogen lamps

like normal tungsten lamps, produce light by an incandescent filament but halogen (i.e. iodine, chlorine, bromine) is added to the normal gas filling. The halogen regenerative cycle prevents evaporated tungsten from blackening the bulb. Halogen lamps have an increased efficacy (about 10% higher than normal tungsten lamps) and extended life compared with normal tungsten lamps (about 2000 hours). These lamps almost perfectly maintain light output through life. Tungsten halogen lamps for normal lighting purposes have a color temperature of between 2800 and 3400 K and the emitted light is whiter (compared with normal tungsten lamps) and has correspondingly cooler color appearance. This type of lamp has the same advantages and disadvantages as normal tungsten lamps. There are two main types of halogen lamps: mains-voltage types (i.e. double-ended, single-ended, double envelope, and reflector lamps) and low-

voltage types (reflector and capsules lamps). Halogen lamps are used either for domestic and display lighting, or for projectors and vehicle headlamps.

1.2. Discharge Lamps

Discharge lamps can be divided into two main groups: low pressure (fluorescent lamps and low pressure sodium lamps) and HID — high pressure (high-pressure sodium, high-pressure mercury, and high pressure metal halide lamps).

1.2.1 Fluorescent lamps

These are low-pressure mercury discharge lamps in which light is produced predominantly by fluorescent powders (phosphor) activated by the ultraviolet energy of the discharge. The spectral light distribution depends on the mix of phosphors. A wide range of color appearance (depending on correlated color temperature) and color rendering group is available. The main advantages are:

- high efficiency (up to 104 lmW^{-1})
- long life (up to 12 000 hours)
- wide range of correlated color temperatures (2700 $\prod$ 6500 K, i.e. from warm-white to cool-daylight)
- wide range of color rendering index (R_a = 50 $\prod$ 98)
- relatively low cost.
  The disadvantages of fluorescent lamps are:
- decrease of luminous flux during life time (after 8000 hours it will be about 70% of the initial value)
- blackening of the tube wall (especially at its ends)
- efficacy sensitive to ambient temperatures (especially in exterior applications, when lamp wall temperature is below optimum value)
  There are a wide range of fluorescent lamps:
- tubular fluorescent lamps (standard, retrofit, high-frequency, miniature, special, rapid start)
- compact fluorescent lamps (with and without outer envelope)

Fluorescent lamps are used either for interior lighting (offices, schools, hospitals, factories, etc.) or for exterior lighting.

1.2.2 Low-pressure sodium lamps

In these visible radiation is produced by the sodium discharge directly, but emitted light is only in the yellow part of the spectrum, close to the maximum sensitivity of the human eye. Efficacy is the highest of all lamp types (up to 200 lmW^{-1}) but the monochromatic light results in no color rendering. The average life is up to 6 000 hours.

Low pressure sodium lamps are used where color rendering is of minor importance and mainly contrast recognition counts, e.g. roads and security lighting, harbors, marshalling yards.

1.2.3 High-pressure sodium lamps

These radiate energy across a good part of the visible spectrum. This increases the color temperature (1950—2500 K) and improves color rendering (up to R_a = 85). Luminous efficacy is high (up to 140 lmW^{-1}) and life is up to 12 000 hours).

This type of lamp is used for road lighting especially in city centers and industrial interior lighting.

1.2.4 High-pressure mercury lamps

These emit part of the radiation from the discharge in the visible region and part in the ultraviolet region. Fluorescent powder

Table 1. Lamp parameters – performance comparison.

Lamp	Power	Luminous flux	Luminous efficacy	Color temperature	Color rendering index	Life
	[W]	[lm]	[lmW^{-1}]	[K]	[R$_a$]	[hours]
Tungsten incandescent	15 ÷ 1000	90 ÷ 18000	8 ÷ 21	2700	100	1 000
Tungsten halogen	5 ÷ 2000	60 ÷ 48400	12 ÷ 33	2800 ÷ 3400	100	2 000
Tubular fluorescent	4 ÷ 140	120 ÷ 8350	25 ÷ 104	2700 ÷ 6500	50 ÷ 98	12000
Compact flourescent	5 ÷ 25	200 ÷ 1500	40 ÷ 65	2700 ÷ 6000	85 ÷ 96	10000
High pressure mercury	50 ÷ 1000	1800 ÷ 58000	36 ÷ 60	3400 ÷ 6000	33 ÷ 52	15000
Metal halide	70 ÷ 2000	2400 ÷ 20000	68 ÷ 95	3000 ÷ 5600	65 ÷ 92	6000
High-pressure sodium	50 ÷ 1000	1300 ÷ 130000	37 ÷ 140	1950 ÷ 2500	23 ÷ 85	12000
Low-pressure sodium	18 ÷ 180	1800 ÷ 32000	100 ÷ 200	---	none	6000

coating of the inner surface of the outer bulb converts the ultraviolet radiation into visible radiation. Luminous efficacy is medium (up to 60 lmW^{-1}), life is up to 15 000 hours and color temperature is in the range of 3400 to 6000 K. The color rendering index is up to 52.

Mercury lamps are used for road lighting, industrial lighting and for some commercial applications.

1.2.5 Metal halide lamps

These are high pressure mercury lamps with other metallic elements, introduced in the form of halides, which operate in the arc tube. The mix of elements gives a wide range of efficacy (up to 95 lmW^{-1}), color appearance (from 3000 to 5600 K) and color rendering (R$_a$ = 65 – 92).

Metal halide lamps are used mainly in commercial interiors and industry, as well as for color TV lighting in studios.

The characteristic parameters of above mentioned lamps are listed in table 1.

2. LUMINAIRES

A luminaire (light fixture or lighting fitting) is an apparatus which controls the distribution of light given by a lamp or lamps and which includes all the components necessary for fixing and protecting the lamps and for connecting them to the supply circuit (Yarham 1994: 2).

Luminaires can take many different forms depending on the type and number of lamps, application form and place, and efficiency or aesthetic priorities.

2.1. Optical Control

The following are the main methods of optical control that can be used in luminaires: reflection, refraction, diffusion, polarization, and interference. Light emitted by a lamp is directed to the work plane by different elements of the optical system like reflector, louver, refractors, diffuser, and shades. The design of the optical system affects the luminaire efficiency (light output ratio), light distribution, degree of brightness control (glare index), appearance, and utilization factor.

2.1.1 Reflection

This process is when the incident light leaves a surface from the incident side without change in frequency. Reflection may be specular (polished surfaces), spread (rough surface), diffuse (matt surface), mixed, selective and nonselective depending on the kind of surface. This technique of light control is very efficient and light can be distributed very precisely thanks to either different shapes of reflectors (circular, parabolic, elliptical), shapes and dimensions of the cells in a grid of louvers or different finish of surface (polished, matt, rough). Reflectors are used in all kinds of projectors, spotlights and floodlights and very often in office luminaires together with another optical element like a louver. Luminaires with parabolic polished louvers can precisely control light output and brightness in all directions. They have a high efficiency, good glare control, and can be used in VDT offices.

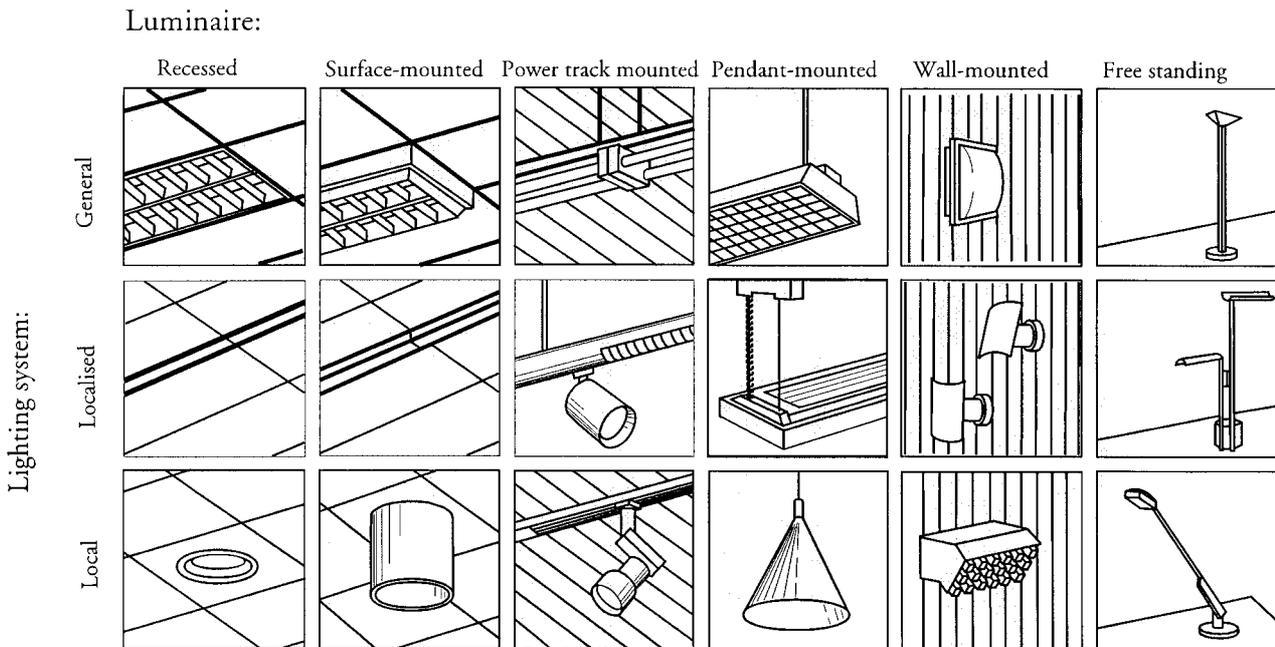
2.1.2 Refraction

This process is when the direction of light changes during its transmission from one medium to another in which its speed is different. This technique usually uses prisms (reflecting or refracting) and lenses (cylindrical, prismatic, and stepped). Those kinds of light directors are made of glass or plastics. Luminaires with refractors made of large numbers of small prisms (named prismatic controllers) are suitable for general office lighting because of their good glare control and efficiency. However, they are not suitable for VDT rooms, because they do not reduce glare sufficiently to prevent reflections in VDT screen.

2.1.3 Diffusion

This process occurs when incident light is redirected by uniform scattering in all directions (according Lambert's cosine law), primarily by the process of diffuse transmission or diffuse reflection. Luminance of the surface is the same in all directions. A diffuser scatters the light emitted by a lamp before it leaves the luminaire. For example, a luminaire with an opal diffuser attachment does not significantly change the light distribution of an installed lamp but reduces its overall brightness. It is not recommended for open-plan offices because the average luminance of diffusers is still rather high and constant in all directions. In small rooms it can be acceptable if the luminaire is not visible at viewing angles during normal work positions.

2.1.4 Polarization

This process takes place when unpolarized light is oriented in a defined direction. Polarized light is mostly obtained by transmitting light through multiple refractive layers. Polarized light can reduce veiling reflections and reflected glare, so that it can be used in VDT rooms.


Luminaire:

Figure 1. Luminaire classification according to mounting position and lighting system (Dybczyñski, 1998: 3).

2.1.5 Interference phenomenon

This is used in reflector coatings to increase the reflectance and in luminaire glass or plastic attachments coatings to increase their transmittance.

2.2. Luminaire Characteristics

The main luminaires characteristics can be listed as follow:

mounting position - luminaires can be mounted in several ways: fixed on the ceiling (surface mounted), recessed into the ceiling, suspended from the ceiling (pendant mounted), free standing and wall mounted (see figure 1).

- light distribution — presented graphically by a polar curve shape which is a schematic illustration of the luminous intensity distribution of the luminaire in characteristic vertical planes. Those curves present the way in which the luminaire controls the light from the lamp. Figure 2 shows different kinds of light distribution, from narrow to very broad, and figure 3 shows classification of luminaires according to upward and downward direction of luminous flux distribution.
- light output ratio — the ratio of luminous flux emitted by a luminaire to that emitted by lamps used in that luminaire. The luminaire is more efficient as the light output ratio is bigger and closer to 1.0.
- utilization factor — the ratio of luminous flux incident on a work plane to the overall luminous flux emitted by luminaire lamps (all luminaires in an interior). For chosen luminaires and their layout in a given interior the utilization factor should be at least 0.5.
- operating condition — the degree of protection against the ingress of dust or moisture is classified according to the Ingress Protection (IP) System. In this system a luminaire is described by a two-digit number, e.g. IP64. The first digit classifies the degree of protection against the ingress of solid bodies, from fingers and tools to dust. The second digit

classifies the degree of protection against the ingress of moisture.
- electrical protection — luminaire classes: 0, I, II, III, according to the type of protection provided against electric shock (where class III indicates the safest usage — the best electrical protection against electric shock).

3. LUMINAIRE SELECTION

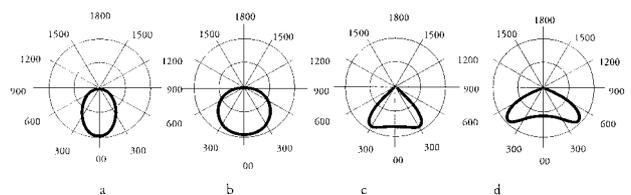
The efficiency of the lighting system is a combination of luminaire efficiency and the organization of work environment, such as task difficulty and location, reflectances of main surfaces in interior and dirt depreciation. Although efficiency is very important, it must be considered together with luminance distribution of the luminaire according to glare control. Higher efficiencies are often obtained by wider light output at angles that can cause the glare. Sometimes a chosen luminaire is either efficient or with good glare control, but does not integrate esthetically within the environment. Luminaires should be incorporated into the environment as an integral part of interior design — more as a decorative element than a disturbing part of the equipment. The luminaire should also integrate mechanically, electrically, and acoustically with the interior design (Rea 1993: 1).


Figure 2. Typical polar curves: (a) narrow distribution, (b) diffuse distribution, (c) dark-light distribution (usually used in VDT rooms), (d) wide distribution.
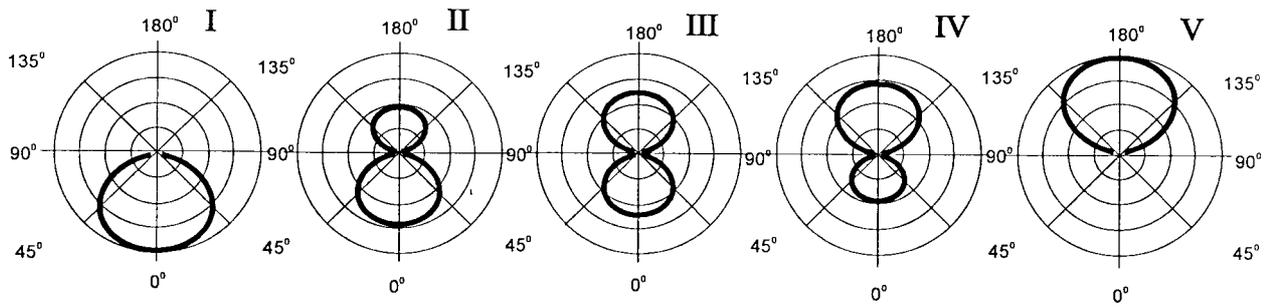

Figure 3. Classification of luminaires according to upward and downward direction of luminous flux distribution: I — direct, II — semi-direct, III — diffuse, IV — semi-indirect, V — indirect.

Mental Workload under Thermal Stress

B. Chase

Department of Engineering, University of San Diego, CA, USA

1. INTRODUCTION

Human performance of cognitive tasks is affected by a variety of psychological, physiological and environmental variables. Exposure to either excessive cold or heat can produce performance decrements on simple cognitive tasks and on more complex perceptual motor tasks. The majority of research in this area has focused on cognitive performance in heat and this will also be the focus here.

Mental workload can be thought of as the amount of mental effort required for task performance. The assessment of mental workload is a process of applying models of human cognition to the analysis of tasks and has as its goal maintaining mental workload at a level that allows acceptable task performance.

For over 50 years researchers have been examining the effects of thermal stress on human cognitive performance. The research thus far paints a somewhat fuzzy picture of the effects of thermal stress on mental workload.

2. THERMAL ENVIRONMENT

2.1. Measurement

Past studies of human performance under thermal stress have employed a variety of measurement techniques. Many studies either did not specify or did not fully specify the environmental conditions. Recent research employs wet bulb globe temperature (WBGT).

2.2. Dry–Bulb Temperature

Most people are familiar with standard household thermometers. Dry bulb temperature is simply the reading of a typical mercury thermometer. The result is a measure of the temperature of the surrounding air. However, there are often other factors that can affect the heat stress of a human.

2.3. Wet–Bulb Temperature

Wet-bulb temperature is obtained by placing a wet wick over the mercury bulb and when air passes over the wick, evaporation and consequently cooling occurs. The rate of cooling from evaporation is dependent upon the humidity of the surrounding air. Consequently, the wet- and dry-bulb temperatures can be used to calculate the relative humidity.

2.4. Globe Temperature and WBGT

A well-known index is WBGT, which attempts to combine the effects of air temperature, water vapor pressure, air speed and radiant temperature into a single, robust value. WBGT is calculated using:

WBGT (outdoor conditions) = 0.7 wbt + 0.2 gt + 0.1 db

WBGT (indoor conditions) = 0.7 wbt + 0.3 gt,

where wbt is wet bulb temperature, dbt is dry bulb temperature and gt is globe temperature. Globe temperature is obtained by taking a thin copper sphere, painted flat black, and placing a thermometer at the center and allowing the thermometer to reach equilibrium.

3. ATTENTION AND COGNITIVE PERFORMANCE

3.1 Attention

The general topic of attention has been investigated since the turn of the century. Scientific inquiry into the subject of attention, while popular around the turn of the century, lost recognition during the first half of the twentieth century (possibly due to the influence of Behaviorism). During modern applied research, attention was of interest, as the devices humans had to operate became more complex, and consequently more demanding. Of interest was the ability to attend to many objects of stimuli at once, such as in guiding a land, air or sea vessel. These activities involve elements of attention like tracking, vigilance, decision-making, communicating, etc.

Fundamental aspects of attention can be described such as selective attention, or the ability to concentrate on certain elements of one's environment while ignoring others. Divided attention describes the ability to divide attention among various tasks, which may be competing for our attentional resources. The idea of *mental workload* is meant as a measure or assessment of the attentional demands a task may place on a human operator.

3.2. Models of Attention

There is a variety of competing models in the area of attention. The current available models can be divided into two types as they pertain to human factors. The first type is often termed a bottleneck model, which refers to a point in the process where a limit of attention may occur. This type of model may be contrasted with a resource model, where attention is viewed as a capacity that has limits. Further, these two models may each be divided into categories. Bottleneck models can be divided into early selection and late selection. Resource models can be divided into single resource and multiple resources theories.

3.2.1 Bottleneck models

In 1958 Broadbent proposed a model known as filter theory. In filter theory, an early selection model, stimuli enter in the central processor individually and are filtered according to whether they are wanted or extraneous items. Later, other models were proposed in which the filter did not serve to block unattended stimuli, but rather attenuated their signal. Others argued for a late selection model, which would place the screening process later in the sequence of events. The main impetus for this approach was the belief that even unwanted stimuli were at some point being identified. While the issue is quite difficult, in an attempt to deal with conflicting evidence, some researchers felt that the bottleneck was not fixed. Rather there could be a shift from early to late selection in the attentional process.

3.2.2 Resource models

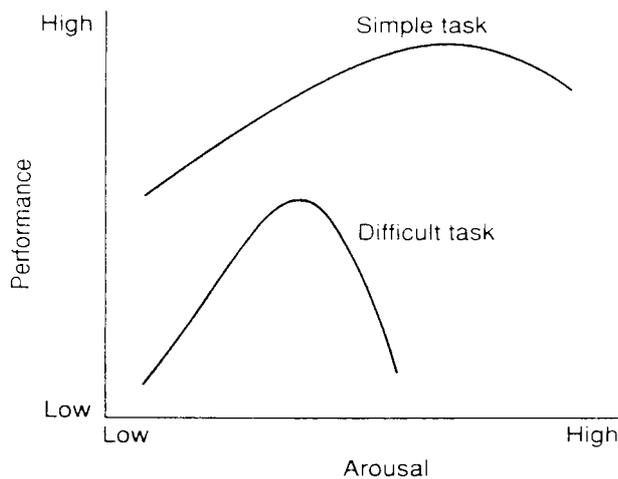
One of the main proponents of the resource model was Kahneman (1973). In his model, attention is viewed as a unitary limited capacity resource. Owing to difficulties in experimental findings, some were led to propose a multiple resource model, which holds that there is no single attentional resource. Rather, there are


Figure 1. Yerkes–Dodson Law.

multiple resources from which we may draw, which may or may not overlap (Proctor and van Zandt 1994).

Basic aspects of attention can be distinguished, such as that of *divided attention*. This refers to the ability to divide attention between two (dual) or more simultaneous tasks. Dual task performance has been studied in great depth in the human factors/ ergonomics literature. Dual tasks are more difficult and demand perceptual motor skills, more closely approximating industrial and military tasks (Ramsey 1995).

3.3. Attention and Arousal

The restriction of attention that occurs during high periods of arousal has been termed perceptual narrowing (Kahneman 1973). An individual's attentional capacity is influenced by his or her arousal. The level of arousal may exert an influence on the amount of attentional resources available. This relationship between arousal and performance underlies a fundamental law known as the Yerkes–Dodson Law (Yerkes and Dodson, 1908). This inverted U-shaped relationship is illustrated in Figure 1.

The Yerkes–Dodson Law states that as arousal increases, performance initially increases. At the point where arousal, presumably from some stressor, exceeds the organisms ability to cope, performance begins to deteriorate. Separate curves can be drawn for different classes of tasks. Simple cognitive tasks appear to be less sensitive to the level of arousal, whereas complex perceptual motor tasks seem to show a greater sensitivity to the level of arousal.

3.4. Dual-Tasks

In situations where an operator's attention must be divided between two competing tasks, the tasks may not have the same priority or emphasis level. In cases such as these, performance on one task can be plotted along with performance on the second task.

The performance trade off or dual-task cost can be captured graphically with a performance operating characteristic (POC) curve. POC is similar to the receiver operating characteristic (ROC) curve, which can plot hit rates against false-alarm rates in signal detection experiments. POC curves allow one to examine such aspects of performance as allocation of attention, divided attention, dual-task cost and an operator's functional performance

region. With these metrics, relative divided attention cost measures can be obtained and compared, which can control for individual differences in task performance.

4. MENTAL WORKLOAD METHODS

4.1. Measurement

There are multiple methods for the assessment of mental workload. The results of these assessments can prove useful in system design and redesign. Further, as the system is broken down into the constituent parts and the workload requirements of the system components analyzed, predictive models of performance can be constructed.

4.2. Assessment Techniques

4.2.1. Primary task measures

Measures of the primary system task can reflect the experimenter's interest and overall system goals determine workload requirements and the choice of these measures on the task of interest.

4.2.2. Secondary task measures

It is assumed that performance on the primary task consumes a certain amount of cognitive resources and a secondary task will use any resources left over from performance of the primary task. Consequently, if the primary task leaves few resources, performance will suffer on some secondary task and performance on this secondary task becomes a measure of mental workload.

When using this method of task analysis, it is important to keep in mind the fact that the secondary task should not seem artificial and distracting.

5. PHYSIOLOGICAL MEASURES

Physiological measures can often remove subjective elements from the analysis. Heart rate analysis can prove quite useful in estimating mental workload. At lower levels of workload, the heart rate frequency can fluctuate, whereas under higher workload heart rate demonstrates greater constancy.

6. SUBJECTIVE MEASURES

On the more subjective side, an easy method for estimating workload is simply to ask the operator how difficult the task. While a highly subjective measure, questionnaires can be constructed in a manner that can allow for greater accuracy in rating. The rating scales should be anchored by thorough descriptions of the extreme and middle scale values and should attempt to analyze the task on multiple dimensions.

6.1. Heat Stress Effects

Studies on the effect of heat have generally yielded inconsistent results. This is partly due to the fact that different kinds of cognitive work are differentially sensitive to thermal stress. The majority of the work in heat and human performance has been concerned with sustained attention or vigilance tasks. However, when analyzing performance on various tasks, one must consider the type of task being performed.

A comprehensive study that took into account the type of task involved and converted, where possible, all temperature measures over to WBGT is Ramsey (1995). By dividing task types

into two categories, Ramsey acknowledged the differentially sensitive nature of task type. The two categories were: mental, cognitive, very simple perceptual motor, sensory, time estimation, reaction time, etc.; other perceptual motor tasks, including tracking, vigilance, vehicle or machine operation, complex or dual tasks, etc.

Category 1 can be thought of as simple cognitive tasks; and category 2 can be referred to as complex or dual-tasks. Ramsey's conclusion in regard to the category 2 tasks (above) is that there is an onset of a statistically significant decrement in performance in the range 30–33∞C WBGT. Simple cognitive tasks are less sensitive to the effects of thermal stress.

Studies in this area have employed a variety of temperature scales (e.g. effective temperature, WBGT, dry bulb temperature); have required the performance of multiple tasks that may draw from different cognitive resources; were often ambiguous about task emphasis, and rarely obtained a baseline of subject performance.

While many past surveys of the literature have focused on the first two difficulties mentioned above (i.e. temperature index and task type), the issues of task emphasis and individual differences in mental capacity have not been properly dealt with in the literature.

The idea of equating baselines is not absent from the literature on attention in general. Past studies have employed this important methodology (e.g. Somberg and Salthouse 1982). A close analogy to equating the baselines of performance is found in the concept of training. If subjects are trained to a specified level of proficiency, one could argue that the task is equally difficult for all participants. This, however, is not persuasive. The method of extended practice has been criticized as an invalid method of equating. Participants will invariably differ in the time taken to achieve a threshold of performance and this difference in the amount of practice may exert significantly on the ability to detect overall differences in performance. Any differences may, in fact, be due to differences in the level of automaticity. Further, it has been argued that heat stress limits based as they currently are, upon physiological responses to stress, ignore the true goal of productive and efficient system performance. Continuing exposure after behavioral performance and efficiency begin to fail, but before physiological limits are reached, is not appropriate for system performance and efficiency (Hancock and Vasmatzidis 1998).

6.2. Reducing Heat Stress

The second Industrial Revolution is bringing about a transition in the type of work being performed. Work activities, in industrial and military settings, are becoming more cognitively demanding. Therefore, the purely physiological approach to environmental stress is no longer sufficient. A cognitive performance approach to evaluating the interface of the worker and the environment is required.

Reduction of stress due to heat in industrial and military settings can be accomplished through a variety of mechanisms. The most effective approach is to reduce heat at the source or to lower, where possible, the environmental temperature and humidity. The use of air conditioners, fans, and/or dehumidifiers can accomplish heat reduction at the source. Along the path from the source to the individual, shielding may be used. At the individual level, interventions could include: loose fitting clothes,

reduction in work rate, enforced rest breaks with provided drinking water and other fluids, and performing outdoor work at cooler times of the day.

Workers should be trained in proper work habits for work in hot environments. Use of equipment such as air-cooled, water-cooled and ice-bag vests can ameliorate the effects of heat.

In terms of heat exposure limits put forth by OSHA (Occupational Safety and Health Administration), one must look at the air velocity, the temperature in WBGT units, and the workload of the constituent tasks.

7. CONCLUSION

As industrial work becomes more cognitive in nature and less physical, safety issues need to evolve to account for the hazards that environmental stress may impose on the workforce. There is a need for universal standards in regard to environmental stressors for different categories of work. Heat, in particular, is a complicated issue and when multiple stressors are imposed, things become quite complex. Data concerning the effect of environmental heat on human cognitive performance in military and industrial settings is one clear future need. A further area of fruitful investigation would be the derivation of predictive models of human behavior under stress. Such models could be quite valuable in the simulation of performance and human reliability in both extreme and more common work environments.

Once the decrement in performance due to heat is observed, one must determine the point of decrement onset by testing at a variety of temperatures. Further aspects of performance can also be investigated, such as ability to allocate attention in varying emphasis levels. By requiring participants to switch attention between two tasks, it can be determined whether heat affects the ability to ignore irrelevant information, attend solely to one task, switch the emphasis level, and equally to share attention among two equally discriminable tasks.

By examining behaviorally based measures rather than physiologically based measures, heat standards and predictive models can be developed that focus upon behavioral performance. In this way, exposure would not continue past the point of performance break down, which may occur before physiological system limits are reached. This area of investigation has come a long way, but future efforts will no doubt lead to more useful findings concerning heat and human performance.

Noise at Work

P.J. School

1. INTRODUCTION

Undesirable sound in the 20 Hz to 20 000 Hz (20 kHz) range is called noise. Noise may be constant or may vary in duration, frequency, or magnitude. Kryter (1970) and Price *et al.* (1989) provide convincing evidence of the debilitating effects of noise on humans. Noise impairs human performance, and high levels cause temporary hearing impairment or permanent hearing loss. Therefore, noise is a Human Factors engineering consideration.

The following is a succinct description of essential concepts that may be used to quiet freestanding items such as pumps, motors or engine-powered equipment. A very extensive coverage of noise and noise control is provided by Harris (1991). Lord *et al.* (1980) is a readable text that contains several examples of practical designs. Hirshorn (1989) is a concise reference.

2. NOISE REDUCTION

2.1. Feasibility

Feasibility determination involves methods that permit the prediction of the magnitude of noise reduction and the cost of noise reduction effort. Basically, data are gathered on a predecessor or mock-up item. Those data are used to generate a notional design and a cost estimate to implement that design. That estimate is compared with medical, worker compensation or other costs that would accrue if the item was not quieted.

If noise reduction is infeasible, measures such as posting warning notices requiring use of hearing protectors or prohibiting access to a noisy area may be used. Because most hearing protection devices impair speech intelligibility and some devices cause discomfort, personnel tend to avoid their use. Also, people occasionally forget to wear hearing protectors. Consequently, the effectiveness of such measures relates to training, monitoring and management control.

2.2. Reductions Achieved

Over the past 15 years, quieting efforts on several free standing, diesel engine powered items produced 5–20 dB noise reductions. Those noise reductions led to attractive cost and human performance benefits.

This experience showed that 6 dB reductions are often readily achievable. Twelve-decibel reductions require more effort and insight. In a few cases, reductions of > 18 dB were achieved. Those large noise reductions involved relocating noisy components, adding vibration isolation, adding parts such as intake and cooling air silencers or balancing rotating parts.

2.3. Sound Level Measurement

Subjective judgement of sound levels is unreliable; therefore, noise assessment or abatement requires sound level measurement and first decimal place accuracy. Instruments that comply with the American National Standards Institute (ANSI) S1.4 Type 0 or Type I sound meter requirements provide sufficient accuracy (ANSI S1.4-1983, para. 3.2). A calibrated Type 0 meter is accurate to ± 0.4 dB; the Type I is accurate to ± 0.7 dB.

2.4. Fundamentals

2.4.1. Sound levels

Sound levels in decibels may be obtained from sound power or sound pressure measurements. Sound power levels (L_w) are expressed as acoustic power in watts (W). Sound pressure levels (L_p) are expressed as the magnitude of air pressure changes in pascals. The term "sound level" indicates that the data are log base 10 transformed.

2.4.2. Sound power level

Sound power level in decibels (dB L_w) is defined as:

$$L_w = 10 \log_{10} (W/W_{ref}), \text{ where } W_{ref} \text{ is } 10^{-12} \text{ watt}$$

or

$$L_w = 10 \log_{10} W + 120.$$

Thus, sound power decibels equals 10 log based 10 of the ratio of a sound power level to the 10^{-12} watt reference level.

2.4.3. Sound pressure level

Sound pressure level in decibels (dB L_p) is defined as:

$$L_p \text{ dB} = 10 \log_{10} (P/P_{ref})^2, \text{ where } P_{ref} \text{ is } 20^{-6} \text{ pascals}$$

or

$$L_p \text{ dB} = 20 \log_{10} (P/P_{ref}).$$

Thus, sound pressure level in decibels equals 20 log based 10 of the ratio of a sound pressure to the 20^{-6} pascals reference level.

2.4.4. Decibels are logarithmic

The sound level algorithms contain a $\log_{10}$ term; therefore, sound levels must be logarithmically added or subtracted. The following decibel addition and subtraction nomographs provide approximations. The algorithms that follow the nomographs are more accurate than the nomographs.

2.4.5. Decibel addition

To add two sound decibel levels ($L_1 + L_2$), subtract L_1 from L_2 to yield X; then arithmetically add the corresponding Y to the larger of the two levels.

Add $X =$	0	1	2	3	4	5	6	7	8	9
$Y =$	3	2.5	2.1	1.8	1.5	1.2	1	0.8	0.6	0.5

Add $X =$	10	11	12	13	14	15 to 19	20
$Y =$	0.4	0.3	0.3	0.2	0.2	1	0.04

Example: If L_1, L_2 are both 100 dB the difference is 0; thus, $X = 0$ and $Y = 3$ dB; so, 100 dB + 100 dB = 103 dB.

The preceding nomograph is based on the following algorithms:

$$\log^{-1} (L_t/10) = \log^{-1} (L_1/10) + \log^{-1} (L_2/10)$$

or

$$L_t = 10 \log_{10} [\log^{-1} (L_1/10) + \log^{-1} (L_2/10)]$$

where

L_t = total sound level
L_1 = a sound level
L_2 = another sound level.

2.4.6. Decibel subtraction

If one has a known overall sound level (L_t) which is the sum of two levels, a known level (L_1) and an unknown level (L_2), then L_2 can be determined by arithmetically subtracting L_1 from L_t to yield "X" for the following nomograph. Then, the "Y" that corresponds to the "X" may be subtracted arithmetically from L_t to yield the unknown level L_2.

Subtract									
X =	0.1	1	2	3	4	5	6	7	8	9
Y =	16.4	6.9	4.3	3	2.2	1.7	1.3	1	0.8	0.6

Subtract						
X =	10	11	12	13	14	15 to 19	20
Y =	0.5	0.4	0.3	0.2	0.2	0.1	0.04

Example: If the overall sound level (L_t) is 100 dB and one of the two emitters (L_1) is 95.0 dB, then X = 5 and Y = 1.7. Therefore, the L_2 level is 100 dB − 1.7 = 98.3 dB.

The decibel subtraction algorithms are

$$L_2 = 10 \log_{10} [\log^{-1} (L_t/10) - \log^{-1} (L_1/10)] \text{ and}$$
$$\text{delta} = \log^{-1} (L_t/10) - \{10 \log_{10} [\log^{-1} (L_t/10) - \log^{-1} (L_1/10)]\},$$

where

L_t = total sound level
L_1 = measured sound level of one emitter
L_2 = an unknown sound level produced by another emitter
delta = the amount to be subtracted from the overall (L_t) level.

2.5. Inverse Distance Relationship

Sound waves from a point source that is surrounded by nothing but uniform density air (a free field) radiate in a spherical pattern. Under those circumstances, sound pressure levels are inversely proportional to the distances from the emitter.

A way to extrapolate sound pressure level over distance in a free field is called the "6 dB rule." According to the rule sound pressure levels increase or decrease by 6 dB if the distance to the source is halved or doubled. Using the rule, if the sound pressure level emitted by a point source is 100 dB at 10 m then the level at 5 m would be 100 + 6 dB = 106 dB; and at 20 m the level would be 100− 6 dB = 94 dB.

Sound waves radiating from a sizeable emitter do not become spherical until they travel some distance from the emitter. The area where sound waves have not become spherical is called "the near field." Extrapolations to or from the near field are likely to be inaccurate. Therefore in the near field, sound level measurements are preferred to extrapolations. Textbooks suggest that the near field extends four to seven times the largest item dimension. Thus, if an item's largest dimension is 2 m then the near field could extend 8–14 m from the item.

2.6. Octave Data

An audio spectrum is needed to decide the feasibility of noise reduction and the design. Full octave or fractional octave measurements can provide a sound magnitude versus sound frequency spectrum.

Noise measurement octaves are approximate frequency multiples. Commonly used full octave band center frequencies are 31.5, 62, 128, 250, 500 Hz, etc. One-third octave noise measurements provide a more complete audio spectrum. The common one-third octave center frequencies are 31.5, 40, 50, 63, 80, 100, 125, 160, 200, 250 Hz, etc.

2.7. Sound Level Weighting

A widely published family of curves (Fletcher and Munson 1933) shows that human hearing is non-linear with respect to both frequency and sound pressure. "A-Weighted Decibel Level" (dB(A)) measurements take the non-linearity of human hearing into account. Therefore, much noise reduction work is done with dB(A) data.

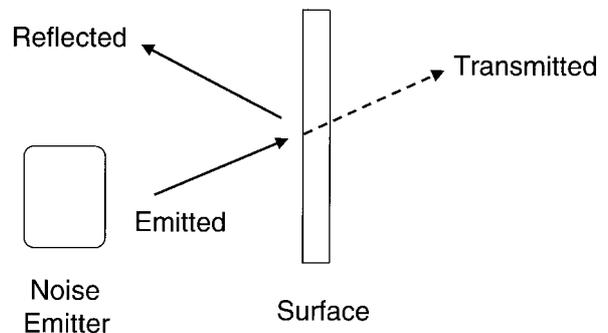
2.8. Sound Wave Fates

Though other phenomena may occasionally be of interest, three sound wave fates are almost always of interest. A sound pressure wave may

1. radiate in all directions from an emitter;
2. be reflected from a surface; or
3. be absorbed by a surface.

If a sound wave strikes a surface, some of it may be transmitted through the surface.

For simplicity, Figure 1 depicts a single set of wave paths as straight lines rather than a spherical pattern. If a sound wave

1. does not strike a surface but instead radiates through uniform density air, the sound pressure level will decrease 6.02 dB with each doubling of the distance; or
2. if the wave strikes a mostly reflective surface, most of the sound will be reflected toward the emitter, some of the sound will be absorbed in the surface and the rest will be transmitted through the reflective surface; or
3. if the wave strikes a mostly absorptive surface, most of the sound will be absorbed (converted to heat) in the surface,


SIMPLIFIED SOUND PATHS

Figure 1.

some of the sound will be reflected by the surface, and the rest will be transmitted through the absorptive surface.

Most surfaces reflect, absorb and transmit sound. Designing a noise-reducing surface typically involves using those characteristics in ways that result in sufficient noise reduction while avoiding unacceptable cost, weight or size gains.

2.8.1. Transmission loss

Sound level reductions that occur from one side of a surface to the other are called "transmission loss." Reflecting sound or absorbing sound can produce transmission loss. The noise spectrum of interest and design limits (such as weight and size) determine whether one uses reflection, absorption, or the combination of both to achieve transmission loss.

3. NOISE REDUCING AN ITEM

3.1. Noise Levels Add Logarithmically

The overall sound level produced by a group of emitters is the sum of the levels produced by each emitter in the group. For example, if an emitter had a sound level of 100 dB and a second emitter was added, then the sound level would increase to 103 dB. On the other hand, if two emitters are > 10 dB apart, the combined level will increase < 0.5 dB. Thus, noise-reduction effort usually focuses on emitters that are < 10 dB of the overall level.

3.2. General Noise-reduction Strategies

Two common strategies for reducing noise are (1) surrounding the noisy item with a noise attenuating enclosure or (2) quieting emitters that comprise the item.

If one cannot change the design of the noisy item itself, noise reduction usually involves an enclosure. With engine-powered items, enclosure design usually requires the use of absorption and reflection. Many items require cooling airflow and that may be provided by sound-attenuating ducts.

3.3. Noise Emitter Determination

Noise reduction efforts begin with overall noise and significant emitter noise measurements. To focus attention productively, one ranks significant emitters (emitters that are within 10 dB of the overall noise level) from highest level to lowest level. Significant emitters may be located by measuring levels at short distances, by making suspected components temporarily inoperative or by touching suspected areas to detect vibrations or rattles. Suspected high frequency (> 1 kHz) emitters may be confirmed by surrounding them with home insulation type glassfibre. To confirm suspected low frequency (< 1 kHz) emitters, surround them with lead-filled foam polymers or other dense material such as lead roof flashing.

3.4. The Ideal Mass Law

Thin, lightweight absorptive materials produce large transmission losses at frequencies > 1 or 2 kHz. At frequencies < 1 kHz, absorptive materials are usually impractical because the thickness needed would be unacceptable. So, reflection is used to achieve low frequency transmission losses.

Reflection-caused transmission loss for a single wall surface can be estimated with an idealized approximation of "the mass law." Hirshorn (1989: D-2) provides the following algorithms for ideal transmission loss sound pressure calculations.

3.4.1. Ideal mass law for English units

Transmission loss (T_L) = 20 log W + 20 log F – 33.5,

where

W = mass density of the reflecting surface (lb per ft^2)
F = frequency (Hz).

3.4.2. Ideal mass law for metric units

Transmission loss (T_L) = 20 log W + 20 log F – 47.5,

where

W = mass density of the reflecting surface (kg per m^2)
F = frequency (Hz).

Figure 2 shows ideal transmission loss for two surface mass densities. Please note that each doubling of either the mass density or the frequency of sound impinging on the surface increases the transmission loss 6 dB.

A comparison of ideal mass law calculations to data gathered with 10 lb/ft^2 material shows that calculated values deviate from measured transmission losses by 5–8 dB at frequencies < 1 kHz (Hirshorn 1989: D-3). Low frequency deviations from ideal mass law numbers are caused by factors described in some detail by Lord *et al.* (1980; 242–7).

To adjust for Ideal Mass Law deviations from empirical data, we estimate low frequency transmission losses by subtracting 6 dB from each of the calculated ideal transmission loss numbers < 1 kHz. Then, we use measurements made on prototyped enclosures to determine if the low frequency transmission losses lead to sufficient overall noise reduction. If not, we adjust the design by changing the surface density or by adding damping to the surface.

Damping increases low frequency transmission losses by converting sound to heat or by shifting the surface resonance to a lower frequency. Thus, damping can avoid some of the weight gain associated with increasing the surface mass density of an untreated surface. Damping may be achieved by adhesively

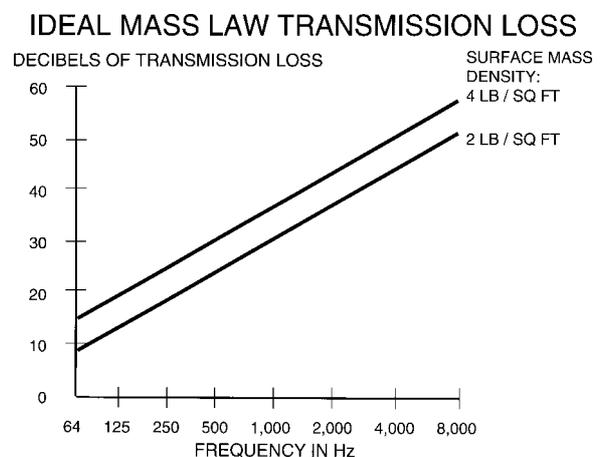


Figure 2.

attaching damping materials to the surface or by making the surface with composite materials that provide good damping.

3.5. Calculating Absorption

Many acoustics texts list sound absorption coefficients for commonly used materials. Additionally, manufacturers of acoustic materials provide lists of absorption coefficients.

According to Hirshorn (1989; C-6), the sound absorption coefficient equals sound energy absorbed (converted to heat) divided by the incident sound energy. Therefore, absorption-caused transmission losses are calculated by multiplying the sound power level by the appropriate (frequency dependent) absorption coefficient of the absorptive material. To do that, sound pressure levels (L_p) are converted to sound power levels (L_w) that are multiplied by the appropriate (frequency dependent) absorption coefficients.

According to Harris (1991; 1.12, 1.13), the metric units L_w to L_p to algorithm is:

$$L_w = L_p + 20 \log_{10} r + 10.9 - C,$$

where

> r = distance from the emitter (m)
> $L_w = 10^{-9}$ watts reference level
> C = an air density correction term.

The English units algorithm is:

$$L_w = L_p + 20 \log_{10} r + 0.6 - C,$$

where

> r = distance from the emitter in feet.

C varies from +0.55 at 1100 millibars, −10°C, to −0.73 at 900 millibars, 55°C. Harris provides a C = 0.6 at 1000 millibars, 20°C.

Those algorithms apply to situations in which sound can radiate in a free (unobstructed) field. An enclosure that surrounds a machine is anything but a free field. Therefore, sound reverberates inside an enclosure and "builds up."

Estimating reverberative buildup with calculations is arduous and error prone. Instead of attempting to calculate reverberative buildup, we develop a design by degrading the calculated transmission losses for frequencies < 1 kHz by 6 db each. Then, we construct a mock-up enclosure and change the thickness or type of liner material as measurements on the mock-up indicate.

4. NOISE ENCLOSURE DESIGN RECOMMENDATIONS

4.1. In General

1. Use a calibrated sound meter to obtain overall dB(A) sound levels and overall full or fractional octave data. Then identify the high level emitters and gather the same data at those loci.

2. Rank significant emitter levels from greatest to least dB levels.

3. Focus effort on emitters that are within 10 dB of the overall sound level, and do whatever is practical to quiet each.

4. Select a surface mass density that causes the transmission losses (each minus 6 dB) < 0.75 kHz to meet design goals.

5. Initially line the interior enclosure surface with thick absorptive material.

6. Assure that the total area of all unsealed openings through the enclosure does not exceed 1% of the total enclosure surface area.

7. Iterate the design to optimize tradeoffs of weight, noise reduction, and component accessibility.

4.2. Recurrent Design Elements

Over several enclosure design efforts (1) sufficient low frequency transmission loss was usually obtained with 1–2 lb/ft² surface material; and (2) an absorptive liner consisting of 1–3 inches of glass fiber usually was needed.

On unquieted engine-powered items, noise emitted from the engine fan, crankcase, engine air intake, hydraulic components or the power train was usually within 10 dB of the overall noise level. Exhaust noise was usually not within 10 dB.

4.3. Tips

- For early design mock-ups, a low cost enclosure can be made of common 0.5-inch thick gypsum wallboard mounted and sealed with duct tape. To reduce reverberative buildup, the inside should be lined with glass fiber.
- Commonly available spreadsheet software can be used to aid calculation.

1. BASIC DEFINITIONS

All disturbing, annoying, strenuous and hazardous sounds influencing the hearing organ and other senses of a human body are considered as noise.

From the point of view of physics all sounds are mechanic vibrations of an elastic medium (gas, liquid or solid). Those vibrations can be considered as an oscillating movement of medium particles around the state of equilibrium, causing the change of the medium pressure versus the static (atmospheric) pressure. Out of this change of pressure (it means, the disturbance of equilibrium), which in a form of successive local condensations and thinnings of medium particles is transferred into the space surrounding the vibration source, an acoustic wave is being formed.

The difference between the pressure instantaneous value at the acoustic wave passing pressure value is called the acoustic pressure, p (expressed in Pa). Considering the wide range of an acoustic pressure from $2 \_ 10^{-5}$ to $2 \_ 10^2$ Pa the logarithmic scale is used and as a consequence the notion of an acoustic pressure level, L, expressed in dB is applied — according to the equation:

$$L = 10 \lg \frac{p^2}{p_0^2} \qquad (1)$$

where p is root mean square pressure value (Pa), p_0 is threshold of rms pressure value, called the reference sound pressure value, equal to 20 mP.

This is a nominal value equivalent of an acoustic pressure of the single tone (sinusoidal vibration) of 1000 Hz frequency at which the hearing impression forms, it means, the so-called threshold of audibility for that frequency occurs.

Ranges of an acoustic pressure occurring in an environment are shown in Figure 1.

All values characterizing the noisiness of work environment — which are going to be discussed in the further parts here — maximal sound A level, peak sound C level, A-weighted sound level, the level of personnel exposure to a noise related either to an 8-h work period or to a week work period are quantities based on the acoustic pressure level.

The acoustic pressure levels corrected according to the frequency-weighting characteristics A and C sound level meters are called the sound A level and the sound C level respectively.

The maximal sound A level means the maximal effective level of sound A occurring during the observation while the peak sound C level the maximal instantaneous level of sound C occurring during the observation.

The equivalent A-weighted sound level, $L_{Aeq,T}$ (the value used either for the description of the noise varying in time or the variable exposure time) is defined as a mean value of the sound A level varying in time being an equivalent to the reaction of a hearing organ exposed to the influence of a constant level noise in a weighted period of time. It is expressed in dB and given by the formula:

$$L_{Aeq,Te} = 10 \lg \left[\frac{1}{T_e} \int_0^{T_e} \left(\frac{p_A(t)}{p_0} \right)^2 dt \right] \qquad (2)$$

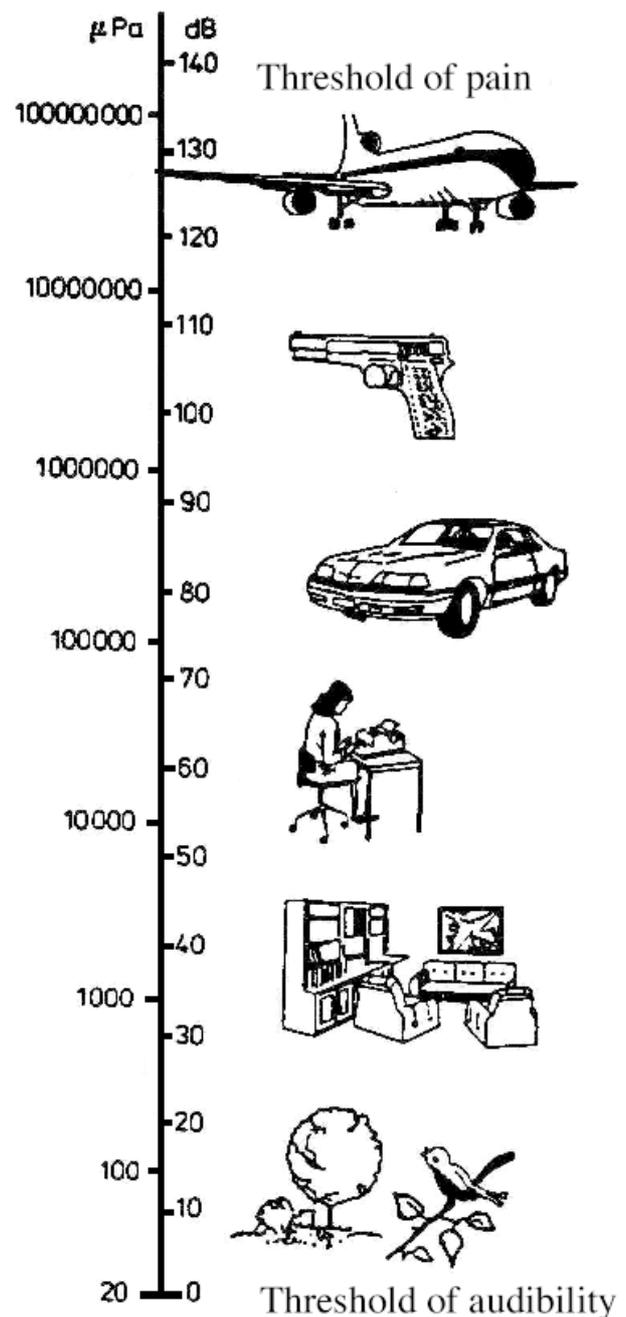

Figure 1.

where T_e is time of exposure (s), p_A is instantaneous value of an acoustic pressure, corrected according to the frequency-weighting characteristics A (Pa).

The A-weighted sound levels, in dB, related to a normal work period (either 8 h or a week) are called the sound exposure level related to the 8-h work period — $L_{EX,8h}$ or related to the week work period — $L_{EX,w}$ and are given by formulae:

$$L_{EX,8h} = L_{Aeq,Te} + 10\lg\frac{T_e}{T_0} \qquad (3)$$

$$L_{EX,w} = 10\lg\left[\frac{1}{5}\sum_{i=1}^{n}10^{0,1(L_{EX,8h})}\right] \qquad (4)$$

where $L_{Aeq,Te}$ — equivalent A-weighted sound level related to the sound exposure time T_e (dB), T_0 is reference time = 8 h = 28 800 s, i is consecutive workday in a specified week, n is number of workdays in a specified week (can be different than 5).

Instead of the exposure time level related to the workday or week another expression called the daily or weekly noise exposure is in use, $L_{A,Te}$ (Pa^{2}s). The interrelation between the noise exposure and the noise exposure level related to 8 h work period is as follows (2–4):

$$L_{A,Te} = 1.15\cdot10^{-5}\cdot10^{0,1L_{EX,8h}} \qquad (5)$$

The knowledge of several additional acoustic phenomena is needed for the effective application of technical means of noise control. They are:

- Velocity of an acoustic wave propagation (speed of sound), c, it means the velocity of the propagation of disturbance of the medium equilibrium defined as the ratio of the distance traveled by the disturbance in an elementary time interval to the value of that interval. For example this velocity equals 340 m/s in the air of temperature 20°C and at the normal atmospheric pressure.
- Acoustic vibration period, T is the shortest time interval after which the same state of an observed phenomenon (vibrations or disturbances) is repeating itself.
- Acoustic vibration phase, f, is the value of a vibrating particle deviation — in the given point and at the given moment — from the mean value of the particle location.
- Acoustic vibration frequency (sound frequency), f, is the number of vibration periods in the time unit.
- Acoustic wave length, l, is the distance between two successive points, measured in the direction of the disturbance propagation, in which the vibrations are in the same phase (or the distance traveled by the wave front during one full period).

The acoustic wavelength is given by the expression: $l = c/f$, in m, where c is the sound velocity in m/s and f is the frequency (Hz). For the audiofrequency range: f = 16–16 000 Hz and the wavelength: l = 21–0.021 m.

In simplification, one can say that the noise is the sum of a large number of sinusoidal vibrations. Factoring the complex vibrations into a sum of single vibrations is called the spectrum determination or the spectrum (frequency) analysis of noise.

A transmission of the disturbing energy is connected with an acoustic wave propagation in a medium. The acoustic wave energy is characterized by the following notions and values:

- Sound power of a source, N_a, in W is it is the measure of the energy radiated by the source in the unit of time:

$$N_a = \frac{E_a}{t} \qquad (6)$$

where E_a is acoustic energy of a source (W◊s), t is time (s).

- Sound intensity, I_a in W/m^2, the value of an sound power transmitted by a unit area perpendicular to the direction of an acoustic wave propagation:

$$I_a = \frac{N_a}{S} \qquad (7)$$

where N_a is sound power (W), S is surface area (m^2).

The following relationship exists between the sound intensity, I_a (W/m^2) and the acoustic pressure (p):

$$I_a = \frac{p^2}{\rho\cdot c} \qquad (8)$$

where r is medium density (kg/m^3), c is sound velocity (m/s).

Similarly to the acoustic pressure, because of the wide range of an acoustic power and sound intensity variations, the logarithmic scale is in use and notions of:

- sound power level, L_N (dB):

$$L_N = 10\lg\frac{N_a}{10^{-12}} \qquad (9)$$

- sound intensity level, L_L (dB):

$$L_i = 10\lg\frac{I_a}{10^{-12}} \qquad (10)$$

The sound power level is the basic value characterizing the emission of noise from its source and therefore it is applied for the estimation of a machinery noisiness. In practice, the sound power level corrected according to the frequency-weighting characteristics A, called a sound power level A is the most often used.

Taking into consideration the type of noise influence on people it can be either called the annoying noise — not causing any permanent effects in humans, or the harmful noise — which either causes permanent effects or creates a certain risk of their occurrence.

In respect of its time dependency the noise is either steady — when the sound A level in a certain point varies not more than by 5 dB — or transient (variable in time, interrupted) — when the sound A level in a certain point varies by more than 5 dB. One kind of the transient noise is the impulse noise consisting of one or more sounds, each of a duration < 1 s (PN-N-01307:1994).

DIVISION OF SOUNDS CONSIDERING THEIR FREQUENCY

Inaudible sounds	Sounds audible for humans			Inaudible sounds
	Audible low tones, sensitivity of human organs	Middle tones, sharpened sensitivity of human hearing organs	Overtones, weaker sensitivity of humans	Ultrasounds
1 10	10 100 20	0 10	00 40	00 10000	20000 Hz

Audibility range for dogs

Audibility range for bats

Machine noise

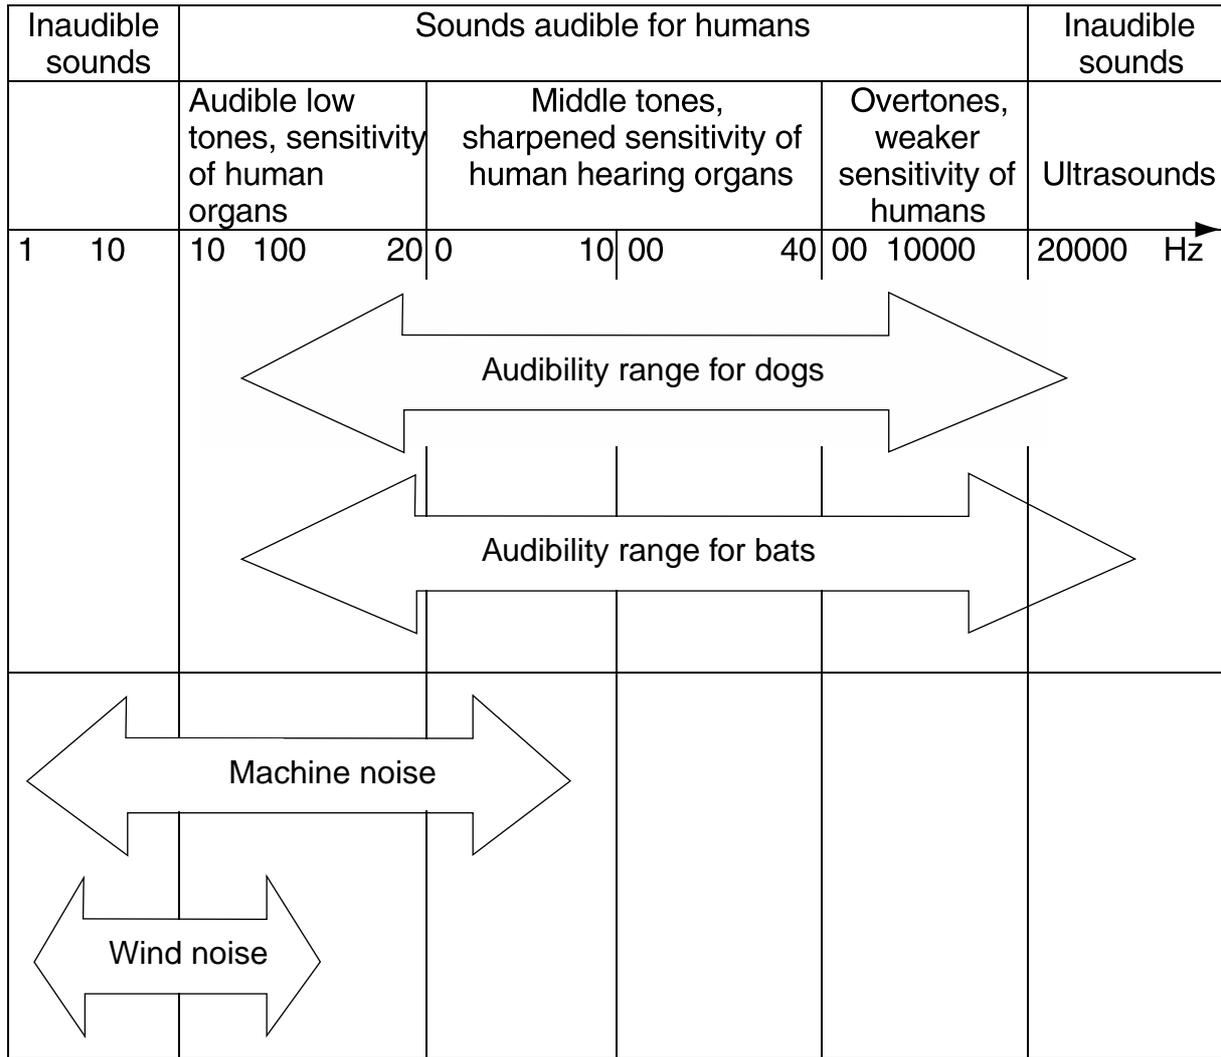
Wind noise


Figure 2.

Taking into account its frequency range the noise can be divided into three groups:

- Infrasound noise, in which spectrum there are components of infrasound frequencies from 2 to 16 Hz and of audible ones up to 50 Hz (PN-N-01338:1986) [26].
- Audible noise, in which spectrum there are components of audible frequencies from 16 to 16 000 Hz.
- Ultrasound noise, in which spectrum there are components of audible and ultrasound frequencies from 10 to 100 kHz.

There are also some other methods of differentiations of noise, e.g. taking into consideration the cause of its formation and the classification of its sources. There is, for example, an aerodynamical noise — formed as a result of the air or other gas movement, and a mechanical noise caused by friction and collisions of solids, mainly elements of machines. There is also a way of dividing noise by considering an environment in which it occurs. A noise in industry is called an industrial noise, a noise in housing areas, public utilities and rest areas is called a communal noise while the noise in means of transportation a traffic noise.

The schematic presentation of the sound division when taking into account their frequencies is given in Figure 2.

1.2. Loudness and Noisiness

The relation between physical values characterizing sound and a subjective feeling is not simple, however strictly defined. Subjective characteristic values of a sound are loudness — depended on its intensity, and a timbre — depended on the spectrum frequency and timing (duration, time variation of the intensity — sound building up and decay).

Interrelations of the sound loudness and intensity in the whole audibility range is presented in Figure 3. Narrow lines represent curves of the equal loudness level, giving the isophone contours. The intensity range is very broad, for example for the tone of 1000 Hz frequency (standard value in acoustics) it spreads out from the threshold value of $2 \_ 10^{-12}$ W/m², hardly noticeable by an ear, (equivalent to the threshold of audibility of an acoustic pressure of $2 \_ 10^{-5}$ Pa) to the 10 W/m² being the threshold of pain.

Taking into account the wide span of the intensity of an

Figure 3.

Figure 4.

auditory sensation area as well as the fact that the impression of loudness is (in agreement with the Weber–Fechner's law — valid for all senses) proportional to the logarithm of the sound intensity, the level of the sound intensity (equation 40) related to the threshold of audibility of the 1000 Hz frequency tone has been introduced: $I_0 = 10^{-12}\,W/m^2$.

In Figure 3 the straight horizontal lines represent equal sound levels from 0 to 130 dB in 10-dB intervals (marked on the axis of ordinates) and acoustic pressures marked on the left hand side of the same axis. The frequency given on the axis of abscissae is also in the logarithmic scale.

2. INFLUENCE OF NOISE AND ITS EFFECTS ON A HUMAN BODY

The negative influence of noise on a human body under the condition of occupational risk can be divided into two kinds (Figure 4):

- health effects (hearing organ, general health condition, etc.),
- functional effects (non-hearing-related influence on a human body).

2.1. Influence of Noise on a Hearing Organ

The harmful influence of noise on a hearing organ is connected with the following features and risk occurrences:

- A-weighted sound level or sound A level (for a steady noise) > 80 dB. Weaker stimuli are not harmful for the hearing organ even when acting for a long time without any interruption (Table 1).
- Long time of the noise exposure. The effects accumulate in time, they depend on the acoustic energy doze transferred into a body in a certain period (Table 1).
- Continuous exposure to noise is more harmful than interrupted. Even short brakes allow for the regeneration process of the hearing organ. The impulse noise is especially harmful. It is characterized by such rapid and high increase of the acoustic pressure that the defending mechanism of the hearing organ preventing the energy penetration into the ear has no chance to react.

Table 1. The risk of noise induced impairment of hearing as a function of the A-weighted sound level and the time of exposure (ISO 1999: 1975)

A-weighted sound level, dB	Risk of impairment of hearing,% Time of exposure in years							
	5	10	15	20	25	30	35	40
< 80	0	0	0	0	0	0	0	0
85	1	3	5	6	7	8	9	10
90	4	10	14	16	16	18	20	21
95	7	17	24	28	29	31	32	29
100	12	29	37	42	43	44	44	41
105	18	42	53	58	60	62	61	54
110	26	55	71	78	78	77	72	62
115	36	71	83	87	84	81	75	64

- Noise spectrum with the majority of components of medium and high frequencies. Noise of such spectrum is more dangerous for the hearing than the one with the maximal energy in the low frequency range. That is connected with the fact that the sensitivity of a human ear is the highest in the frequency range 3–5 kHz.
- Special, individual susceptibility to impairment of hearing. It depends on the inherited features as well as acquired ones (e.g. as a result of past diseases).

Table 1 illustrates the individual susceptibility to noise. Of persons who worked for 40 years in the environment where the equivalent sound level equaled 90 dB, 21% would suffer from hearing loss. Lowering the level to 85 dB decreases the percentage of sufferers to 10%. Persons of a special susceptibility to the harmful influence of noise will be mainly in that group.

The effects of noise influence on the hearing organ can be divided as follows:

- Impairment of anatomic structures of the hearing organ (perforations, diminution of eardrum membrane) being mainly the result of a single and short exposure for noise of the peak acoustic pressure > 130–140 dB.
- Impairment of a hearing efficiency manifesting itself as the increase of the threshold of audibility. It is normally the result of a prolonged exposure to noise of the A-weighted sound level > 80 dB. This increase of the threshold can be reversible (temporary threshold shift) or permanent (permanent hearing loss).
- The audiometric examinations reveal the permanent hearing loss. The average permanent hearing loss of 30 dB at frequencies of 1000, 2000 and 4000 Hz on the side of a better ear, after making allowances for age, is considered the critical loss. It is the base for the diagnosis and the medical certificate of the occupational deafness as the occupational disease.
- The occupational hearing loss (the occupational deafness), the permanent disability without the possibility for any improvement has been for years ranked high on the list of occupational diseases. There are ~3000 new cases yearly what constitutes one-third of all cases registered in Poland.

2.2. Non-Hearing-related Influence of Noise

The non-hearing-related influence of noise on a human body is not fully recognizable. The anatomical connection of a nervous hearing system with a cortex enables hearing stimuli to influence other brain centers (especially the central nervous system and the endocrine glands system) and as a consequence a state and functioning of many internal organs.

It has been experimentally proofed that significant disorders of a body physiological functions can occur when the acoustic pressure level > 75 dB. Weaker acoustic stimuli (55–75 dB) can cause distraction of concentration, hindrance of work and the reduction of its efficiency. It can be stated that the non-hearing-related effects are generalized responses of a human body on a sound influence as the factor contributing to the progress of several illnesses (high blood pressure, gastric ulcers, neurosis, etc.).

Among non-hearing-related effects their influence on understanding and concealing of speech and sound security signals should be mentioned. Difficulties in a verbal communication in a noisy environment (of 80–90 dB level) and concealing of warning

signals not only increase the strenuousness of working conditions and reduces the work efficiency but also can be the reason of injury at work. The criterion of speech understanding is one of the main criteria of the noise estimation in an environment.

3. MEASUREMENTS AND THE ESTIMATION OF NOISE IN AN ENVIRONMENT

Taking into consideration the purpose of measurements the methods are divided into:

- methods of measuring machine noise; and
- methods of measuring noise in places occupied by people (at work places).

3.1. Methods of Measuring Machine Noise

Those methods are applied for the determination of values characterizing noise of a machine considered as a separate noise source at certain experimental and exploitation conditions. Such values are: an acoustic power level A or an acoustic power level in frequency bands (calculated either on the bases of the acoustic pressure level or the sound intensity), the A-weighted sound level and the sound C peak level at work places (for machines equipped with the work place fixed the machine), a noise source direction indicator (if necessary), an acoustic pressure level and a sound A level — measured at specified measuring points (e.g. in case where the acoustic power level is impossible to be measured). (In an agreement with standard EN ISO series 11200 they are called the averaged in time pressure level of an acoustic emission corrected by characteristics A, and the peak level of an acoustic emission corrected by characteristics C.)

The measured values are applied for:

- Comparison of measured levels with the established boundary values.
- Designing, implementation and the estimation of noise control and reduction means.
- Comparison of machine noises either of the same kind or of different kinds.
- Establishing the sound A level or the acoustic pressure level at a specified distance from the source.

All those values should be determined according to the European and international standards EN ISO 3740 and EN ISO 11200.

3.2. Methods of Measuring and Estimating Noise in Places Occupied by People

Those methods are used for establishing the degree of risk to be noise exposed for people at their work places and in specified distances from the noise source or sources. The results are mainly used for the comparison of existing acoustic conditions with the conditions required by standards and hygienic regulations. They are also helpful in the estimation and choosing the proper enterprises for noise control.

Methods of measuring noise in the work environment are given in standards. The instrumentation system, noise dosimeters or integrating sound level meters of a type 2 or better accuracy and at least 53 dB impulse range should be applied (they should meet the requirements of IEC 804:1985 and IEC 1252:1993).

There are two basic methods of measurements: direct and indirect.

The direct method consists of the continuous measurement during the whole time of worker exposure and of reading the meters, e.g. the noise dosimeter or the integrating sound level meter. Those results precisely describe the workers' risk.

The indirect method is based on the noise measurement done in the shorter time than the one being assessed and the use of mathematical formulae for the estimation of values needed.

The mode and frequency of taking measurements, the way of their registration, storing and making available for workers are given in the regulation of the Ministry of Health and Social Security.

The estimation of the occupational risk is based mainly on the comparison of measured or estimated noise values with the permissible ones (the level of noise exposure, the maximal sound A level and the peak sound C level) being in force simultaneously. Even if only one of those values is higher than allowed the noise is regarded as exceeding the permissible value.

3.3. Permissible Noise Values in Work Environment

Allowed noise values in regard of a hearing protection — according to standards of many countries — are as follows:

- Noise exposure level related to 8-h work day ($L_{EX,8h}$) should be < 85 dB and the equivalent daily exposure should not overcome $3.64 \_ 10^3\,Pa^2\,s$ or (only when the noise is affecting a human body unevenly in separate days of a week).
- Noise exposure level related to the work week ($L_{EX,w}$) should be < 85 dB and the equivalent week exposition should be < $18.2 \_ 10^3\,Pa^2\,s$.
- Maximal sound A level (L_{Amax}) should not exceed 115 dB.
- Peak sound C level (L_{Cpeak}) should not exceed 135 dB.
- The last two values are important for the estimation of short and impulse noises.
- Given above standard regulations are compulsory if any special rules are not stating still lower values (e.g. at a juvenile work place — $L_{EX,8h}$ = 80 dB and at a pregnant woman work place — $L_{EX,8h}$ = 65 dB).
- Taking into account the possibility of fulfilling the basic tasks by workers (it means considering the non-hearing-related noise effects — the strenuousness criterion) the noise values should not be higher than listed in Table 2.

Table 2. A-weighted sound level $L_{Aeq,Tc}$ for employees present at their working places (in accordance with PN-N-01307:1994)

No	Work place	A–weighted sound level, $L_{Aeq,Tc,}$ dB
1.	Direct control cabins without a phone connection, laboratories with noise sources, rooms with computers, typing machines, fax, and other rooms of similar destination.	75
2.	Dispatcher's cabins, observation and remote control cabines with a phone connection used in a process control, rooms for precision works and other rooms of similar destination.	65
3.	Administration rooms, design offices, rooms for theoretical works, data processing and other rooms of similar destination.	55

Notice: Values in Table 2 should not be related to 8 h work day. They concern nominal time, T_e, during which an employee is present at the certain work place.

3.4. Noise Risk and Sound Sources in Work Environment

Large number of employees of basic branches of the economy and industry, in many countries, work under the risk condition because of annoying and stressful factors of the work environment, among them noise of an exposure level > 85 dB.

The most endangered are workers of industry, building, forestry and transport, metallurgy, machine industry, chemical industry, mining and electric power plants.

Main noise sources in machinery and equipment are shown in Figure 5.

Assuming that the main noise sources at work places are machines, equipment and technological processes, one can specify the basic groups of noise sources [5]:

- Machines being the energy sources, e.g. engines (maximum sound A level up to 125 dB), compressors (up to 113 dB).
- Tools and pneumatic engines, e.g. hand operated pneumatic tools: hammers, chisels, grinders (up to 134 dB).
- Machines for comminution, crushing, sieving, cutting, cleaning, e.g. ball mills (up to 120 dB), vibration sieves (up to 119 dB), crushers (up to 119 dB), shaking grids (up to 115 dB), circular saws for metals (up to 115 dB).
- Machines for plastic forming, e.g. pneumatic hammers (up to 122 dB), presses (up to 115 dB).

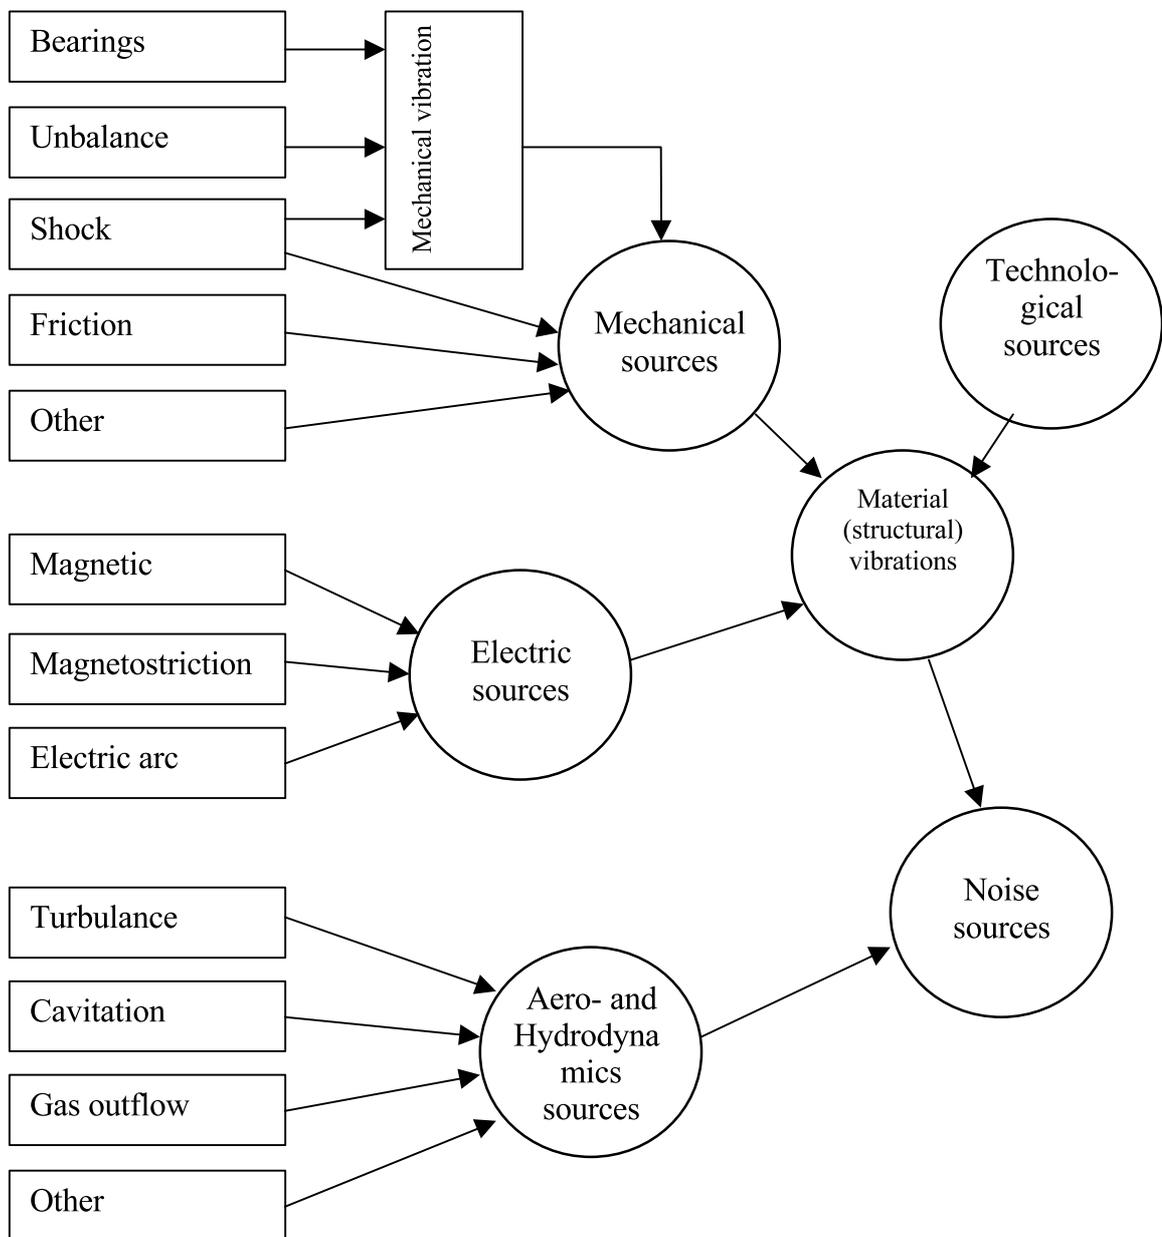
NOISE SOURCES IN MACHINES AND EQUIPMENT


Figure 5.

- Metal working machines, e.g. grinders, automatic lathes, boring machines (up to 104 dB).
- Woodworking machines, e.g. chisels (up to 108 dB), planers (up to 101 dB), moulders (up to 101 dB), circular saws (up to 99 dB).
- Textile machines, e.g. winders (up to 114 dB), looms (up to 112 dB), spinning frames (up to 110 dB), drawing frames (up to 104 dB), twisters (up to 104 dB), carding machines (up to 102 dB), flow devices, e.g. valves (up to 120 dB), vents (up to 114 dB), works transport devices, e.g. overhead cranes, conveyers, feeders (up to 112 dB).

4. METHODS AND MEANS OF THE NOISE PROTECTION

According to the European and national regulations an employer is obliged to provide the protection against hazard connected with the noise exposure and ensure the application of:

- Technological processes not generating any excessive noise.
- Machines and other technical equipment causing as small as possible noise, not in excess of the quantity allowed.
- Solutions lowering the noise level at work places (with the priority for means of the noise reduction at its source).

At those work places, where regardless of applying all possible means of the noise reduction, the noise level is exceeding the limit, an employer is supposed to:

- Find out the reason of such noise and to design the program of technological and organizational activities aimed at lowering that noise.
- Provide employees with hearing protections, matching the noise characteristics as well as individual features of workers and to enforce the use of such protections.
- Limit the noise exposure time and to introduce work breaks.
- Mark the noise hazard zones and, when reasonable and feasible, to limit the access to such zones by fencing them.

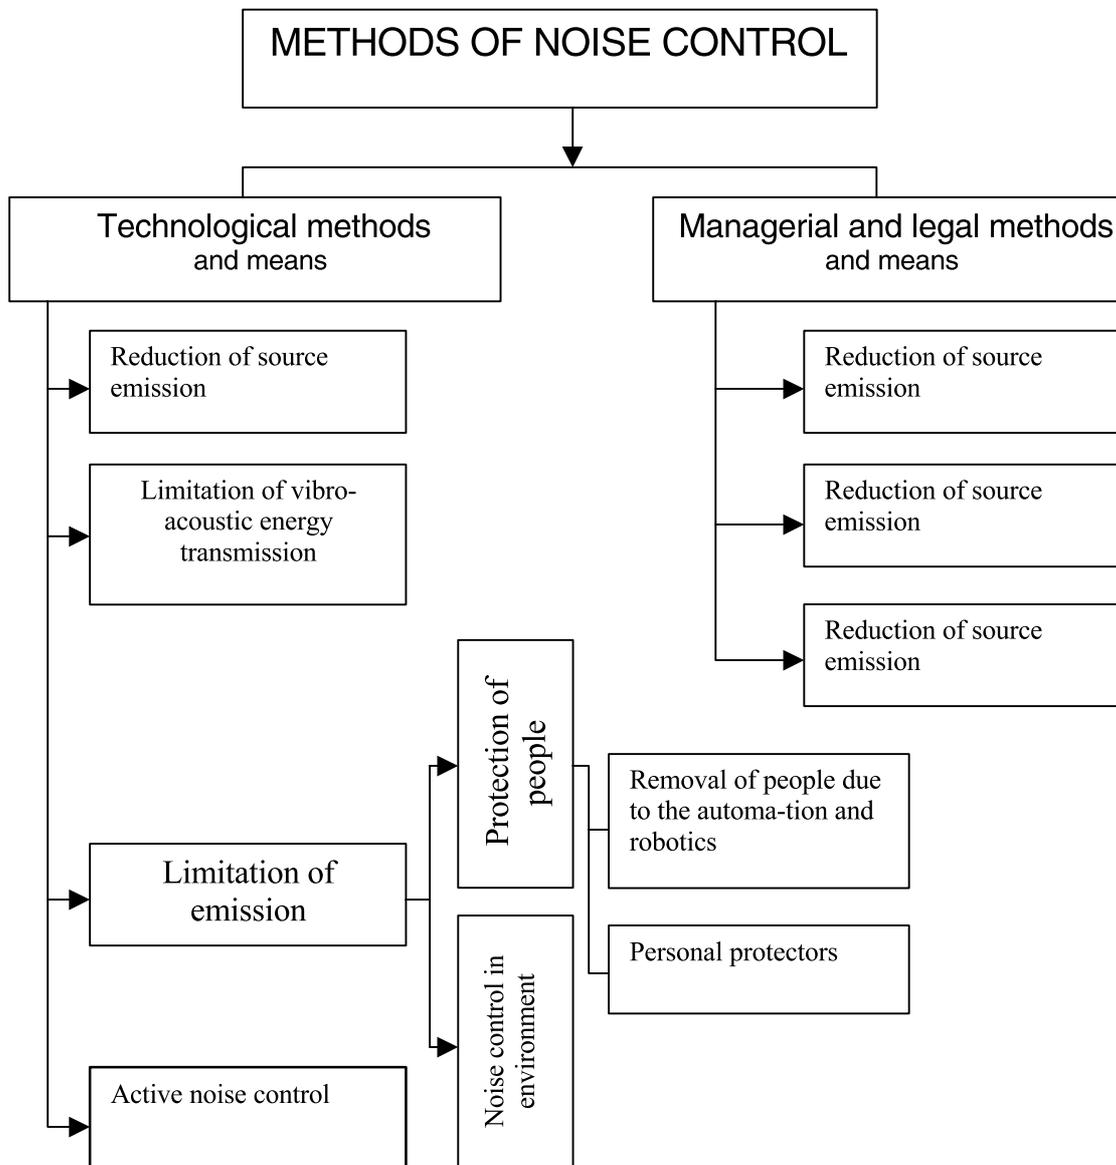
Persons employed at those work places must be provided with the information concerning:


Figure 6.

- Noise measurements results and the health hazard they are facing.
- Activities undertaken in connection with noise exceeding the limit.
- Proper selection of individual hearing protection devices and the way of their use.

When the noise at work places is exceeding the limit employees are undergoing periodic medical examinations. In case of significant and dynamic progress of hearing defects the frequency of audiometric examinations should be increased and the time between successive tests shortened to 12 or even to 6 months. In case of an impulse noise hazard or noise of the A-weighted sound level > 110 dB the audiometric examination must be done at least once a year.

Methods of noise control are schematically presented in Figure 6.

4.1. Technical Means of Noise Reduction

4.1.1. Change of a noisy technological process into a less noisy

The loudest technological processes can be substituted by less loudly ones, e.g. forging by hammer can be substituted by rolling and forming while machining by hand operated tools can be substituted by electric and chemical treatment and mechanized tools.

4.1.2. Mechanization and automation of technological processes

Mechanization and automation of technological processes together with the sound insulated control cabins for the personnel is one of the most modern, futuristic and in the same time the most efficient way of noise and other hazards (e.g. dustiness, high temperature, injuries) elimination.

Majority of cabins used nowadays in industry ensures the noise reduction by 20–50 dB at frequencies > 500 Hz.

4.1.3. Constructing and implementing of silent-running machines, equipment and tools

Changes of technological processes and the introduction of mechanization and automation require longer periods of

realization and cannot be implemented for small-series or an atypical production.

Very efficient silencing of sound sources in machine (the reduction of a sound emission) can be done by:

- Reduction of forces causing vibrations (and restricting their spectra), e.g. by careful balancing of machine elements, changes in a stiffness and system structures, changes in a frictional resistance.
- Change of aerodynamic and hydrodynamic conditions (e.g. by a change in geometry of intake and exhaust of energetic media and a velocity of their flow).
- Reduction of a radiation efficiency coefficient (e.g. by changes of dimensions of vibro-acoustic energy radiating elements, change in materials, and an insulation of boards in a system).

4.1.4. Acoustically correct layout of a plant and utilization of rooms

The following guidelines should be observed at the design stage of industrial buildings:

- Buildings and rooms requiring silence (e.g. laboratories, design offices, places for the scientific research) should be isolated from buildings where a noisy technological process is being performed.
- Machines and equipment should be grouped, if feasible in separate rooms, according to their loudness.
- Noise can be significantly raised by not proper utilizing of a room, especially by too dense location of machines. The shortest recommended distance between machines is 2–3 m.

4.1.5. Acoustic dampers

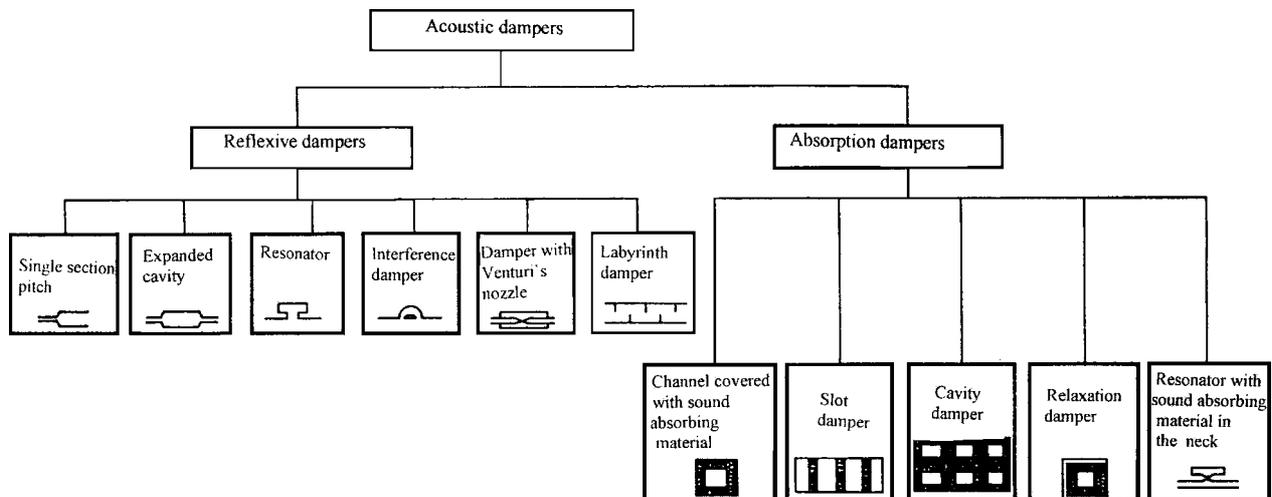
Reduction of noisiness in the air and other gas ducts (ventilation systems, intake and exhaust systems of fluid-flow machines, e.g. compressors, blast machines, turbines, engines) can be achieved by the application of acoustic dampers. Modern constructions of acoustic dampers do not cause any losses of a machine power. They create a high resistance against noisy transient flows, while not choking steady flows that transport the air or gases. Well-known dampers of that kind are reflexive dampers, it means the


Figure 7.

acoustic wave filters and the absorptive dampers containing the sound absorbing material.

The reflexive dampers operate on the bases of the reflection and interferention of acoustic waves and have very good damping qualities in the range of low and medium frequencies. They are applied where the flow velocities are significant and the temperatures high, mainly in engines, blowers, compressors and sometimes also in ventilators.

The absorption dampers counteract the acoustic energy transmission along ducts by absorbing majority of that energy by the sound absorbing material. They damp mainly medium and high frequencies and therefore are used in ventilation ducts. In practice both kinds of dampers are often used because industrial noise sources emit the energy in a wide range of frequencies.

A different kind of dampers comprise active dampers. In Figure 7 the classification of dampers together with their schematic presentation is shown.

4.1.6. Sound insulated enclosures

An attenuation of the noise source can be achieved by enveloping it, as a whole or a part of it, in an enclosure. Sound insulated enclosures should efficiently damp sound waves emitted by the sound source while not disturbing the normal work and maintenance of enveloped machines.

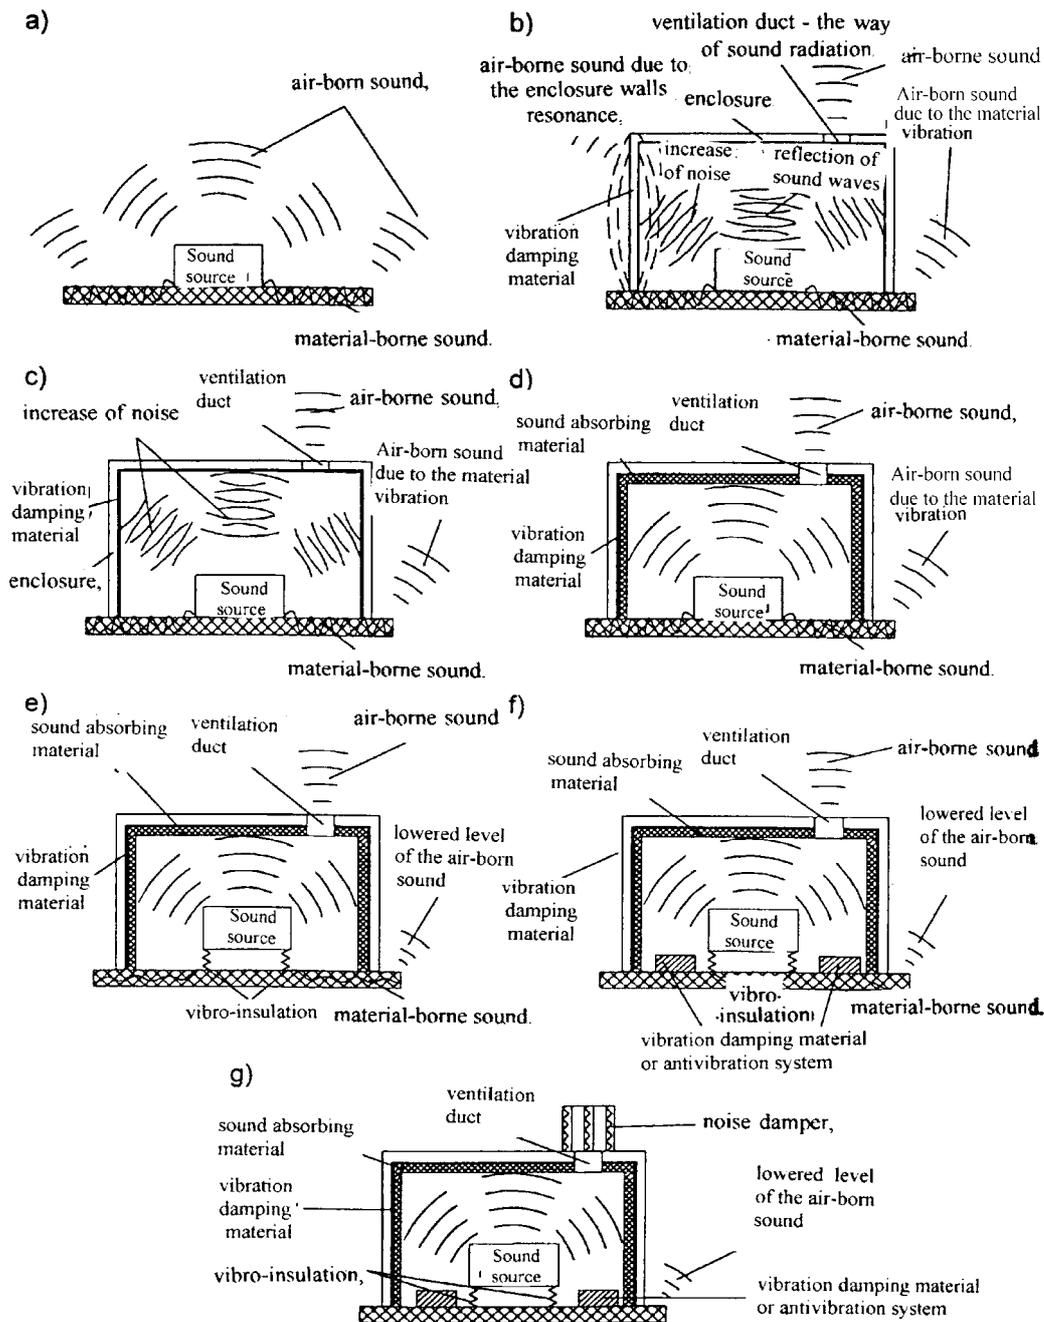
Typical, the most often used enclosures, have sound insulated walls made out of steel sheets covered from the inside by a


Figure 8.

damping mass or the sound insulating materials. There are also enclosures with multilayered walls.

Correctly made enclosures can attenuate the sound A level by 15–20 dB. Partial enclosures are much less efficient.

Ventilation ducts and other openings, necessary for the technological process, lower the performance of the enclosure. Application of acoustic silencers, e.g. in the form of channels covered with the sound absorbing material, is needed for openings.

Examples illustrating the principle of operation of the enclosure are given in Figure 8.

4.1.7. Sound absorbing screens

Sound absorbing screens are used as shields of work places. Their aim is to damp the noise emitted by different machines in the direction of a work place as well as to damp the emission from that place into an outside space. To achieve the maximum efficiency the screen should be placed as close as possible to the sound source or the work place.

Basic elements of a screen are: an insulation layer inside (usually a steel plate of a proper thickness) and sound absorbing layers outside (plates of mineral or glass wool shielded by perforated sheets).

When the screen is being used in the interior it should be a part of the whole acoustic system to cooperate with other elements damping the reflected waves energy (sound absorbing materials). Effectiveness of properly installed sound absorbing screens is estimated to be 5 — 15 dB in the distance of 1.5 m behind the screen on the axis perpendicular to its surface.

The principle of operation of the acoustic screen is shown in Figure 9. The acoustic energy source in an open space is shown in Figure 9a. The same source with the screen — in Figure 9b

(also in an open space). The acoustic energy source with the screen located inside the room with the ceiling reflecting acoustic waves — Figure 9c, and absorbing them — Figure 9d.

4.1.8. Sound absorbing materials

Sound absorbing materials applied on walls and a ceiling of the room increase its absorbing capacity. Achieved in such a way the lowering of the reflected waves sound level leads to the diminishing of the total noise level in the room.

Porous materials such as textiles, mats of mineral and glass wool, plates and porous wall plasters, plates and porous plastic mats, plastics sprayed under pressure, are the most often applied.

The maximum of the adsorption coefficient of the properly chosen sound absorbing material should occur in the same frequency range where there is the maximum component of the noise spectrum and the allowed noise values are exceeded.

As the experience shows satisfactory damping results (lowering the noise level by 3–7 dB) could be achieved in such rooms where the original noise absorption was small.

Sound absorbing systems such as ceilings, partitions, protective walls, produced in Poland or imported from abroad are available nowadays off-the-shelf.

4.1.9. Hearing protectors

In all cases when the sound level near the work place exceeds the allowed value and all means of the noise reduction are not available immediately the hearing protectors should be used.

Such protectors are also used when an excessive noise occurs seldom or a worker maintaining a noisy machine only occasionally has to enter the place when this machine is located.

The basic value describing the acoustic performance of hearing protectors is their damping of the sound (called previously

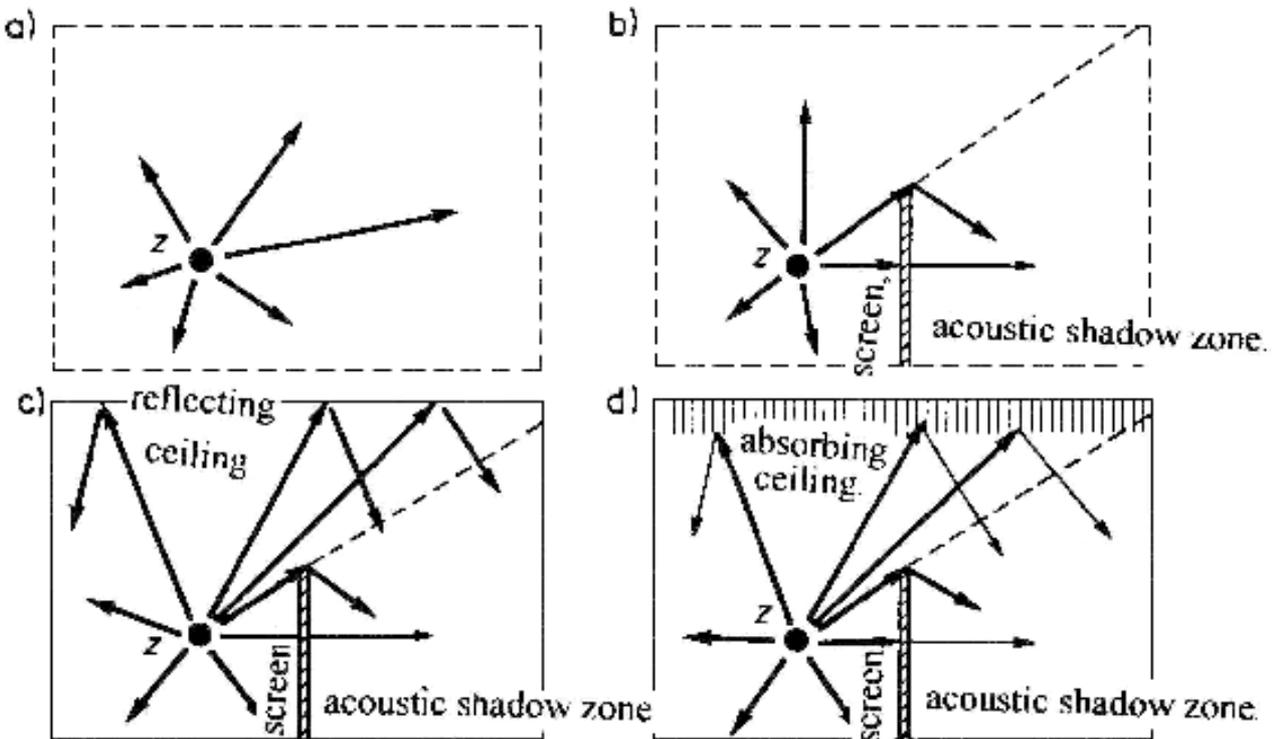

Figure 9.

the acoustic effectiveness) [8]. The hearing protectors are considered satisfactory when the A-weighted sound level under the protector is lower than the admissible value (85 dB).

Considering their construction the hearing protectors can be divided into: antinoise pads (expendable or reusable), antinoise ear-protectors (either with an on-head hold down spring or an on-helmet one) and anti noise helmets.

Selection of protectors for each real acoustic condition should be done with the consideration if they are going to give the satisfactory protection to the hearing organ. Choosing protectors for each work place is done on the bases of acoustic pressure levels in octave frequency bands or sound A and C levels measured at those places and parameters of hearing protectors granted the certificate of the safety mark B.

4.1.10. Active methods of noise reduction

The low frequency noise is especially difficult to limit. Known and used for years traditional (passive) noise reduction methods for the frequencies below 500 Hz are not effective and very costly. In recent years more and more often the active methods are being used. Their characteristic feature is the compensation of noise by sounds from the additional external energy sources. Those sources are controlled by signals of the specially shaped amplitudes and phases. Matching the control factors it is possible either to provide or to absorb the vibro-acoustic energy from specified places in the system.

The general principle of the active compensation of the acoustic field parameters is as follows:

- Primary sound source, called the compensated source, generates the acoustic wave, called the primary wave or the compensated wave.
- Secondary sound source, called the compensating source, generates the secondary acoustic wave, called the compensating wave.
- Destructive interferention of both waves takes place at the specified observation point.

To get the satisfactory noise reduction, strictly described relations between amplitudes and phase shifts of the compensated and the compensating signals must occur at the observation point. In an ideal case the full reduction of the compensated signal will be reached. It will happen only when the compensating signal is the ideal inversion of the compensated one.

Active noise reduction systems, the most often applied in practice, are the active noise dampers of fluid-flow machines and internal combustion engines (the damping efficiency is 15–30 dB for the frequency up to 600 Hz). Active systems are also used often in hearing protectors, they allow to increase the damping effectiveness by 10–15 dB in the frequency range 50–300 Hz.

5. INFRASOUND NOISE

5.1. Factor characteristics

Noise in which spectrum there are components of the infrasound frequencies (2–16 Hz) and the audible frequencies (up to 50 Hz) is called the infrasound noise. At present another expression — low frequency noise (comprising the range from 10–250 Hz) — is more and more often used.

Infrasounds, contrary to the popular believe of their inaudibility, are received by the body by the special hearing way (mainly by the hearing organ). Their audibility depends on the acoustic pressure level. The individual hearing perception especially of low frequency sounds is very different. The lower frequency the higher their audibility threshold, e.g. for frequencies 6–8 Hz the threshold is at ~100 dB, for frequencies 12–16 Hz at ~90 dB.

Apart from the special hearing way the infrasounds are also received by receptors of the vibration feeling. Thresholds of that perception are ~20–30 dB higher than audibility ones.

When the acoustic pressure level > 140 dB the infrasounds can cause permanent harmful changes in the body. The resonance of internal organs of the human body can occur, what is subjectively felt as an unpleasant internal vibration (from 100 dB already). Apart from the heaviness in ears it is one of the most typical symptoms identified by persons under the influence of infrasounds. However the dominant effect of infrasounds, occurring even at the small excesses of the audibility threshold, is their strenuousness. Over-tiredness, discomfort, sleepiness, loosing of balance and psychomotor skills, disorder of physiological functions are symptoms senses in a different degree by individuals. Changes in the central nervous system characteristic for the weakening of a vigil state (especially dangerous for drivers and machine operators) are the objective proof of those subjective feelings.

Main infrasound sources in a work environment are fluid-flow low-rotation machines (compressors, ventilators, engines), electrical equipment (mills, boilers, chimneys), metallurgical furnaces (especially electric-arch furnaces) and casting devices (moulding machines, shakeout grits).

5.2. Permissible Values and Measuring Methods

The infrasound noise at work places is characterized by the acoustic pressure level in octave bands with mid-band frequencies of 8, 16 and 31.5 Hz. The permissible values established for the health protection of employees are listed in Table 3.

In case of protected work places for juvenile and pregnant women the permissible values are lower (Table 4) [18,19].

Taking into account the possibility of performing basic tasks by employees (the criterion of the infrasound

Table 3. Permissable values of the infrasound noise established for the health protection of employees

Mid-band frequency of octave bands [HZ]	Acoustic pressure level for 8 hr noise exposure, [db]	Maximal acoustic pressure level, [db]
8; 16	110	137
31.5	105	132

Table 4. Permissable values of infrasound noise at the juvenile and pregnant women work places

Mid-band frequency of octave bands [HZ]	Acoustic pressure level for 8 hr noise exposure, [dB]
8; 16	85
31.5	80

Table 5. Permissable values of the infrasound noise - with the possibility of performing basic tasks by employees' taken into account

No	Work place	Mid-band frequency of octave bands, [HZ]	Acoustic pressure level for 8 hr noise exposure, [HZ]
1	Dispatcher's cabins, remote control cabins, rooms for precision works and others of similar destination	4; 8; 16; 31.5	90 85
2	Administration rooms, design offices, rooms for theoretical work, data processing and others of similardestination	4; 8; 16; 31.5	85 80

strenuousness) acoustic pressure levels should not exceed values given in Table 5.

Methods of the infrasound noise measuring are described in normatives. Measurements can be done in a direct way (utilizing a mobile frequency analyzer) or in an indirect way (when noise is measured at industrial conditions and the frequency analyses done in a laboratory).

Presently, in accordance with the international standard ISO 7196: 1995 [34], measurements of a sound G level, it means the acoustic pressure level corrected to the frequency G characteristics, are also recommended. The G-characteristics corresponds roughly to the threshold of the infrasound hearing perception and — as the experimental results show — correlates well with the subjective estimation of the sound strenuousness.

According to the recommendation included in the newly established standards: ISO 9612: 1997, ISO 7196: 1995, the proposal of the American Conference of Government Industrial Hygienists (ACGIH) as well as with regard to a progress in the knowledge of the infrasound influence on the human body and with the development of measuring techniques the discussions on the verification of the national NDN infrasound noise standards are planned.

5.3. Methods of Hazard Limitations

In the prevention of the infrasound noise harmful influence the same rules and regulations as in case of a normal noise apply. However the protection against infrasounds is more complicated because of the significant length of the infrasound waves (20–170 m) for which traditional walls, partitions, screens and sound absorbers are not very effective. In some cases infrasound waves are increased because of the resonance of rooms, structure elements and the whole buildings.

The best protection against the harmful infrasound noise gives its suppression at the generating source, it means directly in machines and devices.

Other solutions are:
- Use of sound dampers at inlets and outlets of the air (or gas) in fluid-flow machines.
- Proper foundation engineering (with the vibro-insulation) of machines and devices.
- Stiffening of walls and building structures in case they are getting into a resonance.
- Applying sound insulated cabins of a heavy structure (made of bricks) for machine and installation operators.

- Applying active methods of the noise reduction (connected with the active absorption and sound compensation).

6. ULTRASOUND NOISE
6.1. Factor Characteristics

An ultrasound noise is the noise which spectrum contains components of audible and ultrasound frequencies — from 10 to 100 kHz.

Air ultrasounds being a part of the ultrasound noise can penetrate the human body through the hearing organ as well as the whole body surface. Investigations of the ultrasound noise influence on the hearing organ condition are rendered difficult because in an industrial environment the ultrasounds are usually accompanied by the audible noise. Then it is difficult to assess if the deterioration of hearing is the result of the audible or the ultrasound components only or simultaneous action of both kinds.

However the prevalent opinion is nowadays that as a result of non-linear phenomena occurring inside the ear the subharmonic components are formed under the influence of the ultrasounds. Their acoustic pressure level is of the same order of magnitude as the basic ultrasound partial. In consequence of that phenomenon the hearing impairment concerns the subharmonic frequencies of the ultrasounds.

Apart from its harming the hearing, the negative influence on the vestibular organ in the internal ear manifested by headaches and dizziness, balance disorders, nausea, drowsiness, over-tiring has been found.

Examinations of the non-hearing connected influences have shown that the occupational exposure at the ultrasound noise of levels > 80 dB — in the range of high audible frequencies and > 100 dB — in the range of low ultrasound frequencies, causes changes of the vaso-vegetative nature.

Main sources of the ultrasound noise in a work environment are technical ultrasound devices which generate ultrasounds indispensable for the performing of the technological process. The ultrasound noise can be also generated by high-speed engines: compressors, pneumatic devices, metal working machines and some textile machines.

6.2. Permissible Values and Measurements Methods

The ultrasound noise at work places is described by the acoustic pressure levels in one-third-octave bands of mid-frequencies from 10 to 100 kHz.

Permissible values, established with a view to protect the employees' health ca not surpass the values given in Table 6.

Table 6. Values of the acoustic pressure level of the ultrasound noise - allowed having employees' health in view

Mid-band frequencies of one-third-octave bands KHZ	Acoustic pressure level for 8 hr noise exposure dB	Maximal acoustic pressure level dB
10; 12.5; 16	80	100
20	90	110
25	105	125
31.5; 40; 50; 63; 80; 100	110	130

Table 7. Permissable values of the acoustic level at work places for the juvenile and pregnant women

Mid-band frequencies of one-third-octave bands KHZ	Acoustic pressure level for 8 hr noise exposure dB	Maximal acoustic pressure level dB
10; 12.5; 16	75	77
20	85	87
25	100	102
31.5; 40; 50; 63; 80; 100	105	107

At the protected work places (juvenile, pregnant women) lower values are allowed. They are presented in Table 7.

6.3. Methods of Risk Limitation

The same rules and requirements apply for the prevention of the harmful influence of the ultrasound noise as for a normal noise. The medical examination of workers should be performed every 2 years.

Taking into consideration the short-waves propagation (of low frequency ultrasounds) in the air (wave lengths from 3 mm to 2 cm) it is relatively easy to reduce its harmful influence on humans, e.g. by airtight sealing and enclosing of sources, remote control of the technological process in which ultrasounds are being applied, avoiding direct contact with an ultrasound transducer, using individual protection means, etc.

Performance Effects of High G Environments

W.B. Albery

Biodynamics and Acceleration Branch, Air Force Research Laboratory, Wright-Patterson AFB, OH 45433, USA

1. INTRODUCTION

Since man first flew in a powered aircraft in 1903, he has had to perform flying tasks in a > 1 G environment — macrogravity. Macrogravity poses problems to the human physiologically, ergonomically and cognitively. Physiologically, the human loses eye-level blood pressure at 22 mm Hg/G as G increases from 1.0 to 9.0, for example in the F-16 aircraft. To maintain consciousness and perform in the high G environment, the human must be protected against the effects of high G. Ergonomically, the human gets heavier as G increases. A 200 lb man weighs 1800 lb at 9 G! Arms, legs and head are heavier, and tasks such as flipping switches on the instrument panel require trajectory strategy and practice with a 10 lb arm that now weighs 90 lb. Cognitively, the loss of eye-level blood pressure and reduced eye–brain-level arterial oxygen saturation (< 80%) relate to flying performance decrement. What can be done to counter these effects of high G? Modern air forces have developed countermeasures to these performance effects of high G environments.

2. FUNDAMENTALS OF THE HIGH G ENVIRONMENT

The body axes for sustained acceleration are shown in Figure 1. The inertial resultants of body acceleration are listed in Table 1. Centrifugal acceleration is expressed in terms of angular velocity and the radius of turn:

$$G = (w^2 r)/g,$$

where w = angular velocity in radians/s and G = unitless measure of acceleration, r = radius of turn (m) and g = gravitational constant (9.8 m s^{-2}). A typical human centrifuge with a 20-ft radius (6.1 m) can generate 9 G by turning at 38 revolutions/min, which is ~4 radians s^{-1}.

The easiest axis for the human to tolerate sustained acceleration is in the chest-to-back (+Gx) direction. This is why astronauts are launched on their backs. Volunteers have been exposed up to +16.5 Gx unprotected for brief periods. Subjects completely immersed in water have endured > 30 G (von Gierke *et al.* 1991). The least tolerable direction is the –Gz or eyeballs-down direction. Some pilots have been exposed to brief periods of -Gz, but the increased blood pressure at the eye–brain level is very uncomfortable. The lateral direction (±Gy) is less tolerable than ±Gx exposures. Most high G aircraft routinely expose the pilot(s) to +Gz. Man, protected and straining, can achieve +9 Gz for short periods and perform complex piloting tasks.

3. PHYSIOLOGICAL EFFECTS OF HIGH G

The high G environment is also characterized by its effect on human physiology. The accepted model of human G tolerance is the hydrostatic column model of man (Burton and Whinnery 1996). In this model, the eye–heart distance results in a change in blood pressure measured at heart level and at eye level (Figure 2).

It is shown that, as one sits in the normal 1 G environment, there is a differential in the eye-to-heart blood pressure. This is illustrated in the seated pilot at the left. The effect of additional +Gz is illustrated where the pilot's neck is elongated. Since each G costs 22 mmHg blood pressure, at 6 G the pilot has –12 mmHg blood pressure at eye level. This –12 mmHg blood pressure must be raised > 0 to keep the eyes and brain perfused. The loss of eye-level blood pressure is typically countered by three protective techniques:

- Cardiac compensation: the baroceptors in the circulatory system sense a reduced blood pressure and signal an increase in heart rate. The increased heart rate increases blood pressure.

Table 1. Nomenclature for inertial resultant of body acceleration.

Linear motion	Physiologic descriptive	Physiologic standard	Vernacular descriptive
Forward	chest-to-back G	+Gx	eyeballs-in
Backward	back-to-chest G	–Gx	eyeballs-out
Upward	positive G	+Gz	eyeballs-down
Downward	negative G	–Gz	eyeballs-up
To right	left lateral G	–Gy	eyeballs-left
To left	right lateral G	+Gy	eyeballs-right

Figure 1. Body axes of sustained acceleration.

Figure 2. Hydrostatic column equivalents.

- Straining maneuver: a self-initiated strain against a closed glottis that raises intrathoracic pressure, which in turn increases eye-level blood pressure.
- Anti-G suit/positive pressure breathing: artificial means of raising one's blood pressure; the anti-G suit inflates and increases pressure to the legs and abdomen. This increased pressure aids in venous return to the heart, which improves G tolerance. The US Air Force has developed a positive pressure breathing system that inflates the pilot's lungs as a function of increasing G (12 mmHg/G to a maximum of 60 mmHg). This system, called COMBAT EDGE, has helped protect humans to +12 Gz for brief periods.

4. ERGONOMIC EFFECTS OF THE HIGH G ENVIRONMENT

The pilot becomes heavier in the seat as G increases. Arms, legs, torso and head all become heavier, and with the same motor control and musculoskeletal systems used at normal 1 G, man initially has problems controlling movements of the head, arms and legs at high G.

4.1. Ability to Move Under Increased G

Increased gravitational fields increase the weight of body parts. Body parts can become elongated or compressed under the G vector; this can affect the shape and function of the soft internal organs including the heart, lungs, kidneys, liver, etc. Higher muscle forces are required to keep the head, torso and limbs in desired positions. At G forces of ~+2 Gz there is increased pressure on the buttocks, drooping of the face and noticeably increased weight of all body parts; at this level of G force it is difficult to raise oneself, and at +3–4 Gz it is nearly impossible. Experiments were conducted in the Wright-Patterson AFB (WPAFB) Dynamic Environment Simulator (DES) centrifuge where subjects arose from a seated position and performed a whole-body jump at Gz levels up to 1.8 Gz as the centrifuge rotated. Although most subjects had no problem standing up at 1.8 Gz, jumping and leaving one's feet was very difficult (Albery and Woolford 1997). Above +3–4 Gz, controlled motions require greater effort, adaptation and learning to offset loss of fine motor control. While seated in a high-performance aircraft, one typically cannot raise the arm at forces > 8 Gz or legs at > 3 Gz. Head pitching is difficult at > 4 Gz, and some individuals who get their heads pitched forward at high Gz (> 6 G) are unable to right themselves in the seat until the acceleration is unloaded. The hand can be raised slightly at 25 Gz. One can barely slide the feet on a floor > 5 Gz. Speech is severely affected, yet possible, up to +9 Gz if the operator is utilizing protective techniques properly (see above).

4.2. Arm Trajectory at High G

When reaching for a switch on the instrument panel at high G, the tendency of the pilot is to complete the movement below the switch because the arm is now heavier due to increased +Gz. The pilot learns after several attempts to initiate the trajectory of the arm–hand at a location above the switch. A re-calibration of gross motor movement occurs during long exposure to even low-level acceleration (Albery and Woolford 1997).

5. COGNITIVE EFFECTS OF HIGH G

Very rarely does high-sustained acceleration affect only one factor such as speech, vision or manual dexterity. Task performance is manually measured through subjective reports, physiological and behavioral techniques. Cognitive performance is significantly affected when eye-level arterial oxygen saturation is < 80%. Percent arterial oxygen saturation ($\%S_aO_2$), as measured with a pulse oximeter, can drop to < 80% when the ventilation/perfusion ratio is not evenly matched. This can occur when subjects are exposed to high G. Complex task performance has been shown to deteriorate when $\%S_aO_2 < 80$ (Albery and Chelette 1998). Percent cerebral oxygen saturation ($\%rO_2$) is also used as a physiological measure in centrifuge research (Chelette et al. 1998).

5.1. Characterizing Human Performance at High G — Exposures up to 3 Minutes

In studies at the Air Force Research Laboratory, WPAFB, human performance during simulated aerial combat sorties has been characterized via "performance surfaces" (Figure 3). These 3-D projections allow the observer to look at the cognitive and physiological performance of the subject as a function of brief exposures to sustained acceleration (+ Gz).

In figure 3, the performance task score is shown on the vertical axis, time spent at Gz > 8 is shown on the one horizontal axis, and the physiological variable, minimum cerebral oxygen saturation (min rO_2), is shown on the other horizontal axis. One can see from this performance surface that the best performance in terms of score was when the subjects spent only 10 s at 8 G and when rO_2 was at its highest, 65%. Chelette et al. (1998) compared male and female performance during a 3-min simulated air-to-air combat situation that exposed subjects to 9 Gz. They found no significant differences between male and female flying performance.

5.2. Characterizing Human Performance at High G – Exposures from 3 to 11 Minutes

Some pilots and many centrifuge subjects have endured G exposures that included peaks to 9 G for several minutes. While evaluating new protective garments, humans have endured 10 Gz continuously for 3 min. Subjects performing a dual-task simulated aerial combat maneuver in the DES centrifuge endured up to 27 peak exposures to 9 G over 11 min and still maintain

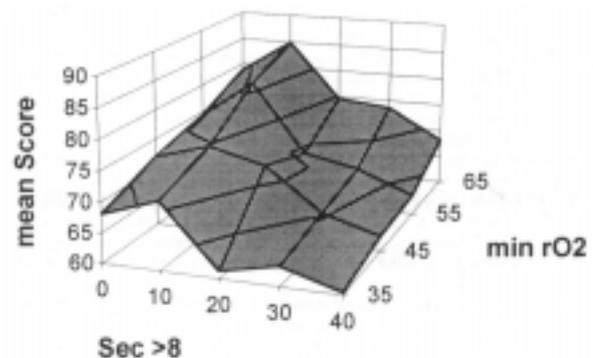

Figure 3. Performance surface.

excellent tracking and secondary task performance. This exposure is much longer than what a typical dogfight would probably last, but illustrates the enhanced protection of humans wearing new COMBAT EDGE-type G protection garments.

5.3. Effect of High G on Orientation Perception

Sustained acceleration (G >1) can also have a profound effect on human perception. Some of these effects are discussed in the Previc chapter. It is believed that the otolith organs of the vestibular system are gravity transducers (graviceptors) and, as such, play an important role in human perception of motion, especially in the absence of visual cues.

5.3.1. Somatogravic illusion – high G pitch-up sensation

Sustained acceleration experienced by pilots during catapult launching of Navy aircraft off the decks of aircraft carriers has been implicated as a contributing factor to aircraft mishaps. The catapult launch generates a + Gx acceleration on the pilot which can elicit a somatogravic illusion (a false sensation of body tilt that results from perceiving as vertical the direction of a non-vertical gravito-inertial force). Pilots of carrier-launched aircraft need to be especially wary of the somatogravic illusion. These pilots experience pulse accelerations lasting 2–4 s and generating peak inertial forces of +3–5 Gz. Although the major acceleration is over quickly, the resulting illusion of nose-high pitch can persist for > 30 s afterward, resulting in a particularly hazardous situation for the pilot unaware of the phenomenon. Navy scientists reproduced on the centrifuge the pitch-up sensation experienced by pilots during catapult launches, and warnings were issued to all pilots taking off from aircraft carriers.

5.3.2. G-excess illusion

The G-excess illusion is a false or exaggerated sensation of body tilt that can occur when the G environment is sustained at > 1 G. This illusion has been implicated in a number of low-level turning and looking mishaps in the USAF. It is believed that the otoliths "over report" a roll or pitch when the pilot and the aircraft are in a > 1 G maneuver. This over reporting occurs because the otoliths are "tugged" more than usual when G > 1 and this is perceived by the pilot as an increased roll or pitch attitude. If a pilot experiences the G-excess illusion, the tendency is to compensate for the illusion, which can cause overbanking, loss of altitude and even controlled flight into the terrain. Chelette et al. (1998) duplicated the G-excess illusion on the WPAFB DES centrifuge (Albery et al. 1997). Rolling and/or pitching the head while in an excess G environment (> 1) can cause an illusory sensation of vehicle tilt. This illusion occurs in the pitch axis if the head is forward, but translates to the roll axis as the head is turned toward one shoulder.

5.4. Time and Mass Estimation in Macrogravity

Time, mass and reaction time perception experiments have been conducted under high levels of G stress (Albery et al. 1997). G

levels up to and including +8 Gz affect time perception. The longer the time estimation, such as > 15 s, the greater the error. Subjects tended to underestimate the length of longer tasks, as if they wanted to finish the task early. Likewise, for mass discrimination, it was found that performance is impaired during increased +Gz. The ability to discriminate between the heaviness of several objects became more difficult under G stress. In several studies involving choice reaction time (more than one possible selection) in acceleration stress, it was found that reaction times actually decrease under G stress. This effect of improved reaction time performance under acceleration can be possibly attributed to the alerting cue phenomenon (subjects are more "on their toes" when exposed to short periods of sustained acceleration).

6. CONCLUSIONS

Most humans can tolerate and perform in G levels up to 4 G for tens of seconds without straining and unprotected. Above 4–6 Gz, the loss of eye-level blood pressure must be countered for the pilot to remain conscious. Performance is degraded. By straining and raising one's eye-level blood pressure, unprotected pilots can be trained to endure +9 Gz and to perform complex tasks for brief periods of exposure (10–15 s).

Using anti-G protective pants, vest and positive pressure breathing, pilots can be trained to endure +9 Gz and perform complex flying tasks for minutes at a time. Human task performance tends to decrease under high G as a function of decreasing eye-level blood pressure and reduced arterial oxygen saturation, which directly affect cognition.

No gender differences have been found in male–female flying performance in the high G environment, when the subject/pilot is well protected.

High G can have profound effects on vision, orientation perception, and time and mass perception.

Physiological Costs of Noise Exposure: Temporary Threshold Shifts

H. Irle, J.M. Hesse, and H. Strasser

Ergonomics Division/University of Siegen

Paul-Bonatz-Str. 9-11/57068 Siegen/Germany

1. INTRODUCTION

Annual statistical surveys of mutual industrial accident insurance associations show that noise induced hearing loss – as has always been the case – is the number one of the occupational diseases. Approximately 1/3 of all known cases originates from detrimental acoustic stress in the working environment of industrial countries. That is, however, only the tip of the iceberg of aural and extra-aural effects of noise, i.e., of acoustic stress that is unwanted, disturbing, aggravating, and frustrating; that impedes conversation; and that, in some circumstances, can cause damage to the hearing. Expenditures in the form of monetary compensation for the irreversible hearing damage associated with noise are still relatively low in comparison with the damage to the economy of more than 20 billion US $ per year, as, e.g., calculated by the German Association for Noise Control. For these reasons, "noise" is being attacked on various levels. The great variety of brochures, books, and journals as well as technical regulations, guidelines, standards, and safety regulations reflects both the broad and deep knowledge of "noise" and the technical possibilities for noise control. But it should not be forgotten that even tolerable noise with a rating level of 85 dB(A) / 8 h in the production sector is associated with essential "physiological costs" which the ear has to pay.

2. TEMPORARY AND PERMANENT THRESHOLD SHIFTS

High noise levels, at least, lead to Temporary Threshold Shifts (TTS) which are dependent on the preceding exposure and last for varying time periods. If such TTS are not subsided completely at the beginning of a subsequent noise exposure, the hearing threshold shifts can become permanent. Moreover, high noise exposures beyond a level of 120 dB inhere a high risk for acute damage in the inner ear.

Permanent Threshold Shifts (PTS) as the long-term aural effects normally do not occur after just days, weeks, or months of risky noise exposures but are the then irreversible consequences of noise exposures over years. PTS can be regarded as the accumulated sum of the temporary threshold shifts which still remain 16 h (i.e., 1000 min) after the end of an 8 h-working day. Therefore, they may be represented in the equation PTS = S TTS$_{1000}$. As TTS can be regarded as a predecessor of PTS, this measure has some prognostic value and is used in ergonomics to evaluate noise exposures with respect to "physiological costs" the ear has to pay for noise with varying levels, exposure times, frequencies, and time structure (e.g., continuous noise, impulse noise).

3. AUDIOMETRIC MEASUREMENTS TTS$_2$, T(0 DB), AND IRTTS

Figure 1 shows what can be measured audiometrically when subjects have been exposed to noise. The lower curve represents the hearing threshold of otologically normal young subjects. It means, e.g., that a minimum signal amplitude of about 4 dB is necessary to hear a 1 kHz tone. Test tones with a lower frequency have to be increased in level according to the hearing threshold to, e.g., about 10 dB at 250 Hz or 30 dB at 64 Hz, and lowered to smaller values in the area of about 4 kHz which represents the most susceptible frequency range of the human ear.

As the normal hearing threshold is the result of averaging over hearing thresholds of a representative large group of subjects, the individual hearing threshold of a subject must not be congruent with this curve but can take its course below or (as shown in Figure 1) some decibels above the normal threshold. When the physiological responses of noise exposures have to be quantified it is always necessary to determine the individual resting hearing threshold as a reference base. After an acoustic exposure, threshold shifts can be measured in a standardized procedure as represented in the upper curve. Normally within 2 minutes after the end of an exposure the maximum threshold shift has to be quantified in dB audiometrically. It is advisable to concentrate on the maximum relative hearing threshold shift above the individual resting hearing threshold (in this case at 4 kHz). This parameter, the so-called TTS$_2$, is a classic characteristic value of audiometric examinations.

Furthermore, it is advisable with this frequency of the maximum threshold shift to monitor the restitution of the hearing threshold shift (back to the resting threshold) at exactly predetermined points in time (Figure 2). This point in time t(0 dB) is also an important characteristic value of the acoustic strain analysis. When a linear time scale is used, the shape of the restitution of a temporary hearing threshold shift resembles an exponential function. If, however, it is plotted against a logarithmic time scale (see the block in the upper right corner of Figure 2), the regression function TTS(t) is a straight line.

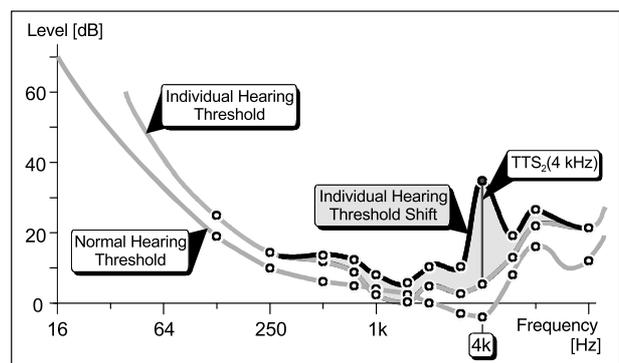
In order to allow an overall assessment and a comprehensive


Figure 1. Hearing threshold of otologically young subjects (lower line), example of a resting hearing threshold (middle line) and threshold shift of an individual after a noise exposure (upper curve) with a maximum in the area of 4 kHz, measured within 2 min after the end of the acoustic exposure.
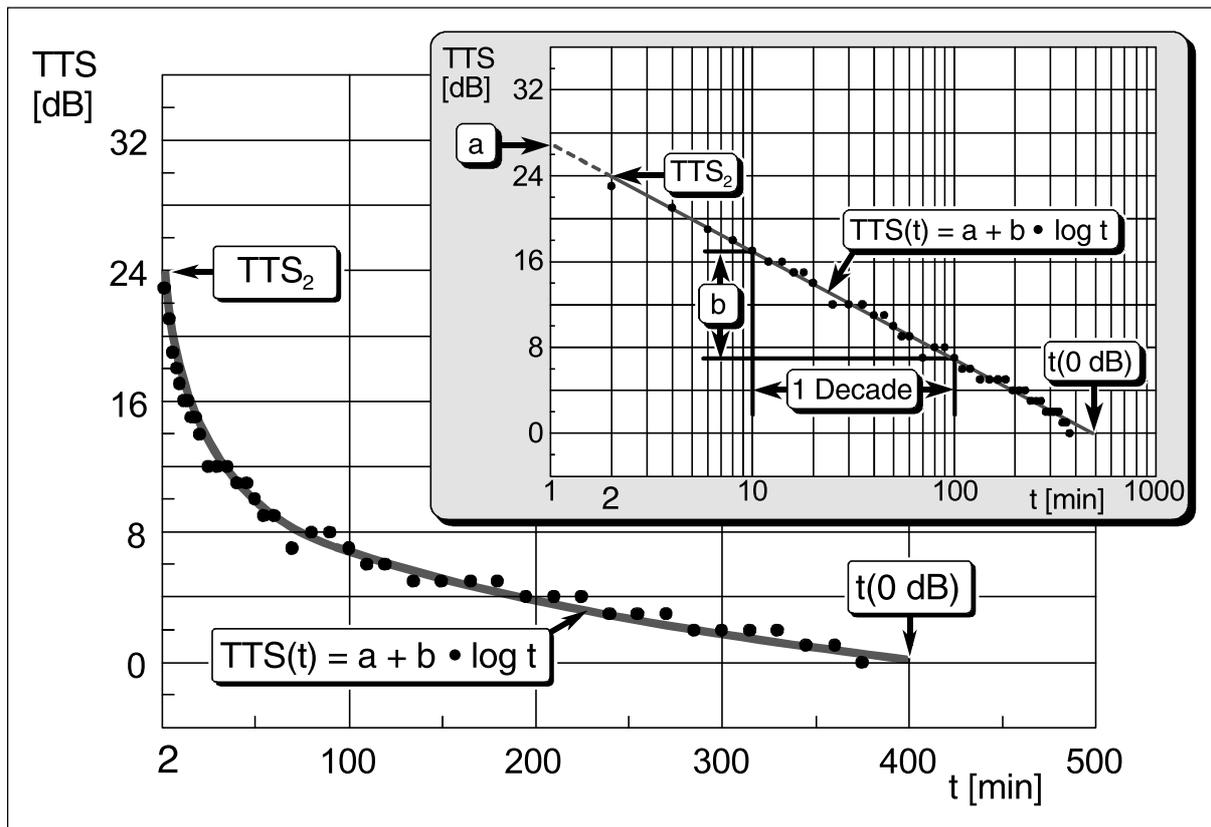

Figure 2. Example for registered TTS-values for the recovery period with a linear and a logarithmic time scale as well as representation of the regression function TTS(t).

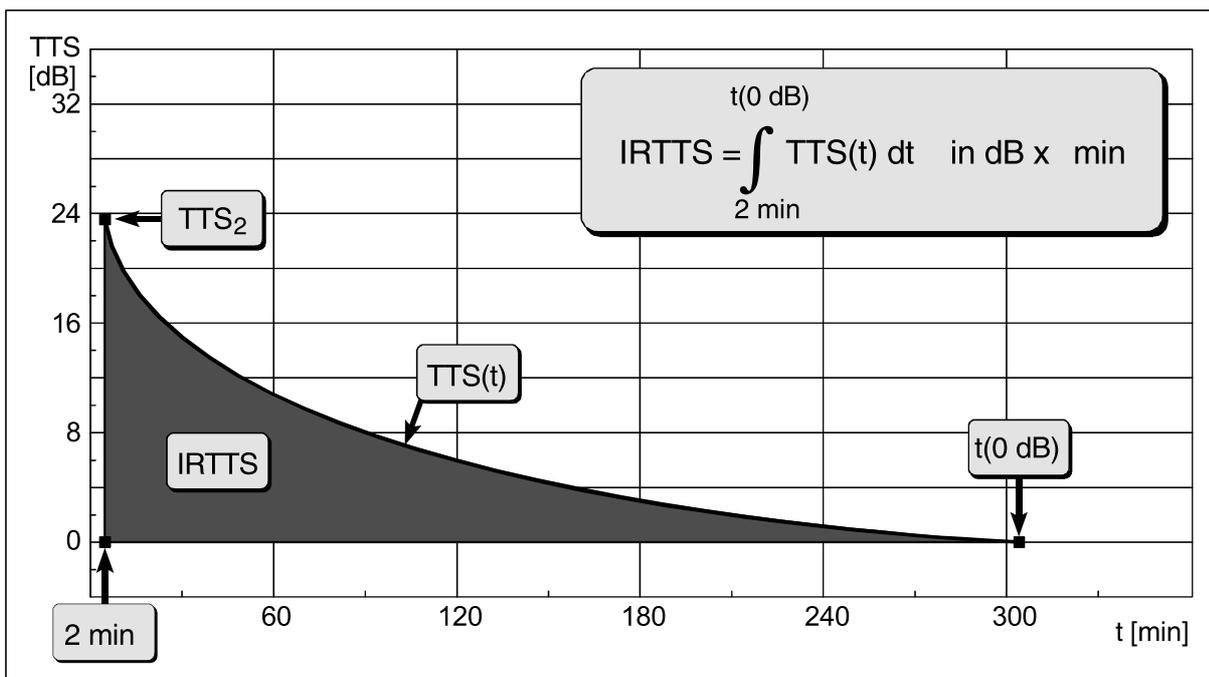
statistical analysis, the area under the regression line has to be determined, as can be seen in Figure 3. This Integrated Restitution Temporary Threshold Shift (IRTTS) is computed as the integral of the regression function TTS(t) from 2 min after the exposure to the point t (0 dB). The IRTTS is a numeric value for the total threshold shift (in dB x min) which has to be "paid" by the hearing in physiological costs for the exposure. This global characteristic value is similar to the sum of work-related increases of heart rate which can be measured after finishing dynamic muscle work until total recuperation from cardiovascular stimulation.


Figure 3. Exemplary representation of the IRTTS (Integrated Restitution Temporary Threshold Shift).

In the following, results of comprehensive investigations will show that essentially varying physiological responses to equally rated noise exposures do exist.

4. PHYSIOLOGICAL COSTS ASSOCIATED WITH CONTINUOUS AND IMPULSE NOISE WITH THE SAME AMOUNT OF ENERGY

During revisions of Occupational Health and Safety Guidelines in Europe and the US (N.N. 1986, N.N. 1990, N.N. 1998), at least linearly evaluated noise levels of more than 140 dB (or levels L_{AI} >130 dB(A)) have been declared as harmful to hearing. Yet, impulse noise with levels below that is not necessarily considered critical, as long as the daily noise dosage, resulting from the number of single impulses and their respective exposure times, does not exceed an energy equivalent rating level of 85 dB(A). However, from an ergonomics point of view, the equating of impulse and continuous noise (on the basis of the 3-dB-exchange rate) must be questioned (see, e.g., Strasser and Irle 2000). The energy equivalent measuring and rating procedure assumes that noise with the same energy inheres the same long-term damage. According to Figure 4 this should be valid for 85 dB(A) / 8 h and, e.g., 94 dB(A) / 1 h, as well as 113 dB(A) / 45 s and for the splitting-up of this short-time continuous exposure into energy equivalent series of impulses with the same level of 113 dB(A).

For safety purposes and with respect to ethical and moral aspects, and to absolutely insure that no harm is done to test subjects, acutely "dangerous" exposures of impulse noise with levels over 120 dB(A) never should be provided in laboratory studies, but 113 dB(A) is still considered acceptable. According to Miller (1974), similar threshold shifts can be expected from 94 dB(A) / 1 h and 85 dB(A) / 8 h. Therefore, for economical reasons, studies with 94 dB(A) over 1 h can be carried out instead of providing exposures over 8 h.

In cross-over-trial laboratory studies Ss were exposed to 94 dB(A) for 1 h, 113 dB(A) for 45 s, and impulse noise with a level of 113 dB(A) (180 x 250 ms-impulses, 450 x 100 ms-impulses, 1800 x 25 ms-impulses, and, finally, 9000 impulses for 5 ms, each. Five-ms impulses with noise levels between 110 and 120 dB are common in practice, e.g., while hammering metal plates. All impulses were separated by 3-s noise intervals so that test duration lasted up to 7 h 30 min for the 5-ms-impulse exposure. Simultaneous to the acoustic exposure of the Ss via headphones, the noise exposure was also checked with an identical pair of headphones with an artificial head measuring system (Figure 5). For the audiometric measurements which have been described in section 3, the Ss were placed in a soundproof cabin in order to reduce disturbing outside noise and guarantee the replication of environmental conditions. For details see Hesse *et al.* (1994).

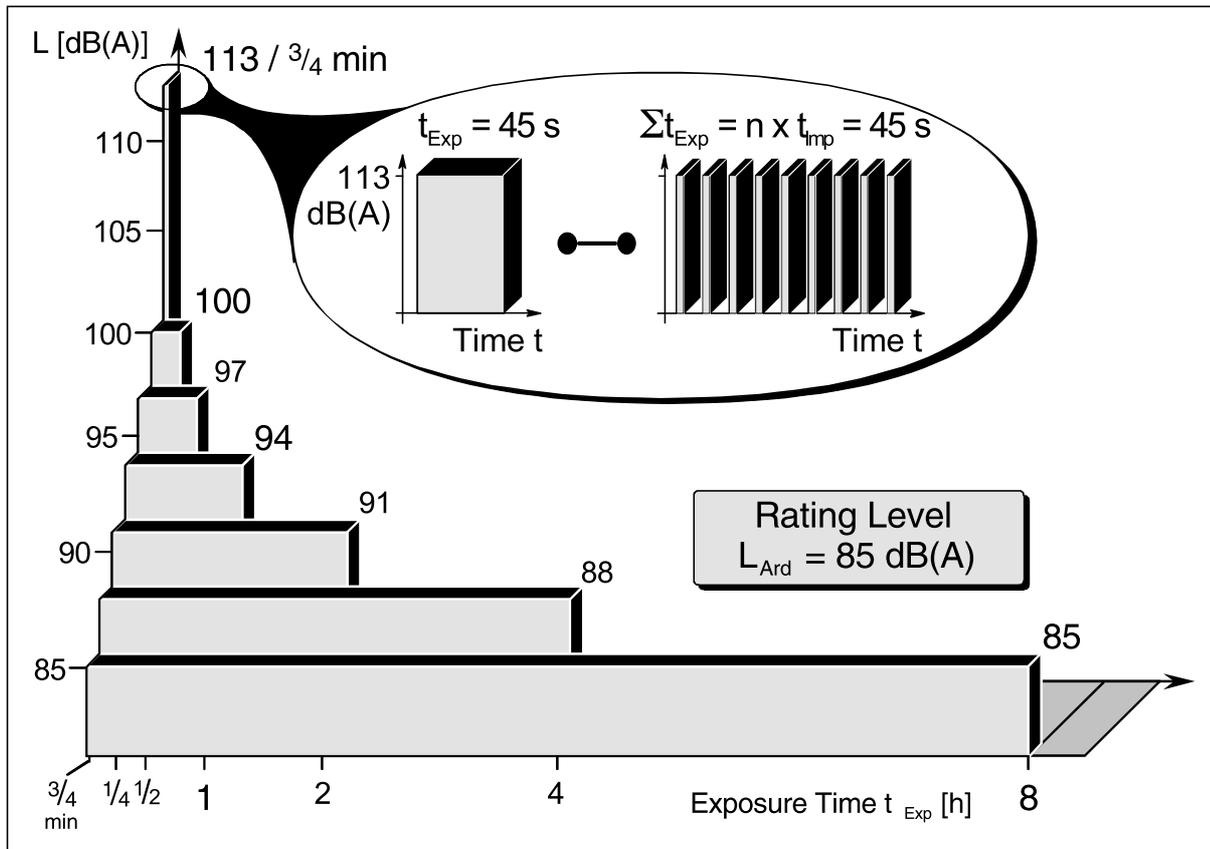
As an example, Figure 6 shows the measured values of all subjects, the arithmetically averaged values, as well as the regression lines for 4 of altogether 6 noise exposures. Also, the statistically calculated data are summarized next to the real measured values in the upper right corner of each part of the figure. For continuous noise of 94 dB / 1 h (Figure 6a), e.g., the regression function TTS(t) is 28.5-12.45 · log t, the TTS_2 = 24.8


Figure 4. Varying levels and exposure times representing an energy equivalent noise exposure with a rating level L_{Ard} of 85 dB(A).
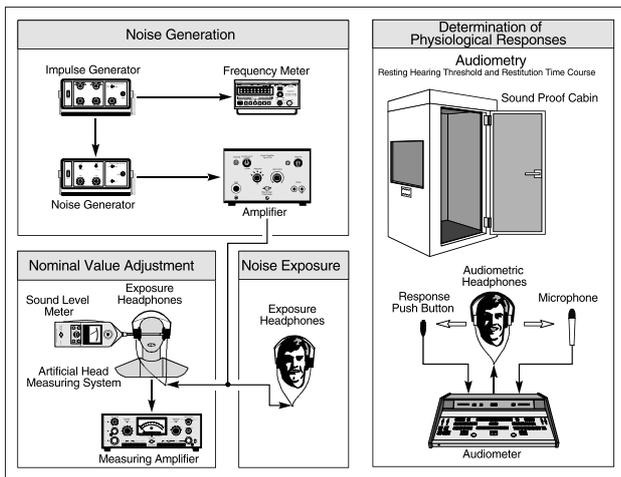

Figure 5. Schematic test set-up for noise exposure and audiometric measurements in a soundproof cabin.

dB which was calculated via this regression function, and the length of time t(0 dB) it took to reach the resting hearing threshold is 195 minutes. The physiological responses which vary from subject to subject can be seen in the real measured values of the TTS_2 – with an interindividual range from 13 to 32 dB – and in the time required to reach the resting hearing threshold t(0 dB) – with a range from 70 to 210 min – thus explaining the statistical correlation value (r^2) of only 0.75. If the arithmetically averaged values and their course along the regression line are examined, the approximation is clearly excellent, which can also be seen in the statistical correlation value (r^2) of 0.99.

Figure 6b shows the results of the short-time continuous noise exposure of 113 dB for 45 seconds. It can be seen that an increase of the level of continuous noise together with a corresponding shortening of exposure time leads to a weakening of physiological responses. The TTS_2 values are essentially lower and the restitution times are substantially shorter.

Figure 6c shows the restitution after the exposure to 180 impulses of 250 ms, each, and shows that the physiological responses already have the tendency to be higher than those resulting from continuous noise at the same level. Both TTS_2 – with values around 15 dB – and the restitution time – with values up to 100 min – are increased. This tendency becomes even more pronounced with 100-ms impulses, whereby the threshold shifts reach values of more than 16 dB and last on average up to more than 300 min (not graphically shown here). When the length of the impulses is reduced to 25 ms, the physiological cost again grows substantially.

Finally, 9000 5-ms impulses result in an essential increase of physiological costs. As can be seen in Figure 6d, the TTS_2 exceeds 20 dB and the restitution time is up to 600 min, i.e., 10 h.

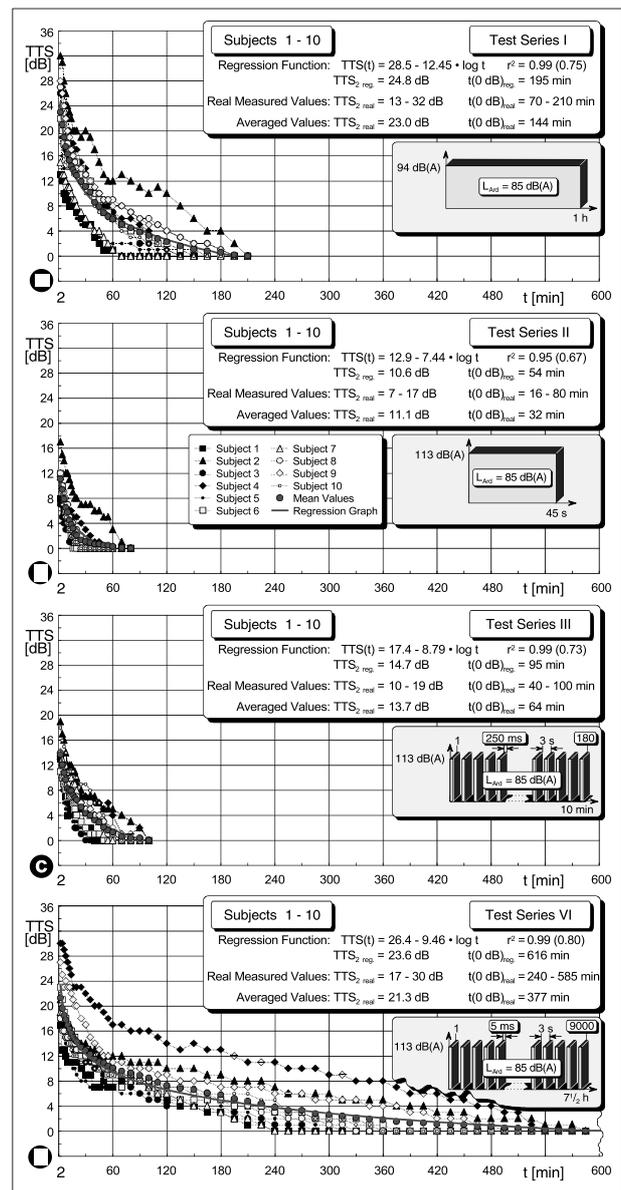
Figure 7 shows a simplified plotting of all restitution time courses TTS(t) which reveals a substantial increase of physiological costs associated with the splitting-up of continuous noise (113 dB(A) / 1 x 45 s) into shorter and shorter impulses. If the damage-risk based on the energy equivalence principle – with its roughly comparable consequences of strain – is accepted, then the position of the regression lines for all test conditions would have to be at least similar. This, however, not at all can be confirmed by the results of the investigations.


Figure 6. Individual and mean restitution time course for all 10 Ss after the exposure to 94 dB / 1 h (a), 113 dB / 1 x 45 s (b), 113 dB / 180 x 250 ms (c), and 113 dB / 9000 x 5 ms (d). All exposures contain the same sound energy.
(**Source: Hesse et al. 1994**)

The overall physiological costs in the form of IRTTS also differ greatly with varying exposures. The ratio of IRTTS resulting from the two extremes "113 dB(A) for 45 s" (147 dBmin in TS II) and the energy equivalent exposure to 5-ms impulses (2473 dBmin in TS VI) amounts to 1:16. According to the results of significance tests, the consistent increases of physiological costs are in a strong causal-deterministic relation with the shortening of the length of the impulses.

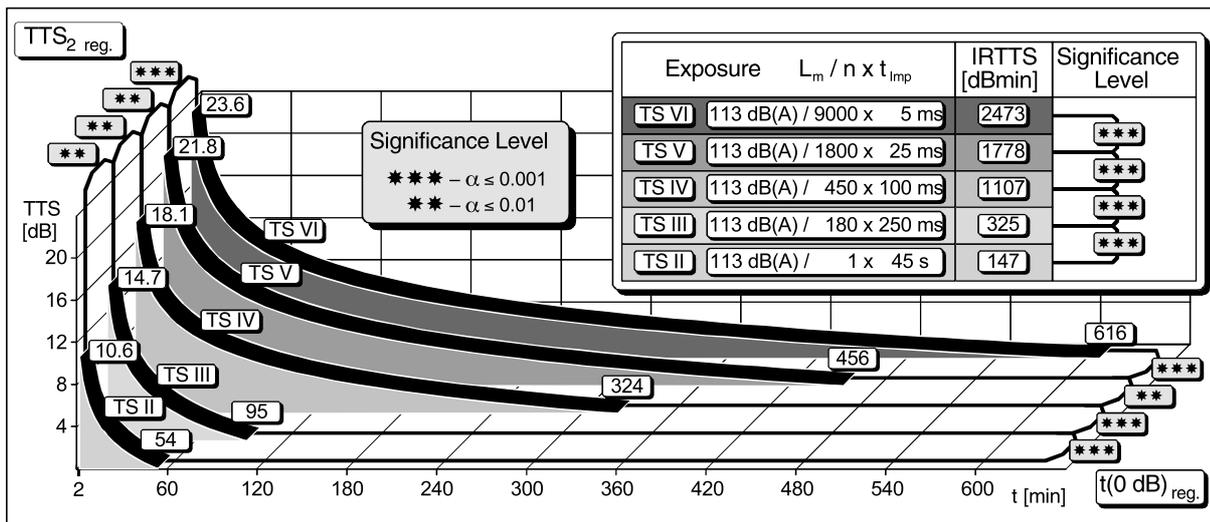
In order to quantify these results with regard to the damage-risk based on the energy equivalence principle, the IRTTS values of all five test series with 113 dB were standardized to the total physiological costs resulting from the exposure to 94 dB for 1 hour (TS I) (Figure 8).


Figure 7. Restitution time course TTS(t) with characteristics TTS$_{2\ reg.}$, t(0 dB)$_{reg.}$, and physiological cost IRTTS as well as symbolic labeling of significance levels for the differences between the responses to the exposures with equal exposure level.

L$_m$ = 113 dB(A) and exposure time t$_{Exp}$ (n x t$_{Imp}$) (according to the one-tailed WILCOXON test) (Source: Strasser *et al.* 1995)

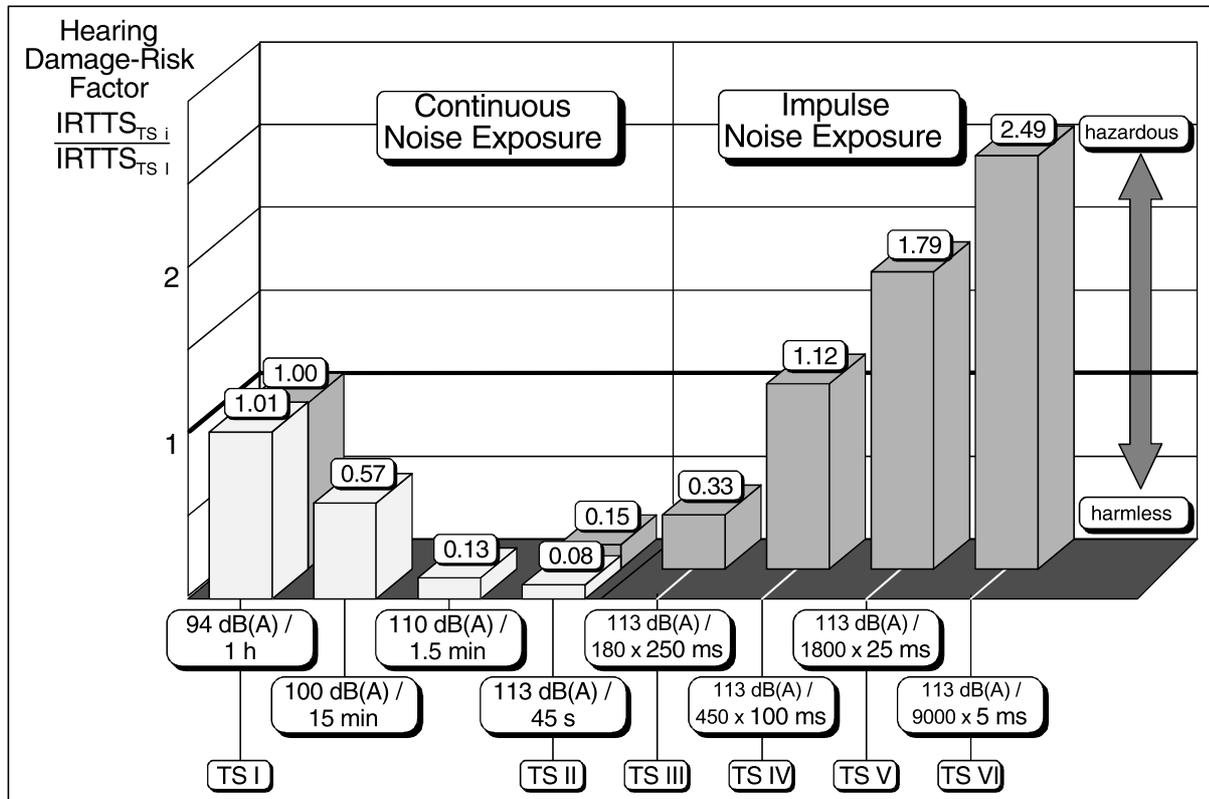
Values of this ratio as a "risk factor" > 1 thus stand for an increased danger whereas values < 1 mean a lower risk for hearing. Compared to impulse noise based on IRTTS of 94 dB/1 h, the risk with 5-ms impulses is 2.5 times higher. Compared to continuous noise of 113 dB / 45 s, the risk with 5-ms impulses is even 16 times more dangerous. The results of prior studies, which were carried out with other subjects and with continuous noise of 100 dB / 15 min, 110 dB / 1.5 min, and 113 dB / 45 s, also energy equivalent to 94 dB / 1 h or 85 dB / 8 h, confirm the high reliability of the results of the studies; e.g., the IRTTS values for 94 dB(A) / 1 h are almost identical.


Figure 8. Hearing damage-risk criterion of energy equivalent continuous and impulse noise exposures determined via the comparison of IRTTS values with IRTTS (94 dB(A) / 1 h) = 1.00 (Source: Hesse *et al.* 1994).

5. PHYSIOLOGICAL COSTS OF ENERGETICALLY NEGLIGIBLE CONTINUOUS AND IMPULSE NOISE

Noise exposures – even if they do not exceed the rating level of 85 dB(A) – are often annoying, disturbing, and performance-reducing, and, furthermore, they can cause considerable hearing threshold shifts. As a result of a continuous noise of 94 dB(A) for 1 hour – energy equivalent to 85 dB(A) / 8 h – hearing threshold shifts (TTS$_2$) of approximately 20 to 25 dB must be expected immediately after the exposure as shown above. Usually, the restitution time for these threshold shifts is at least 2 hours. The sum of the temporary threshold shifts which can be audiometrically monitored represents a measure of the "physiological costs" of noise for which the organism – in addition to the psychological effects – must "pay." Such hearing threshold shifts, if and when recovery is completed before another acoustic exposure occurs, still may represent a "normal" fatigue of hearing. Yet, if restitution time is greatly prolonged, a daily exposure to noise can lead to a Noise Induced Permanent Threshold Shift (NIPTS). The same may occur if recovery from a temporary threshold shift as a response to continuous noise cannot take place in noisy surroundings. That happens in situations where, e. g., a continuous noise exposure with a limited duration is followed by a lower noise of longer duration. Furthermore, often impulse or continuous noise does not occur exclusively; rather, it is a combination of both.

If low level continuous noise or impulse noise is added to an already existing high level continuous noise, numerically no essential increase in the rating level results. Yet, it cannot be expected that the aural strain of these exposures is always negligible. Therefore, according to Figure 9, in cross-over test series, subjects were exposed to noise of 94 dB(A) for 1 hour (TS I), energy equivalent to an 8 h-rating level L_{Ard} of 85 dB(A). In a second test series (TS II), the same exposure was combined with 900 energetically negligible 5-ms impulses with a level of 113 dB(A) which increased the rating level by only 0.4 dB. Whereas the noise exposure of TS I and TS II was followed by an idealized resting phase in a soundproof cabin, in a third test series (TS III) the continuous noise of 94 dB(A) / 1 hour was followed by 3 hours of white noise at 70 dB(A). Such an additional load increases the L_{Ard} by merely 0.1 dB to 85.1 dB(A). In all three test series the noise-induced temporary threshold shift (TTS$_2$) and its restitution (see upper part of Figure 9) were measured.

As shown in Figure 10, the continuous noise exposure of 94 dB(A) for 1 hour was associated with a TTS$_2$ of somewhat more than 20 dB which disappeared completely after about two hours. The additional impulse noise caused only a small increase in the TTS$_2$. Yet, more importantly, the restitution time increased from about 2 h to 3 h. The TTS$_2$-values of TS III did not differ from those resulting from TS I. That was expected as the conditions up to that point in time were identical. But due to the additional subsequent energetically irrelevant exposure, the mean restitution time increased considerably from 126 min up to 234 min (about 4 h). The mean total physiological costs represented by the Integrated Restitution Temporary Threshold Shift (IRTTS) increased in TS II by approximately 40 % (902 versus 660 dBmin) and in TS III even by 140 % (1613 versus 660 dBmin).

6. GENERAL CONCLUSIONS

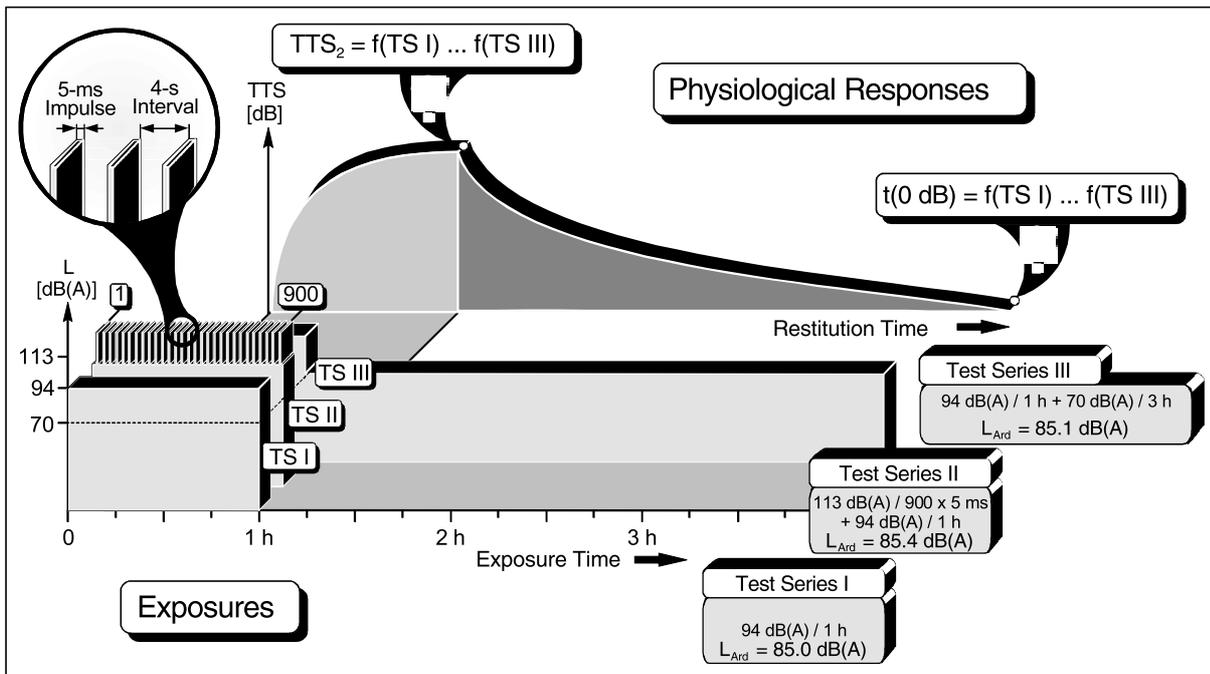
The exemplary results presented above have shown that energy equivalent impulse noise exposures that differ in their time structure lead to quite different physiological costs. Whereas the difference in aural strain from impulse noise compared to continuous noise does show fewer substantial effects in the temporary threshold shift two minutes after the end of the exposure (TTS$_2$), the effects are distinctly pronounced in the different restitution times, i.e., the strain compensation. Taking


Figure 9. Hypothetical restitution time course of the temporary threshold shift (TTS) associated with three noise exposures with nearly equal rating level L_{Ard} per day.
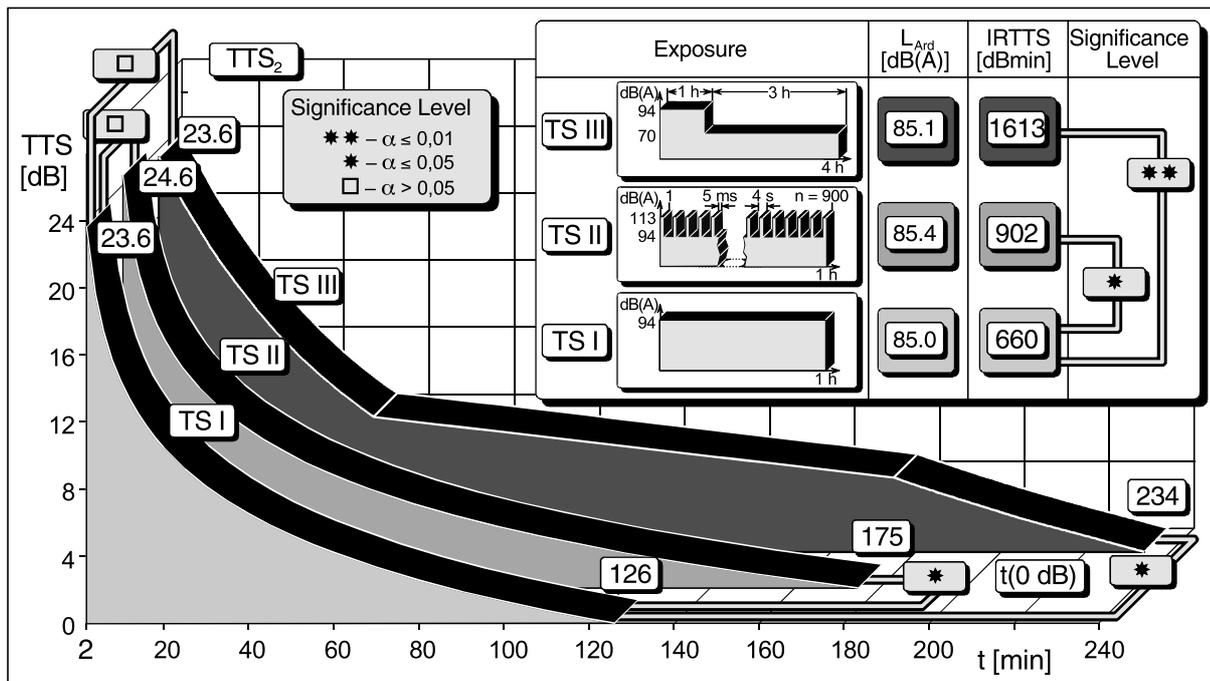

Figure 10. Restitution time courses TTS(t) and IRTTS (in dBmin) as physiological cost associated with preceding noise exposures (94 dB(A) / 1 h in TS I, 94 dB(A) / 1 h + 9000 x 113 dB(A) / 5 ms in TS II, and 94 dB(A) / 1 h + succeeding 70 dB(A) / 3 h in TS III). All test series inhered the same noise energy of legally tolerated 85 dB(A) / 8 h (source: Irle *et al.* 1998).

this into consideration, the IRTTS as an integral parameter proved to be an indicator for potentially long-term hearing-physiological damage more valid and reliable than commonly used TTS_2. Because reversible auditory fatigue is always of certain prognostic value for irreversible hearing impairments, the results disprove the validity of the damage-risk based on the energy equivalence hypothesis. Especially in the areas close to the lower and upper end of the exposure continuum which is still legally allowed, it must be explicitly stated again that hearing cannot be energy equivalent.

The results reported also show that levels of noise which have no influence on the rating level which traditionally is calculated according to the energy equivalence principle are often of great importance, as they can lead to considerably prolonged restitution times. Therefore, the purely energy equivalent determination of the rating level of both impulse noise and low sound levels can lead to an underestimation of latent problems so that over time a reversible TTS can evolve into a permanent threshold shift. This is also of importance for the acoustic design of break rooms for noise-exposed workers. Conditions which allow an undisturbed restitution of hearing should always be present.

Tolerance to Sustained +G_z Acceleration

R. R. Burton

Human Effectiveness Directorate, Air Force Research Laboratory, Brooks AFB, TX 78235–5118, USA

1. INTRODUCTION

The environments produced by accelerating a human body are grouped into three main categories: (1) transient, (2) sustained and (3) chronic. Acceleration takes place when the velocity of a body changes either in magnitude or direction. Changes in acceleration that last 1 or 2 s and do not achieve steady-state are termed transient, abrupt or impact. Sustained acceleration is usually a steady-state environment with short periods of changing accelerations at the beginning (onset) and ending (offset) of the acceleration environment. The duration of this exposure is usually £ 1 h. Chronic acceleration is a steady-state exposure that lasts for several hours, days or even years. Not surprisingly with these types of definitions that rely on the duration of exposure, there are not clear distinctions where transient acceleration ends and sustained acceleration begins. The same can be said about sustained and chronic accelerations. Because of the very short duration of transient acceleration, the environment is developed using sleds or drop towers. This article deals with sustained acceleration that uses the centrifuge to provide the acceleration as does chronic acceleration studies.

Reasons for studying these types of accelerations are to develop information on human effects as they primarily relate to the following activities: (1) transient for impact injuries, (2) sustained for pilot tolerance during fighter aircraft maneuvers and (3) chronic for long-term space flight.

For more information on transient acceleration, see Brinkley and Raddin (1996) and for sustained and chronic acceleration, see Burton and Whinnery (1996) and Burton and Smith (1996).

2. PHYSICAL PRINCIPLES

The human, in the sustained acceleration environment, physiologically responds to the inertial force generated by the acceleration. The forces of acceleration (a) are described by Isaac Newton's three laws of motion. The first law states that a body remains at rest or in motion in a straight line until acted upon by a force. The second law of motion defines the force (F) required to overcome the first law, i.e. F = mass (m) x acceleration (a). The third law states that for every action there is an equal reaction, thus establishing the physical principles of acceleration in circular motion as generated by a centrifuge, i.e. centripetal (acceleration) force (a) establishes an equal centrifugal (inertial) force (G). Thus, a centrifuge or an inside loop of an aircraft produces the same acceleration with an equal inertial force acting in the opposite direction.

Equation 1 predicts the centripetal acceleration resulting from the motion involved:

$$a = r v^2, \tag{1}$$

where a is centripetal acceleration (m s^{-2}), v^2 is radians s^{-1} and r is the radius of the circle (m).

Radian degree tables are available but for simple calculations, 360∞ = 6.28 radians. The product of equation 1 is "a" (m s^{-2}) that for convenience is divided by Earth's gravitational constant (9.81 m s^{-2}) providing a value that is in multiples of Earth's gravity (1 g). Thus, "g" is frequently used in place of "a." Hence, $g = G$, the inertial force (G) resulting from the acceleration (g) defined in equation 1 as "a" is also measured and is equal.

"G" resulting from "g" is the parameter of importance in defining human tolerance to acceleration levels (intensities). The physical and physiological effects on the body come from G. Of particular importance for the human tolerating increasing levels of sustained G, is the distribution of blood within the body.

Fluid pressures within an acceleration field obey the hydrostatic pressure law (equation 2):

$$P_H = h \, d \, g, \tag{2}$$

where P_H is hydrostatic pressure, h is column height, d is specific density of the liquid and g is the level of acceleration.

Since $g = G$, equation 1 predicts the effect of G on arterial pressure (P_a) and blood flow within the body. Hence, it has been adapted for use as a human G-level tolerance prediction model (equation 3; Burton and Whinnery 1996):

$$G_{LT} = (P_a \sum d)/h, \tag{3}$$

where G_{LT} is G-level tolerance of a person seated upright, h is eye-heart vertical distance (350 mm), P_a is mean arterial blood pressure at eye level is 100 mmHg and d is specific density of mercury (13.6) used in blood pressure measurements.

3. AXIAL SYSTEM NOMENCLATURE

Since equation 3 predicts the G level that a human can tolerate, it becomes clear that "h" (eye–heart *vertical* distance) plays a major role in G-level tolerance determinations. Thus, the orientation of the body in the acceleration environment must be identified when defining G-level tolerances. Thus, a standard axial system of nomenclature has been adopted to identify this relationship for all acceleration-related studies (table 1).

3.1. Relaxed G Tolerance

There are two definitions of human tolerance to sustained acceleration. First there is the level of acceleration that can be tolerated with a cardiovascular basis, using visual criteria, known as G-*level tolerance*. The other tolerance is the duration of acceleration that can be tolerated with a metabolic basis, using symptoms of fatigue G-*duration tolerance*. Obviously both of these tolerances have common dimensions of G level and duration, i.e. the difference is in the dimension criteria that determine the tolerance.

3.2. G-level Tolerance

Natural, control or basic human G-level tolerance (+G_z) is measured on relaxed subjects on a centrifuge with G onset rates of ≥ 1 G s^{-1} (Burton *et al.* 1974). This tolerance measurement is called "rapid onset relaxed" (ROR). The subject is seated upright with "g" directed towards the head and, of course, corresponding G directed towards the feet. The G level is increased until a

predetermined tolerance criterion is reached. Several criteria exist: (1) greyout, (2) blackout or (3) loss of consciousness. The first two criteria are visual, recognized by the subject who terminates the centrifuge exposure by activating a hand brake. Greyout (also known as peripheral light loss or tunnel vision) is a dimming of the vision while blackout (central light loss) is total loss of vision. Greyout visual symptoms occur because blood flow in peripheral regions in the retina of the eye ceases as systolic P_a at eye-level falls from a normal level of 125 mmHg to ~40 mmHg. Blackout occurs with eye-level P_a = 20 mmHg. With blackout, subjects are still conscious, thus they can hear and are aware. This visual symptom is possible because intra-ocular pressure is 20 mmHg that causes the retinal blood vessels to collapse with ~20 mmHg P_a in the head. Recovery from these visual symptoms is immediate upon reestablishing blood flow to the eye.

A subject loses conscious, known as *G*-induced loss of consciousness (G-LOC), when blood flow to the brain ceases. Recovery from this condition is not immediate as with visual symptoms, but requires 15–30 s. Thus, G-LOC is an extremely dangerous condition as the aircraft remains totally without control while the pilot is recovering consciousness. *G*-level tolerance can be predicted solving equation 3 and is ~4 *G*, i.e. each *G* requires ~25 mmHg P_a at heart level (Burton and Whinnery 1996).

If the subject is not physically relaxed, *G* tolerance will increase, e.g. simply gripping one hand will increase it by 0.6 *G*. Contraction of arm, leg and abdominal muscles can increase *G* tolerance by several *G* thus forming the basis for a maneuver that is used by pilots to increase their *G* tolerance during high *G* exposures (see below).

The use of slow-onset of *G* rates (i.e. 0.1 *G* s^{-1}), known as gradual onset relaxed (GOR) exposures, defines a *G* tolerance that is ~1 *G* higher than ROR tolerances. GOR tolerance is increased above ROR because of the activation of a physiologic reflex (baroreceptor initiated) that increases heart rate, causes arterial vessel constriction thus raising P_a. This reflex is more pronounced in fighter pilots than subjects not regularly exposed to *G* suggesting that a type of environmental adaptation has occurred.

3.3. G-duration Tolerance

G-duration tolerances for relaxed subjects are measured using a constant *G* level that continues until the subject becomes fatigued and ends the exposure by applying a hand brake that stops the centrifuge. *G*-duration tolerances for *G* levels (£ 5 *G*) are predicted using:

$$G_D = 2666\ e^{-1.265G}, \qquad (4)$$

where G_D is *G*-duration tolerance (min) and *G* is *G*-level exposures ≤ 5 *G*.

4. METHODS TO INCREASE G TOLERANCE

Sustained *G* levels above those naturally tolerated by a human, is an environment that is studied because it is generated by fighter planes during maneuvers that are used in air combat, i.e. aerial combat maneuvers (ACM). The ACM is a very dynamic activity as pilots rapidly change their aircraft positions using inside loops as they attack the enemy or for defensive purposes. Therefore, fighter aircraft are designed to develop very high *G* levels (i.e. 9

G) because highly maneuverable aircraft, that can make tighter turns or make them more rapidly, have a great advantage over their adversary during ACM.

Thus, pilots are exposed to *G* levels far in excess of their natural *G*-level tolerances of ~4 *G*. To allow pilots to tolerate these high *G* levels for considerable periods without having G-LOC, methods have been developed that provide protection against *G*. These methods are called "anti-*G*" or "*G* protection". However, it is important to understand that they do not truly "protect" a pilot against the effects of *G*. Anti-*G* methods do not block the effects of *G*, but only increase pilots' *G* tolerances thus exposing them to higher *G* levels and increasing the potential hazards of *G* exposures.

4.1. Anti-G Suit

Various types of anti-*G* suits were developed in World War II by the USA, Canada and Australia. The US-design anti-*G* suit with a few modifications is used today by fighter pilots from all nations that have high-performance aircraft. This garment is made of fire-retardant material that covers pneumatic bladders that apply pressure to the legs and supports the abdomen (Burton and Whinnery 1996). This suit is inflated with pressurized air, controlled by an anti-*G* valve at 1.5 psi/*G* to a maximum of 10 psi. This suit increases *G* tolerance by 1.0–1.5 *G* by increasing P_a and elevating the position of the heart during *G* – the latter reducing "h" of equation 3.

4.2. Anti-G Straining Maneuver

Also during World War II, a physical maneuver, called the M-1, was perfected in conjunction with the anti-*G* suit. M-1 uses the combination of muscle contractions and a forced exhalation against a closed or partially closed glottis (Wood *et al.* 1946). This maneuver can increase pressure within the lungs by as much as 100 mmHg resulting in a similar increase in P_a. This method is now called an Anti-*G* Straining Maneuver (AGSM) that with the increase of P_a at eye-level of 100 mmHg increases *G*-level tolerance by 4 *G* (equation 3). By combining the AGSM with the anti-*G* suit, pilots can tolerate 9 *G*, to match the acceleration-level capability of their aircraft (Burton and Whinnery 1996). On the other hand, performing the AGSM is extremely fatiguing to the pilots thus limiting their *G*-duration tolerance capability.

Obviously this maneuver is very important to pilots as it forms the basis for 50% of their *G* tolerance. Since it must be learned, training programs have been developed that teach pilots, on a centrifuge, how to perform an effective AGSM.

Since muscle contractions form the basis for the AGSM, physical conditioning programs have been developed for pilots to increase their muscle strength, thus performing this maneuver with less effort and slowing the onset of fatigue.

4.3. Positive Pressure Breathing During G (PBG)

Positive pressure breathing (PPB) systems were first developed to protect pilots flying in low-pressure environments from hypoxia. This system forces air into the lungs above the ambient environmental pressure thus increasing oxygen levels in the arterial blood. To assist in breathing against this increased pressure in the lungs, a counter-pressure is applied outside the chest at the same pressure level, using a type of inflatable vest. This

PPB system has been developed recently as a *G*-protection method known as positive pressure breathing during *G* (PBG). Pressures as high as 60 mmHg are used that require little physical effort by the pilot. Since PBG increases pressure in the lung like the AGSM and with much-less effort, pilots fatigue less rapidly thus increasing their *G*-duration tolerance. An operational version of PBG is now commonly used internationally by pilots flying high-performance aircraft (Burton and Whinnery 1996).

4.4. Reclining or Pronation of Pilots

Subjects using seats that have reclined backs are placed in a supine position and exposed to +*G*$_x$. Subjects can also be pronated resulting in –*G*$_x$ exposures (table 1). These positions reduce "h" of equation 3 thus significantly increasing *G* tolerances. A *G*$_x$ level tolerance as high as 15 *G* has been realized. Although this method for increasing *G*-level tolerance is very effective, cockpit design complexities have prevented its use in fighter aircraft.

5. HIGH SUSTAINED G (HSG) TOLERANCE

Anti-*G* methods described above have increased *G* level and duration tolerances far above normal relaxed levels. This environment is known as high-sustained *G* (HSG; Burton *et al*. 1974). Advanced anti-*G* methods allow > 9 *G* to be tolerated by pilots thus providing them more than adequate protection for flying 9 *G* fighter aircraft. These high-*G*-level tolerances are measured using the same visual and G-LOC criteria that determine relaxed *G*-level tolerances (see above).

G-duration HSG tolerances are limited because of pilot fatigue that results from performing the AGSM. These tolerances are measured using continuous *G* exposures that can be at a constant *G* level or can be variable. Variable *G* profiles are designed to simulate ACM that are used by pilots in combat and training thus the name Simulated ACM (SACM; Burton and Shaffstall 1980). The SACM is most commonly used to measure HSG duration tolerances. *G*-duration tolerances for a continuous and constant *G* profile are predicted using:

$$G_D = 14.08 \, e^{-0.328G}, \qquad\qquad (5)$$

where *G*$_D$ is as in equation 4 and *G* is *G*-level exposures > 5–9 *G*.

This equation can be used also to approximate SACM tolerances by increasing the predicted tolerance by 20–30% (Burton 1998).

6. PERFORMANCE WITH G EXPOSURE

Pilot must have excellent awareness during ACM, known as Situation Awareness (SA). Good SA is a very high priority item for fighter pilots. Without a doubt their most critical SA is during ACM. To preserve their SA, pilots must maintain good vision during *G* exposures. The occurrence of tunnel vision (greyout) or blackout with *G* exposures will greatly reduce their performance thus anti-*G* methods are very important for pilots' SA. Of course, G-LOC with loss of awareness eliminates SA and all performance capability for at least 30 s.

Subject performance during exposures to increased *G* has been measured using subjects on the centrifuge. Unfortunately values obtained from these studies are difficult to evaluate relative to pilot performance during ACM (Burton *et al*. 1974). These studies generally show an exponential decay in motor function (i.e. target tracking) beginning at 3 *G* with increasing reductions in performance to 60–70% at 7 *G*. These levels of performance reduction during HSG appear to be unrealistically high for pilots that train to achieve near perfection in their performance during ACM.

The major problem in measuring performance relevant to the fighter pilot is the complexity of the visual and cognitive requirements of the ACM while interacting with *G*. An operational ACM can not be accurately duplicated on the centrifuge. Perhaps in the future improved visual displays and the use of Virtual Reality may provide the means to measure pilot performance more accurately in the laboratory.

Toxicology

S. Konz

Department of Industrial and Manufacturing Systems Engineering, Kansas State University, Manhattan, KS 66506, USA

1. TOXINS

Toxicology deals with the long-term effects of foreign chemicals upon the body – it considers health. A toxicology problem might be the effect of 10 years' exposure to a solvent; industrial hygienists are the technical specialists for toxicology problems.

Chemicals *affect* the *body* with *doses* producing a *response* (Konz 1995: chapter 24). For their "effect," the threshold limit values (TLV) discussed below usually use non-reversible functional changes in an organ (usually the kidney or liver). These effects are more like "corrosion" than "short circuits"; that is, they take place gradually over a long period.

Initially, the "body" is an animal body, not a human body. Animals are given various doses and results are extrapolated to humans (using a safety factor). Of course, there can be questions whether the appropriate animal was used and whether the safety factor is sufficient.

TLV need to consider dose–response. Part of the problem is that the body has the ability to transform toxins to less toxic forms and eliminate them from the body. This transformation ability varies greatly with people as does their individual susceptibility. TLV assume a 70 kg adult.

2. TOXIN ROUTES

From a toxicology viewpoint, a toxin must enter the blood. Three potential entrance points are the skin, mouth and lungs.

The skin is not permeable to *most* compounds. Unfortunately, there are a few that do penetrate the skin (they have "skin" next to them in TLV tables). A potential problem is entry through breaks in the skin (cuts, abrasions). The mouth (eating, drinking) is another potential entry route. But the lungs are the primary source of toxin entry to the blood. Most retained particles are < 5 mm in diameter; larger particles tend to be filtered out in the nose and upper airways.

3. TOXIN TARGETS

Targets are divided into exterior (skin) and interior (organs).

The skin is the largest organ system of the body; toxicology problems of the skin are called dermatoses or dermatitis. Dermatitis is divided into atopic and contact dermatitis. In allergic contact dermatitis, the person takes 14–21 days for an allergy to develop following initial contact; then, however, the person is sensitized and the response occurs very quickly. One can even become sensitized by various medications (e.g. benzocaine, neomycin, merthiolate and some topical antihistamine creams).

3.1. What to Do?

Protective clothing helps – especially aprons and gloves. Naturally the material should not be permeable to the chemical it is defending against. Also use splashguards on machines. Personal cleanliness is important; be sure employees have the proper workplace facilities to keep clean. Avoid solvents and strong soaps;

add skin moisturizers after washing the hands. Work clothing washed at home may transfer the toxin to the worker's family.

The first interior target is the lungs/respiratory system. Problems range from an increase in airflow resistance (asthmatic response) to chronic interstitial lung disease. The lungs have a defense system (macrophages: "big eaters") that disposes of the particles that settle in the lungs. Inert particles, however, present problems to the macrophages – killing them and forming scar tissue (and thus lack of active lung surface area) or causing cancer.

If the toxin passes into the blood, it attacks other organs. Examples are lead (nervous tissue), cadmium (kidneys) and carbon monoxide (hemoglobin). An unborn baby is especially sensitive to some of these toxins as it does not have a good ability to eliminate poisons; the most critical time is the first 3 months of pregnancy.

4. TOXIN ELIMINATION

The primary elimination organs are the liver and the kidney.

The liver transforms fat-soluble compounds to water-soluble compounds and re-inserts the compounds into the blood (although some bile goes to the small intestine). In the kidney, the blood gives up the water-soluble compound, which then is eliminated in the urine.

Since not all the blood goes directly to the liver, some blood (with the compound) goes to various "target organs." That is, there is a "race" between the kidney de-toxifying the compound and the compound affecting a target organ.

Sometimes there are two compounds competing for the same liver enzyme, thus slowing biotransformation. Examples are alcohol and barbiturates, or cigarette smoke, and cotton dust or asbestos. It has been reported that asbestos workers who smoke cigarettes have a 92 times greater chance of lung cancer than the general population. Heavy metals (lead, methyl mercury) inhibit enzymes.

5. THRESHOLD LIMIT VALUES

Each year, the American Conference of Governmental Industrial Hygienists (ACGIH, 6500 Glenway Avenue, Building D-7, Cincinnati, OH 45221, USA; tel.: +1 (513) 661 7881) issues updated TLV. (Although the ACGIH calls its limits TLV-TWA, the US government calls its limits Permissible Exposure Limits (PEL), the National Institute of Occupational Safety and Health calls its limits Recommended Exposure Limits (REL), and the American Industrial Hygiene Association (AIHA) calls its limits Work Environment Exposure Limits (WEEL)).

The ACGIH gives three different types of TLV: a time-weighted average (TLV-TWA), a short-term exposure limit (TLV-STEL) and a ceiling (TLV-C).

TLV-TWA is the concentration, for a normal 8 h workday and 40 h week, to which nearly all workers may be repeatedly exposed, day after day, without adverse effects. It primarily recognizes chronic (long-term) effects. For administrative simplicity, the TLV assume that concentration x time is a constant. That is, you would get the same effect from eight aspirins taken once in 8 h as from one aspirin taken each hour for 8 h. What an assumption!

TLV-STEL is concerned with acute (short-term) effects of (1) irritation, (2) chronic or irreversible tissue damage and (3) narcosis of sufficient degree to increase the likelihood of accidental

injury, to impair self-rescue or to reduce work efficiency. STEL is a 15 min time-weighted exposure that should not be exceeded any time during the day, even if TLV-TWA is met. There should not be more than four STEL exposures of 15 min/day; there should be at least 60 min between each STEL exposure. For TLV with no STEL listed, ACGIH recommends "STEL should exceed 3 times the TWA for no more than 30 min/day; under no circumstances should STEL exceed 5 times TWA, provided that TWA is not exceeded."

TLV-C is the concentration that should not be exceeded during any part of the working day.

Excursions (peaks) are the recorded values of the toxin. They are permitted above the TWA and STEL (but not above the C). For example, acetic acid has a TWA = 10 ppm. An exposure of 12 for 4 h can be balanced by an exposure of eight for the remaining 4 h. The TWA would even permit an exposure of 80 for 1 h, if balanced by exposure of 0 for the remaining 7 h. This, however, is where the STEL comes in.

STEL for acetic acid is 15. Thus the exposure of 80 for 1 h is too high.

TLV needs to be adjusted if (1) the concentration varies during the day, (2) the day is not 8 h and (3) exposure is to more than one substance.

First, assume a worker was exposed to acetone for 4 h at 500 ppm, 2 h at 750 ppm and 2 h at 1500 ppm. The equivalent exposure is:

$$\text{TWA} = (C_a t_a + C_b t_b \ldots C_n t_n)/8,$$

where TWA is the time-weighted average (equivalent 8 h exposure), C is concentration of $a, b, c \ldots$ (ppm or mg/m^3) and t is time of exposure to concentration $a, b, c \ldots$ (h). For the example:

$$\text{TWA} = [(500)(4) + (750)(2) + (1500)(2)]/8$$
$$= 6500/8 = 812.$$

Since 812 is greater than the TLV-TWA of 750, the exposure is not acceptable.

Next, assume a worker was exposed to 600 ppm of acetone during the entire working day but worked 12 h/day. Then:

$$\text{TWA} = [(600)(12)]/8$$
$$= 7200/8$$
$$= 900.$$

Since 900 > 750, the exposure is not acceptable. Assuming the worker worked only 4 h/day yields 600 (4)/8 = 300. Since the 300 < 750, the exposure is acceptable.

Finally, consider exposure to a mixture of substances. The following formula assumes the effects are additive, not independent or multiplicative:

$$\text{TWA}_{\text{mixture}} = (C_1/\text{TLV}_1) + (C_2/\text{TLV}_2) + (C_3/\text{TLV}_3),$$

where $\text{TLV}_{\text{mixture}}$ is the equivalent TWA mixture exposure (maximum of 1 permitted), $C_{1,2,3}$ is the concentration (8 h) for a specific substance and $\text{TLV}_{1,2,3}$ is the TLV for a specific substance.

Assume exposure for 8 h to 500 ppm of substance 1 (TLV = 750), of 45 ppm of substance 2 (TLV = 200) and 40 ppm of substance 3 (TLV = 100). Then:

$$\text{TWA}_{\text{mixture}} = 500/750 + 45/200 + 40/100$$
$$= 0.667 + 0.225 + 0.400$$
$$= 1.292.$$

Since 1.292 > 1, the exposure is not acceptable.

6. CONTROLS

Controls are divided into engineering, administrative and personal protective equipment.

6.1. Engineering Controls

6.1.1. Substitute a less harmful material
Use solvents with higher TLV (e.g. toluene with TLV = 100, not benzene with TLV = 10). Use water-base cleaning compounds instead of organic base; use latex paints instead of oil (solvent) based paints; use glues without solvents.

6.1.2. *Change the material or process*
Reduce carbon monoxide by using electric-powered fork trucks, not gasoline-powered. Use electrostatic spray painting. Remove grinding particles or solder fumes with a vacuum system instead of blowing them into the room using compressed air. Reduce use of cleaning solvents by cleaning before the substance has time to harden or oxidize; an analogy is dishes in a dishwasher.

6.1.3. Enclose (isolate) the process
As a first approximation, cost of air handling is proportional to the volume moved. The operating cost is twofold: (1) the direct cost of electrical power for the fans and (2) the hidden cost of replacing the conditioned air (heated or cooled and humidified and purified to desired values). Reduce the volume of air handled by capturing substances and vapors before they are dispersed.

Two guidelines are: (1) Physically enclose the process or equipment and (2) remove air from the enclosure (hood) fast enough so that air movement at all openings is into the enclosure (i.e. negative pressure).

One example of enclosure is using plastic strips (such as used for strip doors) around solvent tanks; even better is a lid on the tank. A sealer coat on a concrete floor reduces dust; less dust means less air changes/h and thus lowers heating/air-conditioning costs.

6.1.4. Use wet methods
Wet floors before sweeping; steam cotton; use moistened flint in potteries; clean castings with a high-pressure water jet instead of abrasive blasting.

6.1.5. Provide local ventilation
The flow sequence should be input air, worker, contaminant, exhaust air. That is, the worker is upwind of the contaminant.

Local ducts are much more efficient (25–50% increase in duct velocity) if they have a flange (flat plate perpendicular to the duct axis) equal to duct diameter at the duct entrance.

Dumping the exhaust "out the window" is not satisfactory. Clean it with filters, cyclones, vapor traps, precipitators, etc. Discharge exhaust so it escapes from the "cavity" that forms around buildings; otherwise it may become the input air.

6.1.6. Provide general (dilution) ventilation
Use general ventilation when the contaminant is released from non-point sources. Forced ventilation (fans, blowers) is preferable to natural ventilation (open doors, windows) since air direction, volume and velocity can be controlled.

6.1.7. Use good housekeeping

Remove dust from the floor and ledges to prevent dust movement by air currents, traffic and vibration. Fix leaking containers. Clean up chemical spills.

6.1.8. Control waste disposal

Each disposal problem needs to be considered separately. Establish specific procedures for safe disposal of dangerous substances, toxic residues, contaminated wastes and containers with missing labels. Drain systems become chemical storage systems; be sure you know what is going to mix in your drains.

6.2. Administrative Controls

6.2.1. Reduce exposure time

Reduced exposure time not only reduces exposure but also it increases recovery time. For example, if exposure is reduced from 8 to 4 h/day, the body's daily recovery time goes from 16 to 20 h. Even more important than the absolute recovery time is the relative recovery time. At 8-h exposure, recovery is 16 h, or 2 h recovery/h of exposure. At 4-h exposure, recovery is 20 h, or 5 h recovery/h of exposure.

6.2.2. Periodically monitor employees

The TLV concept is to monitor the *air* around a person. "Biological monitoring" is monitoring the inside of a person's body (e.g. blood, urine). The ACGIH now publishes Biological Exposure Indices for ~40 substances.

6.2.3. Train supervisors, engineers and workers

Knowledge is power. Material Safety Data Sheets (MSDS) are required by the Hazardous Communication Standard (29 CFR 191.1200). Manufacturers and distributors of hazardous chemicals must provide MSDS; employers are responsible (1) to inform their employees about the chemicals and (2) to train employees in safe use of the chemicals.

6.2.4. Screen potential employees

The goal is to avoid use of workers who are hypersensitive to a substance. Examples would be people with allergic contact dermatitis and pregnant women who would be exposed to teratogens. Unfortunately, due to discrimination claims, screening employees has many potential problems.

6.3. Personal Protective Equipment

The third (and last) line of defense is personal protective equipment. Examples include respirators and protective clothing (aprons, gloves). Respirators protect versus airborne toxins while protective clothing protects the skin. Dentists should wear a mask over their nose to reduce the breathing of particles from the drilling of fillings. Note that toxins, which normally could not penetrate the skin, can penetrate the skin if it is broken (cut, rash).

Working Clothing – Thermal Properties and Comfort Criteria

R. Ahasan† and J. Salovaara‡

†Division of Work Science, University of Oulu, Finland‡Department of Industrial Design, Helsinki University of Arts and Design, Helsinki, Finland

1. INTRODUCTION

Owing to unsuitable clothing, worker's physiological reactions are often reflected as deterioration of their work performances. A high level of protection by clothing can also severely impede heat exchange through the sweat evaporation. Thus, reliable measures to evaporative heat transfer through the design of suitable clothing should be developed. In this context, the thermal properties of clothing are reviewed, and corrective measures are emphasized that can match with worker's physiology, and on the effects of thermal balance, work performance and the comfort criteria.

Work clothing has a major contributing role to the workers' physiological response. It complicates the emission of body heat and cause physiological reactions through increasing of sweating, heart rate, heat cramps and frequently impedes worker's performance (Beshir 1994). Physiological changes and seasonal acclimation can lead thermal effect if clothing does not match properly with the working environment. Working conditions also may be stressful due to incorrect or insufficient clothing, and for high metabolic rate of the workers. The effect of air temperature (T_a °C) and humidity is mainly reflected in skin temperature (T_{sk} °C) and in the clothing fabrics (Woodcock 1962). Higher humidity also causes excessive thermal stress more than in the dry conditions (Candas et al. 1979, Boisvert et al. 1993). Sweat rate increases occurs more with the humidity in clothing with higher insulation, and it can lead to an increase in T_{sk}. Thus, increasing concern has been growing from the concerned professionals about undesirable exposure to working clothing. Kenney et al. (1987) demonstrated workers' physiological limits in varying thermal environments. They illustrated the effects of moisture absorption in increased thermal load integrating the coefficients of properties of heat exchange. Lotens (1993) derived a clothing model that handles most of the physical phenomenon. Crockford (1994) illustrated especial garments, which can reflect 40% incoming radiation, and can reduce the convection loss by 25% and if the clothing have 20% of maximum evaporative capacity (E_{max}). Sen and Dutta (1985) discussed about heat radiation, and they proposed aluminum-foiled clothing for workers who are involved with furnace and steel millwork. Crockford et al. (1984) mentioned about the design and suitability of protective clothing for workers. In a hot, humid climate, radiative heat load may > 400 W/m² and metabolic heat load may range > 300 W/m², and thus, evaporative cooling is to be maintained (Kähkönen 1994). Physical work in hot, humid climate is heavy and characterized by static and dynamic loads of variable duration and intensity (Ahasan 1996). Workers with low physical capacities are usually less able to tolerate heat, and

they need good clothing. Environmental control measures are also important to reduce the risk of heat illness. In this regard, ISO 7933 and NIOSH (1986) has been devised some principles that work rate (or workload) should be compensated for by a reduction of heat load. Crockford (1994) added that lower E_{max} might limit the physical workload. By shortening the time of work exposure or changing the climate, thermal load can be reduced.

The limiting values (i.e. warning level of acclimatized persons) in accordance with ISO (International Standard Organization) and NIOSH (National Institute of Occupational Safety and Health, USA) standards provide the maximum level of safety for majority of employees (Ilmarinen 1978). However, reduction of climatic and metabolic stress, and improvement of protective clothing remain a major challenge on the selection of fabrics. In this regard, several thermal indices and heat exchange model have been developed by Holmer (1995) to select clothing ensembles (Gagge et al. 1986). For this, individuals' metabolic condition, stature, sex, age and even social, religion and culture are very important considerations. Often clothing insulation is not adjusted to meet the requirements of actual activity level. Thus, in the design and purchase of working clothing, local criteria should be considered.

Working clothing must be wearable that can balance evaporative cooling, and be really available in the local market. The design has to be simple and easy to manufacture locally. It must be comfortable and likely to be functional for effective sweat evaporation through its fabrics. Many developing countries are poor in economy, where physical work combines with heat stress and cause acclimation through sweating. In this sense, thermal properties of tropical clothing (Ahasan et al. 1996) are very important that determine heat exchange rate, and as such, act as a resistance to heat loss through the evaporation of sweats. Therefore, correct choice of working clothing depends on the heat stress index, permissible limit values, thermal properties and local climatic condition.

2. THERMAL PROPERTIES OF WORKING CLOTHING

Working clothing affect heat transfer from and to the human body mainly through the insulation and permeability of the fabrics. The subjects can feel pleasant due to optimum insulation and ventilation (i.e. concentration gradients) in the clothing across the textile layers (Olesen and Nielsen 1983, Nielsen et al. 1989). For instance, in tropical countries, heat radiation and humidity have a direct effect for which clothing has to be selected carefully. Solar heat radiation is continuos a serious heat problem for the workers in tropics, even moderate physical workload could be heavy and stressful in that situation (Sen 1965). Holmer (1985) also has reported the detrimental effects of moisture absorption in working clothing and insulation characteristics. Havenith and Lotens (1994) and Shapiro et al. (1995) discussed the effects of sweat absorption in working clothing.

Water absorption, transporting properties and drying rate of sweats are also evaluated (Nordon and David 1967, Nielsen and Endrusick 1990, Nielsen 1992) from the selected clothing ensembles. Evaporated sweat may condense and accumulate and thereby influence the distribution of humidity in working clothing (Madsen 1976). With evaporative heat transfer, it has been possible to reduce up to 50% using cotton clothing (Kenney et

al. 1987). High relative humidity (RH) can also affect clothing layers which is prevalent in the tropics. Ha and Tokura, (1995) noted that sweats are significantly higher in polyester than cotton and a wet fabric in direct contact with skin produce an unpleasant sensation as *chilly effect* or *clammy feelings*. Radiative energy in tropical climate is an additional heat load while wearing color-absorbing and reflecting clothing (Lotens and Pieters 1995). That is why thermal properties of clothing ensembles and fabric materials are to be given priority.

2.1. Clothing Insulation

Insulation characteristics are important for working clothing to select proper clothing ensembles. It plays a vital role for moisture distribution and sweat absorption and, has a leading influence on comfort of clothing (Fanger 1972, Givoni and Golman 1972, Holmer and Elnäs 1981, ISO-9920, Nielsen and Toftum 1992). Fabric surface and its thickness, i.e. amount of air trapped inside fabrics, mainly determine thermal insulation of clothing (or Clo). Clo (e.g. thermal insulation or resistance of fabrics are necessary to maintain the thermal balance between T_{sk}, textile materials and T_a) for different clothing ensembles can be found from DIN standard 33403, Olesen and Nielsen (1983) and the ISO's draft standards. It can control the heat exchange rate between skin and environment. Clothing insulation is varied to the individual's physiological response, and to the combination of workload, RH, T_a, air velocity (V_a) and clothing ensembles. Olesen *et al.* (1982) has evaluated Clo by movable thermal manikin on the effects of body posture and activity level.

Permeability of clothing ensembles indicates the ability of water vapor to pass through the fabrics (i.e. ventilation). High permeability means more sweat will be allowed to evaporate and high ventilation can enhance cooling of skin through sweat evaporation. Light and moderate insulated, permeable with good ventilated clothing (long sleeve shirt, trouser, socks and shoes having 0.6 Clo) are recommended where no risk of high contamination (Holmer and Elnäs 1981). Fabric thickness and clothing layers also reflect clothing insulation (Larose 1947). Typical clothing ensembles (Holmer and Elnäs 1981, ISO-9920, Oohori *et al.* 1985, McCullough *et al.* 1989) are listed in Table 1, which are comparatively available.

2.2. Clothing Ensembles and Fabric Materials

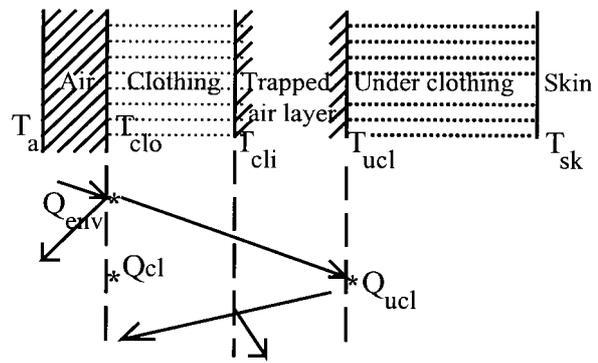
Clothing ensembles and fabric materials have a significant impact on thermal properties and comfortability. Nielsen (1993) emphasized on dissipation of metabolic heat that can be reduced


Figure 1. Radiation effect on clothing ensemble consisting outer garment and under clothing.

up to 25% depending on proper fabrics. High humidity and solar radiation cause excessive sweating and, thus, Hall (1971) developed a simplified method for clothing ensembles. Lotens and Pieters (1995) evaluated radiation effect on two-layer clothing (Figure 1).

Heat is absorbed first in the outer layer (Q_{cl}) and partly transmitted to underclothing (Q_{ucl}), until the radiation energy is completely distributed over the clothing layers and then to the environment (Q_{env}). The resultant temperature in the fabrics (T_{ucl} for underclothing, T_{cli} for inside of outer clothing and T_{clo} outside of outer clothing) depend on the distribution of Q_{env} over the clothing layers, and on the heat resistance of fabric layers and the boundary conditions (T_{sk}, T_a). Absorption properties of working clothing show a greater or equal transit in T_{sk} and may have beneficial effect on thermal sensation. During absorption, vapor concentration moves upward (Figure 2) along the line, and in a downward direction for desorption (Havenith and Lotens 1994). Sweating is related with fabrics and clothing ensemble are also needed to be formulated from the required sweat rate (SW_{req}) and Clo which depend on physical properties of fabrics (Table 2): thickness (density, course, number/inch), specific weight (sp. wt.), thermal resistance, water absorbency; thermal conductivity; moisture transfer, air permeability (AP), water vapor resistance (WVR) and heat flow transmission rate (HFTR).

Absorption capacity for actual wearer has seldom quantified, but Nordon and David (1967) developed a numerical method including the rate of equilibrium between fabrics and surrounding air. To simulate clothing ensembles, Havenith and Lotens (1994) developed a computer model based on geometry of clothing and activity of worker. They focused on the prediction of thermal

Table 1. Clothing insulation and permeability index of clothing ensembles.

Clothing ensembles		Clo–values		permeability index		TER
($R_{T,evp}$)		I_{cl}	I_T	i_m	i_{cl}	(Pa m²/w)
1. Cotton shirt, trouser, underwear, shoes	0.65	1.25	0.39	0.32		30
2. T-shirt, underwear, socks, shoes	0.84	1.41	0.39	--		34
3. Shirt, pant, underwear, belt, socks		1.00	1.51	0.30	0.27	44
4. Aluminized coat, CST uniform	1.36	1.89	0.33	--		53
5. Aluminized coat (midnight) CS-uniform	1.74	2.19	0.30	0.27		68
6. Chemical protective clothing (Goretex)	1.40	1.90	--	--		180

(I_T is total insulation; i_m and i_{cl} are permeability index and/or boundary layer, and clothing layer respectively under the standard conditions. $R_{t,evp}$ is the total evaporative resistance)

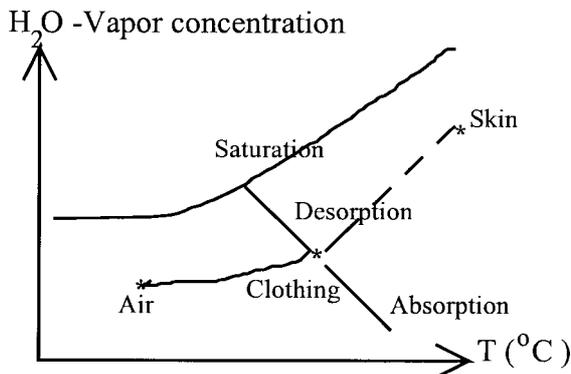
H₂O -Vapor concentration


Figure 2. Effects of H₂O vapor absorption in clothing, at skin and in surrounding air.

effect on heat balance through the process of vapor absorption in different fabric's layer. David (1965) reported the effects of saturated sweat absorption in clothing ensembles, using a thermal manikin. More recently, De Dear *et al.* (1989) reported the thermal effects, moving from one environmental humidity to another with absorbing and non-absorbing clothing.

2.3. Heavy Protective Clothing for Working in Dangerous Conditions

Heavy protective working clothing is important for pesticide sprayers, in chemical plants (or wastes disposal), food industries and in nuclear power plants (Raven *et al.* 1979, Mihal 1981). Flameproof clothing is used for fire brigades, and nuclear, biological and chemical (NBC) clothing is used for particular situation to reduce the danger of work hazards. Heavy protective over-garment and water-repellent fabrics are also used in heavy protection; however, this clothing is very expensive. Protective clothing with microporous and ventilated fabrics significantly can improve heat exchange and reduce physiological strain. An adjustable valve must be efficient in NBC clothing to washout most of the metabolic heat. NBC clothing poses heavy constraints to work even with moderate work, particularly with high humidity. Therefore, proper schedule of work and better ventilation should be provided (Ohnaka *et al.* 1993). Protective clothing should design that heat tolerance in terms of dynamic changes to inside body temperature must not be above the tolerance level, as well as to improve work tolerance and can protect against chemical liquids, dusts, aerosols and poisonous substances. For better comfort and performance, temperature of space between skin and clothing layer (T_L) should be monitored carefully. Cortili *et al.* (1996) found a reliable match of T_L between 36.2 and 36.4°C (when V_a = 0.1 and 0.5 respectively) that may valid mainly in the tropical climates (T_a = 35°C, RH = 85%).

2.4. Typical Working Clothing

Typical clothing and its model depend on multifactors such as sex, age, health, stature and body composition. Even social status, culture, religion and region can affect thermal responses. For instance, Thai female workers are shorter than Tanzanian women are, and their clothing is not similar. Females in SAARC (Southeast Asian Association for Regional Co-operation: India, Nepal, Bangladesh, Pakistan, Bhutan; Maldives, Sri Lanka, etc.) countries use *sari* (one piece of long cloths that is to be trapped and cover all the whole body, blouse and petticoats). *Sallower* and *kamiz* (long legged trouser and shirts) are popular for young women. *Lungis* (hollow type long legged clothing) and sandals are very common in men's wearing in these regions. In the big cities, working clothing are usually pants, shirts, aprons and shoes. Women in the ASEANS (Association of Southeast Asian Nations) use pants, skirts and tops. African and Arab women use hollow type dresses. Owing to religion, shorts and light clothing are forbidden in some Muslim countries (e.g. Malaysia, Saudi Arabia), and even there are State rules that clothing must be worn for complete cover of all sexual parts. However, working clothing should be selected so that it can reduce physiological and climatic stress. Generally, cotton, nylon and polyester are used as light working clothing. Traditional or regular working clothing is generally light dresses that includes trousers, T-shirt, sandals or canvas shoes (0.5–0.7 Clo).

ACGIH (1991) devised summer clothing (0.6 Clo); Ramsey (1978) suggested normal clothing (0.5–1.0 Clo); Goldman (1981) added regular clothing (0.5–0.7 Clo); and Bernard *et al.* (1986) preferred cotton coveralls (0.7–1.0 Clo). Jogging shoes, socks, shorts, single jacket or T-shirt are athletic clothing. Aluminized garments are used for workers in the steel and re-rolling mills to protect from radiant heat. Further, proper working clothing should be considered from the available fabrics, which are cheaper and thermally matched with metabolic reactions, because ISO and NIOSH recommended clothing are not easily suitable and cheap in some circumstances.

3. COMFORT CRITERIA

Comfort criteria are very important for the design of working clothing. To assess proper working clothing, thermal properties of fabrics, and the effects of metabolic reactions should be considered. Feeling of clothing discomfort also depends on the type of tasks, jobs, work environment and body heat balance on clothing ensemble (Wyon *et al.* 1975, Hafez and Beshir 1987). ISO standards have been evaluated thermal sensation and discomfort levels using various clothing ensembles. Galbraith *et al.* (1962) evaluated comfort sensation while wearing cotton clothing, e.g. light gray, pure white or mixed cotton, linen or polyester (65% cotton plus 35% polyester or linen) are also

Table 2. Physical characteristics of textile materials [ISO 5084; ISO 5085; CAN2-4.2M77 (1977)]

Fabrics	Thickness (mm)	SP.wt (g/m²)	TR (Km²/w)	AP (1/m²/s)	WVR (mm air)	HFTR (%)
Cotton	1.52	153	0.028	1741	*	62
Polyester	0.73	280	0.016	104	1.4	69
Polyester/ cotton mixed	2.40	210	0.058	983	2.3	55

preferred. Ramsey (1978) described physiological responses for general guidelines, but this approach does not contribute to the heat balance equation. Fanger (1972) developed mean thermal sensation on clothing effects. Neilsen *et al.* (1989) predicted comfort level using subjective and physiological rating scales. Havenith and Lotens (1984) compared semipermeable and impermeable garments to heat dissipation and discomfort of thermal sensation. Hensel (1981) showed the relationship between thermal discomfort and skin wettedness by various ensembles. For thermal comfort, seasonal variation in T_a, V_a, heat radiation and humidity are to be selected properly (Vokac *et al.* 1976) because physiological change and seasonal acclimation can lead to thermal effect if activity and clothing ensembles do not match properly.

Working clothing effect on climatic and physiological parameters is to be integrated for acceptable thermal sensation (Sprague *et al.* 1994). In general, subjects in tropical climates feel comfortable using light clothing due to solar heat and higher humidity (e.g. RH $\cong$ 70–85%). Moisture absorption is generally regarded as a prime factor in thermal comfort that depends on fabric rigidity, wicking, clinging, liquid buffering, drying ability and other thermal properties of working clothing. Condensation of evaporated sweat is highly relevant with comfort criteria (Gonzalez *et al.* 1986); and the color of clothing and the wavelength of radiation effect on clothing are very important (Nielsen 1990).

4. DISCUSSION

Recommendations for proper working clothing should rely on the understanding of physiological effects of heat exposure to clothing by environmental control that can enhance safety and work performance. Kenney *et al.* (1986) emphasized acclimatization control advocated by specific measures (using natural and cross ventilation, heat barriers, reduction of physical work, rest breaks or provision of driving water). Local contexts are to be applied for physiological adaptations with working clothing and climatic variables, because threshold limits (TLV) or recommended standards as national legislation in tropics are yet to be established. In most cases, workers or entrepreneurs know those parameters, but they do have some sort of thermal sensation from which clothing can be selected. Acceptable working clothing must be choice on physiological and climatic conditions which match properly. The workers are to be advised to wear proper clothing and trained through metabolic heat reduction scheme (Ramsey 1995) and overall environmental control) by certain control (NIOSH 1986, ISO 7730, ASHRAE 1992, Olesen and Madesen 1995). To protect from the ill-effects, TLV or certain standards are important for clothing control that keep the body heat balance and that can bring a massive advantage to worker's health, safety, efficiency and productivity. Following standards are important for recommendations: general guidelines for metabolic heat exposure limits, and selection of normal clothing, unacclimatization and environmental control (Kodak 1983, NIOSH 1986); appropriate Clo and design of clothing (Ramsey 1978, 1995, Bernard *et al.* 1991); modification of wet-bulb glove temperature (WBGT) index and correction factors for various clothing (ISO 7933, ACGIH 1991); estimation of thermal insulation of clothing (ISO 9920); evaluation of moderate thermal work environment, and prediction of thermal sensation and

discomfort (ISO 7730); guidelines for evaluation of thermal strain (ISO (9886); subjective judgement of thermal sensation (ISO 10551) and ergonomics of thermal environment (ISO 12894).

This established standard means a situation or measures above which work should not be resumed wearing working clothing. According to ASHRAE (1977), comfort range is ~23–27°C. Fanger (1970) added that clothing having 0.5–0.7 Clo is better for sedentary work during lower V_a (> 0.3 m/s). Sen (1982) advised that T_{room} @ 23.5∞C is comfortable at lower humidity levels (e.g. 50% RH). He found a comfort zone in the Indian climate to be at 26°C in corrective effective temperature for those engaged in light or moderate work. Air-conditioning systems are used in many commercial offices, market complexes or banks where a thermal comfort zone is taken into consideration.

Common ergonomics approaches are the arrangement of proper clothing materials with less thermal impact (Epstein *et al.* 1986). Fabric thickness affects insulation and can influence mean skin temperature because of vapor diffusion and moisture transportation from skin to the clothing ensemble (Bakkevig and Nielsen 1994). For example, a fishnet textile allows more air to sweep the sweating and at the same time can act as effective ventilation (Nielsen and Endrusick 1990). Normally cotton, gabardine and mixed fabrics (cotton, gabardine, linen) are a benefit in the tropics (Kogi and Sen 1987). They added that fabrics should be flame-resistant, flexible and washable. Foot and underwear are to be suitable. Sandals are extensively used for light wearing, especially in the tropical developing countries, but to ensure more safety, canvas shoes are recommended. Soft rubber or plastic shoes can be used for moderate work. Gym shoes and boots are recommended for heavy work where protection (e.g. from burning or cutting) of feet is a vital. Sweat accumulation is generally higher in underwear that can be affected by fiber types. Excessive sweat may feel uncomfortable, and thus underwear clothing (i.e. fabric construction) should select carefully (Bakkevig and Nielsen 1994).

It has been evident that most of the protective clothing severely restrict evaporative heat loss and increase thermal strain, but microporous fabric significantly can protect against chemical liquids, dusts or aerosols, and impermeable fabrics can protect against gases and vapors. NBC clothing restricts heat loss by evaporation when radiation is direct or omnidirect. So, adjustable valves for air outlet must be provided to transmit sweating and heat through the clothing fabrics. Smith *et al.* (1994) emphasized on TLV and exposure time that physical fatigue can be normalized. Madsen (1976) suggested that workers in cold storage, slaughtering house or in fish processing factory need multilayered clothing (I_T = 1.20 Clo). He added that outer layer should be cotton, middle layer a mixed polyester and cotton, and inner layer could be pure cotton. Makambaya (1994) added special working clothing (outer wind-proof and waterproof garments) for high wind and rain. Hygroscope and damped humidity-gradient fabrics are also suitable to transfer saturated sweat from the skin. Anyway, open and thin garment-knits are preferred especially for tropical countries.

5. CONCLUSION

Most of the entrepreneurs do not afford costly clothing for their workers; however, working clothing should be selected on the basis of thermal properties (e.g. suitable and adjustable Clo),

available in the market and long lasting with reasonable price. Generally, cotton fabrics are the cheapest and comfortable in the tropics. NBC and/or heavy protective clothing are used in the cold climate, which are bit expensive. But modifications of heat exchange should be adjusted carefully whatever working condition is. Moreover, it has been evident that impaired heat exchange with heavy protective clothing contributed to most of the physiological strain. The workers' general opinion is that protective clothing is sometimes more of a handicap than a protection. Therefore, it is important to know a reliable indicator of thermal load in a wide range of different combination of physiological and climatic variables on these clothing.

Physiological effect and significance of clothing on tropical human are not yet completely known. In this regard, subjective assessment is to be evaluated where local influences, such as asymmetric radiation, draught, vertical rays or direct radiation are existed. Moreover, control of heat exposure must satisfy national health and safety standards (or legislation); however, many countries are yet to establish legislation. Clothing must be worn to reduce the thermal impact as well as to protect physical and environmental work hazards. Thus, thermal properties of clothing should evaluate on the effects of local population (i.e. on physiological adaptation with local climate) that can match with thermal comfort sensation. The practitioners normally estimate metabolic rates following heat stress standards, but thermal comfort reflect on the integrated state of thermoregularity system, where T_{sk} and internal body temperature (T_{body}) must be integrated together. Metabolic rate and clothing values must be keyed in by ergonomist to design a proper choice of working clothing. So, careful control of exposure duration, thermal indices (T_a, RH, V_a, radiant heat flux, solar radiation, etc.) and metabolic factors (sex, age, obesity, health status, physical fitness, skin temperature and wetness, etc.) are important to be considered (Lee 1980). Wearing NBC clothing results in increased respiratory strain and elevated T_{body}, and inspiratory or expiatory effect. But distributing it in multilayered ensembles can reduce sweat accumulation. Sweat may not evaporate completely in these clothing, but if inner layers are absorbing in nature then it will perhaps be benefited. Outer layers must be easy to open to allow sweat be exposed to the air. Latent heat of condensed sweat must be available for conduction to clothing surface and to the environment. Under certain conditions, evaporative sweat may condense before escaping to the environment, giving off its heat to the surrounding clothing layers. The concept of basic insulation (I_{cl}) is valid for a limited range of ensembles and thermal conditions. In this regard, effect of condensation evaporation (efficiency and conductive heat exchange) is needed further experimental work along with consideration of work posture, body motion and wind effects.

Recent modifications by ISO standards are rational but not promising for low-cost ensembles. Sweat rate prediction by the WBGT index may not reflect the actual heat stress for clothing design if there is high T_r, T_a or V_a. It also seems that climate condition in thermal work environment for which ISO standards are applicable is too narrow in the tropical climate. The estimating errors of I_{cl} may not be always correct in evaluating thermal environment and selection of proper clothing. Tropical countries are experienced with heavy physical work, and wearing protective clothing can increase sweating and vapor concentration that

results in uncomfortable feelings. In most of the developing countries workers are less educated and are lacking knowledge about work hazards. Environmental control should relate with the use of proper clothing to enhance safety and work performance. A model should derive for standard clothing especially for SAARAC, ASEANS, African, Arab and other tropical countries that handle most of the physical phenomena influencing heat transfer criteria. Hence, further R & D should focus on the ability to interact sweat transportation, heat dissipation, and on how such effects can modify Clo for cheaper and available clothing. Standard clothing recommended by ISO, NIOSH or ASHRAE is also very expensive and, therefore, ergonomics of low-cost clothing should be a great achievement.

Part 8

System Characteristics

Accident Analysis and "Human Error"

E. Hollnagel

Graduate School of Human–Machine Interaction Linköpings Universitet, S-581 83 Linköping, Sweden

1. INTRODUCTION

An accident can be defined as an unexpected event with an undesirable outcome. Both criteria are important, since neither an expected unpleasant event, nor an unexpected pleasant one qualify as an accident. As long as accidents have happened, people have tried to understand them, both to satisfy themselves that the causes were not in conflict with the accepted wisdom of the world, and to help finding ways to prevent that the same — or a similar — accident should occur again.

The concern for accidents and their causes has attracted considerable interest in the last half of the twentieth century, mainly due to a number of spectacular accidents in complex industrial systems. The more famous of these are the explosion at the Flixborough plant (1974); the accident at the nuclear power plant at Three Mile Island (1979); the explosion of the Challenger space shuttle (1986); the meltdown at the nuclear power plant in Chernobyl (1986); the aircraft collision at Tenerife (1977); and the multitude of problems on the space station MIR (1998).

In accidents such as these, failures of human action and judgement have often been seen as part of the causes, and in a growing number of accidents the main cause has been attributed specifically to "human error". In the 1960s the number was around 30%, but grew during the following decades so that the number at present often is put as high as 70–90%. This development is, of course, not the expression of a simple fact or relation. Rather, there are a number of reasons for this trend, for instance: (1) that technological systems have become more complex, hence more difficult to control; (2) that improved models and methods for "human error" analysis have made this cause more likely; (3) that technological systems have become more reliable, hence raising the relative number of other causes; or (4) that it is sometimes cheaper and more convenient to put the blame on a human than to redesign an entire system.

2. MODELS AND METHODS FOR ACCIDENT ANALYSIS

An accident model is a generalized description of how an accident may have happened. Such models are invariably based on the principle of causality, which states that there must be a cause for any observed event. The early accident models tended to see accidents as caused either by failures of the technology or incorrect human actions ("human errors"). This view was gradually extended to recognize both the contribution of latent system states, and the complexity of conditions that could end in an incorrectly performed human action — even leading to the extreme notion of "error forcing" conditions. In contemporary accident models, a distinction is made between actions at the "sharp" end, which often are the initiating events, and actions at the "blunt" end, which create the conditions that either make an action failure near inevitable or turn minor mishaps into major disasters.

Despite these developments, specifically the increasing sophistication in accounting for the organizational determinants of accidents, there is an almost intransigent preference to refer to "human error" as a singular concept. The history of accident analysis clearly demonstrates that the notion of a cause itself is an oversimplification, since a cause represents a judgement in hindsight rather than an unequivocal fact. This acknowledgement, notwithstanding, accident models seem to be firmly entrenched both in the idea that a "true" or root cause can be found, and in the idea that "human errors" necessarily must be part of the explanations. This view should be contrasted with the pragmatic, so-called ecological, view which points out, first, that action failures are both an unavoidable and necessary element of efficient human performance and, second, that the same types of action failures occur across tasks and domains. Without making shortcuts or using heuristics people would be unable to work effectively, and without failing every now and then they would not be able to learn. The challenge for cognitive systems engineering and artifact design is, of course, to make sure that the systems are so robust that minor variations in performance do not lead to fatal consequences, yet so sensitive that users have the freedom necessary to create and optimize control strategies.

3. THE NATURE OF "HUMAN ERROR"

Since the 1960s many attempts have been made to provide a technical definition of the concept of error. Yet despite the fact that the term "error" has a relatively simplistic meaning in everyday life, the term is extremely difficult to pin down precisely when considered from a technical point of view. One reason is that the same term is used to denote either (1) an outcome or consequence, (2) the act or event itself, or (3) the possible cause. Such ambiguity is clearly not conducive for developing accounts of causes and effects. A further reason is that analyses of the nature and origins of error from different professional points of view, often have quite different and, at times, incompatible premises. Thus, an engineer might prefer to view the human operator as a system component subject to the same kind of successes and failures as equipment. Psychologists, on the other hand, often begin with the assumption that human behavior is essentially purposive and can only be fully understood with reference to subjective goals. Finally, sociologist have traditionally ascribed the primary error modes to features of the prevailing sociotechnical system and in a sociological analysis items such as management style and organizational structure are often hypothesized as the mediating variables that influence error rates.

Irrespective of the above differences there seem to be at least three intuitive parts to any definition of error:

- First, there must be a clearly specified *performance standard* or *criterion* against which a response can be measured. Engineering reliability analysts have traditionally used objective measures, such as system parameters, as the standard for acceptable performance. In contrast, investigators working from the standpoint of cognitive psychology have tended to rely on subjective criteria such as the momentary intentions, purposes, and goal structures of the acting individual. According to this view there are two basic ways that an action can go wrong. In one case the intention to act is adequate but a subsequent act does not

go as intended. Here the "error" is conventionally defined as a slip. In another case, actions proceed according to plan but the plan is inadequate. Here the "error" is usually classed as a mistake (Norman 1981).

- Second, there must be an *event* which results in a measurable *performance shortfall* such that the expected level of performance is not met by the acting agent. Many researchers of human performance ascribe to a pessimistic view according to which "human errors" provide strong evidence of design defects of the human information-processing system. Considerable research has therefore aimed at identifying the design defects of the human mind. Once identified the assumption is that guidelines can be developed to determine in which situations the human operator can and cannot be trusted with the care of complex plant and equipment. A more optimistic viewpoint is found in a line of research that emphasizes that most "human errors" have their origins in processes that perform a useful and adaptive function. This approach takes a much more beneficial view of the variability of human cognition and performance, and relate ''error mechanisms'' to processes that underpin intelligent functioning and especially the human ability to deal with complex data that are characterized by a high degree of ambiguous and uncertainty.

- Third, there must be a degree of *volition* such that the actor has the opportunity to act in a way that will not be considered erroneous. Thus, if something is not avoidable by some action of the person, it is neither reasonable nor acceptable to speak of an error. This, presumably, also includes the so-called error forcing conditions, even though the full implications of that approach have not yet been realized. Factors that occur outside the control of the individual, for example, "acts of God" or acts of nature, are therefore better defined as accidents.

4. ACCIDENT ANALYSIS

Accident analysis denotes the set of methods and principles that are used to find, in a systematic manner, the cause — or causes — of an accident. The engineering practice of accident analysis

is based on the assumption that there is a true or real cause of an accident — sometimes referred to as the root cause. This should be contrasted with the more recent view of, for instance, cognitive systems engineering, according to which the cause is a social construct (Woods *et al.* 1994). Formally speaking, a cause is the identification, after the fact, of a limited set of aspects of the situation that are seen as the necessary and sufficient conditions for the effect(s) to have occurred. In order for a cause to be an acceptable explanation, it must be possible to associate it unequivocally with a system structure or function (people, components, procedures, etc.), and to do something to reduce or eliminate the cause within accepted limits of cost and time.

Accident analysis methods are usually based on a hierarchy of causes, although most hierarchies represent convenience rather than a taxonomy. The classification causes has undergone a significant development during the last 30 years or so (Figure 1). In the early days of accident analysis, i.e. the 1950s and 1960s, causes were roughly seen as belonging to three groups called technical failures, "human error", and anything else – called "other". The development in the categories, paralleled by a development in accident analysis methods, has in particular taken place within the groups of "human error" and "other". As far as the latter is concerned, the major new categories have described various causes of organizational failures, including safety culture, quality assurance, and pathogenic organizations. As far as the former is concerned, the development has been to distinguish between causes in different types of work (management, maintenance, design, and operation), and further to increase significantly the categories for "human errors", going from omissions and commissions to detailed information processing failures or ''cognitive errors''.

4.1 Traditional Human Factors and Ergonomic Approaches

Models of operator error developed within a human factors and ergonomic tradition generally provide a useful framework the development of practical tools to classify errors in terms of their external manifestations. The objective of such analyses is usually to predict the probability of *simple* error forms, which may occur

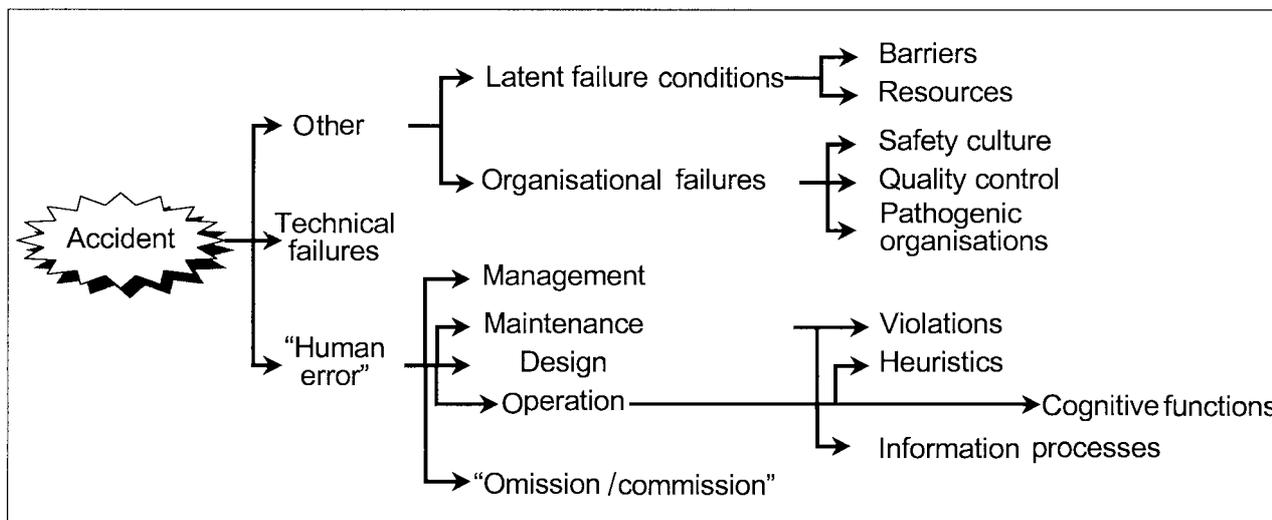

Figure 1: Development in the classification of causes.

in human—machine interactions, such as the distinction between "errors of omission" and "errors of commission". Although more complex models of human error have been specified at the level of observable behavior, the basic limitation of the approach is that it provides little information regarding the possible psychological causes. Thus, the analytic capability of traditional ergonomic models is typically quite low and resultant models contain few general principles that can be used to construct a description of failures in terms of underlying psychological functions.

4.2 Information-processing Models

In contrast to traditional human factors approaches, information-processing models have a highly developed basis and analytic capability, but cannot always easily be converted to useful and practical tools for performance analysis or prediction. The analytic capability of information-processing models derives mainly from the large number of general statements relating to error tendencies or mechanisms that can be incorporated into such models. Since the models often are of a rather loose nature, many of these explanations are unfortunately ad hoc and lack a clear theoretical foundation. (For example, it is commonly assumed that short-term memory is capable of processing a strictly limited number of chunks of information and that demands in excess of this amount typically cause the short-term memory system to fail.) Furthermore, when information-processing models permit the formulation of general predictions that certain types of error will occur, the extent to which such predictions transfer to a real-world setting is unclear. Analyses of accident and near-miss reports, for example, frequently describe situations where information-processing failures occurred although the situations were well within the presumed performance capabilities of the human operator. Conversely, there are many well-documented instances where operators have succeeded to control a situation where information-processing models would have predicted failure.

Information-processing models also face the problem that the capabilities of the human are far from being stable or constant. In analogy with physical artifacts, each of the components of the human information processing system are assumed to have identifiable capabilities, hence also boundaries (high and low). Yet despite heroic attempts to define and measure the basic capabilities, success has been strictly limited. This fact could be taken as an indication that the underlying approach is wrong, i.e. that the human is not really an information processing system — although people in many ways can be described as such with considerable benefits.

4.3 Cognitive-systems Engineering

Models of erroneous actions generated from the standpoint of cognitive systems engineering tend to do quite well in terms of analytic capability, predictive capability, technical basis, relation to existing taxonomies, practicality, and cost/effectiveness. Currently, the main shortcoming is that they fall short of the ideal with regard to their ability to predict likely error forms. They are, however, not bettered in this respect by either ergonomic models or information-processing models. Moreover, cognitive-systems models are particularly strong in terms of their technical content because they are based on viable and well-articulated

models of human action. Cognitive-systems engineering focuses more on how human performance is influence by the internal and external context than on how it can be explained by hypothetical models of cognitive functions and structures. The models therefore provide a better basis for the development of practical tools for error analysis and subsequent reduction.

4.4 Sociotechnical Approaches

Since the late 1980s, a further approach to human error modeling has been on the rise, which places the focus on the organizational and operational context in which the work takes place (Reason 1997). The main background for this approach is the recognition that a common factor in a large number of accidents is the organizational condition. As the view on human error gradually became more refined it was acknowledged that incidents evolved through a conjunction of several failures and factors, and that many of these were conditioned by the context. This evolved into the previously mentioned notion of people at the "sharp end" of a system as contrasted with people and events at the "blunt end". The basic idea is that human performance is a compromise between the demands from the monitored process and the resources and constraints that are part of the working environment. The demands and resources meet at the sharp end, and the result shows itself in the actions that people make. The demands come from the process, but by implication also from the organizational environment in which the process exists. The resources and the constraints are more explicitly given by the organizational context, e.g. in terms of procedures, rules, limits, tools, etc.

The sociotechnical approach is in many ways the inverse of the classical information processing approach, which concentrates on the internal human information processing mechanisms. The sociotechnical approaches therefore run the same danger of focusing on one aspect of the situation, the context, thereby neglecting the other. The sociotechnical approaches are nevertheless valuable as reminders of the need to consider both sides — cognition and context. At present the sociotechnical approaches have not been developed to the stage where they can provide a potential explanation for human erroneous actions. As a matter of fact, they tend to reduce the relative contribution of individuals and of the operator's cognitive functions. It is not inconceivable that in the future more mature sociotechnical approaches will be developed, which can enrich the explanations of human erroneous actions. At present, however, they have not reached this stage.

5. CONCLUSIONS

One lesson of almost 40 years of research into "human error" is that it is not a specific category. Rather, everything is a "human error" if only one goes back far enough. The logical consequence of that is that the analysis may also go a step beyond the "human error", and thereby avoid simple-minded explanations. Although the relativity of the analysis is an unresolved issue, one inescapable conclusion is the realization that human actions are not a special type of causes. Human erroneous actions are rather a symptom of the conditions of work, and of the demands from the organization and the environment (the end users). Technology is often used in clumsy ways that are not well adapted to the needs of the people at the "sharp end". This results in unnatural and

unusual demands on the practitioner that tend to congregate at the higher tempo or higher criticality periods of activity. The manifestation of this has been an apparent epidemic of failures labeled as "human error". Yet it is only by seeing erroneous actions as an indication of missing adaptation, that the findings from accident analyses can be used constructively to understand and prevent accidents.

Adaptive Automation

M. W. Scerbo

Department of Psychology, Old Dominion University, Norfolk VA, 23529, USA

1. INTRODUCTION

Automation refers to the allocation of functions usually performed by a human to a machine. Automated machines or systems enable humans to increase their span of operation or control, perform functions that are beyond their normal abilities, maintain performance for longer periods of time, and perform fewer mundane activities. Automation can also help reduce operator workload and human error.

On the other hand, automation changes the nature of work and can create new types of problems. Excessive trust in automation can lead to complacent behavior and a diminished ability to notice system failures. Skills can deteriorate when activities traditionally performed by operators become automated. Further, automation can lead to increases in workload when system and operator goals are in conflict.

Adaptive automation can address some of these shortcomings through a more dynamic approach to function allocation. In adaptive automation, the level of automation or the number of systems operating under automation can be modified in real time. In addition, changes in the state of automation can be initiated by *either* the human or the system. Consequently, adaptive automation enables the level or modes of automation to be tied more closely to operator needs at any given moment.

2. BACKGROUND

Adaptive automation has its roots in artificial intelligence. In the 1970s, efforts were directed toward developing adaptive aids to help allocate tasks between humans and computers. By the 1980s, adaptive aiding concepts were being applied to advanced fighter aircraft. A collaborative effort among the Defense Advanced Research Projects Agency (DARPA), Lockheed Aeronautical Systems Company, McDonnell Aircraft Company, and the Wright Research and Development Center, called the Pilot's Associate program, was aimed at providing pilots with an intelligent system that could supply them with appropriate information in the proper format when it was needed. The Pilot's Associate was a network of cooperative knowledge-based subsystems that could monitor and assess the status of its own systems as well as events in the external environment (Hammer and Small 1995). The information could then be evaluated and presented to the pilot. The Associate could also suggest actions for the pilot to take. Thus, the system was designed to function as an assistant for the pilot.

During the same period, researchers and developers in the computer industry were developing adaptive interfaces. For instance, Wilensky, Arens, and Chin (1984) describe their experience with intelligent help for the UNIX operating system. Their UNIX Consultant (UC) was designed to provide general information about UNIX, procedural information about executing UNIX commands, as well as debugging information. The UC had several subsystems designed to analyze the user's queries, deduce the user's goals, monitor the interaction history of the user, and plan and present the system's response. Thus, the UC system can both respond to user queries and offer suggestions when user difficulties are detected.

3. EXAMPLES OF ADAPTABLE AND ADAPTIVE SYSTEMS

Research on adaptive technology has led to some confusion regarding the nature of systems that are *adaptable* and those that are *adaptive*. Table 1 presents a taxonomy of adaptive technology. One dimension addresses the underlying source of flexibility in the system; that is, whether the information displayed or the functions themselves are flexible. The other dimension concerns how the changes are invoked. In adaptable systems, changes among presentation modes or function allocation are initiated by the user. On the other hand, in adaptive systems both the user and the system can initiate changes in the state of the system.

Oppermann and Simm (1994) point to EXCEL as an example of a system where the presentation of information can be modified to meet the user's needs. EXCEL is a spreadsheet program that permits the user to change the structure and layout of dialog boxes. Specifically, the user can substitute a dialog box for the default data entry mode.

An example of an adaptive information system is described by Mason (1986). This system provides a flexible version of the on-line UNIX Programmer's Manual based on the idea of adaptive prompting. Initial requests for the Manual are answered with a default set of instructions that assume the user is a novice. Subsequent queries are monitored and evaluated and the system changes the nature of the information presented to match the level of expertise exhibited by the user. Thus, the system modifies its presentation of information automatically to provide the appropriate level of detail for the determined skill of the user.

The Naval Dynamic Allocation Research Testbed (N-DART) described by Morgan, Cook, and Corbridge (1999) is an example of a system in which functions can be adapted to the user's needs. The user plays the role of an anti-air warfare coordinator whose job is to counter incoming threats quickly and efficiently. The system compiles the tactical picture and evaluates the threats automatically. The operator is responsible for addressing all threats and assigning appropriate weapons to counter the different types of threats. The task of assigning weapons can be allocated to the system. Morgan and her colleagues found that performance was improved when weapon assignment was allocated to the system during periods of high workload.

Researchers at NASA have developed an adaptive system that

Table 1. Taxonomy of Adaptive Technology.

Source of Flexibility	Invocation	
	Adaptable	Adaptive
Information Presentation	MS EXCEL Oppermann and Simm (1994)	Adaptive on-line Programmer's Manual Mason (1986)
Functionality	N-DART Morgan *et al.* (1999)	Biocybernetic, Closed Loop System Pope *et al.* (1995)

uses an index of EEG to moderate task load (Pope, Bogart, and Bartolome 1995). In their system, EEG signals recorded from the scalp are sent to a LabView Virtual Instrument (VI) that computes an index of engagement. Based upon the value of this index, the VI determines whether a change in task mode is required and sends the appropriate signal to a PC running the operator's task. The index is continually updated and comparisons between successive values are assumed to reflect changes in engagement and to initiate switches among task modes. Thus, this system is one in which the functionality is modified in real time to meet the needs of the user.

4. ADAPTIVE STRATEGIES

Recently, Morrison and Gluckman (1994) described a taxonomy aimed at understanding how adaptive automation *ought* to be implemented. One dimension is based upon different methods of modifying system functionality. For instance, entire tasks can be allocated to either the system or the operator, or a specific task can be partitioned so that the system and operator each share responsibility for unique portions of the task. Further, a task could be transformed to an alternative format to make it easier for the operator to perform.

The second dimension described by Morrison and Gluckman (1994) concerns the triggering mechanism for shifting among modes or levels of automation. They describe three ways that this can be accomplished. With goal-based strategies, changes among modes or levels of automation are triggered by a set of criteria or external events. For example, a goal-based adaptive system might automate certain activities only during specific phases of a task typically associated with high workload or when the occurrence of critical events or emergency situations is detected. A second method would use physiological measures that reflect operator workload to trigger changes among modes like that of the Pope *et al.* (1995) biocybernetic system described above. A third strategy would use an index of the operator's performance as a basis for change among modes of operation. This could be accomplished by utilizing models of operator performance. Under this approach, the system would change modes of operation based upon information about the current state of the system, external events, and expected operator actions predicted from patterns of user activity. Alternatively, real-time measures of operator performance could also be used to invoke the changes in automation.

5. AUTHORITY AND INVOCATION

One important issue associated with adaptive automation concerns authority and invocation, i.e. who should have control over changes among modes of automation? One could argue that the operator should always have authority over the system because he or she is ultimately responsible for the behavior of the system. In addition, it is possible that operators may be more efficient at managing resources when they can control changes in the state of automation.

On the other hand, there may be times when the operator needs to change automation modes at the precise moment he or she is too busy to make that change. Further, the operator may not be the best judge of when and if automation is needed. Finally, there are situations where it would be very beneficial for the system to have authority over automation invocation. If lives were at stake or the system was in jeopardy, allowing the system to intervene and circumvent the threat or minimize the potential damage would be paramount. Thus far, this debate is still unsettled.

6. A TEAM PERSPECTIVE

Scerbo (1996) has discussed some of the unique issues facing users of adaptive technology. For instance, both the operator and the system will have to learn the capabilities and limitations of one another. Efficient performance with the system may require extensive training. Although the user and the system will have unique responsibilities, they may have to collaborate on others. During periods of high workload, the system should be capable of stepping in and assuming some of the user's responsibilities. In addition, it is critical that the operator and system are capable of exchanging information freely and effortlessly.

Activities like collaboration, backing up one another, and communication suggest that knowledge of team performance may be useful in designing adaptive technology. There are several factors that are important for efficient team performance including: activities associated with the acquisition and distribution of information to team members, the need to distribute work equitably, setting the proper pace of work and coordinating and sequencing activities among members, setting team objectives and monitoring team performance. Many of the same kinds of functions apply to adaptive technology. For instance, the operator and system need to know the capabilities and limitations of one another, functions must be allocated between the system and operator so as to stabilize workload, and system performance must be continually monitored and evaluated. In fact, Hammer and Small (1995) described the Pilot's Associate as "an electronic crew member".

7. CONCLUSION

Adaptive technology represents the next step in the evolution of automation. These systems will be qualitatively different from those available today. The users' experiences with these systems are apt to be less like working with a tool or machine and more like interacting with a co-worker. Thus, training, communication, and social, organizational, and motivational factors will be far more critical than they are in present-day systems. In addition, the researchers and designers of adaptive automation will also be faced with new challenges. Current system analysis, design, and evaluation methodologies are apt to be woefully inadequate. Standard human factors methods and techniques will not be applicable to many of the human performance issues with this technology. Instead, an understanding of how humans share tasks and information will be more beneficial. Fortunately, the evolution of adaptive automation is still in its infancy. Consequently, designers, cognitive engineers, and psychologists still have time to begin to address the broad range of issues that surround adaptive automation before the technology is widely implemented.

Affordances

M. J. Dainoff and L. S. Mark

Center for Ergonomic Research, Department of Psychology, Miami University, Oxford, OH 45056, USA

1. DEFINITION

Affordance refers to a fundamental relationship in ergonomics — between the user and those elements in the world with which the user interacts during the performance of goal-directed actions. Insofar as the basic problem in ergonomics can be regarded as elucidating the *fit* between the human being and those things (tools, workplaces, environments) with which he or she interacts (Grandjean 1982, Dainoff and Dainoff 1986), affordances become a conceptual tool for ergonomists to assess goodness of fit.

The concept of affordance was developed by the perceptual psychologist J. J. Gibson (1979) to refer to the mutuality between physical attributes of people and their environments with respect to the behavioral acts required to function in that environment. For example, consider the simple act of reaching for an object across a table. The object can be said to afford reaching without standing if the actor's arm and trunk are large enough relative to the distance of the object. Gibson was primarily interested in a theory of perception and action; for him the challenge for the actor was to perceive whether the existing layout of surfaces in the environment would support a particular goal-directed action. This work evolved into a clearly defined perspective, complete with its own journal, called ecological psychology. The focus of ecological psychology has been rooted in evolutionary biology (relating the perceptual and motor capabilities of animals — including humans — to physical attributes of the environments in which they evolved). Recently ergonomists have attempted to utilize this approach, and particularly the concept of affordance, to examine the environments and tools constructed by humans.

Affordances were introduced to a much broader audience by Norman (1988) in his *Psychology of Everyday Things* (albeit with a different theoretical perspective). Affordances have been explicitly included as a component of Helander's (1997) overview of the field in his Presidential Address to the International Ergonomics Association. There is now a distinct perspective which can labeled ecological ergonomics (Flach 1995).

In particular, for complex work environments, we can conceptualize hierarchies of affordances, in which the goals at one level of the hierarchy serve as means for accomplishing goals at a higher level of the hierarchy (Vicente and Rasmussen 1990, Vicente 1999). For example, the higher-order goal may be wanting to purchase a book. At the first level of the hierarchy, signing on to the Internet affords locating an online bookseller's web site. At the web site, finding the book in a catalogue (second level of the hierarchy) affords making the purchase.

Affordances can be defined as those properties of the environment of an animal that have consequences for the animal's (goal-directed) behavior (Turvey 1992). This definition can serve as a starting place for unpacking the concept of affordance as a tool for assessing fit. (See Karwowski's 1991 discussion of compatibility for a complementary theoretical perspective on this issue.) Ultimately, we want to ensure that the designed environments are able to support goal-directed actions that are healthy, safe and productive.

2. CONSTRAINTS ON ACTION CAPABILITIES

What are the determinants of a person's action capabilities in a given environment? We can define two classes of constraints. Personal constraints refer to both body dimensions (anthropometry) and biodynamic constraints (body mass, strength, flexibility, etc.) related to the individual acting within an environment. Environmental constraints include both size and shape of objects and surfaces as well their physical properties relevant to the action. Thus, the highest step a person can climb bipedally is determined by his/her leg length and the ability of leg muscles to generate sufficient force to lift the center of mass over the surface of support (Warren 1984). Similarly the surface of support must support the action. It can't be too high relative to the person's leg length, it must be sufficiently flat, strong enough to support the person's body weight, and not too slippery.

It should be emphasized this ratio between leg length and step height is a constant proportion across people of different sizes (Warren 1984). Mark and Vogele (1988) showed a similar relationship with leg length for the perception of maximum sitting height. Other such intrinsic relationships have been found for reaching, stepping through apertures, stepping across gaps, and grasping; see Dainoff *et al.* (1999) for a more extended discussion.

3. PERCEIVING AFFORDANCES

It appears that information about affordances relating to simple actions can be scaled in terms of relevant dimensions of the user's body. Moreover, there is evidence (Mark 1987) that people actually use this information in determining their capabilities to perform goal-directed actions. However, as Mark *et al.* (1990) indicate, active exploration by the user of his/her environment may be essential to revealing the critical information that specifies the affordance. In their study, they perturbed users' judgement of maximum seat height by having them wear blocks on their shoes. This artificial change in leg lengths was appropriately compensated for by those users who were permitted actively to explore their environment while wearing the blocks. However, users who did not explore the environment did not compensate for their new "leg" lengths.

What is the role of cognition in all of this? First, the same object or environment may be an affordance for action and one situation and not in another. What may change is the nature of the goal-directed activity (i.e. task). Thus, a skilled carpenter will use one grade of sandpaper to prepare a surface for painting, and a finer grade for finishing. This user must understand which affordances (sandpaper density) are relevant to achieving the goal, and be able to focus attention on the relevant information specifying those affordances (e.g. numeric printed code, visual and tactile appearance). This is made more or less difficult depending on how well the designer understands the importance of such affordance-specifying information to the user. Finally, there are typically many different action patterns leading to a given goal; some of those are more likely to enhance health, comfort, and productivity than others. Part of the user's task to select from among multiple affordances, those which support more desirable action patterns.

4. AN EXAMPLE: THE ECOLOGY OF SITTING DOWN TO A MEAL

Consider the simple problem of sitting down to eat a meal. We assume that the user will require both a chair and a table. (This assumption includes an implicit recognition of a broader social/cultural context including the act of eating being accompanied by eye contact and conversation among a group of diners.) These two elements of the environment (chair and table) should afford the possibility of the user being able to attain a reasonable posture while manipulating eating tools (knife, fork, spoon) and food objects. The question is: can a typical dining room chair be considered an affordance for the particular action sequence called sitting down to eat? The answer is yes only if the user in question is an adult. It would not be an affordance if the user in question is a 3-year-old child. Thus, within the definition of affordance we are required to simultaneous assess the physical characteristics of the chair and table along with the capabilities of the user — in this case, anthropometric attributes such as leg height and seated elbow height.

The situation is worth examining in more detail. The action sequence of eating at a table (within the context of modern Western culture) entails a certain set of postural requirements. The food must be manipulated with either tools (knife, fork, spoon) or, for certain foods, directly with the fingers. There is an envelope of postural configurations within which these actions can occur with some degree of comfort and effectiveness.

The goal is for food items to be divided into portions whose dimensions are compatible with the size of the mouth and jaw, and to be transported from the plate to the mouth (with minimal spillage). To accomplish this goal, the trunk must be not far from vertical, the forearms and hands not far from horizontal and slightly above the plate. For a adult whose relevant anthropometric dimensions fall within a certain range, these postural demands can be achieved; hence, the table–chair *system* is an affordance for this particular action sequence for this particular group of users, in the sense that its properties have behavioral consequences for the these users.

It should be noted that, even within the envelope of acceptable postural configurations, there will be variability in comfort and effectiveness. People with shorter trunks and longer upper arms will find the table height a bit too high; people with longer legs will have to angle them downward and backwards to keep from bumping into the underside of the table. In both cases, comfort and even efficiency may be reduced.

However, at some point, the user's postural capabilities will fall outside of the envelope of acceptability, and the system will no longer afford this action sequence. This is, of course, the case with small children. The seat height may be too tall for the child to climb onto without assistance. However, even if the child is helped into the chair, the table will be so far above the location of the elbows, that the postural requirements for food manipulation and transport cannot be met.

In considering common solutions to this problem, an additional user capability must be considered; namely, the fine motor control of fingers required to achieve effective manipulation of food tools and food objects. *Effective* in this case can be operationally defined in terms of absence of spilled food, and amount of food actually transported. (This could be further elaborated in much greater detail within the social context of 'table manners' or etiquette.)

One solution is to provide a high chair with detachable tray. This eating system is essentially a miniature version of the adult size chair and table, in which the distance between seat surface and eating surfaces corresponds to a child's anthropometric dimensions. Thus, children within a certain range of seated elbow heights will have the capability of postural adjustments within the required envelope. At the same time, this system has the flexibility of fitting into adult social action patterns. It can either be made an adjunct to the adult table — allowing the child to be part of the social interaction — or it can be independent. Thus, by raising the child's eye height to the approximate level of the adults, this solution affords the possibility of the child either eating in the direct presence of adults or at least having the possibility of eye contact with surrounding adults even if not at the table. On the other hand, the high chair (usually) requires that the child be lifted into and out of the chair by an adult.

A second solution involves child-sized furniture. This affords appropriate postural configurations necessary for eating, but at the cost of social interaction with adults. There are, of course, circumstances where this particular definition of the action pattern sitting and eating is desirable (e.g. children's parties, large family meals with several children).

5. ANALYSIS OF CONSTRAINTS

The above example represents the application of affordance analysis to a specific case of practical ergonomic design. In particular, theory and practice come together in considering how the relationship between a goal-directed user and his/her environment is integrated with respect to constraints (personal and environmental) on the user's actions. The sitting and eating example can be used to elaborate these constraints.

With respect to personal constraints, we can first consider anthropometric dimensions scaled with respect to corresponding environmental dimensions; i.e., the child is too small to use an adult chair. Biodynamic constraints refer to the agility and strength necessary to carry out the manipulative actions of handling tools and food while maintaining the appropriate supporting posture (i.e. trunk and head upright and arms and hands extended).

For the individual action capabilities (for eating) to be expressed in *performance*, support is required from relevant properties of the environment. That is, design of furniture dimensions (environmental constraint) must be scaled to human body dimensions (personal constraints). In the pre-industrial era, tools and clothing were crafted individually for each person, so that these scaling relationships were natural. With the advent of mass production, sizing becomes an issue. A limited number of products must be designed to fit a variable population of users. In the clothing industry, fit is approximated by a limited number of standard sizes which can, in certain circumstances, be modified by alterations. Whitestone and Robinette (1997) provide an excellent discussion of fit in the design of military helmets). In transportation, and, more recently, office furniture, fit is approximated through adjustable dimensions.

However, household furniture, such as dining room tables and chairs, are not adjustable. Why is this, since, fit in terms of mapping of individual and environmental constraints, is rarely perfect? In the case of sitting at a table to eat, the consequences

of a moderate degree of lack of fit (reduced comfort and performance) are typically not serious. The meal does not last long enough for the lack of affordance to matter. (Western travelers who have had to eat while kneeling through a traditional Japanese banquet may disagree!)

6. AFFORDANCES FOR COMPUTER WORKSTATIONS

Suppose the dining room table is converted into a computer workstation. This work system, which previously afforded a relatively comfortable dining experience, will not, for many users, support the same level of comfort and performance for prolonged periods of computer use. The postural envelope will be somewhat different, but the duration and intensity of action sequences will be considerably longer. At this point, the nature of the task becomes important.

Tasks are an *expected* set of goal-directed actions that are to be executed by the individual within some physical environment. Inappropriate tools (environmental constraints) for a given task result in poor fit. If the mismatch among individual, environmental and task constraints are such that the postural envelope is exceeded (awkward posture and excess force) for prolonged periods of time without adequate rest pauses, the result may be a class of musculoskeletal disorders which have been given the misnomer of "ergonomic illnesses" (see National Research Council 1998 for a review of these issues).

The now relatively widespread availability of adjustable "ergonomic" chairs, keyboard/input device support surfaces and worksurfaces for computer workstations reflect the general realization of the level of demands associated with prolonged computer work. The result is that user is now faced with the problem of coordinating multiple degrees of freedom of adjustability (Dainoff 1998). In a modern task chair, the seat surface may be tilted upward and downward, raised up and down, and slid backwards and forwards. The backrest may be inclined and each armrest may be raised up and down and angled in and out. Keyboard support surfaces are available which also move up and down, side to side, and in and out. Monitor support surfaces do the same.

Consequently, such workstations should represent an effective affordance for prolonged computer work in that the multiple degrees of freedom of adjustment will allow task-appropriate postural configurations for a wide range of individual users. Unfortunately, the user is often either not aware of the range of adjustment mechanisms available, or if aware, does not understand why such adjustments are important (Mark and Dainoff 1988). Thus, the added adjustability is not either used or even misused. In short, the user does not perceive the affordances of the system.

The affordance research of Mark *et al.* (1990) discussed earlier can be easily related to the problem of instructing users of adjustable chairs and worksurfaces. Users must be shown how to actively explore the ranges of adjustability and encouraged to do so as to reveal the potential ranges of postural orientations relative to their own body dimensions. Thus, in a real sense, the thoughtful designer of office furniture is not only creating affordances, but enhancing the user's opportunities for perception of the information specifying those affordances.

7. GENERALIZATION

We have seen that, to the extent that the combination of personal and environmental constraints afford goal-direction action patterns which are safe, healthy, and productive, fit can be said to have been achieved.

The preceding discussion has involved constraints that have been primarily physical; however, the same kinds of considerations apply to more cognitive domains.. Getting lost while navigating through a web site might more clearly be expressed in terms of lack of perceivable affordances. A case in point is the emerging discipline of ecological interface design (Vicente and Rasmussen 1990, Vicente 1999). These authors have demonstrated that is possible to design displays of complex industrial processes which reveal the underlying affordances for operator control. This work provides ample documentation of the usefulness of affordance theory in designing practical solutions to complex problems utilizing hierarchies of mean–ends relationships.

Automation in Vehicles

N.A. Stanton and M.S. Young

Department of Psychology, University of Southampton, SO17 1BJ, UK

1. INTRODUCTION TO VEHICLE AUTOMATION

The theme of vehicle automation is likely to receive increased attention from ergonomists and psychologists in the coming years as the gap between concepts, prototypes, and production vehicles narrows. Although much is written on ergonomic issues connected with vehicle operation, such as occupant packaging, driver comfort, safety, design of controls and displays (see Peacock and Karwowski 1993) little attention is given to vehicle automation. Even texts which address future vehicles tend to concentrate on Road Traffic Informatics and not automation (Parkes and Franzen 1993).

The need for vehicle automation has been well rehearsed by the engineering community. Stanton and Marsden (1996) have introduced three main arguments in favor of vehicle automation. The first argument assumes that driving is an extremely stressful activity and consequently, the suggestion goes, automating certain driving activities could help make significant improvements to the driver's well-being. The second argument is based on the fact that human error constitutes a major cause of road accidents; thus it could be reasonably suggested that the removal of the human element from the control loop might ultimately lead to a reduction in accident statistics. The final argument is based on economic considerations and presumes that automation will enhance the desirability of the product and lead to substantial increases in unit sales.

Examples of new vehicle control systems that replace drivers include Adaptive Cruise Control (ACC) and Active Steering (AS). ACC controls both speed and headway of the vehicle, slowing the vehicle down when presented with an obstacle and restoring target speed when the obstacle is removed. In this way ACC differs from traditional Cruise Control (CC) systems. In traditional cruise control, the system relieves the driver of foot control of the accelerator only (i.e. relieving the driver of some physical workload), whereas ACC relieves the driver of some of the decision-making elements of the task, such as deciding to brake or change lanes (i.e. relieving the driver of some mental workload), as well as physical demands of accelerator control. Likewise AS replaces the driver by guiding the vehicle along the road and maintaining the vehicle within the lane. This is achieved with the aid of onboard cameras that are able to detect the lane markings and therefore the position of the vehicle within the lane. This system should reduce the incidence of lane sharing (driving across both lanes) and lane creep (weaving in and out of lanes).

Potentially, then, automation as embodied by ACC and AS are welcome additional vehicle systems that will add comfort and convenience to the driver. However, certain ergonomics issues do arise when considering any form of automation and these need to be addressed to improve overall system performance (Stanton and Marsden 1996). It is envisaged that although these systems will behave in exactly the manner prescribed by the designers and programmers, this may lead to some scenarios in which the driver's perception of the situation is at odds with the system operation (Stanton and Marsden 1996). There is also little known about the effects of combining advanced vehicle systems — for example, the operation of ACC and AS together — and the relative merits compared to either system operated alone.

2. COMPARING STUDIES OF VEHICLE AUTOMATION

To our knowledge, there are only three empirical studies in the public domain that report upon the effects of vehicle automation on driving performance. We will briefly review these studies in this section.

The first study to be considered was conducted by Nilsson (1995) who sought to compare driver behavior and workload in critical scenarios in manual and ACC conditions. The driving simulator was a moving base Saab 9000 with automatic gear box. Nilsson claims that the simulator was able to evoke 'impressions, reactions and actions which are very close to those experienced by the driver in real driving' (Nilsson 1995: 1255). Nilsson compared drivers' behavior between the manual and ACC conditions in critical traffic situations. All of these scenarios required intervention by the participant. Workload was measured using the NASA Task Load Index, which is a subjective rating scale.

The second study sought to examine the ability of drivers to reclaim control under an ACC failure scenario (where the ACC system fails to detect a vehicle in its path), and compare the level of mental workload with that under manual control of the vehicle (Stanton, Young, and McCaulder 1997). A fixed-base driving simulator based on a Ford Orion with automatic gear box was used (the Southampton Driver Simulator). On the basis of the first study, it might be reasonable to expect drivers to have some difficulty in detecting ACC failure. Measures were collected of all primary driving task performance data and secondary task (using the rotated figures task) data was collected to provide a measure of driver workload and compare task demand in manual and ACC scenarios. In addition, the automated condition was designed to present a failure situation that is anticipated in ACC operation. Participants were instructed to follow a lead vehicle at a speed and distance that felt comfortable so that driving demands could be held constant in the manual and automated conditions.

The third study was devised to investigate driver behavior and workload demanded by the driving task in manual and automated scenarios (Young and Stanton 1997). The automated scenarios were Active Steering (AS), Adaptive Cruise Control (ACC) and combined automation (AS and ACC together). Studies I and II only considered the implementation of a single system, whereas study III considered the effects of combining systems. Study III used the Southampton Driver Simulator (as used in study II). Drivers were instructed to follow a vehicle at a comfortable distance for the each of the experimental trials and were also asked to attend to the secondary task whenever they could. After completing each trial, participants were asked to complete a workload questionnaire.

Taken together, the three studies seem to show that automation will have an impact upon driving performance. First, it seems the parameter under automated control is held at a more consistent value than when it is under manual control; for example, ACC holds the target speed of a vehicle more constant than manual accelerating and braking, and AS keeps the vehicle

more consistently in the center of the lane than manual steering. Second, for some functions (e.g. AS and combined ACC and AS) automation is accompanied by reductions in driver workload. Third, some drivers fail to intervene effectively in automation failure scenarios. Finally, subjective reports suggest that the driving public judge automated systems in a fairly positive manner.

3. PSYCHOLOGICAL ISSUES

An in-depth analysis of the psychological factors associated with the operation of automated systems is required to enable recommendations to be developed. This study plans to investigate the seven main psychological issues in detail. First, is the issue of *locus of control*, the extent to which removal of control from the driver affects performance of the vehicle? Second, is the issue of *trust* that the driver has in the automated systems? Third, is the *situational awareness* of the driver about the operational status of the technological system and the driving context? Fourth, and connected to the third issue, is the issue of *mental representation* that the driver builds up of the automated systems. Fifth, is the issue of *mental and physical workload* associated with automation? Sixth, is the issue of *feedback*, comparing human and automated intervention? The final issue is that of *driver stress* and its implications for vehicle automation. All of these factors are well established in the psychological literature but have yet to be fully explored with respect to vehicle automation.

4. CONCLUSIONS

Whilst these latter arguments are rather speculative at present, and there is clearly much more research effort required, we do hope to indicate pertinent issues for predicting and explaining the results of the research. We feel that the studies presented show that the simulator environment is ideal for this research, as it provides an environment which is both safe and repeatable.

We also feel that the data from the moving-base simulator look comparable to that from the fixed-base simulator. This suggests that the data from fixed-base simulator may be equally valid. The studies do suggest that there are some effects of automation which impact upon driving performance that need exploring further. Finally, we would like to suggest a framework for psychological research into vehicle automation that comprises the issues raised in the final section. Rather than link each issue to every other issue, or make no links at all between the issues, we have attempted to identify the obvious links. This is offered as a starting point for our investigations, rather than a fully validated model.

Compatibility

C. D. Wickens

University of Illinois, Institute of Aviation, Aviation Research Lab, 1 Airport Road, Savoy, IL 61874, USA

1. OVERVIEW

Compatibility refers to "the capability of … performing … in harmonious … or congenial combination with another or others" (*American Heritage Dictionary*). As applied to the psychology of information processing, the concept thus refers to the congenial or harmonious combination of information representation at a set of entities (i.e., more than one). In the context of human factors (human interaction with systems), five such entities concern us: (1) information represented within the system; (2) information displayed by the system; (3) information perceived by the human; (4) information understood by the human using their cognitive mental model; and (5) information associated with the response. From the perspective of compatibility, the representation of the display and within perception can be combined into a single entity. In psychological research, the term "stimulus" usually refers to perception. In human factors applications, the concern is typically with the display, which is perceived. Since compatibility defines the harmonious relationship or *mapping* between sets of entities, there are several types of compatibility to consider here. High compatibility between the display and either the mental model or the response is a critically important feature for effective systems design (Wickens 1992, Proctor and Van Zandt 1994).

2. STIMULUS RESPONSE COMPATIBILITY

Historically the compatibility concept was first articulated in terms of the compatibility of *spatial* relations between a set of stimuli and a set of responses (Fitts and Seeger 1953). Compatible relations between stimuli and responses lead to shorter response times and fewer errors in responding to the stimuli. These relations can be described either in terms of location or in terms of movement.

2.1. Location Compatibility

Location compatibility is revealed by the rapid response when the location of the response is close to, or involves movement toward, the location of the stimulus. For example, the finger touches an illuminated light, or touches a key that is closer to that light than to any other light (solid arrows of Figure 1(a)). This defines a mapping of "colocation", which supports effective design. However, when stimuli and responses (or displays and controls) cannot be colocated, stimulus-response (SR) location compatibility can still be achieved by creating an array of stimuli that is *congruent* with the array of controls (Figure 1(b)). For example, controls on the left of a linear control array should be mapped to displays on the left of the display array, even if the two arrays themselves are quite distant from each other. A circular array of controls will be compatibly mapped to a circular array of displays, etc.

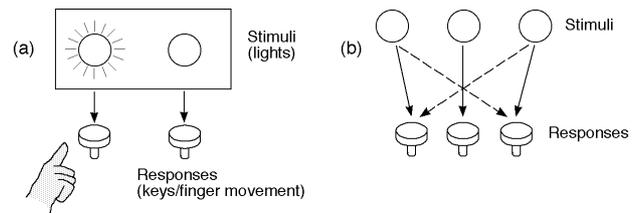
Good location compatibility, defined by either colocation or congruence, is the basis for effective design of control-display interfaces (such as stovetop controls for stove burners), because


Figure 1. (a) Compatible (colocated) mapping between stimulus lights (top) and response (below), which can either be a movement toward the source or depressing a key or button. (b) Compatible (congruent) mapping between an array of displays and an array of controls, as shown by the solid arrows. Note that the stimuli are not themselves close to the responses. The dashed arrows represent an incompatible mapping.

the mapping is visually apparent and does not require any learning or training to use (Norman 1988).

2.2. Movement Compatibility

When controls involve some degree of motion, as when manipulating a joystick, mouse, slider or rotary dial, then compatibility is preserved when the direction of motion of the control is congruent with the direction of movement of a display, which is to be either tracked by the movement, or presents feedback of system elements controlled by the movement. For example, a circular (steam gauge) display is movement compatible with a rotary control but not with a linear control; a screen symbol should move upward (not downward or sideways) to reflect the action of a vertical control activity.

2.3. Noncompatible Mappings

Mappings that violate either location or movement compatibility may do so in one of two qualitatively different forms. *Incompatible* mappings are those in which the stimulus directly signals an inappropriate *but available* response. For example, considering the dashed arrows of Figure 1(b), a display on the left is mapped to a control on the right. Such mappings offer a direct invitation for error, because the appearance of the stimulus may directly activate the inappropriate response. *Acompatible* mappings are those when the response that might be signaled by the stimulus is not available. For example, a rotary dial mapped to a linear indicator, or a vertical array of lights mapped to a horizontal array of indicators, or the appearance of the digit "1" mapped to the spoken response "A". An acompatible mapping will not necessarily lead to greater errors, but will generally produce longer response times. Acompatible or noncompatible mappings result whenever there are added mental transformations between the stimulus and the response. For example, the mapping $1 \rightarrow A$, $2 \rightarrow B$, $3 \rightarrow C$ imposes such a transformation, and is thus less compatible than the mapping $a \rightarrow A$, $b \rightarrow B$, $c \rightarrow C$.

2.4. Modality-based Compatibility

Auditory stimuli appear to be more compatible with voice responses, and visuospatial stimuli more compatible with manual responses (Teichner and Krebs 1974, Wang and Proctor 1996). The basis for this effect is said to lie in the nature of the feedback provided by the responses. When the feedback itself is congruent with the appropriate stimulus, this "ideomotor" compatibility is

attained (Greenwald 1970). This will be the case if the correctly mapped vocal response is to repeat the sound of the auditory stimulus, or if the hand moves in the same direction as an illuminated light. Spatial compatibility effects appear to be most pronounced when modality compatibility is high (Wang and Proctor 1996).

2.5.   Expectancies and Population Stereotypes

Although many aspects of SR compatibility can be accounted for by the direct spatial or modality relationships between stimuli and responses (or displays and associated controls), many others are mediated by the *expectancies* of the operator regarding these mappings. Because these expectancies are generally learned through experience with past mappings, and because that experience is typically shared by a group of people, the expectancies are typically called *population stereotypes* (Smith 1981). For example, it is a population stereotype in North America to expect that movement of a switch upward will activate power; whereas in Europe people expect it to remove power. Population stereotypes often mediate acompatible relationships. For example, it is expected that rotating dials clockwise will increase a controlled variable, and it is expected that increase will be signaled by an upward or rightward movement on a linear display. It is also expected that the digits 1, 2, 3 will be mapped to the letters A, B, C, because both scales are mapped according to an experienced learned ordering. Because these population stereotypes are embodied in expectancies, based upon knowledge and learning, they form the basis of *cognitive compatibility*.

3.   COGNITIVE COMPATIBILITY

Cognitive compatibility expands upon SR compatibility in two respects:

- It accounts for behavior that is not stimulus driven, but characterizes instead that of the operator who *intends* to perform a particular action (a cognitive plan, such as "increase a variable"), responds in such a way as to execute the intention, and then evaluates system feedback of the action.

- It accounts for cognition and understanding in many environments in which human responding itself is relatively infrequent or impoverished, compared to the amount of displayed information. Thus, in such circumstances, it is important that the displayed representation of the system is compatible with the operator's expectancies of how the system behaves, in order to support better understanding of system changes.

These operator expectancies have often been embodied in the psychological concept of the *mental model* of complex systems (Norman 1988). The mental model represents the operator's conception of the physical and causal relations of the real system under control or supervision. A mental model can be accurate or inaccurate. When discussing cognitive compatibility it is important to preserve compatibility between three entities: the system, the display, and the mental model. Compatibility between the physical system and the mental model is achieved through appropriate training (or learning) of the system. If these two are compatible (i.e., the operator correctly understands the system dynamics and relations) then compatibility between the display and both the mental model and the true system, will support effective system monitoring. In this regard it is important to con-

sider the synergism between display and learning. That is, a display which is compatible with the physical system dynamics will serve as an effective training aid to form a mental model which is compatible with those dynamics.

For relatively simple systems, with few dynamic components, cognitive compatibility can be relatively easy to achieve. For example, the *principle of the moving part* (Roscoe 1968) dictates that moving elements on a display should move in the same direction and pattern of the operator's expectation of that motion. The *principle of pictorial realism* (Roscoe 1968) dictates that the configuration of elements on a display should be congruent with (and therefore a pictorial representation of) their counterparts in the real system. However, in designing compatible displays for more complex systems, like those involved in the supervision of nuclear power plants or other energy conversion systems, where there may be hundreds of time-varying elements, it becomes far more challenging to achieve cognitive compatibility.

There must be careful analysis of the constraints between various system elements, and careful analysis of the relationship between these constraints and the goals of the designer and system monitor/supervisor. This analysis is embodied in the design of what are called *ecological interfaces* (Vicente and Rasmussen 1992). Thus, while one aspect of cognitive compatibility may be achieved by configuring the location of and connections between displayed elements, in a way that represents the location and connections in the real system (the so-called mimic diagram), a second aspect must depict constraints and relationships between more abstract system variables in a way that is compatible with the well-trained operator's mental model. These more abstract variables may not have a particular physical location within the system. For example, such a display could show the conservation of mass and energy

Figure 2. Ecological interface display showing the relationship between flap settings, bank, and airspeed in an aircraft, as these are configured to depict the potential for an aircraft stall. As each of these variables changes value, it will affect the area of the rectangle, which is the stall margin. If this area reduces to zero, the aircraft will stall (Reprinted from Wickens and Andre, 1990, with permission of the Human Factors and Ergonomics Society).

in a thermodynamic process, or the relations between airspeed and angle of attack in an aircraft to represent the stall margin of an aircraft. It would present these variables in a way that is compatible with how a well-trained supervisor understands their relationship (Figure 2).

4. PROXIMITY COMPATIBILITY

Underlying the configuration of any display of multielement systems, which must therefore include multielement displays, is the concept of proximity or nearness. Furthermore, the concept of proximity can be defined across all four entities of the compatibility representation: system, display/perception, cognition, response. Two display elements can be brought closer together or moved further apart; two response devices can be varied in the same manner. Furthermore, cognitive or processing proximity can be defined by the extent to which two variables need to be related (compared or otherwise integrated) in performing the task at hand, and system proximity refers to the proximity of elements in the system itself. The *proximity compatibility principle* (Wickens and Carswell 1995) dictates that compatible relations will exist to the extent that proximity relations are preserved across the three different information processing stages. For example, if the task processing (cognition) requires close proximity of information channels (information integration or comparison), the displayed elements corresponding to those channels should also be close. The converse proximity relation applies as well. If two channels of information should be processed independently (lower task proximity), their processing will be relatively better served by display channels that are not in as close proximity.

The concept of proximity at various stages can be elaborated considerably. For example, task (or cognitive) proximity between two information channels may include simple comparisons (Is the actual value of a quantity equal to the commanded value?) or more complex integrations (What is the total amount produced, given the rate of production and the time of production?). Furthermore, there are several different ways of achieving display proximity. Moving two elements close together is the simplest way. But perceptual proximity can also be achieved by displaying two elements in the same color, by connecting them with a line, by using similar representations (e.g., both digital or both analog signals), or by *configuring* the elements such that an emergent feature arises from their combination. Two relevant examples are shown in Figure 3. In Figure 3(a) command and actual values are displayed by vertical bar graphs on the same scale and aligned with the same baseline. Hence the integrated variable — their equivalence — will be directly signaled by the emergent feature, the flat line perceived across their tops. In Figure 3(b) production rate and time are displayed as the height and width of a rectangle respectively. Hence the integrated variable — total amount — will be directly signaled by the emergent feature, the area of the rectangle.

5. THEORIES AND PRACTICE OF COMPATIBILITY

There is no single uniform theory of compatibility; there are several different theories that underlie different aspects. For example, the Kornblum *et al.* (1990) theory of dimensional mapping, in which certain features of a perceptual array automatically activate response tendencies, provides a strong theoretical account for differences between compatible, incom-

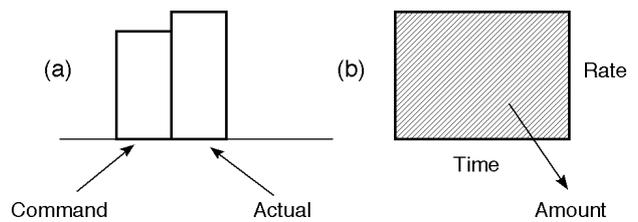

Figure 3. Configural displays illustrating the proximity compatibility principle. (a) Display of command and actual values of a system: the emergent feature signaling 0 error is the continuous line across the top of the two bar graphs. (b) Display of rate × time: the emergent feature of amount (rate × time) is signaled by the area (height × width) of the rectangle.

patible, and acompatible mappings. Various cognitive theories of mental model formation and representation can form the underlying theoretical base for cognitive compatibility in general, and some aspects of ecological interface design in particular (Vicente and Rasmussen 1992). The proximity compatibility principle has as its underpinnings theoretical conceptions of attention, and the distinction between focused attention (best served by low proximity displays) and divided attention (best served by close proximity displays), as well as the theories of perceptual similarity.

Above all, it is best to describe the concept of compatibility, as applied to good system design, as based upon the careful linking of engineering and psychology: human factors engineering must provide the *task analysis* regarding what information is available and relevant, what actions are required, and what cognitive (i.e., internal) states must be monitored and understood in order to achieve the goals of effective system operation. The psychology of information processing must be consulted to understand the natural or preferred representations at the different stages (e.g., "on" is conceived as "up"; common color is perceived as related), or what dominant population stereotypes are relevant for the design space at hand; and the craft of the engineering psychologist must then be applied to join the two domains in configuring compatible designs in systems as diverse as stove controls, calculators, airplanes, or nuclear power plants.

Computer Systems Design for Psychophysical Safety of Human Operations

A.Yu. Burov

Centre of Ecology, Ergonomics and Safety, ELAN Ltd, Kyiv, Ukraine

1. INTRODUCTION

The analysis of accidents in power plants shows that one of the main causes of the increase in their number is a discrepancy of operators' psychophysiological capabilities and professional demands. The economic losses are stipulated not only for accidents, but also for the unefficient operation of equipment. Besides, the operators who do not meet professional requirements get sick and receive work trauma more often. There is a necessity to implement a monitoring of operator's psychophysiological professionally important qualities (PPIQ) during all stages of their professional career (initial professional selection, periodical and daily check). Such an approach allows not only reduced economic damage because of unefficient and erroneous human actions, but also prevents premature deterioration of his/her health and a premature quitting of the job.

Ergonomic approaches to the evaluation of operator's fitness to work have typically assumed that the functional characteristics of the operator (e.g. knowledge about task, skill level, information processing capacity, etc.) are invariant. They are assumed not to be influenced by such variables as operator mood condition, sleep disorders, time spent on task, etc. Research efforts aimed at enhancing the safety and reliability of the complex process plant operations have focused, as a result, on the improvement of the technical skills of the operator, as well as on reducing operator requirements imposed by automating processes. In complex technological systems human involvement in causing the accidents is estimated to be in the range of 40–60% (power plants) and 80% (aircraft accidents). This testifies to the inadequate evaluation of the operator's efficiency by existing techniques. The monitoring of an operator's physiological parameters during their professional career is known to be related to effective skill utilization and can be used to enhance system performance. While the requirements for professional knowledge and skills may be defined for various kinds of physical and mental work, the evaluation of their functional state over time suffers from the failure to take into consideration not only the levels of psychophysiological parameters, but also the changes of the operator's states, especially those occurring over different periods (year to year, day to day variations, within work schedule variations, variations produced by changing shifts, etc.). The direct or indirect measurement of psychophysiological changes allows for the evaluation of the structure (or moment-to-moment state of the operator) of the functional state of the operator, allowing one to predict the operator's individual fitness and reliability for effective work.

The objective was the development of a methodology and applied systems of psychophysiological maintenance of an operator's fitness to work during all stages of their professional career in order to reduce human errors and to raise his/her efficiency.

2. SYSTEMS FOR EXPERIMENTAL PSYCHOPHYSIOLOGICAL RESEARCH

To make psychophysiological research methods valid to the industrial implementation, it is necessary to integrate scientific research into industrial systems when using new developments in the field of psychophysiological initial professional selection, e.g. of operators, periodical and day-by-day check of human fitness to work as applications for the industry.

To solve this problem, a computer system for psychophysiological research was developed that could be simply converted to the industry systems for the initial psychophysiological professional selection, periodical and day-by-day check of operators' fitness to work (Burov and Chetvernya 1996). The system is intended for psychophysiological research and provides:

- the opportunity of running a complexity, rate, sequence of presentation, colorful and dimensioned characteristics of test tasks;
- registration of characteristics of each test task performance;
- registration of physiological parameters;
- synchronization between test tasks and physiological parameters;
- database control; and
- time series analysis and statistical modeling.

To record physiological parameters, a hardware–software complex is used, which consists of a set of sensors, a multichannel analog–digital converter, a personal computer and software. The software realizes the functions of control process of registration, processing and database control of physiological signals realization. Depending on the tasks, analysis of the data received during experimental research can be conducted in different directions, e.g.:

- assessment of the level of the individual's psychophysiological parameters as regard a surveyed group;
- dynamics of psychophysiological parameters during psychological tests performance;
- connection of physiological parameters and mental activity parameters; and
- study of psychophysiological reaction of a human organism to external factors (industrial, household, medical).

The researcher has flexible possibilities to control the experiment (Figure 1). The developed interactive display systems (IDS) of psychophysiological security allow one to solve research and assessment problems on the base of following principles:

- adaptation of used tests to functions that are being investigated;
- ergonomic information display on the screen;
- minimal touch;
- taking into account the time factor;
- taking into account the dynamics of the operator's work;
- specialized database management system (DBSM) as the core of the system; and
- using of external criterion.

Figure 1. System structure for psychophysiological researches.

3. SYSTEMS FOR INDUSTRIAL USE

Observation of the mentioned principles permits one to create psychodiagnostical systems for industrial purposes on the basis of the system of psychophysiological research as the specialized variant for the solution of concrete psychodiagnostical tasks — a system for initial professional selection, and daily and periodic psychophysiological check. Thus, the architecture of the system is transformed to account for the following:

- exception of subsystem for registration of physiological parameters;
- transmission of test control from researcher to the DBSM; and
- store in the database only the resulting data and, as a consequence, more economical use of computer resources.

Such a structure provides the availability of the managing program (monitor); subsystems, ensuring of functions of training, testing, data processing, construction of evaluations and of predictive models. The implementation of all these functions, as well as functions of database control, is executed by specialized DBSM, which guarantees the integrity of internal database and data exchange with an external program environment within the system.

The IDS allow one to bring unified to effect on method and to form keeping of information, got on all control stages of functional state (FS) and operator fitness to work (OFW):

- Psychophysiological professional selection (with recommendations on training individualization).
- Periodic psychophysiological monitoring check of FS and operator OFW including professional aging.
- Daily (pre-shift) check of professional OFW of operator in "regular" routines.
- Daily (inter-shift) check of professional OFW of operator in extreme routines.

- Means of functional rehabilitation (psychophysiological correction of functional operator's state).
- Training process support included in teaching aids.
- PPIQ training with specialized psychological playing simulators.

All IDS intend to work in real-life conditions and can be combined with automated systems, both instructive and simulated, and they do not need additional personnel of medical and psychological specialists.

The systems of initial psychophysiological selection are aimed at estimating unspecific professionally important qualities that prevent from mastery good by selected profession or to work in the profession. The means and estimation methods must be sufficient to make a decision concerned a potential professional fitness.

The periodical check systems allow the estimation of the permanent organism descriptions and personality, their evolution and can be used periodically (e.g. once a year). Time of inspection can be considerable (> 1 h), but the inferences of status must be sufficient to make a decision concerned with the renewal options of the professional activity.

Systems for initial psychophysiological selection and periodic check can use an objective medical-biological and psychological information concerning human state — psychophysiological parameters registered by special apparatuses in laboratory conditions.

Daily pre- and inter-shift check. The pre-shift psychological check must be directed at revealing the unfitness to professional activity affected by functional (non-constant) changes in physiological or psychological status of the individual.

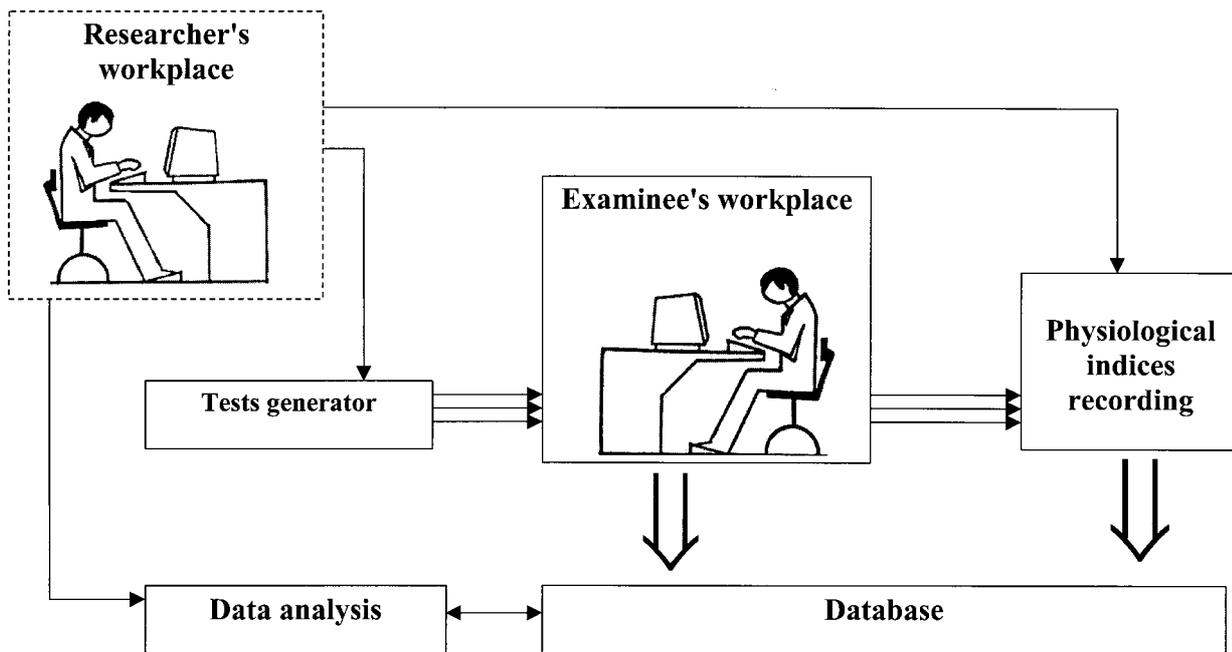
An inter-shift psychophysiological check is directed to evaluate the psychophysiological activity's cost and human


Figure 2. General structure of an industrial system for the psychophysiological security.

reserve. The means and methods of verification of this type exert a minimal influence on the professional activity, but are sufficient for detention of possibility for its continuation on a proper level.

The means and methods of functional rehabilitation restore the functional abilities, which decreased as a result of professional activity. Such methods can include diverse exercises and measures on renewal of health, and also have a full arsenal of physio- and psychotherapeutic means.

At present, to realize this approach the systems of industrial application were developed and used:

- for psychophysiological initial professional selection;
- for periodical check; and
- for daily check.

The systems permit the evaluation of the reliability and efficiency of an operator's work, as well the construction of the prognosis of changes of these parameters during his professional career. The results of valuation and prognosis permit one to make arrangements, not to admit the unreliable operator to work or to increase his reliability and fitness for work to make preventive measures for accident precautions.

Psychophysiological initial professional selection (Burov and Chetvernya 1995a, b). The efficiency of operator's work depends not only on his/her professional knowledge and working conditions, but also on conformity of psychophysiological features of a person to the requirements of the trade. As the results of preliminary researches have shown, the following structure of tests for the determination of professional fitness group of operator is optimum: structure of personality, structure of intelligence, an individual's psychodynamic features, and a bent for certain kinds of mental activity. The most informative parameters of efficiency of tests performance are included in the model of a "standard operator" enabling one to conduct the psychophysiological prediction of the group of the professional fitness of a candidate for operator.

Periodical check. The periodical check is intended for the

evaluation of changes of PPIQ slowly varying that permits one to evaluate the moment when the operator needs to do some rehabilitation steps or when it is necessary for him to be prepared to leave his trade if the irreversible age-related changes came. With this purpose the system of valuation of an operators' professional aging rate is used (Burov and Chetvernya 1996). The results of valuation of staff's professional age are presented as an integrated age value which is calculated by the chosen model, as well as an "age profile," which is a vectorial diagram of the main parameters determining biological and professional human age.

Daily check (Burov and Chetvernya 1997) used the system of valuation of an operator's functional state and prediction of his professional fitness to work in the workplace which is a method of providing feedback to the operator so allowing him to make necessary changes in case of deviation from his individual norm. The following problems are solved in the system:

- Development of objective methods of evaluation of a humans' psychophysiological condition in a relation to the norm.
- An individual approach to evaluation of a human's serviceability, that is a construction of individual psychophysiological norm instead of the group's one.
- Development of organization-technical aspects of evaluation's use.

The system allows:

- Economic running of the technological object (power industry, aviation).
- Economy of energy resources.
- An increase of the operators' professional "longevity."
- One to make the system self-adjustable. It forms automatically the individual "norm" of operator's working ability.
- The achievement of a high precision of prognosis (85–90%).

The use of the systems allows one to monitor the operator's psychophysiological fitness for work on all stages of his/her

professional biography to secure the necessary level of the human–machine system's effectiveness.

Creating Pleasurable Products

P. W. Jordan

Philips Design, Building W, Damsterdiep 267, 9700 AE Groningen, The Netherlands

1. INTRODUCTION: NEW HUMAN FACTORS

Usability-based approaches to product design tend to view people as *users,* while products are seen as *tools* with which these users complete tasks. Because of this usability-based approaches to user requirements specifications can be limited, tending to emphasize the practical aspects of interacting with products, while paying little attention to emotional or hedonic aspects of interaction.

Over the past 4–5 years much of industry-based human factors has moved away from usability-based approaches and towards pleasure-based approaches to defining user requirements. Pleasure-based approaches look at people holistically — as rational, emotional and hedonistic beings. They look at products as *living-objects* with which people have *relationships*. Such approaches have been described as "New Human Factors" (Fulton 1993).

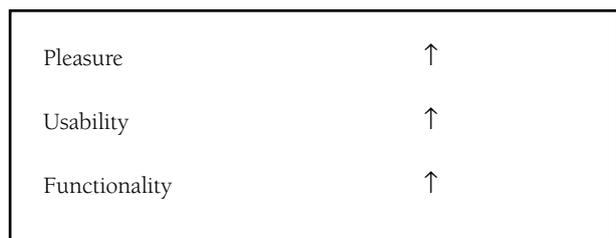
2. HIERARCHY OF USER NEEDS

Pleasure can be thought of as being at the top of a hierarchy of user needs (Figure 1).

2.1. Level 1 — functionality

Clearly a product will be useless to the user if it does not contain appropriate functionality. A product cannot be usable if it does not contain the functions necessary to perform the tasks for which it is intended. If a product does not have the right functionality it will dissatisfy the user. To be able to fulfil user needs on this level, the human factors specialist must have an understanding of what the product will be used for and the context and environment in which it will be used.

2.2. Level 2 — usability

Once users have got used to having appropriate functionality, they will then want products that are easy to use. This seems to represent the situation at the moment in many product areas — people are used to well functioning products, now they expect usability too. Having appropriate functionality is a prerequisite of usability, but it does not guarantee usability. To assure usability


Pleasure	↑
Usability	↑
Functionality	↑

Figure 1. A hierarchy of user needs.

the human factors specialist must have an understanding of the design principles associated with usability and an understanding of how to address usability issues in the product creation process.

2.3. Level 3 — pleasure

Having got used to usable products, it seems inevitable that users will soon want something more. Products that offer something extra. Products that are not merely tools, but which are "living objects" which people can relate to. Products that bring not only functional benefits but also emotional benefits. To achieve product pleasurability is the new challenge for human factors. It is a challenge that requires an understanding of people — not just as physical and cognitive processors — but as rational and emotional beings with values, tastes, hopes and fears. It is a challenge that requires an understanding of how people relate to products. What are the properties of a product that elicit particular emotional responses in a person, how does a product design convey a particular set of values? Finally, it is a challenge that requires capturing the ephemeral — devising methods and metrics for investigating and quantifying emotional responses.

3. PLEASURE WITH PRODUCTS: THE FOUR PLEASURES

Pleasure with products has been defined as: "the emotional and hedonic benefits associated with product use" (Jordan 1997). Within this definition, four conceptually separate components of pleasure have been identified (based on Tiger 1992). These provide a framework for considering the emotional, hedonic and practical user requirements within the product creation process.

3.1. Physiological Pleasure

This is to do with the body — pleasures derived from the sensory organs. This covers, for example, tactile and olfactory properties. Tactile pleasures concern holding and touching a product during interaction. This might be relevant, for example, in the context of a telephone handset or a remote control. Olfactory pleasures concern the smell of the new product. For example, the smell inside a new car may be a factor that effects how pleasurable it is for the owner.

3.2. Social Pleasure

This is the enjoyment derived from relationships with others. Products can facilitate social interaction in a number of ways. For example, a coffee-maker provides a service which can act as a focal point for a little social gathering—a "coffee morning." Part of the pleasure of hosting a coffee morning may come from the efficient provision of well-brewed coffee to the guests.

Other products may facilitate social interaction by being talking points in themselves. For example, a special piece of jewelry may attract comment, as may an interesting household product, such as an unusually styled TV set. Association with other types of products may indicate belonging in a social group — Porsches for "Yuppies," Dr Martin's boots for skinheads. Here, the person's relationship with the product forms a part of their social identity.

3.3. Psychological Pleasure

This relates to how the user's mood is affected by interaction with a product — for example, the sense of satisfaction gained

from accomplishing a task. It might be expected, for example, that a word processor that facilitated quick and easy accomplishment of, say, formatting tasks would provide a higher level of psychological pleasure than one with which the user was likely to make many errors.

3.4. Ideological Pleasure

Ideological pleasure refers to the pleasures derived from "theoretical" entities such as books, music and art. In the context of products it would relate to, for example, the aesthetics of a product and the values that a product embodies. For example, a product made from biodegradable materials might be seen as embodying the value of environmental responsibility. This, then, would be a potential source of ideological pleasure to those who are particularly concerned about environmental issues. Ideological pleasure would also cover the idea of products as art forms. For example, the video cassette player that someone has in the home, is not only a functional item, but something that the owner and others will see every time that they enter the room. The level of pleasure given by the VCR may, then, be highly dependent on how it affects its environment aesthetically.

4. TECHNIQUES FOR DESIGNING PLEASURABLE PRODUCTS

Having considered and specified the emotional, hedonic and practical benefits that a product should bring to its users, the next step is to determine the design properties through which the product can deliver these benefits. Four techniques — previously reported in the human factors literature — for linking benefits to design properties are outlined below. Two of the methods — Kansei Engineering and SEQUAM — are based on quantitative statistical analyses. The other two are qualitatively based.

4.1. Kansei Engineering

Kansei Engineering (Nagamachi 1995) is an empirical technique aimed at linking the design characteristics of a product to users' responses to the product. The technique involves manipulating individual aspects of a product's design to test the effect of the alteration on users' overall response to the product. This technique has been used to assist in the design of a diverse range of products. Nagamachi (1997) describes examples that range from automobiles through camcorders to brassieres. To demonstrate how the technique works, a case study — reported by Ishihara et al. (1997) — is summarized below demonstrating how Kansei Engineering was applied to the design of cans for coffee powder.

4.1.1. Example of the application of Kansei engineering

In a study aimed at supporting the design of coffee packaging, 72 alternative designs of coffee can were presented to a panel of 10 subjects. The 72 designs represented permutations of various design variables, including, for example, color, font styles, graphics and form. Each member of the panel was asked to rate each of the designs according to how they fitted with a series of descriptor adjectives. These adjectives are known as "elements." There were 86 elements generated from brainstorms with consumers and marketing experts. Examples of these elements were: showy, calm, masculine, feminine, soft, individual, high-

grade, sweet and milky. Ishihara et al. (1997) report that each participant rated each of the 72 designs according to each of the 86 elements by marking five-point Lickert Scales. Thus, each participant made a total of 6192 responses on Lickert Scales!

A cluster analysis was then carried out to determine how panelists tended to group the designs according to their elements. A number of clusters emerged which Ishihara et al. (1997) identified as being linked to particular design features. For example, one cluster of cans emerged that were regarded by the panelists as being "milky," "soft" and "sweet" — this cluster of cans was characterized mainly by the use of beige coloring for majority of their surface. Another cluster was seen as being "masculine," "adult" and "strong" — these elements were all associated with having a large logo on the cans. A third example of a cluster was one that was seen as being "unique," "sporty" and "individual" — this was related to the use of blue and white coloring in the designs.

4.2. Sensorial Quality Assessment (SEQUAM)

This technique (Bandini-Buti et al. 1997) involves analyzing the link between the physical properties of a product and users' responses to tactile contact with the product. Users are presented with models of product components (e.g. car door handles) that are mocked up in combinations of materials and finishes exhibiting a range of tactile qualities. Users are then asked to handle these mock-ups and to comment on their sensorial qualities. SEQUAM has been applied in the automotive sector by FIAT.

4.3. Case Studies

MacDonald (1998) has analyzed a series of products and has suggested links between particular elements of their design and particular pleasures of use. The table below summarizes the outcomes of a study in which the benefits associated with a number of products were analyzed within the context of the "four pleasure framework" (for details of the study, see Jordan and MacDonald 1998) (Table 1).

4.4. Semi-structured Interviews

Jordan and Servaes (1995) carried out a series of interviews asking users about their most pleasurable products. They recorded users'

Table 1. Four pleasure analysis of the benefits associated with a sample of products from MacDonald's case studies.

Product	Associated pleasures
Karrimor's Rucsac Buckle	*physio:* positive click on closing
Global Knives	*physio:* comfortable to hold, weight balance *psycho:* reassuringly hygienic
NovoPen™ (for the injection of insulin)	*physio:* pleasant to hold *socio:* plays down negative associations (from others) *psycho:* easy and reassuring to use *ideo:* plays down negative associations (from user)
Samsonite Epsilon Suitcase	*physio:* comfortable, lifting, tilting and trailing *psycho:* responsive movement — suitcase 'obeys' user
Mazda Car Exhaust	*socio:* status symbol; *ideo:* positive, youthful self-image

reported reactions to pleasurable products and the product properties associated with these reactions. Reactions to pleasurable products included, for example, feelings of security and comfort, pride, excitement, freedom and nostalgia. Examples of associated properties included features and functionality, usability, aesthetics, performance, reliability and associated status.

5. NOTES ON THE TECHNIQUES

Kansei Engineering represents a thorough, formal approach to the linkage of product properties with user responses. Like SEQUAM it relies on statistical analyses to make these links. Such techniques appear to offer the most reliable and valid means of making product property/user response links. However, when many property dimensions are involved, as in the coffee can example, such methods can become unwieldy and time consuming. Designing 72 concepts and asking respondents to mark > 6000 scales each, simply to give input to the design of a coffee can, seems excessive!

Another possible criticism of quantitative techniques is that, in analyzing the effect of individual design elements, they are implicitly based on the assumption that a design is the sum of its parts. The merit of such an assumption is a matter for debate. It could be, for example, that a "Gestalt" model is more appropriate. Gestalt theories assert that entities, such as designs, must be considered holistically — that is to suggest that the overall response to a design could amount to either more or less than the sum of reactions to each of its constituent parts.

From the Gestalt point of view more qualitative approaches — such as case studies and interviews — may be more appropriate, as they may be better suited to looking at the product as a whole. However, it might be argued that, unless design elements are separated, it is difficult to give designers any meaningful advice about how to create a product that will elicit particular responses.

6. CONCLUSIONS

The trend in industry-based human factors is away from "traditional" usability-based approaches towards "new" pleasure-based approaches. Although the study and application of such approaches is still in its infancy, it is developing rapidly and there are now a variety of frameworks and techniques for holistic user requirements setting and making the associated design decisions. In this paper, a definition of pleasure with products has been given, a framework for considering person–product relationships has been outlined, and techniques for linking product benefits to design decisions have been discussed.

Products have the potential to bring a wide range of emotional, hedonic and practical benefits. Ensuring that these are delivered requires looking both at and beyond usability to create useful, usable and pleasurable products that will delight the customer.

Engineering Principles of Ergonomics

A. Stork

Ergonomics & HCI Unit, University College, 26 Bedford Way, London WC1H
0AP, UK

1. INTRODUCTION

Suggestions that the disciplines of Ergonomics, Human Factors (HF), and Human–Computer Interaction become more like engineering disciplines have resulted in the proposal of a discipline of Cognitive Engineering (CE). The explicit engineering knowledge of this new discipline of CE is termed "engineering principles" (EP). CE and the development of EP are current research topics. The proposed discipline of CE, and the relationship of engineering with pure and applied science, are discussed here under "Cognitive Engineering", to be read along with this entry, which briefly characterizes the current state in the explicit development of EP in CE.

2. ORIGINS

Norman (1986) first terms the explicit knowledge of CE as 'engineering principles', which are "principles that get the design to a pretty good state the first time around". Dowell and Long (1998) identify a requirement for CE to develop "design principles" and distinguish them from craft and scientific knowledge:

> Craft disciplines give way to engineering disciplines: personal experiential knowledge is replaced by design principles; "invent and test" practices (that is to say, trial-and-error) are replaced by "specify then implement" practices. Critically, design principles appear not to be acquired by direct translation of scientific theories. Rather, they are developed through the validation of knowledge about design problems and how to solve those problems.

> Therefore, EP offer a guarantee that their application will support some effective design. The basis of that guarantee is their validation for design.

3. EXPLICIT PROGRESS TOWARDS ENGINEERING PRINCIPLES

There has been little explicit progress towards EP. Dowell and Long (1998) offer a conception of the general design problem of CE to define the scope of EP. They propose that the scope of EP is the design of cognitive human–machine systems to achieve a desired level of effectiveness. Effectiveness is conceptualized as the task quality of the work performed in a domain by the human–machine system, and the structural and behavioral costs to the human–machine system of performing that work. Dowell and Long also distinguish substantive EP, which prescribe the properties of effective designs, from methodological EP, which prescribe the process to prescribe those properties.

A few researchers have moved towards EP based on Dowell and Long's research. They have suggested alternative conceptions of the general design problem, conceptions of EP, strategies for their acquisition, operationalizations of design problems, solutions and putative engineering principles. However, there are, as yet, no explicit validated engineering principles for CE.

4. SOME OBSTACLES TO ENGINEERING PRINCIPLES

This research attracts two main types of criticism. First, that sufficient rigor to deliver EP cannot be applied to human behavior and goals: human behavior is too complex and human goals too nebulous to be adequately formalized or measured. The counter claim is that design is currently based on an, often implicit, understanding of human behavior and goals, and that there has not been a satisfactory attempt at their adequate formalization or measurement. Second, that the conception of the general design problem of CE is insufficient: for example, that social or marketing aspects need to be addressed. The counter claims are, for example, that (1) cognitive structures and behaviors support social structures and behaviors, and (2) that CE needs to limit its scope at some point, and marketing is appropriately outside that scope.

5. CONCLUSIONS

EP cannot be precisely defined at this stage. Further attempts at their acquisition along with further reflection on what actually constitutes engineering knowledge more generally should enable more precise definition in the future.

Ergodynamics

V. F. Venda† and N. I. Venda§

†University of Manitoba, Canada

§The Venda Ergonomic Advantages, Inc., USA

1. INTRODUCTION

Ergodynamics was developed as theory and methods of ergonomic design, improvement, and studies of dynamic work in a dynamic environment (Venda and Venda 1995). Ergodynamics allows the study of work dynamics when the *functional structure* of the work (skills, strategies, methods, technologies) changes. In a more narrow sense, ergodynamics is an application of the *transformation dynamics* theory in ergonomics. A foundation of ergodynamics comprises of the following three laws of ergonomics: mutual adaptation; plurality of work functional structures; and transformations and interactions. Ergodynamics is widely applicable in ergonomic design of work places, work stations and control rooms, in mutual adaptation the in human–machine–environment, in professional training, control systems safety, prediction, planning and optimizing efficiency dynamics during implementation of ergonomic and engineering projects, transfer of new technologies, environments, work functions and skills, management structures, software, products, changing economic strategy, or when an otherwise sudden decrease in productivity, quality, or safety causes unpredicted losses.

2. DEFINITIONS IN ERGODYNAMICS

Ergodynamics is based on the following definitions:

1. Work efficiency is any positive outcome of work ergonomist wishes to maximize. The examples are work safety, health, satisfaction, quality, productivity.
2. Work complexity is any negative outcome of work ergonomist wishes to minimize. The examples are risk of injures, errors, complaints, time spent on one task or product.
3. Work factor is any parameter of interaction and mutual adaptation between human and work environment, including machines, tools, partners, managers, etc. The examples are desk height, workspace, work posture, number of emergency signals perceived by operator, noise and light as they influence concrete worker, etc. Work factor as a factor of human–environment mutual adaptation does not belong to the human or environment alone. It is a parameter of interaction and mutual influence in the course of training, work, overexertion, etc.
4. Mutual adaptation is a process of synthesis and development of human–machine–environment system structure which is a basis for human and system work process and strategy. Ergodynamics studies work structure, strategy, efficiency and complexity in the processes of human–machine–environment mutual adaptation, particularly when human work changes its structure and strategy.
5. Work structure reflects a regularity of internal mutual adaptation processes in human, machine, any other system. Strategy reflects a regularity of external, interactive mutual adaptation processes of human or machine with environment based on the structure.

3. THE FIRST LAW OF ERGODYNAMICS

The First Law of Ergodynamics is the Law of Mutual Adaptation: "Work efficiency is a bell-shaped function and work complexity is a U-shaped function of any factor of mutual adaptation in human–machine–environment system."

As an example demonstrating the First Law, experiments were conducted on typing a text on a laptop computer installed at different heights. Subjects typed the text in a sitting position. Work productivity, Q, measured as a mean number of characters typed in 1 min, appeared to be a bell-shaped function of desk height, F. Work complexity measured as time to type 1000 characters, appeared to be a U-shaped function (inverted bell-shaped function).

4. THE SECOND LAW OF ERGODYNAMICS

The experiment on typing at the laptop computer was extended so the subjects were typing in either a sitting or standing position, given varying desk heights. Two different functional structures for every subject were studied: the processes of reading texts and perception of control board information. A variety of functional structures and strategies was found. For example, the same text may be read by separate letters or by syllables. Then there are two different $Q(F)$ curves for these two strategies.

These studies allowed the wording of the Second Law of Ergodynamics, which is the Law of Work Structures Plurality: "Every work can be done using different structures (strategies) presented by different respective bell-shaped curves for efficiency, $Q_i(F)$, and U-shaped curves for complexity of work."

A visual image of the Second Law is shown in Figure 1, where S_{sub} and S_{op} are two different functional strategies used by laboratory subjects (S_{sub}) and operators (S_{op}) in the same work.

The Second Law explains the plurality of human reactions on the same signal or certain value of an environment factor, F. For example, the same desk height leads to different typing productivities in sitting and in standing positions. The Second Law helps to solve many various ergonomic tasks. For example, it may help predict a human operator's decision-making efficiency when the operator perceiving the same information from the same video terminal but uses different cognitive strategies.

The Second Law explains why ergonomics laboratory results

Figure 1. Bell-shaped curves for subject's (S_{sub}) and operator's (S_{op}) strategies. Q, efficiency; F, work factor.

obtained with subjects using strategy S_{sub} in many cases cannot be used to design and optimize work of operators using different strategy, S_{op}. Figure 1 shows that in the interval of work factor F_1 Æ F_3, the decrease of F recommended based on data for S_{sub} would lead to the inverse effect for the operator: in this interval S_{sub} increases its efficiency and S_{op} decreases its efficiency. This task is discussed in more details in *theoretical ergonomics*.

5. UNIVERSAL AND SPECIALIZED STRATEGIES: A HISTORICAL PROSPECTIVE

A brief outline of the history of work strategies over centuries based on ergodynamics methodology will be given. At the dawn of industry the craftsman was the main production force. Every craftsman performed all the operations needed to produce a whole product. Therefore, the craftsman accomplished tasks in a wide range of work factors, F_{min}/F_{max}, but work efficiency measured as productivity was very low (Figure 2).

There was not often the necessity for the craftsmen to transform work strategies, skills and methods. First, factories implemented some of distribution of functions between industrial workers. The range of tasks for each worker got narrower, and the strategy was more specialized and effective in comparison with craftsmen. At the next stage more detailed functions were distributed between production workers and, thus, work efficiency increased (Figure 2). Assembly-line workers performed

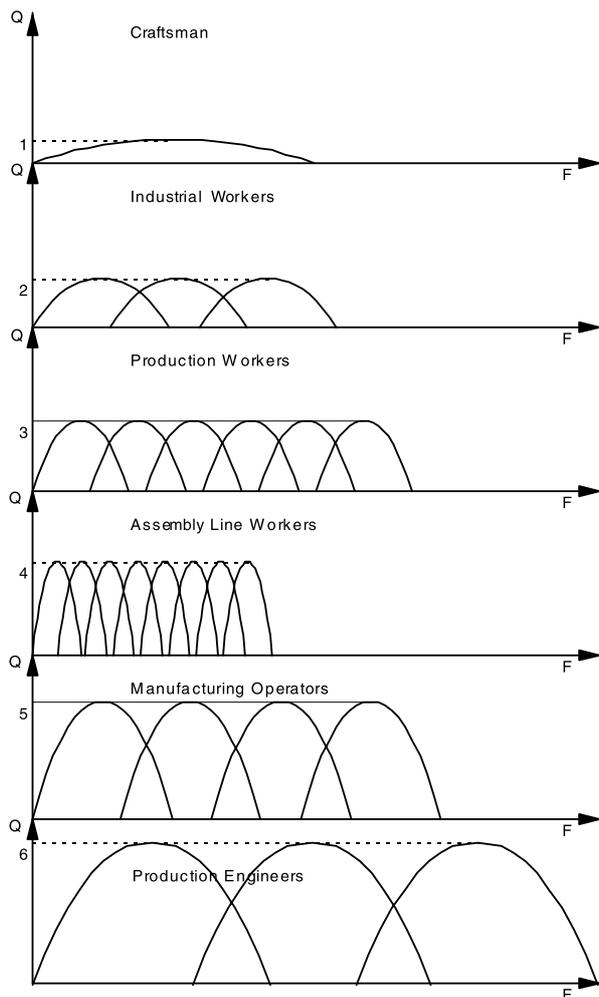

Figure 2. Ergodynamics history of work strategies.

small sets of operations with very high productivity, but this repetitive work led to frequent injures and low job satisfaction. Now a tendency in industrial development takes a reverse direction. Using various semi-automatic tools manufacturing operators can reach a higher productivity while expanding their range of tasks. Production engineers (Figure 2, stage 6) continue this tendency further, thanks to wider use and assistance of CAD, CIM, robotics, computers, expert systems, etc.

6. DISCOVERY OF WAVE–LIKE WORK EFFICIENCY DYNAMICS

The Second Law states the plurality of the work functional structures, but only one functional structure can be used by the individual at one time. If several different structures are available, and only one is used at the time, then a process of transformations between the structures should be specially studied. Traditional monotonic exponential models of human development (dynamics of efficiency) have been in exceptional use around the globe for more than a century (since Ebbinghaus 1885). These models, however, run contrary to the many practical and experimental data.

The following training experiment was conducted. Subjects (12 students at the Engineering Faculty) accomplished a compensatory tracking of dynamic signals presented simultaneously on several (1–6) measurement instruments, with the subject controlling an equal number of switches (1–6).

A distinctly non-monotonic character to the curves was found when $n = 2, 4, 5$ and 6. The data show that increased experience may sometimes result in an actual worsening of performance. It was found that in those periods the subjects were changing a functional structure of their performance of perceiving signals: (1) separately one-by-one; (2) grouping them by two into two-dimensional coordinates of a dot track; (3) by three, as 3-D coordinates of a dot in space that should be moved to the initial point with the coordinates 0,0,0.

When the learning curves were averaged over the number of signals, the result was strictly monotonic. Such averaging is, unfortunately, a traditional method of statistical processing of experimental ergonomic data. It, however, disguises the real dynamics of learning processes, which depend upon the cognitive strategies used and the number of signals being monitored and grouped into different information chunks.

We avoided traditional statistical averaging and analyzed a dependence of the signal tracking efficiency on different cognitive strategies: perception of the signals by one, two and three as an information chunk.

7. THE THIRD LAW OF ERGODYNAMICS

While analyzing all previous experimental data, Venda found that during transformations of any two work functional structures (S_i and S_{i+1}), work efficiency drops to the level corresponding to the intersect point of the curves $Q_i(F)$ and $Q_{i+1}(F)$. Thus, he discovered a transformation state that is a common and equal state for both structures. He suggested the law of transformations for any kind of complex systems (Venda and Venda 1995) and especially for ergodynamics.

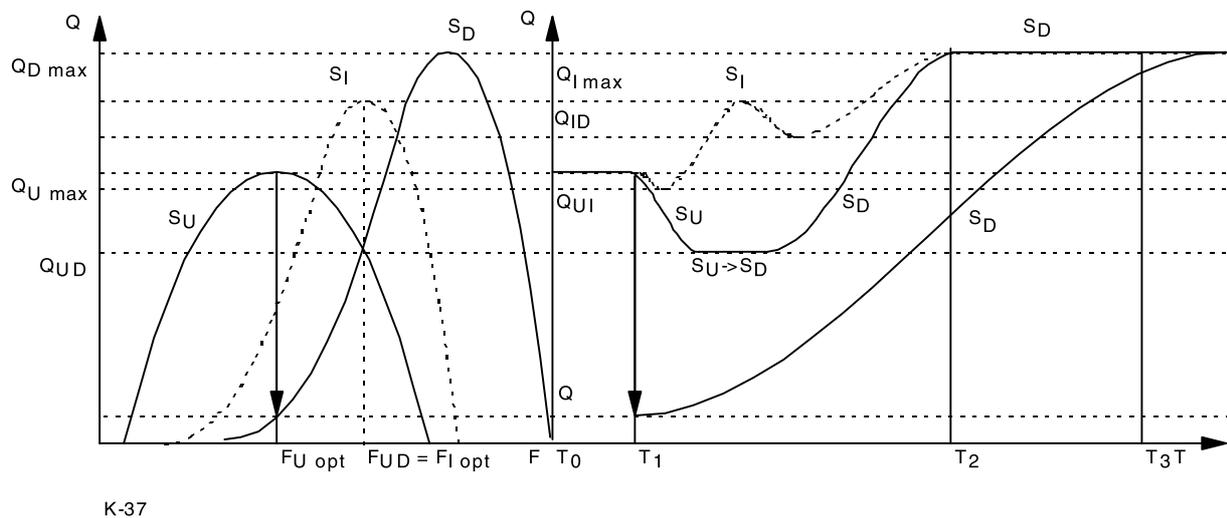
The Third Law of ergodynamics was worded by Venda in 1989 as The Law of Transformations and Interactions: "Transformations and interactions between two different work


Figure 3. Work strategies S_U, S_I and S_D, and transformations between them. Q, work efficiency; F, work factor; T, time.

strategies are maximally effective if they go through a state common and equal for the structures presented as an intersect point of bell-shaped curves $Q_i(F)$ or U-shaped curves $C_i(F)$ of the two strategies."

The common and equal state for two strategies, S_U and S_D, is presented in Figure 3 as the intersect point of the respective $Q(F)$ curves of the strategies: $F = F_{UD}$ and $Q_U(F_{UD}) = Q_D(F_{UD}) = Q_{UD}$.

Work strategies may belong to the same individual and may be used sequentially, transforming one to another. Work structures may belong to different individuals (or human and machine) interacting in the complete work process.

8. ERGODYNAMICS IN IMPLEMENTATION OF ERGONOMICS PROJECTS

Every essential, innovative ergonomics project leads to some kind of transformation in the work process designed or re-engineered.

Let us assume there is an existing user strategy, S_U, that allows maximal efficiency $Q_{U\,max}$. Designer-ergonomist suggests a new work strategy, S_D, that promises maximal work efficiency $Q_{D\,max}$ if work factor (task complexity for example) increases to $F_{D\,opt}$.

There are several trajectories available to transform S_U into S_D:

1. To implement S_D instead of S_U right the way. Then efficiency of S_D while $F = F_{U\,opt}$ will be much lower than $Q_U(F_{U\,opt}) = Q_{U\,max} \gg Q_D(F_{U\,opt})$ (see arrow in Figure 3).
2. Implementation of S_D may be done as transformation of S_U into S_D along with gradual increase of task complexity F from $F_{U\,opt}$ to $F_{D\,opt}$. This trajectory leads to relatively deep decrease of efficiency to the level Q_{UD} with following increase to Q_D max by the time T_2.
3. If the decrease of efficiency to the level Q_{UD} is too deep and unacceptable for the company, the transformation may be done through intermediate strategy S_I, in two stages: $S_U \: Æ \: S_I \: Æ \: S_D$, with much less decrease of efficiency.

Choice of the best transformation trajectory depends on relative integral gains and losses.

9. TRANSFORMATION DYNAMICS IN INDIVIDUALS, COMPANIES AND NATIONS

Transformation means a smooth transition of one system structure (a human being, team, manufacturing facility, company) to another. A "pure" transformation occurs with constant system components and, consequently, its energy and material resources.

If a businessman decides to change a product and technology at his facility, s/he can use two main different politics: transformation or replacement. Transformation means fast and smooth changing of the old technology into a new one, using the same human resources.

Transformations in science, technology, trade and education help a nation or society to save and use a big part of the previous knowledge, skills, equipment, human and business relations. We had applied a transformation dynamics theory to predict the dynamics of a social-economical transformation in the former USSR, and explained transformation difficulties there well in advance (Venda 1989).

Using the Third Law and analyzing characteristic curves of existing and new desirable technological or management strategies, every company may predict, plan and optimally execute transformation of the existing into the new strategy with minimal losses in efficiency.

10. ERGODYNAMICS OF STRESS

There is one special way in fast transformations which are important for industrial companies but even much more important for operators of power plants and air pilots when situations turns from normal to emergency and time for transformation is very limited. Fast and reliable, accurate transformation to successful strategy may save lives and systems. Slow and inaccurate transformations lead to the catastrophes.

Ergodynamics is the first and only existing methodology analyzing this problem. We found one of effective solutions of this problem among many inventions by biological evolution. We mean abilities of living system to turn their states into stress condition.

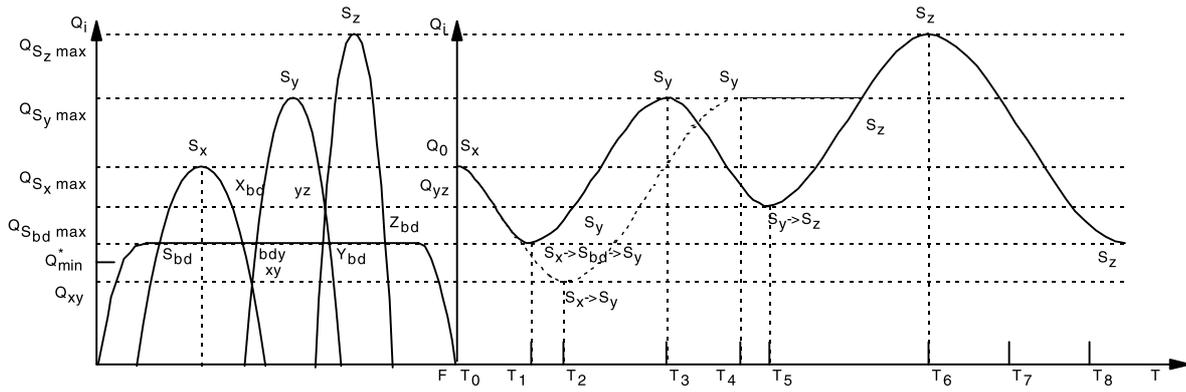
The stress condition looks like partial destruction of the organism structure with low temporary efficiency. System


Figure 4. Three specialized structures, S_x, S_y and S_z, and a basic diversified structure, S_{bd}, and transformations between them. Q, work efficiency; F, work factor; T, time.

structures may be narrowly specialized that allows to reach high maximal efficiency in a narrow range of conditions (DF). High maximal efficiency depends on convergence and synchronization of the system components.

The structure may be more universal, with less maximal efficiency, but very wide range of acceptable conditions. Importance of the stress structure is that it is very universal as a result of divergence of the system components.

Figure 4 presents three specialized structures, S_x, S_y and S_z, and one more universal, basic diversified structure, S_{bd}.

Let us assume system cannot survive if its efficiency (safety) is lower than some minimal level Q^*_{min}. If system has currently structure S_x, it cannot transform to any other structure, S_y or S_z, when F changes and goes outside of range acceptable for S_x, because common and equal state for S_x and S_y, xy, lies lower than Q^*_{min}.

The system can survive if it has a basic diversified structure S_{bd}, then through common states between S_x and S_{bd}, between S_y and S_{bd}, and between S_z and S_{bd}, the system has flexibility to survive in a very wide range of environmental conditions.

This great invention by nature may be effectively used by the industrial companies to maintain flexibility in a dynamic market.

This principle is even much more important for the operators, air pilots and other workers who may be in emergency situation. S_{bd} may be considered as a specially trained standard structure that could be easily obtained from any non-standard structure and then may be quickly transformed into narrowly specialized highly effective structure (strategy) needed to use in the emergency.

11. PERFORMANCE PREDICTION AT TRANSFORMATION STAGES

Speed and reliability of the transformation between two strategies, S_{a1} and S_{a2} (Figure 5), depends on the following factors:

1. Difference in efficiency between current strategy and transformation state to another strategy, D$Q = Q_{a1\ max} - Q_{a1a2}$ (Figure 5); the greater the difference the more difficult, slow and unreliable is transformation.
2. Frequency of transformations between S_{a1} and S_{a2}; if system was trained or accustomed to the transformations between these strategies, the transformation will go fast and correct.
3. How long time the system was in a current condition. The longer the period, the more conservative is the system, the slower and less reliable is transformation.
4. How fast F changes. The faster is change, the more difficult inertial system may keep up with the transformation.
5. Whether the system passes through the points it used to transform to other structures is also important. The search to find a new transformation point and to transfer to a new structure is also important. This search includes trial runs to predict the consequences involved in a change.

So, as we study the probable and actual system structure dynamics, we should examine the current structure, the newly found ones, prehistory and the earlier structures of the system. Suppose that over the range F the structure S_{a2} gives a gain of efficiency DQ. Here the system seeks to pass from S_{a1} to S_{a2}. If, on the other hand, Q decreases for a change in F, the system resists

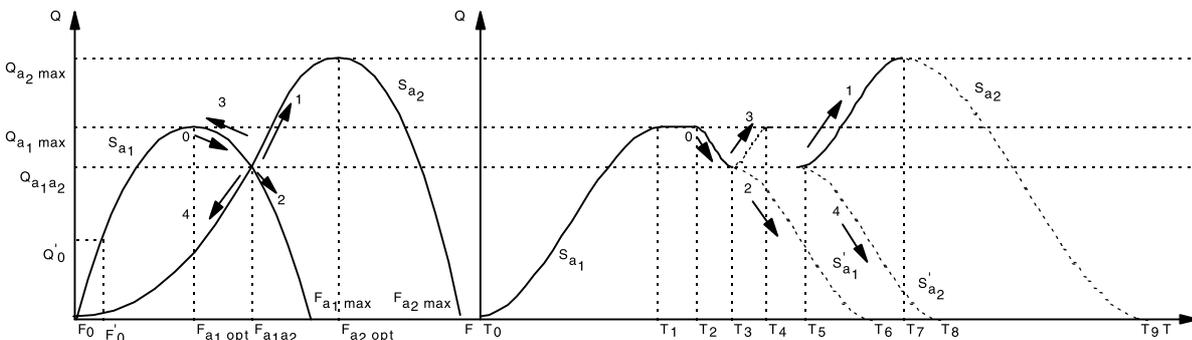

Figure 5. Performance prediction at transformation stages. Q, work efficiency; F, work factor; T, time.

the effect of the changed F. It musters its components' mutual adaptation potential to redress the change.

Even when the transformation state is reached, three types of "losing" pathways can mask real progress. Figure 5 shows that movement from maximal efficiency of the structure S_{a1} at $Q_{a1\ max}$ and $F_{a1\ opt}$, through the transformation point (Q_{a1a2}, F_{a1a2}) may have the following variations:

1. *Successful transformations.* If a system reaches transformation state (Q_{a1a2}, F_{a1a2}), and stays there long enough for the structure to transform from S_{a1} into S_{a2}, and if F increases from F_{a1a2} to $F_{a2\ opt}$, the system will then go to $Q_{a2\ max}$. This behavior model is called *progressive*. Any successful restructuring involves this kind of transformation.

2. *Collapse of the system as a result of ignoring its inertia for transformations.* Let us assume the system is in initial state 0 ($Q_{a1\ max}$; $F_{a1\ opt}$). If the system goes from $F_{a1\ opt}$ to F_{a2} (through F_{a1a2}) too fast, the system's Q will change from $Q_{a\ max}$ to zero (track 0 Æ 2). It will skip the transformation point and fail, having structure S_{a1} when factor $F = F_{a2\ opt}$, because $Q_{a1}(F_{a2\ opt}) = 0$. This behavior pattern is called *passive system fallback to zero efficiency*. This means that the system is deadlocked.

3. *Return to initial state just in time.* If a system left initial state ($Q_{a1\ max}$, $F_{a1\ opt}$) changed environment from $F_{a1\ opt}$ to F_{a1a2}, but then it does not remain at transformation state (F_{a1a2}, Q_{a1a2}) long enough for the S_{a1} Æ S_{a2} transition and F reverts to its $F_{a1\ opt}$, the system efficiency will be again $Q_{a1\ max}$. This is a standstill policy. It leads to a *relapse*. This throwback will result in track 3 in Figure 5.

4. Track 4 means "Transformation is already in progress, it is too late to go back." If a system stays at the transformation state (F_{a1a2}, Q_{a1a2}) long enough for the S_{a1} Æ S_{a2} transition, and then goes from F_{a1a2} to a direction 4 with lower (previous) values of F the system efficiency will drop to zero. This is the fatal *half measures and retreat* policy: after an extended effort to make the S_{a1} Æ S_{a2} transition, one makes a futile attempt to revert to the past. That was what Gorbachev did when he tried to restore Communist party rule, return to the "socialist ideals," retain the privileges of the party "nomenclatura" and his personal role as the General Secretary of the Communist party. By that time the people of the former USSR has already changed. Gorbachev's attempt to move back a country with new-born strong elements of social and psychological structure and free-minded people led to the crash of the superpower, the USSR and Gorbachev himself in 1991. There was a book published in 1989, *The Waves of Progress*, by V. Venda, predicting and explaining the transformation process in that country well in advance.

This historical lesson should convince everybody that if a functional structure of a firm, technological facility, design team, work skill, country society has been changed then reverse transformation should be planned and organized to avoid catastrophe of the system.

Thus, of the four possible transformation point paths, only the first is successful. The probability of a successful dynamic progress is thus only one in four if the proper transformation concept is taken in account. If there is no proper transformation concept, probability of success in changing structure and strategy may be equal to zero.

So, one should be able to predict and control transformation process to get a success. This, in turn, calls for great courage and determination when the system fails to show the proper efficiency level after a long wait.

The *transformation state (or point)* is defined as a system's critical point, when its future development route is decided. It is the point where two or more structure-strategies have the same efficiency. Any departure from this point, to the left or right, causes a rapid change in efficiency.

Thus, if the main search tendency (for instance, in scientific research) aims at increasing factor values, it must form the embryo of the next structure well before the change. The lower efficiency of the current structure during this phase will also have to be considered. The next structure could thus take over with enough ease and promptness.

12. CONCLUSION

Ergodynamics is helpful at least in dealing with two major challenges of contemporary ergonomics: (1) creating a theory that could accumulate, combine and generalize the ergonomic experience and act as a common foundation for easing ergonomics teaching, studying and practicing; and (2) improving methods of ergonomic design, improvement and studies of dynamic work in dynamic environment.

Ergodynamics is an application of the transformation dynamics theory in ergonomics. Three Laws of ergodynamics are being suggested: (1) The Law of Mutual Adaptation; (2) The Law of Plurality of Work Functional Structures; and (3) The Law of Transformations.

Ergodynamics is an operational methodology of qualitative and quantitative analysis and design of dynamic work functional structures and planning their transformations.

13. RECOMMENDATIONS

1. Ergonomic recommendation for practice may be based on laboratory data only if laboratory subjects' strategies are identical to those of industrial operators and workers.

2. Interactions between human and machine, communications between people must be organized as a processes of mutual adaptation. Maximal efficiency of the interactions may be found as an intersect point of the two interacting strategies' characteristic curves. The same principle based on the Third Law must be used for transformations between strategies of the same person, company or nation.

3. If work task is very well defined in a narrow range of work factor value, specialized strategies allow higher work productivity in a short run, but monotony of work may cause big troubles in a long run.

4. Avoid statistical averaging of data collected while different work strategies were used. Analyze data on each strategy separately.

5. Do not promise clients that implementation of innovative ergonomic project, new hardware or software will immediately lead to increase of efficiency. Temporary dip in efficiency is inevitable, it may be minimized in time duration and depth using laws and principles of ergodynamics.

6. Operators must be trained not only strategies effective in normal and emergency situations but also special skills to transform one strategy into another.

7. While organizing transformations in the company chose the

best transformation trajectory considering relative integral gains and losses.

8. Do not rush to eliminate stress in individuals and company, it is natural, necessary and very helpful in well-planned and organized transformations.

9. When planning transformations analyze current and desired structures and system's prehistory.

10. Do not use monotonic linear or quasi-exponential models to predict performance dynamics if transformations of strategies may occur.

11. Do not use ergostatics in analysis and design of dynamic work. Use ergodynamics.

The Ergonomic Qualities of Products

L. Bandini Buti, L. Bonapace, G. Caggiano, E. Fubini, F. Marcolin, P. Molinari, A. Tarzia and G. Tomei

Società di Ergonomia Applicata, Milan, Italy

1. INTRODUCTION

Is a sharp, pointed knife with a 30-cm blade a safe product? One may be tempted to say not, and it is not the kind of object one would not give to child. Yet a butcher cannot be expected to cut and prepare meat with a round-ended blade!

Thus, we see that it is impossible to give a simple "yes" or "no" answer to the question of a knife's safety, as a product is safe or otherwise not only in terms of its intrinsic nature, but also, and above all, in relation to those who use it, the tasks the user must perform, their specific training and the instructions they have received. It is possible to think of examples other than the knife in the domestic sphere: products range from ovens to pressure cookers, and from stepladders to irons. Arguments made in the context of safety do not change very much if applied to that of comfort. Seating provided on the underground is comfortable, but certainly could not be adopted for use in an office where one sits not for minutes but for hours at a time.

From such observations it would seem that it is not easy to evaluate the quality of a product or system, as reference must be made not only to the specific product, but also to the specific user, the specific environment of use and the characteristics of use. That which might be considered a positive quality by one person may not be by another, or indeed by the same individual in differing circumstances and for other purposes. Such reflections propose a very complex framework for the evaluation of the qualities of a system or product. They require the consideration of the potential qualities of the product, the characteristics of the user and above all the interface between these.

Markets that have become extremely competitive at national, international and even global levels, and users who demand high levels of performance, require products and services to be ever more responsive to the actual needs of the user, and this has tended to bring about an increase in the number of options available, causing the greater part of products, from those in the workplace to cars, and from electro-domestic appliances to entertainment systems, to become increasingly complex and difficult to understand for those who use them.

The concepts and methods of ergonomics are being used more and more in the evaluation and design of products, and are consistent both with existing European regulations and directives and those currently being drafted. In recent years, industry, stimulated by a market more sensitive and awake to the concept of health and well-being, has begun to recognize an ergonomic approach to industrial design as a planning method capable of surveying, revealing and predicting the needs brought about by the complex system of inter-relations between man and machine and between these and the environment. We are becoming ever more conscious of the fact that safety and the safeguarding of health can only be confronted in the design phase and that ergonomics is a design technique that is capable of dealing effectively with design quality.

2. ERGONOMICS AND QUALITY

The analysis of individual behavior in the use of a product or system (i.e. of factors linked to highly variable factors in the user, such as perceptive capabilities, psycho-physical characteristics at the moment of use, habits, knowledge of and familiarity with the product and relevant procedures, etc.) covers a high level of complexity and must be confronted with approaches that have the use of solid and proven methodological foundations to inform the process of making choices with objective arguments (i.e. arguments that may be evaluated, compared, measured and transmitted.

Ergonomics has developed theories and tested criteria and methods capable of highlighting the wishes and needs of users and evaluating the usability of products and systems, and which have shown themselves to be effective in the conception of products and systems, proving successful at intervening in the design phase with innovative proposals.

Studies of product quality highlight the user's perception of the qualities of the product or system. Perception is the first, indispensable step on the road to correct use; in fact, if a quality, even if present, is not perceived, it will have a reduced, or indeed, no effectiveness.

A product's qualitative characteristics may be defined as common, perceivable, non-perceivable, self-explanatory and induced.

2.1. Common Qualities

These are qualities that must be considered common and generalizable to all potential users; they are those linked closely to safety and security, which may in no case be left out of consideration.

2.2. Perceivable Qualities

These may be perceived through the normal senses of the individual (sight, touch, hearing, feeling a weight in one's hand, smell, taste). They are linked to experience (like the mechanical characteristics of wood which are expressed by its configuration, its weight which is perceived as a guarantee of its robustness, etc.) but also to stereotypes (such as considering wood a noble and reliable material, but plastic, on the other hand, artificial and as such not noble and perhaps toxic, etc.). Perceivable qualities change over time with the enriching of individual experience (such as the weight of a product being perceived as a guarantee of a large technological content, a perception that has been changed by the advent of miniaturization).

2.3. Non-perceivable Dualities

These may not be perceived by ordinary senses of the individual. They are either hidden (such as the quality of the structure of a panel covered by an outer finish, etc.) or, to be quantified, require the execution of analyses and tests (such as the durability of paint over time, safety requirements, toxicity of the product, etc.). Such qualities need to be studied, analyzed and guaranteed by specialist bodies, laboratories or other experts.

2.4. Self-explanatory Qualities

These are present when the product itself informs the user of its qualities and use, through its appearance. Above all, they are present in products of a mechanical nature, products whose form is necessarily conditioned by their mechanical nature (such as typewriters, scissors, corkscrews, etc.). With electronics, products become increasingly less self-explanatory and thus require ever-greater intervention in the design phase in order to manipulate the product's image to render it more self-explanatory.

2.5. Induced Qualities

These are proposed by various means of advertising as possible or necessary for the user. For example, car safety campaigns have induced safety as a problem and robustness as a quality in the public eye; an increasing ecological awareness has led to respect for the environment on the part of producers in production, use and disposal of goods, becoming a required quality.

The qualities that users ask for and expect also change when innovative products or systems become widely available, so that that which was optional or an accessory yesterday becomes a minimum requirement today. In the case of motor vehicles there are many such examples of products realized as optional but which have become qualitative standards of reference: electric windows, power-assisted steering, central locking, motorized wing-mirrors. One should also note that many options created only to facilitate a particular operation become transformed through use. Again with cars — the case of the motorized right (left in some countries) wing mirror which, today, is often used to check the distance between the car wheel and the sidewalk during parking.

3. THE USER

Ergonomic design proposes that the characteristics of a product respond to the actual needs of the end-user and that they may be used with a minimum physical and psychological "cost." Ergonomic design requires, therefore, the needs analysis of the user and the "costs" related to use.

The generic definition of "user" or that used in the common language of clients, consumers, indeed users themselves, is very limiting and misleading compared to the objectives of ergonomics which intends all those who enter into contact, even sporadically or casually, with the product.

3.1. User Classification

For a correct evaluation of ergonomic quality it is necessary, therefore, to define who will use the product, which group of users they belong to, which means they possess for the use of the product, and what their needs are.

3.1.1. Those who work with the product

These are the end-users of the product and they are:
- *unique*, when the product is destined for exclusive or private use;
- *multiple-defined*, when the product is destined for a defined an definable group of people, such as occurs with photocopiers or drinks machines in a large office;
- *multiple-generic*, when the product is destined for an undifferentiated collective use such as occurs with automatic teller machines or with photocopiers or drinks machines in public places; and
- *improper*, when the product may be used by categories differing from those for which it was intended (e.g. use on the part of children, use of professional products by hobbyists).

For some products, users might be *generic* in that anybody may be interested in using them, while for others the users may be *defined* since the products are destined for use by characteristic groups, such as military conscripts, Italians only, school children, licensed drivers, etc.

3.1.2. Those who work on the product

They are:
- generic "maintenance" people, who are often identified with those who work with the product and are not in possession of any specific training (e.g. changing ink cartridges in printers and photocopiers and re-filling them with paper, changing batteries, changing the wheel on a car, etc.);
- professional maintenance workers who are in possession of suitable and specific knowledge and tools; and
- personnel authorized for production and fitting.

3.1.3. Those who handle the product

These are retailers, warehouse workers, transport workers, installation workers, both those involved with distribution and those involved with the end-user.

those who use the product	• those who work with the product • those who work on the product • those who handle the product • those who eliminate the product	end-user maintenance and production personnel retailers, warehouse workers, transporters ecological workers
user category	• generic category • defined category	anybody, undefined by sex, age activity....
means possessed	• diffused/innate knowledge • specific knowledge • learning • instruction • specific training	language, meaning of symbols, etc. previous product experience product self-explanation instruction booklets, exemplification professional training, licences
needs expressed	• primary • of functional quality • of aesthetic quality	what one can do how one can do it pleasure in doing

Figure 1. Product users.

3.1.4. Those who eliminate, remove and destroy the product

These are ecological, recycling and disposal workers.

3.2. Knowledge Possessed by the User

Users may also be classified in relation to the means they possess for the correct use of a specific product. These means may be:

3.2.1. Innate/diffused knowledge

That is, what is considered common knowledge among large population groups (for us, those in industrialized society), whether this be innate or gained in the course of physical and intellectual development, such as knowledge of one's mother tongue, of the meaning of symbols and colors, the automatic performance of the actions of screwing and unscrewing, etc.

3.2.2. Specific knowledge relative to the product

That is, knowledge acquired through the use of the product or other similar products. For example, habitual use of computer technology renders more natural the management of symbolic systems.

3.2.3. Self-explanatory knowledge derived from the messages that the product transmits

Self-explanatory knowledge derived from the messages that the product transmits without the use of verbal means, but with the application of diffused, innate or specific knowledge which acquire a universally self-explanatory value (as with codes relative to upside-down, left-right, or hot-cold on controllers).

3.2.4. Instructions accompanying the product

Instructions accompanying the product, which regulations have in many cases rendered obligatory, and which should complete rather than replace the self-explanatory capacities of the product. They are the instructions and recommendations for use, printed instruction booklets or those on computer (the "help" facilities in programs), or the various types of "demos" for applications and video arcade games.

3.2.5. Specific Training

Specific training, when it is necessary to be in possession of a license or specific professional qualification to use a product such as with the use of electro-medical equipment on the part of sanitary personnel or the use of specialist military equipment

3.3. Needs Expressed by the User

One may define a group of users as homogenous from the point of view of needs expressed, which can be distinguished on three levels:

3.3.1. Primary needs

These regard the basic needs that affect one's motivations for buying a product. Typically, to communicate, to move around, to sit, etc.

3.3.2. Needs of a functional quality

These regard the mode in which primary needs are acquitted. They regard the sphere of ergonomics: safeguarding of health, safeguarding of physical integrity and comfort.

3.3.3. Needs of a symbolic and aesthetic nature

These regard the sphere image and the quality of the relationships this tends to establish between subject, object, environment (agreeability). Umberto Eco states (1982) "one must not think that symbolic functions are something added to the object, rather they form part of its functions and it would be a mistake to think that if 'form follows function,' form mustn't also follow symbolic function."

The three levels analyzed are never disconnected. That is, no primary need can be acquitted without the user also expressing the need for functional and formal qualities; subdivision into categories must, therefore, be considered only as a useful analytical instrument.

We have already that needs, when they are subjective, are specific to each individual depending on their anthropometric, physiological, functional and cognitive characteristics. It would, however, be reductive to think of the individual as unchanging both in the short and long term. Indeed, in relation to particular points in time (the stress, tiredness, motivation, etc. of the moment) and environment (lighting, noise, climate and microclimate, etc.) their needs can change considerably.

3.4. Typology of Needs

Various types of need can be distinguished:

3.4.1. Real needs

Those whose satisfaction allows one to perform complex, productive or leisure activities, which have an effect on quality of life and work and which go beyond the abstract pleasures of possession and control.

3.4.2. Imaginary needs

These do not derive from the desire or need to improve performance, but rather they refer to models induced by opinion leaders, the mass media or social trends. In a consumer society, desires often correspond to needs that are not in the sphere of utility but of representation. The confines between needs of a symbolic character and simply succumbing to consumerism are fragile and not easily defined. A lot of people, for example, would like to own a motorcycle not so much to be able to travel with more ease and speed, as for the intrinsic pleasure of owning it, or in the sphere of Information Technology, many people acquire the most up-to-date models of computer, equipped with lots of powerful applications, but they simply have no need for them; here pleasure is simply derived from the domination of technology.

3.4.3. Latent needs

These are real needs of the individual that are not expressed as they are felt to be unobtainable or simply because they are not recognized, but whose presence is felt. Identifying these needs is important for innovations.

3.4.4. Future needs

These are needs that will manifest themselves in the future, but are not yet expressed as the technological, economic and social conditions which will render them topical are not mature. One might predict that some important future needs will be expressed in the sphere of the use of leisure time and that they will only be fully expressed with the lengthening of life after work and the

shortening of the working day. The importance of considering future needs resides in the fact that between the idealization and the realization of a project on an industrial scale a lengthy period of time usually passes; thus it is not sufficient only to consider the present when working on a project but one must try to predict what the needs of the user will be when the product finally enters the market. It is not easy to study future needs in as much as they are usually only expressed by small signs and trends that must be interpreted. They also evolve with the offering of new levels of performance and quality which tend to render previous proposals obsolete and to create new points of reference and new standards, with the associated moving of the scale of values asked for (expected).

4. THE ERGONOMIC QUALITIES OF INDUSTRIAL PRODUCTS

In recent years the concept of "usability engineering" has been consolidated, a concept developed principally for application to products in the area of Information Technology. This area has been formalized with the creation of normative ISO 9241 (Ergonomic requirements for office work with visual display terminals — VDUs), which deals with the design of office equipment making use of video terminals. Part II of ISO 9241, "Guidance on Usability," deals with approaches to usability and provides a basis for measuring and specifying such approaches. It emphasizes the fact that products do not have an intrinsic usability, since this is determined by the characteristics of the user, of the task to be performed, and the immediate environment, as well as by the characteristics of the product itself.

This regulation indicates that it is possible to effect comparisons between planned solutions. The effectiveness, efficiency and satisfaction of two products (or two design situations) being used in the same context can thus be compared. Usability may thus be operatively defined as the effectiveness, efficiency, and satisfaction with which specific users reach specific objectives in particular environments.

- *Effectiveness* is the accuracy and completeness with which a user reaches the global objectives set for a system. Measurements of effectiveness relate the objectives and secondary objectives of use in the system to the accuracy and completeness with which such objectives may be reached.
- *Efficiency* is the accuracy and completeness of the objectives reached in relative to the resources used. Measurements of efficiency relate the level of effectiveness reached to the

spending of resources, such as physical and mental efforts, time spent and economic costs.

- *Satisfaction* is the level of comfort and acceptability in using the system, the subjective reactions of the system user. Measurements of satisfaction relate to the comfort and acceptability of the global system for those who must use it and for those affected by its use.

Normative ISO 9241 clearly states that there is no such thing as the ergonomic quality of a product, but that one may speak of the ergonomic quality of an object in a situation of determined use on the part of a determined subject in a determined environment (i.e. that ergonomic quality is not attributed to the product itself but to the use of the product). The concepts expressed in this chapter stem from the work of the "Industrial Design and Ergonomics" group of the Società Italiana di Ergonomia (SIE) and we believe it is possible to extend such affirmations, formulated for VDU, to ergonomic quality in industrial products in general, and we, therefore, believe it is possible to definitively affirm that:

- the ergonomic quality of an industrial product is an attribute of the use of the product and not of the product itself; and
- the ergonomic quality of an industrial product is refers to the user, to the task to be performed, to related equipment, to the immediate physical and organizational environment.

These affirmations would seem to exclude the possibility of defining the ergonomic qualities of various products or, further, of certifying them, which would rule out the possibility of providing clarity and certainty for the user. We, on the other hand, have come to the conclusion that it is possible to identify, evaluate and diffuse ergonomic quality in industrial products, operating on the characteristics, parameters and qualities of the product.

The ergonomic characteristics of a product are the aspects that have either a positive or negative influence on the relationship between the product and the particulars of possible users, of possible environments, and of possible uses, and they represent the first level of study.

The ergonomic parameters are criteria capable of measuring, evaluating or judging the ergonomic characteristics of the product in objective terms.

The ergonomic qualities of products are linked no more to general conditions, but to specific situations of use on the part of determined users and in determined environmental contexts. The ergonomic quality of products is determined by verifying the positive or negative effects of the ergonomic characteristics under

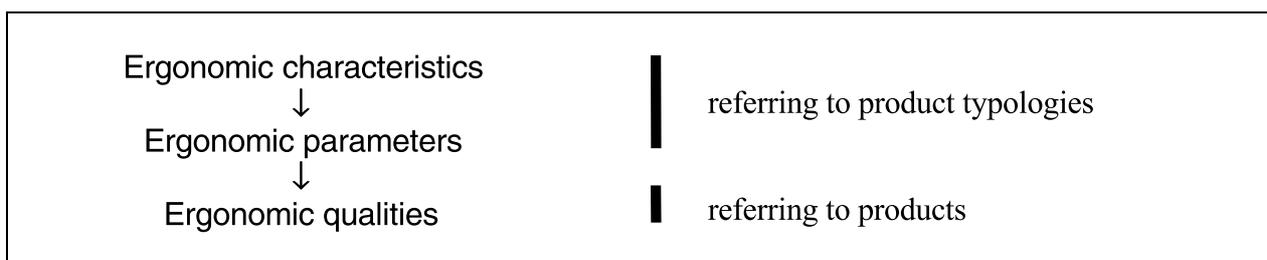

Figure 2. Diagram illustrating ergonomics qualities of products.

determined conditions of use, and evaluated by means of ergonomic parameters.

4.1. Ergonomic Characteristics

Ergonomic characteristics are those aspects which are capable of influencing the quality of the relationship between products and the particular user. Ergonomic characteristics are not, in themselves, either positive or negative, rather they are arguments capable of influencing the psychophysical well-being or the pleasure of those who use the product. All products can be embodied and expressed in terms of product typologies which possess the same ergonomic characteristics, or rather which are homogenous with each other in terms of performance offered and characteristics of the interface with the user. It is not necessarily sufficient for them to offer the same level of performance. In fact, a printed encyclopaedia and the same encyclopaedia on CD-ROM belong to two completely different ergonomic categories, in as much as, even if the content of both is identical, the characteristics of use, the operative knowledge required of the user and the constraints imposed by the work place are completely different.

A product's ergonomic characteristics must be defined for every homogenous product typology, making reference to a number of general arguments relative to the characteristics of the product–user interface. This general list of ergonomic characteristics of a product must be constantly up-dated in line with research developments in the sector, with the evolution of user expectations, and with the enrichment of technology available.

4.2. Ergonomic Parameters

Ergonomic characteristics can only be evaluated and transmitted if they are expressed by "parameters" that indicate and specify the methods, instruments and units of measurement by which they can be described in objective terms. Ergonomic parameters are, therefore, criteria for measuring, evaluating, or judging the ergonomic characteristics of a product.

Ergonomic parameters must make reference to knowledge possessed in relation to various disciplines closely linked to ergonomics, and it will only be necessary to define new parameters in the absence of satisfying parameters. Ergonomic parameters can derive from:

- Methods, instruments, and units of measurement taken from the disciplines closely linked to ergonomics. For example, intensity of sound may be measured in A' decibels, ease of handling by means of measurements made using the metric system, the equilibrium of the object in relation to the center of gravity and its distance from the center of the object, etc.

- Methods, instruments, and units of measurement chosen as the most suitable among those elaborated by disciplines closely linked to ergonomics. For example, to characterize types if noise it will be necessary to make use of the most suitable sonograms, those most representative of the phenomena; to describe forces one will have to choose representative means that place intensity and movement in relation to one another; for a usability analysis it will be necessary to choose one of the many techniques developed for use in this area, etc.

- Definitions of methods, instruments, and units of measurement developed specifically for situations in which the representation of ergonomic characteristics cannot rest on support provided by disciplines closely linked to ergonomics. For example, the definition of human body simulators of different sizes, of units of measurement and study methods for the evaluation of the comfort of mattresses.

- Specific research that it can be necessary to develop for arguments that cannot make reference to an adequate experience of ergonomic characteristics, either because of a lack of relevant literature or because of the newness of the sector or the innovation.

4.3. Ergonomic Qualities

The ergonomic qualities of a product are the responses to the ergonomic characteristics that derive from the use of the product in real life.

Ergonomic qualities, which may be either positive or negative, are, therefore, specific attributes of the product referred to the interaction of the ergonomic characteristics relative to specific users in specific environments and for specific uses. In order to define ergonomic qualities, scales of quality and parameters relative to all the ergonomic characteristics of individual products must be assigned. These scales may be the object of objective measurements or of subjective evaluation. Objective scales refer to measurable parameters that come under the various disciplines closely linked to ergonomics, and which have units of measurement that refer to the metric system.

Evaluation of Software Usability

A. Dillon

HCI Lab, SLIS, Indiana University, Bloomington, IN 47405, USA

1. INTRODUCTION

Usability is a measure of interface quality that refers to the effectiveness, efficiency and satisfaction with which users can perform tasks with a tool. Evaluating usability is now considered an essential part of the system development process and a variety of methods and have been developed to support the human factors professional in this work.

2. CONCEPT OF USABILITY

Historically, the concept of usability has been defined in multiple ways, usually on one of the following bases:

- Semantics: in this case usability is equated to terms such as "ease of use" or "user-friendliness", without formal definition of the properties of the construct.
- Features: here usability is equated to the presence or absence of certain features in the user interface such as Windows, Icons, Menus or Pointing devices.
- Operations: where the term is defined in terms of performance and affective levels manifest by users for certain task and environmental scenarios.

The first type of definition was common in the 1970s but has proved largely useless for design purposes since it offers neither useful guidance for designers nor perspective for evaluators. The feature-based approach stems from the longstanding desire to specify in advance desirable interface attributes that enhance usability. However, this type of definition rests on an assumption that usability is an inherent part of the application. This assumption is false since one could always envisage a combination of users, with certain task demands, in a particular environment, for whom a given set of features would be suboptimal. Recognizing this, most human factors professionals now employ an operational definition in their work.

Shackel (1991) is the major developer of this operational approach. He defined usability as the artifact's capability, in human functional terms, to be used easily, effectively and satisfactorily by specific users, performing specific tasks, in specific environments. The essence of the operational definition is that it explicitly places usability at the level of the interaction between users and the artifact. This takes it beyond the typical features-based definitions common in the field. Furthermore, in setting criteria for assessing usability, this approach better supports the evaluation of any tool and the subsequent interpretation of the test results. Usability therefore refers not to a set of interface features, but to a context-dependent measure of human–computer *interaction*.

3. EVALUATING USABILITY

There exist multiple methods of evaluating usability depending on available resources (time facilities and labor), evaluator experience, ability and preference, and the stage of development of the tool under review. In broad terms it is worth making the following distinctions between evaluation methods:

- User-based: where a sample of the intended users tries to use the application.
- Expert-based: where an HCI or usability expert makes an assessment of the application.
- Model-based: where an HCI expert employs formal methods to predict one or more criteria of user performance.

3.1. User–based Methods

Testing an application with a sample of users performing a set of predetermined tasks is generally considered to yield the most reliable and valid estimate of an application's usability. Performed either in a usability test laboratory or a field site, the aim of such a test is to examine the extent to which the application supports the intended users in their work. Tightly coupled to the operational approach to usability definition, the user-based approach draws heavily on the experimental design tradition of human factors psychology in employing task analysis, predetermined dependent variables and, usually, quantitative analysis of performance supplemented with qualitative methods.

In a typical user-based evaluation, test subjects are asked to perform a set of tasks with the technology. Depending on the primary focus of the evaluator, the users' success at completing the tasks and their speed of performance may be recorded. After the tasks are completed, users are often asked to provide data on likes and dislikes through a survey or interview, or may be asked to view with the evaluator part of their own performance on video and to describe in more detail their performance and perceptions of the application. In this way, measures of effectiveness, efficiency and satisfaction can be derived, problems can be identified and re-design advice can be determined. In certain situations, concurrent verbal protocols might be solicited to shed light on users' thought processes while interacting with the tool so that issues of comprehension and user cognition can be addressed. In a usability lab, the complete interaction is normally video recorded for subsequent analysis of transactions, navigation, problem handling, etc. However, more informal approaches are also possible. Some user-based tests are unstructured, involving the user and the evaluator jointly interacting with the system to gain agreement on what works and what is problematic with the design. Such participative approaches can be very useful for exploring interface options in the early stages of design where formal quantitative assessments might be premature.

In an ideal world user testing with a large sample of the intended user population would routinely occur, however due to resource limitations, user-based tests are often constrained. As a result, there is considerable interest among HCI professionals in determining how to gain the most information from the smallest sample of users. While popular myths exist about being able to determine a majority of problems with only two or three users, Lewis (1994) has shown that the sample size requirement is largely dependent on the type of errors one seeks to identify and their relative probability of occurrence. Whereas three users might identify many problems in a new application, substantially more users will be required to tease out the remaining problems in a mature or revised product.

3.2. Expert–based Methods

Expert-based methods refers to any form of usability evaluation

Table 1.   Relative advantages and disadvantages of each usability evaluation method

Usability method	Advantages	Disadvantages
User-based	Most realistic estimate of usability	Time consuming
	Can give clear record of important problems	Costly for large sample of users
		Requires prototype to occur
Expert-based	Cheap	Expert-variability unduly affects outcome
	Fast	May overestimate true number of problems
Model-based	Provides rigorous estimate of usability criterion	Measures only one component of usability
	Can be performed on interface specification	Limited task applicability

which involves an HCI expert examining the application and estimating its likely usability for a given user population. In such cases, users are not employed and the basis for the evaluation lies in the interpretation and judgement of the evaluator. There is considerable interest in this form of evaluation since it can produce results faster and presumably cheaper than user-based tests.

In HCI, two common expert-based usability evaluation methods are Heuristic evaluation (e.g. Nielsen 1994), and Cognitive Walkthrough (Wharton *et al.* 1994). Both methods aim to provide evaluators with a structured method for examining and reporting problems with an interface. The heuristic method provides a simple list of design guidelines that the evaluator uses to examine the interface screen-by-screen and while following a typical path through a given task. The evaluator reports violations of the guidelines as likely user problems. In the cognitive walkthrough method, the evaluator first determines the exact sequence of correct task performance, and then estimates, on a screen-by-screen basis, the likely success or failure of the user in performing such a sequence. In both methods, the expert must make an informed guess of the likely reaction of users and explain why certain interface attributes are likely to cause users difficulties.

These methods differ in their precise focus. Heuristic methods are based on design guidelines and ultimately reflect the expert's judgement of how well the interface conforms to good design practice. The cognitive walkthrough method concentrates more on the difficulties users may experience in learning to operate an application to perform a given task. In practice, usability evaluators tend to adapt and modify such methods to suit their purpose and many experts who perform such evaluations employ a hybrid form of the published methods.

3.3. Model-based Methods

Model-based approaches to usability evaluation are the least common form of evaluation but several methods have been proposed which can accurately predict certain aspects of user performance with an interface such as time to task completion or difficulty of learning a task sequence. In such cases, the evaluator determines the exact sequence of behaviors a user will exhibit through detailed task analysis, applies an analytical model to this sequence and calculates the index of usability.

The most common model-based approach to estimating usability is the GOMS method of Card *et al.* (1983), a cognitive psychology-derived framework that casts user behavior into a sequence of fundamental units (such as moving a cursor to given screen location or typing a well-practiced key sequence) which are allocated time estimates for completion based on experimental findings of human performance from psychology. In this way,

any interface design can be analyzed to give an estimate of expert users' time to complete a task. The model has shown itself to be robust over repeated applications (e.g. Gray *et al.* 1992), though it is limited to predicting time and only then, for error-free performance in tasks involving little or no decision-making.

4. COMPARISONS OF METHODS

The relative advantages and disadvantages of each broad method are summarized in Table 1. Since usability evaluators are trying to estimate the extent to which real users can employ an application effectively, efficiently and satisfactorily, properly executed user-based methods are always going to give the truest estimate. However, the usability evaluator does not always have the necessary resources to perform such evaluations and therefore other methods must be used.

HCI professionals have recently reported comparisons of evaluation methods but few firm conclusions can yet be drawn. John and Marks (1997) compared multiple evaluation methods and concluded that no one method is best and all evaluation methods are of limited value. Andre *et al.* (1999) attempted a meta-analysis of 17 comparative studies and remarked that a robust meta-analysis was impossible due to the failure of many evaluation comparisons to provide sufficient statistics. Caveats noted, several practical findings follow:

- It is generally recognized that expert-based evaluations employing the heuristic method locate more problems than other methods, including user-based tests. This may suggest that heuristic approaches label as problems many interface attributes that users do not experience as problems or are able to work around.
- The skill-level of the evaluator performing the expert-based method is important. Nielsen (1992) reports that novice evaluators identify significantly fewer problems than experienced evaluators, and both of these groups identify fewer than evaluators who are both expert in usability testing and the task domain for which the tool under review is being designed.
- Team or multiple expert evaluations produce better results than single expert evaluations.
- Finally, there are good reasons for thinking that the best approach to evaluating usability is to combine methods e.g., using the expert-based approach to identify problems and inform the design of a user-based test scenario, since the overlap between the outputs of these methods is only partial, and a user-based test normally cannot cover as much of the interface as an expert-based method. Obviously, where usability evaluation occurs throughout the design process, the deployment of various methods at different stages is both

useful and likely to lead to greater usability in the final product.

5. CONCLUSION

Usability evaluation is a core component of user-centered systems design and an essential competency for Human Factors professionals working in the software domain. Test methods vary from laboratory studies of user performance to model-based predictions based on an examination of the interface specification. Choosing among methods is largely a matter of determining what information is needed and at what stage in the development cycle is the evaluation to occur. It will be difficult for an expert examining a prototype to predict user satisfaction, for example, or for a user to reliably estimate her own efficiency from an interface specification, hence the need for more than one type of evaluation method. Clearly, the ultimate test is the behavior of real users interacting under normal working conditions and any single usability evaluation method is an attempt to predict some or all of the issues that will occur in real use. Improvements in evaluation methodology are therefore tied directly to increases in the theoretical analysis of the determinants of use.

1. INTRODUCTION

Ergonomics, which focuses on the design of human–machine systems with respect to requisite compatibility between the users, products, systems, and environments, is often faced with the complex and uncertain relationships between human characteristics, various artifacts, and human activity requirements (Karwowski 1991). Investigation of such relationships must take into consideration the natural fuzziness in human and system performance, which can be expressed in terms of degrees of vagueness, and which formally can be modeled through gradation in categories (Zadeh 1965). Uncertainty due to fuzziness is inherent to any complex system and to the human thought and perception processes (Smithson 1982). It should be noted that fuzziness, which measures the degree to which an event occurs, and not whether it occurs, differs from randomness, which describes the uncertainty of event occurrence. (Kosko 1992). Furthermore, fuzziness, i.e. a type of deterministic uncertainty, also models ambiguity as a property of physical phenomena.

In order to study complex human–machine systems it is necessary to use modeling approaches that are approximate in nature (Zadeh 1973; Karwowski 1983). Fuzzy systems methodologies allow accounting for human and human–artifact fuzziness, and, therefore, provide the necessary framework for successful modeling efforts in the ergonomics (Karwowski 1991; Karwowski and Mital 1986). As fuzziness occurs at all levels of human interactions with the outside environments, ranging from physical to cognitive tasks, it can be used as the model for human–artifact interactions. It can also help to explain the complex phenomena of human sensation, information processing, decision-making and communication and functioning (Karwowski 1991, 1992; Karwowski and Salvendy 1992).

2. HUMAN–MACHINE FUZZINESS

Contemporary models used in ergonomics utilize formal structures to represent the human–artifact–environment reality as perceived by the human operator (Karwowski *et al.* 1999). However, the process of human perception is intrinsically governed by the natural fuzziness due to the human (human fuzziness), and by complexity and related uncertainty of the system under observation (human–machine fuzziness). Fuzziness is a useful model for human language and categorizing processes, and fuzzy mathematics can be used to augment conventional statistical techniques in the analysis of fuzzy data, reliability analysis and regressions, and structurally oriented methods such as hierarchical clustering and multidimensional scaling (Smithson 1982). In view of the above, fuzzy systems provide a useful framework for modeling variety of complex tasks, situations, systems, artifacts and environments, and their interactions with people.

For example, an assessment of resource demand or mental workload imposed on human operators in human–machine systems is of great importance to assure acceptable levels of performance (Wickens 1987). The measures of mental workload, such as those of perceptual–cognitive effort or response loading, are fuzzy phenomena, by the very nature of the underlying processes (Karwowski 1992). Therefore, the assessment methods must exhibit fuzzy properties of the investigated systems. As fuzziness occurs at many levels of cognitive processes, people have the unique ability to understand and apply vague and uncertain concepts (Hersh and Caramazza 1976). Research in semantic memory showed that people perceive natural categories as sets with no clear boundaries separating members from non-members (McCloskey and Glucksberg 1978). People are also able to comprehend vague concepts of the natural language, as if fuzzy labels represented them, and manipulate them according to rules of fuzzy logic (Oden 1977).

2.1. Human Performance

Human functioning can be described in terms of perception, information processing and decision-making, memory, attention, feedback, and human-response processes. Any task requires processing of information that is gathered based on perceived and interpreted relationships between the system elements. According to the model of human information processing (Wickens 1984), the sensory information coming from the sensor organs is compared to some internal representation of the recognized object stored in the permanent (long-term) memory. After the stimulus is identified, a decision can be made regarding the appropriate course of action. The decision process may require some transformations of the available information in the working memory, information storing in the long-term memory, and generating a response. The response can be realized through a process of coordinated muscular control actions, which effects are perceived through the feedback system. An inherent fuzziness of these natural processes is discussed below.

2.2. Perception and Memory

The purpose of the human perceptual system is to provide sufficient conditions for adaptive behavior (Foley and Moray 1987). Perception is constructed by the observer rather than determined by parameters of physical signals received from the receptors. The process of conscious perception is a fuzzy one, with uncertainties as to the physiological thresholds for physical stimuli, pattern recognition, and judgment requirements. For example, a question of "At what frequency will an intermittent light be perceived as just flickering?" is an ambiguous one, and hence the eye flicker frequency is a fuzzy, not random, phenomenon, as it refers to the degree of noticeable flickering rather than the question of whether it occurs (Karwowski 1992).

Many of the psychophysical laws that relate the magnitude of change in physical stimuli (DI) that will just be noticed by an observer, also exhibit requisite fuzziness. In the Weber-Fetchner Law, the magnitude of change in a physical stimulus that will be just noticed by an observer is a constant proportion of the

stimulus. Referring to the magnitude of DI that will result in a judgment of a difference in the levels of physical stimuli 50% of the time (so called just noticeable difference or jnd), this law is not a probabilistic statement of whether the perception of change will occur. Rather, it concerns the question at what level (degree) of the difference in physical stimuli such a change will be observed.

Human ability to process information from different stimulus objects at one time is limited. However, several dimensions of a single object can be processed in parallel (Wickens 1987). The degree to which many sources of object the human brain can process stimuli and different dimensions of the same objects exemplifies the fuzzy nature of human perceptual and central processing processes (Karwowski 1992). In the human–computer system, information displayed on the screen can be arranged along a continuum that defines the degree to which that information is spatial-analog in nature (i.e. information about relative location, transformation or continuous motion), linguistic-symbolic or verbal. The two end points of this verbal–spatial continuum distinguish the verbal and spatial memory systems (Wickens 1987). The border between these two systems, however, is subject to fuzzy interpretation. For example, the capacity of working memory is limited to 7 (+/-) 2 of the unrelated items (Miller 1956). The important question is to what degree one can recall and operate on a given number of items. The degree to which the memory is short or long is also a fuzzy category (Karwowski 1992).

2.3. Attention and Decision–making

Attention is the ability to process information in parallel or time-sharing fashion (Wickens 1987), which can be measured by the graded (fuzzy) categories of success. The selective allocation of human attention is determined by the human operator's internal model of the statistical properties of the environment (Moray 1984). Decision-making and diagnosis in human–machine systems are also of uncertain nature. Decisions are typically followed by responses, many of which are intrinsically fuzzy. It should be noted here that the prevalent definition of the relationship between choice reaction time and degree of choice (the Hick-Hyman law) is based upon the information content of a stimulus (S) in bits as follows: $RT = a + b\,S$. The presence of human fuzziness cannot be overlooked in the paradigm of stimulus—response compatibility (Wickens 1987), which described the physical relationship between a set of stimuli and the speed of human response. The spatial relations in arrangements of signals and response devices with respect to direction of movement and logic of adjustments, often exhibit high levels of uncertainty regarding the effects of intended and unintended control actions (Karwowski 1992).

2.4. Human Sensations

Traditional methods for quantification of the relationships between human sensations and physical characteristics affecting them are based on multivariate analysis techniques such as multiple regression analysis and quantification theory. With higher order data, however, it is more difficult to find an adequate formula that would represent the non-linearity factor. In addition, conventional methods have typically excluded the ambiguities that can arise in the process of recognizing and making subjective

evaluations of the physical characteristics. Shimizu and Jindo (1995) developed a model accounting for non-linearity property of information processing. The benefits of the fuzzy approach is that uncertainties and non-linearity of human sensations can be accounted for and quantified in order to derive correlations with the considered physical characteristics of the product.

2.5. Mental Workload

Mental workload is the amount of mental effort necessary to perform a given task. Mental workload assessment can be used to maintain a workload level allowing acceptable performance (Proctor and Zandt 1994). Subjective assessment techniques are based on empirical methods that measure workload directly in an operational system or a simulated environment through the use of human operators' judgments. The operators are asked to rate the perceived mental effort, time load, and stress load of particular tasks. Therefore, workload is not as a scalar quantity, but rather a vector quantity associated with multiple dimensions (Moray 1982). The subjective measures of mental workload utilize the scale method, which calls for the subjects to express their feelings through rating scales or questionnaires. Unfortunately, a precise scale often cannot represent the human feelings adequately. Using the linguistic quantifiers can help to overcome this difficulty, as evidenced by recent applications of fuzzy methodologies to risk analysis with mental workload assessment (Liou and Wang 1994; Chen 1996).

2.6. Human Cognitive Processes in Industrial Tasks

Ukita *et al.* (1996) described a fuzzy-based system to model the decision-making process of the human operators involved in tuning of microwave circuits in a real-time environment. The process was automated through the application of a fuzzy knowledge-based system. In a complex tuning process, multiple circuit specification criteria have to be simultaneously satisfied by several trimmers. To reduce the number of trial-and-error steps required to meet specific circuit tuning criteria, and, consequently, the tuning process time, the order of subsequent trimmer adjustments in the tuning process, as well as the extent of each individual trimmer tuning magnitude, must be chosen very carefully. In the past, experienced workers, who would skillfully adjust a set of trimmers by hand, performed the circuit tuning process. The quality of the adjustment process was primarily based on the human operator's mental model of the circuit tuning behavior formulated from the long practice and requires specific cognitive skills of the human operator. Ukita *et al.* (1994) proposed to account for the effect of each trimmer on each of the tuning criterion by a grade of fuzzy membership related to the circuit output. The overall effect of each trimmer on the circuit tuning performance was modeled by an aggregation of the fuzzy grades used for trimmer selection. The model simulation showed that the geometrical average operator was the best method for evidence aggregation of fuzzy evidence in modeling of the human cognitive processes underlying manual circuit tuning tasks.

3. HUMAN–MACHINE RELIABILITY

Human reliability is typically defined as a probability that a person correctly performs some system-related activity in a required time period, or as the probability of a successful performance of a

task. However, given the natural fuzziness of human interactions with the outside world, both probabilistic and possibilistic approaches to human reliability are needed (Terano et al. 1983). Since the human operator characteristics which affect the reliability include such fuzzy processes as sensory perception, motor control, cognitive functions (information processing and decision-making), and meta-cognitive functions (intuition and abstract processing), human reliability models must allow for qualitative reasoning through human error possibility measures, and should account for natural vagueness of higher cognitive functions. Onisawa (1988) proposed the concept of human error based on the possibility measure that is affected by several human performance-shaping factors. Pedrycz (1990) also discussed cognitive aspects of information processing and proposed a fuzzy framework for development of human perception perspective as opposed to machine perspective.

4. FUZZINESS IN HUMAN—COMPUTER INTERACTION

The interactions between people and computers often reflect the cognitive fuzziness of the data, as well as users' uncertainty exhibited in perception of the computing environment. The field of human–computer interaction (HCI) focuses on developing effective models of such inter-relationships, including the fuzzy-based communication tools. Karwowski et al. (1990) discussed the problems of fuzziness due to high complexity of human–computer systems and the nature of user's perception and information processing.

4.1. Fuzzy GOMS Model

According to GOMS model (Card et al. 1983), the user's cognitive structure consists of the following four components: (1) a set of Goals, (2) a set of Operators, (3) a set of Methods for achieving the goals, (4) a set of Selection Rules for choosing among competing methods for goals. Karwowski et al. (1990) proposed extensions to GOMS to account for uncertainty within selection rules and to generalize the Goals, Operators and Methods components as either precise or fuzzy. The Selection Rules were also expressed in either probabilistic or fuzzy variables. A variation of the manuscript editing experiment by Card et al. (1983), with the subject verbalizing five different cursor placement rules, was used. The fuzzy GOMS model utilized the sets of Goals and Operators that were precisely defined, while the (predicted) Methods used by subjects, as well as specific Selection Rules applied to accomplish the editing task included application of linguistic descriptors, fuzzy logic, and possibilistic measures of uncertainty. The rules, methods, and corresponding membership functions were elicited from the subjects, and theory of possibility was used to model the subject's rule selection process. Each of the potential rules was assigned a possibility measure equal to the membership value(s) associated with it during the elicitation phase of experiment. The non-fuzzy GOMS model successfully predicted 58.7% of the responses, while the fuzzy GOMS model predicted significantly more correct responses, i.e. 82.3% of all decisions (Karwowski et al. 1990).

4.2. Computer Screen Design

Effectiveness of the human interactions with computer systems depends to a large extent on computer screen design (Tullis 1981).

Among well-defined relationships between screen formats, there are many rules of thumb, which are based on subjective views and anecdotal knowledge (Grobelny *et al.* 1995). Limited empirical data and lack of consistent measures and quantitative criteria for assessment of screen quality makes the evaluation of system efficiency and comparison of different screen designs difficult. Fuzzy-based linguistic patterns for assessment of the computer screen design quality have been proposed. The linguistic patterns are based on intuitive expressions closely related to natural language and truth-values. The proposed system of concepts, relations and definitions, includes: (1) the implication and definition of linguistic variables, (2) a degree of truth of an implication, (3) intensity levels of implication variables, (4) degree of truth of the consistency of two expressions, (5) definitions of linguistic relationships, and (6) definitions of modifiers for linguistic expressions and connectors.

For example, searching times for desired information can be reduced if the information presented on the screen is organized in groups of closely related items. Furthermore, the amount of presented information greatly influences the searching times. If groups are significantly larger than optimal, the mean group size becomes the main factor that can be used to predict searching times. The study demonstrated that it is possible to achieve rational and relatively easy to interpret assessment of different screen designs in the form of the degrees of truth (Grobelny *et al.* 1994).

5. PHYSICAL WORKLOAD

5.1. Modeling of Manual Lifting Tasks

Application of the psychophysical approach to setting limits in manual lifting tasks requires the subject to adjust the weight of load according to his or her perception of effort in order to minimize the potential for over-exertion or excessive fatigue. Karwowski (1983) and Karwowski and Ayoub (1984) applied fuzzy sets to model and assess the acceptability of stresses involved in manual lifting task. They hypothesized that a combination of acceptability measures of the biomechanical and physiological stresses leads to an overall (psychophysical) measure of lifting task acceptability.

Fuzzy modeling was also used to investigate the relationships between physical weight, its perceived heaviness, and size of load. Luczak and Ge (1989) noted that it is not clear why the handling of a small box with a certain weight is sometimes perceived heavier than handling a bigger box with the same weight (size-weight illusion). They asked the subjects to express the relationships between physical weight and its perceived heaviness. Load heaviness levels were expressed using fuzzy sets, including: "very light," "light, moderate," "heavy" and "very heavy." The derived relationships illustrate how fuzzy measures can be used to quantify natural fuzziness underlying human cognitive processes. Recently, Yang et al. (1998) extended the study by Luczak and Ge (1989) to Asian population of workers, focusing on load heaviness in relation to perceived weight lifted.

Following the 1982 study, Karwowski and his co-workers performed variety of research projects focusing on understanding of human perception of load heaviness, and fuzzy modeling of acceptable and safe weights for lifting tasks (see Yang *et al.* 1998; Karwowski *et al.* 1999). Recently, Karwowski *et al.* (1999) demonstrated experimentally that perception of load heaviness

is subject to fuzziness of human cognitive processes, and concluded that this phenomenon should be taken into account when setting limits in manual lifting tasks. Examples of other important studies in this area include development of the model of ergonomic workload stress index (Chen *et al.* (1994), and fuzzy knowledge-based decision support system for recommending the maximum acceptable weights of lift, based on data generated from the job severity index (Ngo *et al.* (1996).

5.2. WORK–RELATED MUSCULOSKELETAL DISORDERS

Work-related musculoskeletal disorders (WRMDs), such as carpal tunnel disorders, tendinitis, chronic muscle strain, and degenerative joint diseases, are a major occupational health problem (Karwowski and Marras 1997). These cumulative trauma disorders (CTDs) may occur when a force is applied repeatedly over a prolonged period to the same muscle group, joints, or tendons, and are linked to jobs that exhibit repeated or awkward postures. In order to implement adequate prevention and health program, it is necessary to document the relationships between work exposure (prevalence of job related risk factors in a production environment) and specific musculoskeletal disorders. From the perspective of CTDs prevention, a desirable situation is to predict the possibility of occurrence of CTDs in a given occupational setting. A fuzzy system methodology can be used to determine the possibility of occurrence of CTDs, given the available relationships between CTDs, risk factors and their severity level. It should also be noted that in many cases, the human-expert is the only available "measurement device" for observing, coding and classifying interesting data. Therefore, the linguistic expressions are more adequate and reliable tools for human analyses than precise numerical measurements in many real life situations. Zadeh (1978) introduced a concept of the linguistic variable, which enables an application of linguistic, expert-defined expressions. The main point of this approach is that natural language expressions describing level or intensity of a given value can be defined in appropriate spaces as fuzzy sets.

5.3. Fuzzy Modeling of CTDs

Theoretical framework for fuzzy modeling of the risk of cumulative trauma disorders (CTDs) was first proposed by Grobelny and Karwowski (1992). The developed conceptual model for quantification of risk for work-related musculoskeletal disorders was based on fuzzy logic, linguistic variables, and knowledge provided by the human experts. For example, the following linguistic proposition was defined with respect to work-related risks of CTD:

PROPOSITION:
B: IF Required force is BIG THEN Exposure time is SHORT
C: IF Deviation from neutral posture is BIG AND Required force is BIG THEN Exposure time is VERY SHORT

The logical expressions (A AND B AND C) were defined using the "General Desired State Patterns" (GDSP), i.e. "natural" descriptions that constitute a basis for a formal assessment of working environment. The GDSP can be compared with risk factors associated with any industrial job to generate the logical truth-values: FALSE or TRUE, respectively, for jobs fulfilling or not fulfilling the above pattern. This was done according to the principle of implication (truth value determination).

For example, using the categorical risk descriptors (HIF — high force, HIR — high repetition), a general pattern of "desired conditions for repetitive work of the hand" was defined as follows:

PROPOSITION:
A: IF Force is HIF THEN Exposure time is SHORT, AND
B: IF Repetition is HIR THEN Exposure time is SHORT, AND
C: IF Force is HIF AND Repetition is HIR THEN Exposure time is VERY SHORT

Assuming the values of measured risk factors for CTD to be: Force = 8 kg, Repetition = 0.8/s and Exposure time = 10%, one can set the values: HIF(8) = 0.8, HIR(0.8) = 0.8, SHORT(10) = 0.5, and VERY SHORT (10) = 0.25.

The following formula proposed in multivalued Lukasiewicz logic (Grobelny 1988) can then be used:

If p and q are both truth values of P and Q statements, respectively, then truth value of implication

P => Q can be calculated according to: T (P => Q) = min (1, 1 - p + q)

in order to assess the values of this PROPOSITION as follows:
A: min (1, 1 - 0.8 + 0.5) = 0.7
B: min (1, 1 - 0.8 + 0.5) = 0.7

Also, the "min" operator defined in the Cartesian product of relationship space was used to represent the relationship "AND". According to this rule, the left side of the sub-pattern C for exemplary data (Force = 8 kg, Repetition = 0.8/sek) can be evaluated as follows:

min(HIF(8 kg), HIR (0.8/sek)) = min (0.8, 0.8) = 0.8, and consequently: C: min (1, 1 - 0.8 + 0.25) = 0.45

Using the "min" operation for evaluation the whole pattern: (A AND B AND C):

T (PROPOSITION) = min (0.7, 0.7, 0.45) = 0.45.

The "possibility measure" (Zadeh 1978) allows to widen the proposed approach to situations when the input data to PROPOSITION is fuzzy. Assuming that it is possible to obtain a reasonable system of linguistic representations for problems modeled by PROPOSITION, the following expert's opinions could be possible:

Force is ABOUT 4, Repetition is HIGH, Exposure time is MEDIUM. Having all parameters defined and implemented on a computer model, the user can derive the general "pattern satisfaction index", as well as the sub-pattern truth-values, expressing quantitatively the relative CTD risk at the workplace.

Recently, Bell and Crumpton (1997) also proposed a fuzzy linguistic model for predicting the risk of carpal tunnel syndrome (CTS). The model utilizes fuzzy sets to quantify the risk associated with development of this neuropathy. The first set of membership functions involved utilizing the linguistic risk level obtained by the expert knowledge acquisition. The second set of membership functions was derived to rate the possibility of the hazard associated with a particular linguistic variable. The membership functions of the two variables were intuitively determined based on graphical representation of the physical data.

6. CONCLUSIONS

Fuzziness represents natural vagueness and uncertainty inherent to any human–artifact–environment systems. Fuzzy systems

methodologies allow accounting for the human and system fuzziness, and provide a useful framework for investigating the requisite human—system compatibility, and for modeling in the human factors and ergonomics discipline in general. Designers should treat the fuzziness in human performance as natural system requirement.

Human Factors Testing and Evaluation

S. G. Charlton
Department of Psychology, University of Waikato, Private Bag 3105,
Hamilton, New Zealand

1. INTRODUCTION

It can be argued that human factors testing and evaluation is among the most applied of endeavors within an avowedly applied discipline. Testing and evaluation occur near the end of a long human factors chain of basic research, applied research, and product design. Yet, for a variety of reasons, the procedures and findings of tests are not widely disseminated or read, and human factors testing and evaluation remains a somewhat insular discipline. This article explores some of the similarities and differences between human factors testing and the more familiar practice of basic human factors research, in the hopes of making testing more accessible to the wider human factors community.

At first blush, basic human factors research and human factors testing and evaluation would appear to have much in common. Laboratory researchers and testers often share a common background and use similar terminology and techniques. The differences between the two disciplines only become apparent when we survey their goals, work environments, practices, and products.

2. THEORETICAL INTEREST VERSUS PRAGMATIC UTILITY

It has been argued that human factors fieldwork in general and testing in particular too often focus on test-specific measures, failing to address important theoretical issues and the advancement of general human factors knowledge (Mackie 1984). In counterpoint, human factors testers have decried the topics and methods chosen by laboratory researchers as being overly simplistic and of little practical application (Meister 1986).

Academics and students new to the practice of human factors testing are often disconcerted by the expediency and pragmatism required by the testing environment. Experienced testers, on the other hand, may have little tolerance for the details of a key theoretical conundrum, preferring instead to scan the methods section in the hopes of finding useful procedures or forms for field use. These contrasting outlooks, theoretical interest versus pragmatic utility, underlie many of the differences between human factors testers and human factors researchers.

3. WORK ENVIRONMENT

Testers' predilections for pragmatism over theory arise in part from the people involved in testing and who they work with. Whereas a doctorate or other advanced degree is often a prerequisite for academia or research laboratories, these qualifications are seldom needed by testers. In the world of test and evaluation a PhD may actually mark an individual as potentially abstruse or difficult until proven otherwise. One of the defining features of the work environment enjoyed by academics and laboratory researchers is the collegial company of other members of their discipline. In contrast, someone employed in test and evaluation is typically surrounded by individuals with diverse backgrounds, training, and practical experiences.

This day-to-day isolation from one's peers has two effects on the human factors tester. First, human factors testers typically become staunch advocates for human factors as the only spokesperson for their discipline. Second, and somewhat paradoxically, it has the effect of making the tester more acutely aware of other perspectives, those of engineers, designers, and users. In fact, some of the most effective testing occurs when the individuals involved set aside the parochial issues of their own disciplines and coordinate their efforts towards the test program.

4. COVERAGE OF ISSUES

The contrasting outlooks of researchers and testers can best be seen in how they structure the objects of their work, laboratory experiments and tests. Whereas laboratory experiments are focused on one or even a few human factors issues, a test program will cover a potentially vast range of issues. Human factors tests often favor a "scattergun" approach, collecting data across many aspects simultaneously. The careful control of the laboratory is typically sacrificed for the more realistic, and more unpredictable, conditions of the field test. The measures and metrics employed are selected to fit the available test conditions and data management resources rather than out of allegiance to any theoretical perspective.

This "unprincipled" approach has led some laboratory-based researchers to argue that there should be a greater reliance on psychological theory in the selection of human factors test measures. These authors hold that a strong theoretical orientation provides a means of clarifying one's view of the world in designing a test and interpreting the data. In other words, human factors testing, when conducted from a particular theoretical model, would enable the tester to more readily identify the important system issues, focus test resources on those issues, generate predictions, and help to fill in where data is lacking (Kantowitz 1992).

These arguments have not been uniformly well received by the test and evaluation community. Their pragmatic sensibilities tend to reject any approach that carries with it a danger they will be drawn beyond the data in forming conclusions about the results of a test. Although the role of theory in guiding laboratory research is unchallenged, some testers have noted that theories can be seductive in their apparent ability to provide precise predictions about what will happen when a variable is changed in a new way. The danger of theoretical reification, treating the theoretical constructs as if they were real processes and mechanisms, makes many testers chary about relying on them to any great degree in human factors testing and evaluation (O'Brien and Charlton 1996).

5. OBJECTIVE AND SUBJECTIVE MEASURES

Another difference lies in the routine use of questionnaires to collect a variety of human factors test and evaluation data. Although objective performance data is collected for many tests, the cost of instrumentation and impracticality of factorial designs for an invariably short test schedule force testers to rely on test participants as data integrators and to report on many aspects of

performance. This reliance on subjective measures is an anathema to many laboratory researchers trained in a scientific method which worships at the altar of objectivity.

Even the content of test and evaluation questionnaires and interviews is viewed askance by many laboratory researchers. Instead of molecular questions designed to extract the greatest diagnostic value possible on a psychological state or operator task, test and evaluation questions are fairly high-order, asking test participants to integrate multiple aspects of usability and performance. Given the large number of issues to address, a test and evaluation questionnaire must adopt this high-order approach or run the risk of overloading the respondents with overly long questionnaires and compromising the operational fidelity of the test (Andre and Schopper 1997).

6. SAMPLE SIZES AND STATISTICS

Researchers and testers also differ in the statistical treatment of their data. Only rarely will a classical hypothesis testing model comparing control and experimental groups fit a test and evaluation programme. Because of the expense involved in conducting test and evaluation, sample sizes are typically rather small and the data contains a high proportion of ordinal and categorical measures from questionnaires. For these reasons, testers are more likely to use nonparametric statistics than their laboratory-based counterparts.

Testers also make extensive use of descriptive analyses and circumstantial relationships between variables rather than the cause and effect level of proof expected of a well-designed laboratory experiment. Regression analyses, for example, can be used to identify situations and operator tasks that are "at risk" or highly correlated with human error and poor system performance. This approach is analogous to the medical epidemiological approach specifying risk factors associated with a disease in the absence of causal data specifying the physiological mechanism of the disease (Charlton 1992).

When inferential statistics are used in test and evaluation it is to compare the test results to a system requirement or standard. Instead of comparing an experimental treatment to a control group, the comparison is to a specific criterion to achieve a "met" or "did not meet" evaluation of the system under test. The availability of clear criteria for human factors measures, however, is the exception rather than the rule. Although design standards do exist for the layout and anthropometry of an operator's workstation, they are seldom the limiting factors in larger systems. The more important issues in human factors testing involve presenting information and designing tasks so that system operators can correctly understand and respond to the information. Few criteria exist for evaluating the way system information is presented and for determining whether it is adequate to support a diverse and changing repertoire of operator tasks.

7. REPORTS AND PUBLICATIONS

Finally, given the differences between researchers and testers, it should come as no surprise that the product of their work is different as well. The results of human factors tests are documented in technical reports of various sorts. Because of their limited availability and nontraditional format, technical reports are regarded as nonarchival in many academic circles. Because technical reports do not go through the traditional peer review process (although they are subjected to considerable review and editorial scrutiny) they are viewed as of lesser merit than a journal publication. Because of its differences from traditional laboratory research, the subject matter of test and evaluation is often seen as not worthy of publication in journals and books. All of these conditions have conspired to keep some important findings out of the mainstream of human factors.

Although they frequently appear in the reference sections of journal articles, technical reports are difficult to find and obtain. Learning about the existence of an important technical paper is haphazard at best and obtaining a copy depends on the goodwill of the authors. Sometimes a report is not available because a government has restricted its distribution or because a company thinks it contains commercially sensitive information. Some reports do not fit the traditional format of literature review, method, results, and discussion. But it would be unreasonable to change them so they more closely resemble journal articles; they are written for a different audience and for quite different reasons.

Rather than review the literature or describe competing hypotheses, technical reports tell a human factors story to an audience more concerned with the system than with psychological principles. Most laboratory researchers would be ill-prepared to report human factors results in a way that makes sense to decision makers outside the human factors profession. Testers must focus on developing a compelling human factors story that places the findings in the perspective of whether the system passed or failed the test, and why.

In spite of all the differences between technical reports and mainstream books and journals, there is a wealth of information that human factors testers and test results can offer the laboratory researcher. Researchers looking for applied topics to pursue or even fresh ideas on existing areas of inquiry could readily find them in test and evaluation reports. Technical reports are also an underutilized means of verifying the external validity of generalizations made in the laboratory. Until they become more available and more palatable to academic audiences or until there is another conduit for reporting test and evaluation, their usefulness to other researchers will remain thwarted.

8. CONCLUSION

Human factors testing and evaluation is by necessity quite different than laboratory-based human factors research. Tests are dedicated to the evaluation of particular products and processes rather than explicating a theoretical question or general principle of human engineering. The methods of test and evaluation are more sensitive to practical expediency and resource constraints than laboratory research. Their extensive use of subjective measures and nonparametric statistics is unfamiliar and unsettling to many laboratory researchers.

The requirement to select issues and employ methods that are uniquely suited to the testing environment has created a situation where test results are seen as contributing little to the advancement of general knowledge about human factors. By the same token, laboratory research is often viewed as being out of touch with the "real-world" considerations of test and evaluation. Perhaps this article has shown that human factors testing and evaluation is no less worthwhile than traditional research, and ultimately it may serve the same goal: making the products

and processes used by humans safe, effective, and satisfying to use.

Human Factors and Ergonomics Testing

S. G. Charlton

Department of Psychology, University of Waikato, Private Bag 3105, Hamilton, New Zealand

1. INTRODUCTION

Testing brings out the best and the worst aspects of human factors and ergonomics. At its best, it takes knowledge and methods out of the laboratory and makes them available to the general population in the form of tools, processes, and systems that are effective, efficient, intuitive, and easy to use. At its worst, it can represent a battleground where the competing interests of developers and users, scientists and engineers, designers and financial managers, are locked in conflict over the cost, implementation, and even the purpose of system designs.

Human factors and ergonomics testing is conducted to verify the efficiency, safety, and user acceptance of products and processes. This is accomplished through the systematic measurement and analysis of a range of system characteristics, performance variables, and user opinions. There are numerous stakeholders in the test and evaluation process, each bringing different perspectives and motivations to the test proceedings and doing much to shape the how, what, and when of the testing, even the ultimate interpretation of the results. This attention exists not because of the intrinsic interest of human factors issues, but rather because the outcome of human factors testing often has profound implications for production costs, product sales, training, maintainability, and liability protection. Thus, human factors testing often has a significant impact on the ultimate design of new products, yet the issues considered during testing are invisible to the public.

Human factors testing occurs in a variety of forms, and for a variety of reasons, and as a consequence defies a simple characterization based on steps to be accomplished or features to be included. We can, however, consider some of the defining moments encountered in the life of a human factors test, and in doing so illustrate many of the issues and decisions that occur as a test moves from the earliest stages of planning through to execution and evaluation.

2. REQUIREMENTS DEFINITION AND SYSTEM DESIGN

The first defining moment for human factors testing occurs during the early stages of concept exploration and system design, the definition of system requirements and design specifications. The human factors characteristics of the design (e.g., physical ergonomics, software usability, operability, design for maintainability, training, and staffing requirements) must be defined in such a way that they are verifiable during test and evaluation. It is self-evident that the requirements will direct the design effort, but they will also determine the character and accomplishment of the test program. Yet the statement of human factors requirements is as difficult as it is important. The source of this difficulty lies in defining human factors requirements in testable terms with measurable criteria. All too often, consideration of what, if any, human factors requirements a new system or product should have is limited to the simple (and untestable) statement that it should be "user friendly."

Human factors and ergonomics requirements can be stated either in terms of specific design characteristics or in terms of their impact on human and system performance. Requirements based on design characteristics might refer to relevant anthropometric and ergonomic standards for physical sizing of equipment, locations of controls, labeling and display of information, and so forth. Defining human factors requirements in terms of their impact on human and system performance is practised less frequently and requires more analytical effort.

Typical performance-based requirements might state that the system should be designed to enable a novice user to operate it proficiently within 1 hour, prevent operator errors from causing any critical system failures, enable a trained operator to complete an average of 10 transactions within 30 minutes, or some other performance-based measure. Performance requirements adopt a functional or system perspective and individual system components (including operator interfaces, training programs, etc.) are designed to achieve the required performance levels (Andre and Schopper 1997).

3. TEST PLANNING

A second defining moment for human factors test and evaluation occurs in the development of the test plan. The test plan documents the structure of the test, the test participants, the data collection methods, and the analyses to be performed. The written plan may have important contractual and resource functions but it is not nearly as important as the act of test planning. The planning exercise confronts the tester with a number of important trade-off decisions between the degree of test control and the test fidelity, the expertise of test participants and their representativeness, and the comprehensiveness of measures employed and the expense of the test (O'Brien and Charlton 1996).

The first set of decisions confronting the test planner is the overall design and structure of the test. Some aspects of the test design may be determined by the type of human factors requirements that have been defined (if any). Consider the test implications of the two types of human factors requirements described earlier. Characteristics-based requirements will encourage a testing program directed at verifying whether human engineering design standards are met. Checklist evaluations of the anthropometry and even user preferences can be collected early on, using equipment mock-ups and prototype components.

In contrast, performance-based requirements treat the human user as an integral component of the system being designed. The inputs and outputs of the user in relation to the other system components become explicit factors in the evaluation of the design. Because the test must focus on human performance in the context of other system components, the test conditions are more constrained, often requiring a nearly complete system or at least a fully functional prototype to conduct the test.

The next consideration in test design is selection of the test venue and the test participants. The test venues range from the carefully controlled environs of the laboratory to relatively unstructured field trials. The degree of experimental control during a test is a trade-off with the operational realism of the test

conditions. By employing a controlled test scenario in a laboratory or simulator environment the researcher runs the risk of decreasing the representativeness of the test, hence the generalizability of the results produced. Laboratory situations and equipment configurations may differ substantially from the eventual products and conditions of use.

Similarly, while field tests may provide a more realistic portrayal of the ultimate use of the product or process, the multitude of factors outside the evaluator's control (bad weather, delays, data loss, etc.) and the expense of field testing may restrict the quality and quantity of the data produced. Nonetheless, there is an achievable balance between test control and test fidelity, and the system issues and design requirements will have much to do with the final selection of the test venue (Meister 1986).

A related issue concerns the selection of the test participants. Ideally the human factors tester would seek participants who are representative of the intended user population in terms of training and experience, and who are happy and willing to participate in the test, and in sufficient numbers for statistical reliability. But sometimes it may be difficult or inappropriate to obtain truly representative participants for testing an unproven system or product. In the classic case of aircraft design, highly experienced test pilots are used instead of "typical" aviators; this is for safety and because they add expertise to the design effort.

In other cases, time constraints may militate against the use of actual members of the intended user population. This is often the case in the design of new training systems. Rather than test a new training system by subjecting actual students to a lengthy and unaccredited course of instruction, subject matter experts and training professionals can be enlisted to thoroughly exercise and evaluate the potential training effectiveness of the system. The use of subject matter experts as participants carries with it the danger that the test may not capture problems relevant to the ultimate user population. For example, even highly experienced instructors may not detect a significant design flaw until they use the system to teach real students.

Furthermore, when participants are selected on the basis of their expertise, it may be difficult to obtain them in numbers sufficient for statistical reliability. In choosing between representative users and experts, the human factors tester must balance the needs of the test design against the safety, comfort, and availability of the test participants.

Test planning also involves the selection of measurement methodologies. For any aspect of human factors and ergonomics design there are always multiple metrics available to the tester. The measures used in a test are often selected out of familiarity and convenience and they very much depend on the expertise and capabilities of each tester. One test planner may favor a psychological research perspective whereas another may have an industrial engineering orientation, hence the test metrics they employ may differ quite substantially.

A more significant concern lies in the failure to select a comprehensive set of measures. Selection of measures that are insensitive or irrelevant to the design issues at hand may provide false or misleading human factors data. There is no standard suite of test measures, just as there is no standard system to be tested, so for each system a tester must select a set of measures that are relevant to the requirements and design issues, as well as being

comprehensive and appropriate to the test structure (Bittner 1992, Kantowitz 1992).

4. DATA COLLECTION

The next defining moment occurs as the test plans are implemented and data collection begins. Depending on when they occur, human factors tests can be quite dissimilar in their structure, the resources employed, and the conclusions that can be drawn from them. Early on, human factors and ergonomics testing can occur as part of the design and engineering work. Computer design tools, simulations, and physical mock-ups are often used by human factors testers to evaluate ergonomic and safety issues in what is sometimes called developmental test and evaluation. Component-level testing can assess the usability of prototype controls and displays and consider their implications for user performance. Testing at this stage is conducted to reveal and correct problems through a process of design, test, and redesign.

When one or more fully functional prototypes have been developed, testing can begin to focus on full-scale or end-to-end tests with representatives of the intended user population. The testing performed at this stage is somewhat independent of development and design activities. Sometimes called operational testing or acceptance testing, the goal is to determine whether the new prototype can meet the design specifications and requirements. It is typically conducted on complete production-representative articles under realistic conditions and sometimes involves comparison between competing products or systems.

Note that the degree of fidelity inherent (and necessary) is different for tests at various stages of system development. Tests occurring early in development are typically limited to laboratory-based components, whereas the production-representative prototypes needed for full-scale tests will only be available later in the development process. In this context it is important to view testing as a means of minimizing or mitigating the risk inherent in developing and producing a new product. As system development progresses towards production, changes to the design become more difficult and much more expensive to accomplish. The earlier a test can be conducted, the greater the potential savings in terms of costly redesign or engineering changes. Here again the tester is confronted with a trade-off decision: early test results may save a lot of money but only if they produce meaningful and representative results.

5. ANALYSIS AND EVALUATION

The final defining moment we will consider comes in the analysis and interpretation of the test data. A common difficulty with human factors measures used in test and evaluation, particularly those involving cognitive issues such as workload, situation awareness, and decision making, is that they do not possess definite criteria or "red line" limits. For these sorts of measure, testers will typically report the results in a narrative without making an explicit pass/fail judgment on the human factors measure in question. Alternatively, a tester may try to establish the measure's impact on user and system performance post hoc, either logically or through quantitative statistical methods such as multiple regression analysis.

Another evaluation issue can arise regarding the statistical methods used to determine whether a human factors criterion

was in fact met. There are many stakeholders in a system's development, each bringing quite different assumptions to the interpretation of test results. For example, application of data analysis methods used in academia would lead the tester to attempt a statistical proof that the system meets the human factors requirements (against the null hypothesis that the system doesn't meet the requirements). In order to demonstrate with some statistical certainty that the system can meet the requirements when fielded, the system must actually perform somewhat better than the requirement during the test (how much better will be a function of the type II error or alpha level required and the sample size used for the test).

Others involved in system development might reasonably adopt a quite different perspective on the data analysis; they might consider that the burden of proof is on the test to prove that the system doesn't work. Here the component or prototype under test would have to perform significantly worse that the requirement before receiving a failing grade. With large sample sizes and results that are clearly more or less than the requirement, these two positions are not in contention. But with small samples and results slightly above or below the criterion, the evaluator and developer can come into conflict over the conclusions to be drawn from the test data.

A final evaluation issue concerns the logical interpretation of test data. It is a common finding that human error rates are higher than the error rates for system hardware and software. Consequently, the operator is often portrayed as the bottleneck or limiting factor in system throughput, a problem to be solved by additional training. But in many of these cases it can be argued that design flaws are the cause of poor human performance. Furthermore, users will routinely attempt workarounds to make the system function effectively, often with the effect of masking true hardware and software reliability. This disagreement over the cause of poor system performanceæuser error versus designer erroræoften comes down to differences in design philosophy and is not easily settled.

6. CONCLUSION

This article has attempted to illustrate the human factors and engineering test process by describing four defining moments in testing: requirements definition and system design, test planning, data collection, and the analysis and evaluation of results. Each of these defining moments contains fundamental issues and trade-off decisions that must be confronted by the tester. The solutions are as diverse as the systems undergoing test, but they will have significant ramifications for ensuring the products and processes we develop are safe, effective, and satisfying to use.

Human Factors System Design

D. Meister

Consultant, 1111 Wilbur Avenue, San Diego, California 92109, USA

1. INTRODUCTION

The human factors engineering (HFE) orientation toward systems, equipment and products (SEP) design is that each new design (as well as an update or design revision) represents a problem (sometimes a complex one) to be solved by the design team. This is because there is no single design configuration which will satisfy what the customer wants for the SEP. There are always several alternative ways of designing the SEP, some of which are inadequate, others are marginally adequate, and others are optimal or nearly optimal. The problem is in finding the most effective.

The function of the behavioral specialist in design is to evaluate the effect of the design on the likely performance of the human, and to avoid undesirable effects by counseling other members of the design team who are usually engineers with varying backgrounds, but without behavioral training.

The behavioral specialist may also have direct responsibility for the design of the human–machine interface (HMI), the arrangement of those controls and displays that direct the SEP in its operations. The object of the specialist's concern has always been the human, but in the last quarter-century some HFE theorists have emphasized what they call "user-centered" or "human-centered" design (Norman and Draper 1986). Some believe that, in addition to or as opposed to designing an SEP to perform desired mission functions, design should enable SEP personnel to derive pleasure from their work. This is a rather far out point of view because any design geared to functionality (performing mission operations) will also attend to personnel factors, because any diminution of personnel efficiency will also reduce SEP efficiency. Nevertheless, the concept of human-centered design (however exaggerated) generally works to direct more attention to the human in the design process, and this is good.

The paradigm that guides behavioral analysis in design is SOR, which stands for stimulus-organism-response, because the human is a reactive animal. All actions are taken in response to external stimuli (events, phenomena, displays) or to internal ones (self-directed behavior). Design analysis methods usually involve *decomposition* to SOR.

Design in behavioral terms has a cyclical history (initial design analysis, detailed design, design testing, and production). Design is also viewed as an information processing problem. Successful design depends on answering a number of questions which are listed in Table 1. These questions, to which there are no automatically correct answers, will have to be answered again and again as the design becomes more detailed, because changes in design detail require changed answers. The answers to subsequent questions may also require a change in the answers to previous questions; much design involves this kind of *feedback*. For this reason one cannot think of SEP design as a linear process.

The remainder of the discussion will be oriented around how answers to the questions in table 1 are secured. Answering these

Table 1: Questions posed by the design problem

Initial Design Analysis

1. What is the scope of the design problem (is it 'new' design, update, or revision?) How difficult is the problem?
2. What type of SEP is involved (e.g. aircraft, automobile, word-processing computer, general purpose commercial product); and what parameters are involved as a consequence (e.g. visual factors, strength limits, cognitive decision making?
3. What questions about the details of the design problem must be answered?
4. Are all SEP requirements fully described in the design specification?
5. What behavioral implications (e.g. human thresholds) can be drawn from these requirements; and what further information is needed that stems from these implications?
6. What technology and information can be transferred from predecessor SEPs?
7. What characteristics does the human in the SEP have (e.g. specific constraints, like physical handicaps, or needs and desires to be satisfied by design)? How important is the human role in the SEP? because this determines how much emphasis the human will receive.
8. What is the human in the SEP required to do; what is it anticipated that s/he will do; what personnel requirements, if any, have been specified in the SEP requirements; how will the human's performance affect SEP performance?
9. What factors, technological and non-technological (e.g. money, time) will affect personnel and SEP functions?
10. What design tools, analytical or evaluational, should be used to assist in answering the preceding questions?

Detailed Design
(All the preceding questions may/will be asked as design progresses.)

11. What additional information must be collected and analyzed as a result of increasingly detailed design; and where can this information be found?
12. What are the various ways in which the SEP components (e.g. HMI) can be configured? How adequate is the HMI design?
13. What criteria should be used to decide among the various design alternatives? Which alternative is the best, considering all factors? What compromises must be made among competing performance criteria and design characteristics?

Design Verification
(All prior questions may still be asked, in addition to the following):

14. How should the evaluation of the final, total SEP be performed, including behavioral criteria and test methodology?
15. What last minutes fixes, if any, must be made to the SEP production model?

questions will involve the application of behavioral design methods listed in Table 2 (Meister 1985).

The first task of the design team, of which the behavioral specialist is a member, is to scope the nature of the design problem. This is an effort to determine how difficult the problem may be, what questions will be raised by the nature of the SEP under design, and (for the specialist particularly) what behavioral implications can be derived from SEP design requirements.

The scope of the problem is limited in part by whether the problem involves "new" design, an updated design, or a design revision. Unless the SEP is a complete novelty, which is very rare (e.g., the Apollo module), it will have predecessor SEPs which will probably have technology and information that can be

Table 2: Behavioral design methods

1. Training, experience and logic.
2. Function analysis: determination of functions to be performed from description to activity.
   Function allocation: assignment of task responsibility to human, machine, or both.
3. Task description: description of activity in SOR terms.
   Task analysis: determination of factors influencing task performance (includes graphic tools such as operational sequence diagrams and function flow diagrams).
4. Design evaluation methods: checklists, walk-throughs (verbal performance simulation), and comparison of design alternatives.
5. Rapid prototyping (user analysis and exercise of initial design versions).
6. Psychological research methods: performance measurement, interviews, questionnaires, scales.
7. Special measurement methods: workload estimation, situational awareness, human performance models, error and human reliability prediction, concept mapping.

transferred without change or only slight modification to the new SEP. For example, in designing a new aircraft, a highly successful navigation subsystem will be taken directly from an earlier model and installed in the new aircraft. If the SEP is an update, new capabilities must be designed, but everything else in the SEP will be undisturbed. If deficiencies must be revised, the nature of these deficiencies will serve as indicators to what must be changed. The components of the new system may have been tested in an earlier test phase, and if these tests have involved humans, the test data may be behaviorally useful.

Beyond all this, the nature of the SEP under design will alert the specialist to certain areas of potential concern: if the SEP is a device that will be operated in a complex environment, e.g., an aircraft, the nature of the HMI may well produce special problems; if the device is a general-purpose commercial product, special attention will have to be paid to simplicity and to determining user desires.

SEP requirements, as described in the customer's design specification, are another source of information. These specifications may or may not be highly detailed, but in any event they must be analyzed.

In all the preceding analyses, what the specialist will be attempting to determine are the behavioral *implications* of any physical requirement or SEP feature, and what the operator or user of the SEP will be required to do by the SEP.

The term "implications" means effects on the human of a design requirement or the nature of a physical structure of the SEP. For example, if the design requirement specifies that the SEP will be operated underwater, it is apparent that attention must be paid to the development of the human's protective equipment, vision constraints caused by water, etc. Implications are important. Technology eliminates manual operations to which the human has adjusted, and it replaces them with technology's own imperatives, which are not at all concerned with human predispositions. If one cannot keep up with technology, as some aged or handicapped cannot, so much the worse and one will suffer in the end. HFE is opposed to creating a technological world in which the human may be lost.

The design methods listed in table 2 help the specialist recognize potentially negative technological effects. These methods are of two types: (1) general-purpose logic and deduc-

tion, the training provided the specialist, and his or her experience; (2) methods specifically created for HFE design, e.g., task description and analysis (Luczak 1997). The general-purpose methods underlie the more specific ones. Only brief descriptions of the specific methods can be given here, but the references do contain more detail.

The overall goal of the initial design analyses is to determine the behavioral implications of the SEP's physical structure. This is a matter of training, logic, and experience. Fundamental to the discovery of these implications is the specification of what the SEP's mission requires the human to do and what the human is likely to do. Function analysis, task description, and task analysis are the primary methods the specialist uses to answer these questions. Logically, certain human activities require certain human functions. For example, if the human is supposed to receive information about system status, like altitude or bearing in an aircraft, a monitoring function is involved; if an automobile must be driven, this will involve tracking the dimensions of the highway.

Functions are important to the specialist because they may suggest alternative ways of implementing those functions. When pilots carry out their monitoring, stimuli may be presented in the form of individual scales or summary indicators, and displays may combine multiple items of information; the cockpit can be more or less computerized. It is fair to say that analysis of possible effects on the operator will proceed in parallel with determination of the alternative ways in which a function can be designed. If there are *N* possible ways of presenting stimuli, these must be winnowed down to a single one or at most a few alternatives. One way of winnowing them down is to apply various *criteria* (i.e., value judgments): technological adequacy (Can a function be implemented technologically?); cost (Will the cost for a particular alternative be exorbitant?); reliability (Will performance quality remain constant over time?). One of these criteria is behavioral — operability — meaning that if the function is implemented, will it impose too great a burden on the operators? For example, if the function is to be performed manually, will its performance exceed threshold limits? In that case the design alternative must be rejected. Threshold limitations may be physical (e.g., strength required to move a weight) or cognitive (e.g., excessive memory requirements); physical thresholds are easier to recognize than cognitive thresholds. That is because physical thresholds can be demonstrated in action, but cognitive thresholds are often covert. I believe that humans have certain preferred modes of cognitive functioning (stereotypes) and that when a design requires some violation of these stereotypes, human performance suffers.

A great deal has been said in the behavioral literature about user-centered or human-centered design. This is a version of the requirement to make work more pleasurable or gratifying to the worker. What it means is that much greater attention must be paid to user needs and desires.

In contrast to traditional design, which is largely determined by what the SEP is required to do (its mission), user-centered design is presumably driven by behavioral imperatives. HFE system design has always endeavored to prevent egregious violations of human limitations, but for various reasons that concern for the human has been limited (one reason is our limited knowledge of human capabilities and limitations). Now it is proposed

to somehow elevate behavioral considerations to the same importance as that of the mission. How this can be accomplished is unclear because of our lack of knowledge about how to translate desires into physical equivalents. If the SEP does not have a mission to perform, it is hard to see what the human in the SEP will be doing. Our own point of view is that the human in the SEP deserves the greatest consideration commensurate with our knowledge, but the SEP has no purpose other than that provided by the mission.

We have somewhat arbitrarily divided SEPs into special-purpose and general-purpose devices. A commercial aircraft is a special-purpose device because it cannot be operated by everyone; an automobile is a general-purpose device. Much greater attention to the user must be paid in general-purpose devices, because in many cases the user is also the *consumer* who will or will not purchase the device. The ignominious failure of the Edsel Ford in the 1950s is an example of a device that will fail (whatever its technological qualities are) if consumers will not purchase it.

How the designer includes user needs and desires in design is difficult to say. On a molecular level, designers have altered the position of ashtrays or seat belt locations to accommodate presumed user desires, but whether more molar desires can be accommodated is not clear. One method of ascertaining user preferences is called *rapid prototyping*, which came into fashion with the advent of the computer. Rapid prototyping is the development of one or several versions of a design product and then giving them to a sample of users to exercise, use, comment on, etc. Not only opinion data can be gathered in this way (I like device X because . . .), but also performance data (How well can the user use the device?). If it is feasible from a technological, cost, and reliability standpoint, the user's responses to the prototype will be used to modify the prototype and thus to come closer to the user's desires. This procedure was more difficult to perform when hardware (e.g., in the form of wood, plastic, etc.) was involved, but software has facilitated what is essentially design, not by rational methods, but by tryout.

3. DETAILED DESIGN

All design is iterative; all design involves both analysis and evaluation. All design becomes progressively more detailed, and so questions like the behavioral implications of design and their effect on the human are asked at successively later, more detailed stages. All the questions of initial design analysis reappear in detailed design, because the changed level of detail provides a new context for the earlier questions and may therefore lead to new answers.

The greater detail of design also leads to *feedback* of information affecting prior design decisions. We see this most clearly in rapid prototyping, because the information gained by exposing preliminary design versions to users leads to changes in these preliminary designs and perhaps even modification of more basic design concepts which were, until then, considered firm.

Rapid prototyping is the clearest illustration of the role of testing in detailed design. Testing always involves exposure of the design to a human subject, but *evaluation* is also involved. Evaluation is a judgmental process which accompanies testing (e.g. What do the test results actually mean?) but it may also be used outside of testing, as a form of checking the design alterna-

tive. One of the functions of HFE research is to derive what can be termed *guidelines* or principlesæstandards of acceptable design practice. These are often incorporated in checklist form, and published checklists are used to compare the features of a specific design with the guidelines to ensure that no design feature violates one of the checklist principles. Should this happen, presumably the designer would modify the design accordingly.

Checklist evaluation is a form of testing, but it is not conducted by exposing the design to subjects; it is conducted by the specialist alone and is a means of developing confidence in the design characteristics the specialist has created.

4. DESIGN VERIFICATION

During detailed design any prototype testing has been partial, to check on one or more of the design features of special interest to the designer. Such tests are often performed by providing users with simplified versions of a design, emphasizing features of interest and leaving others in skeletal form. There is no attempt to replicate realistic working conditions in the test, nor does the test verify the overall adequacy of the final system. This is the function of the *operational system test* (OST).

The OST endeavors to test the final preproduction SEP in a manner that replicates as much as possible the actual operational conditions under which the SEP will be used. The complete SEP is involved; subjects for the test (those who will exercise the SEP) are to be as similar as possible to eventual users (if they are not such users themselves).

A full-scale OST is a major test activity and will almost always involve extensive planning. One would hope that rapid prototyping would also involve such planning, but the procedure seems to encourage a certain conceptual sloppiness. The planning requires the development of an OST test plan which includes the following sections:

- *Purpose* of the test (Will the SEP perform its mission successfully; will test personnel encounter any inordinate difficulties; what if anything needs to be revised in the design?). The OST has overall general purposes, but there may also be more detailed, specific purposes (to test such and such a feature); all of them should be specified, so that none will be overlooked in gathering data.
- *Description of the system*. This is largely pro forma and becomes important only if certain subsystems are not to be included in the test.
- *Geographic location* of the test, test instrumentation, etc. Also largely pro forma, but desirable if others besides test personnel will read the final report. All these OST sections will find their way into that final report, so writing these things into the test plan gives one a leg up on that report.
- *Performance criteria*. These are all-important. How is one to determine whether the test actually verifies the adequacy of the SEP? Criteria which may be somewhat general (e.g., mission completion) must be decomposed into their component individual measures (e.g., follow a ground track at 500 feet altitude without deviation of more than ±100 feet to reach a specified destination 1500 miles from takeoff). The example is that of a highly sophisticated terrain-following bomber. For a product/equipment like an automobile, the mission performance measure might be in terms of handling qualities, e.g., handles well in curving around obstacles. Measurements in-

volve both objective performance criteria (e.g., tracking, speed) and subjective criteria (e.g., rating the adequacy of the design by the user, design features particularly liked or disliked). Regardless of the type of SEP, it is desirable to have test personnel express their opinion about design features; to have them do this, however, it is necessary to specify the features of interest and to provide measurement instruments (e.g., checklists, scales).

- *Test instruments* must be described in detail, unless they are in common use. All instruments for securing subjective data must be described in detail, because they are almost always developed for a specific test. If the instrument is in common measurement use (e.g., a photometer), one need only refer to the instrument manufacturer. If automatic measurement instruments are part of the operational equipment, this needs to be indicated.
- *Test procedures* describe how the OST will be conducted. If certain test functions must be performed at certain times, these must be listed. Test procedures should also include any conditions that must be compared (e.g., night/day operation, performance under varying sea states or traffic conditions). Ordinarily the OST is not a research study, where conditions are compared to determine the importance of variables. OST performance will be compared under varying conditions only if those conditions are important in routine use of the SEP.
- *Anticipated data.* It is advisable to list the categories of data that will emerge from the testing, e.g. number and frequency of specific errors and response speed. This is necessary because a plan must be developed in advance of the test data to permit a statistical analysis of those data; that analysis will in part depend on the nature of the data anticipated.
- *Statistical analysis* of the test data. The anticipated statistical analysis is critical to the OST, because unless it is specified in advance, the data collected may not be appropriate for a particular analysis.

The OST resembles a formal experimental study, but there are other ways of testing a new design to verify it. Usability testing can be performed in special laboratory facilities (in which case it would be much like OST). In one form of *usability testing* a new SEP is given over to actual users (companies), and the SEP is used in a routine way (Weimer 1995). There is less control over conditions of performance, but if the specialist imposes controls over that test, very realistic data can be obtained.

Although the OST and the usability test are the final situations in SEP design, they have consequences for the design process. If all goes swimmingly, production management can proceed to distribute its products. In many cases, however, the OST and the usability test will point to design features that must be corrected.

These final tests are unlikely to lead to complete rejection of the SEP, because it cannot perform its assigned mission; previous tests would have indicated something wrong that had to be fixed, and it would have been fixed. More common, however, is the revelation of a number of detailed design faults that need fixing; and among these faults may be behavioral deficiencies (e.g., inaccuracies in operating procedures, the placement of controls and displays vexatious to test subjects). Fixes for such inadequacies will be made immediately, if they do not involve "bending hardware" or changing software code. Other fixes that require some modification of the final design will require debate; engineering management prefers to rely on additional training of personnel, warnings in operator manuals, etc., to any but the most minor changes in the basic design. Behavioral specialists may have to argue long and loudly if they are to gain their way—if they do.

System design may appear to be over with completion of final tests, but this is an illusion; as was indicated previously, systems are updated to include features that were not in the original design (e.g., provision of multivariate displays to replace discrete indicators). Despite the best efforts of all involved, the final production design may eventually reveal inadequacies that absolutely require redesign. There is life after the original design has been completed. Like a crossword puzzle, the design problem may be completed, but since designs have only a finite existence, there will be other designs and other problems.

What has been presented is merely an outline, a skeleton, of what happens in every design process. The number of individual variations is very great, especially in a design process that is pursued over long periods. This is one of the things that is most fascinating about the design process — its almost infinite variation.

1. INTRODUCTION

Quality improvement is concerned with improving products, services, quality of work, design, manufacturing and decision making within an organization in order to satisfy both the internal and external customers. Such philosophy forms a basis for the quality management system (QMS), which aims to achieve the highest levels of business quality and productivity. Such a goal can be realized through different management methods, such as process reengineering, effective product design, employee involvement and teamwork, training in statistical techniques, and customer focus. As a result, a myriad of different quality standards, methods and awards systems have evolved in the recent past (ISO 9000, BS8800, Malcom Baldrige National Quality Award (MBNQA), European Quality Award (EQA), ISO 14000, ISO TC/159, Occupational Safety and Health Association (OSHA), American National Standards Institute (ANSI) Z-365, etc.), all of which focus on the continuous improvement in different areas of the organization.

There also many obstacles to achieving global quality, including the effects of rapid technological changes, increasing complexity of products and processes, rising production costs, customers resistance to price increase, increasing demands for employee well-being, and natural environmental protection. Recently, there has been increased emphasis on the continuous company-wide improvements that link quality, ergonomics, occupational health and safety, and (natural) environmental health.

Traditionally, the QMS solutions did not go far enough in addressing the complex varieties of organizational life (quality, ergonomic, safety, marketing, purchasing, human resource management, etc.), often resulting from the complex and conflicting needs and expectation of all stakeholders involved in the organization. Because of the strong ties between the product's quality defects, working conditions defects and operational defects, it is important to develop and implement a comprehensive model for the management system that integrates quality, ergonomics and safety (occupational and health and natural environmental) aspects of organizational performance.

2. QUALITY MANAGEMENT, ERGONOMICS AND SAFETY

2.1. QMS Theory and Practice

Market, capital, management, employees, motivation, materials, machines, information and product or service requirements directly influence quality of products and services. QMS is a management philosophy aimed at improving competitiveness, effectiveness and flexibility through planning, organizing, understanding each activity, and involving each individual at each level of business activities. This concept was adopted by the Japanese and renamed as the company wide quality control (CWQC). The main characteristics of the CQWC as practiced in Japan are:

1. Quality emphasis extends through market analysis, design, and customer service rather than only the production stages of making a product.
2. Quality emphasis is directed towards operations in every department from executives to clerical personnel.
3. Quality is the responsibility of each individual and work group, not some other group such as inspection.
4. There are two types of quality characteristics as viewed by the customer those that satisfy and those that motivate. Only the latter are strongly related to repeat sales and quality image.
5. The first customer for a part or piece of information is usually the next department in the production process.

The works of Deming, Juran and Cosby have extended concept of quality from purely a technical issue to the management issue. The concept of total quality management (TQM) established foundations for implementation of the ISO 9000, which was developed in an effort to address the consistent quality needs for growing international trade.

2.2. Ergonomics

Ergonomics seeks to design tool and tasks to be compatible with human capabilities and limitations with the purpose of providing work conditions that assures safety, health, well-being and efficiency. Many studies in industrial settings aim to reduce effort, improve process, quality and occupational safety. These applications have evolved over the years from the micro-ergonomics (design of individual workstation) to a macro-ergonomics approach focusing on design of the entire corporation. The importance of ergonomics to the improvement of quality of life, product and services in the industrial settings, has prompted some organizations to develop standards or guidelines at the following levels:

- Basic standards related to fundamental properties of humans.
- Functional standards related to ergonomics characteristics of equipment, processes, product and safety.
- Environmental standards related to the effects of physical factors of the environment on human performance in the range between comfort and health hazards.
- Standards for ergonomics test procedures and for processing ergonomics data to be applied either in development of standards in the above categories or in assessing conformity to already accepted standards.

In 1975, the ISO Technical Committee 159 on 'Ergonomics' was formed to develop standards in the ergonomics area. There are also other standards that were not produced by ISO. For example, the Occupational Safety and Health Association (OSHA) in the USA has recently drafted an ergonomics regulations that focus mostly on repetitive strain injuries, like lower back pain and carpal tunnel syndrome (CTS). The American Standards Institute (ANSI) Z-365 developed a procedure for managing prevention of the cumulative trauma disorders (CTD) of upper extremities.

2.3. Occupational Health and Safety Management Systems

Although working environment has improved considerably during recent decades, occupational accidents still occur as a result of inadequate workplace design. Such accidents constitute a major problem facing industry today. Occupational health and safety management focusing on employees is the fundamental responsibility of any organization. Safety can be defined as the state for which the risk (or probability) of a hazard-related incidents is judged to be acceptable. Traditionally, safety focuses on the control of loss, actual or potential, while safety management is the application of management principles to the issues of safety.

Safety management aims to prevent repetition of accidents that have occurred in the past. However, to create and maintain the safe working environment, management must depend on the proactive rather than reactive prevention efforts. To address this issue, many organizations (British Standards Institute, National Institute for Occupational Safety and Health (NIOSH), ANSI, etc.) have developed codes of practice, procedures, and management systems. etc. to augment management's effort in improving the working environment. The BS8800 — Occupational Health and Safety Management Systems developed in the UK is an example of such a system.

2.4. Natural Environmental Safety

The natural environment is defined as the surroundings in which an organization operates, and it extends from within the organization to the global system. Many organizations strive to achieve and demonstrate sound environmental performance by controlling an impact of their activities, products and services on the natural environment. This is partly due to the public and management concerns over the safety of products, human comfort, destruction of natural environment, and the high cost of compensation or clean-up expenses incurred as a result of accidents. The universally accepted ISO14000 Natural Environmental Management System can be utilized as the subsystem for integration purposes.

3. INTEGRATION OF QUALITY, ERGONOMICS AND SAFETY

The integration of quality management system with ergonomics or safety issues has received some attention in the past. Rahimi (1995) and Weinstein (1996) proposed approaches for integrating safety, health and environment into TQM, by advocating simultaneous and continuous allocation of resources to top-down and bottom-up engineering improvement, through well-organized self managed teams and parallel training systems with flattened organization structures. They attempt to bridge the gap between TQM and its applications to safety by outlining a process for developing and implementing a safety management system that incorporates TQM concepts with the ISO 9000 quality requirements and hazard specific technical mandates.

Eklund (1997) proposed an approach for ergonomics and quality improvement by integrating the ergonomics and TQM knowledge. The field of quality would gain by incorporating ergonomic knowledge especially in the areas of work design and human capability, since these factors are decisive for improving the human performance, while the quality of work is strongly influenced by operator. Luczak *et al*. (1998) pointed out that the

objectives of ergonomics and TQM have a close relationship through the MBNQA evaluation criteria, which covers product

quality, process quality and quality of working life. Recently, Zink (1999) proposed a model that shows how to integrate the quality aspects into a normative management frame. The proposed comprehensive change management process involves having a

vision for a set of commonly agreed goals. Such process is summarized in Figures 1–3.

Smith (1999) proposed an approach that applies the Juran's servomechanism model to illustrate the interaction of ergonomics

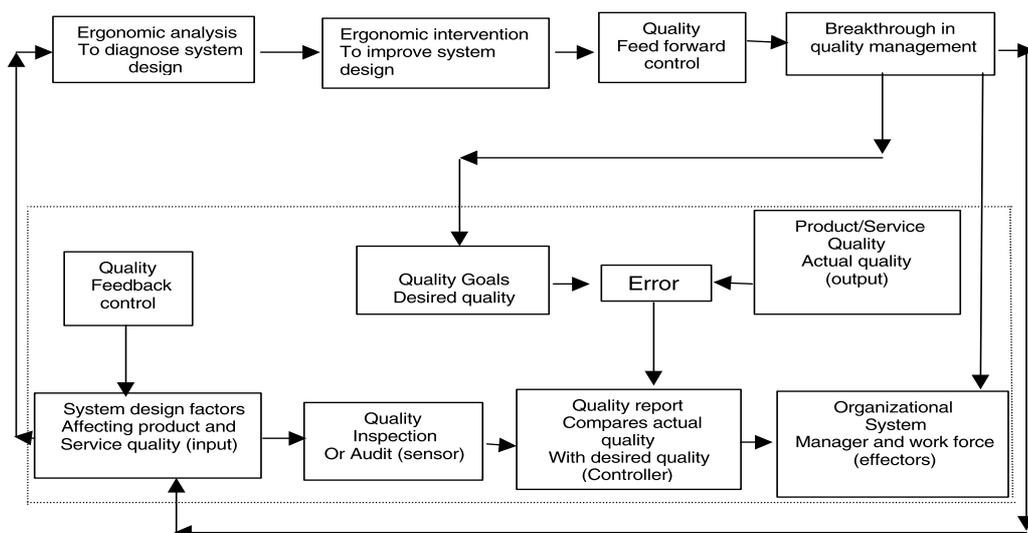

Figure 4. Model of breakthrough in quality management as a feed forward control process with ergonomic analysis and intervention specified as key contributors to feed forward control (modified from Smith 1999).

and quality. The servomechanism assumes that there is an unvarying sequence of events that occur in breakthrough from one level of performance control to the new (improved) level. This is mediated by comparing feedback from the actual system performance with performance targets. This approach is shown in Figure 4.

Carayon *et al.* (1999) presented a macro-ergonomic model of work design that takes into account not only the products and process quality, but also the quality of working environment. According to the model, TQM can influence different aspect s of work design and quality of working life (QWL). The proposed approach is shown in Figures 5 and 6.

Tables 1 and 2 show the major elements of quality, ergonomics, and safety under the traditional approach, and within-the-organization elements that interfere with the ergonomics principles. These elements influence the corporate strategy with respect to planning for quality and safety.

In many cases the production problems are not only related to ergonomics, quality or combination of these alone, but also to safety (occupational health, natural environment), as these problems are interwoven and strongly related. As a result, they must be managed simultaneously, with an integrated management system.

The analysis of the concepts of quality management, ergonomics, and safety, shows several identical elements, including leadership, evaluation and continuous improvement,

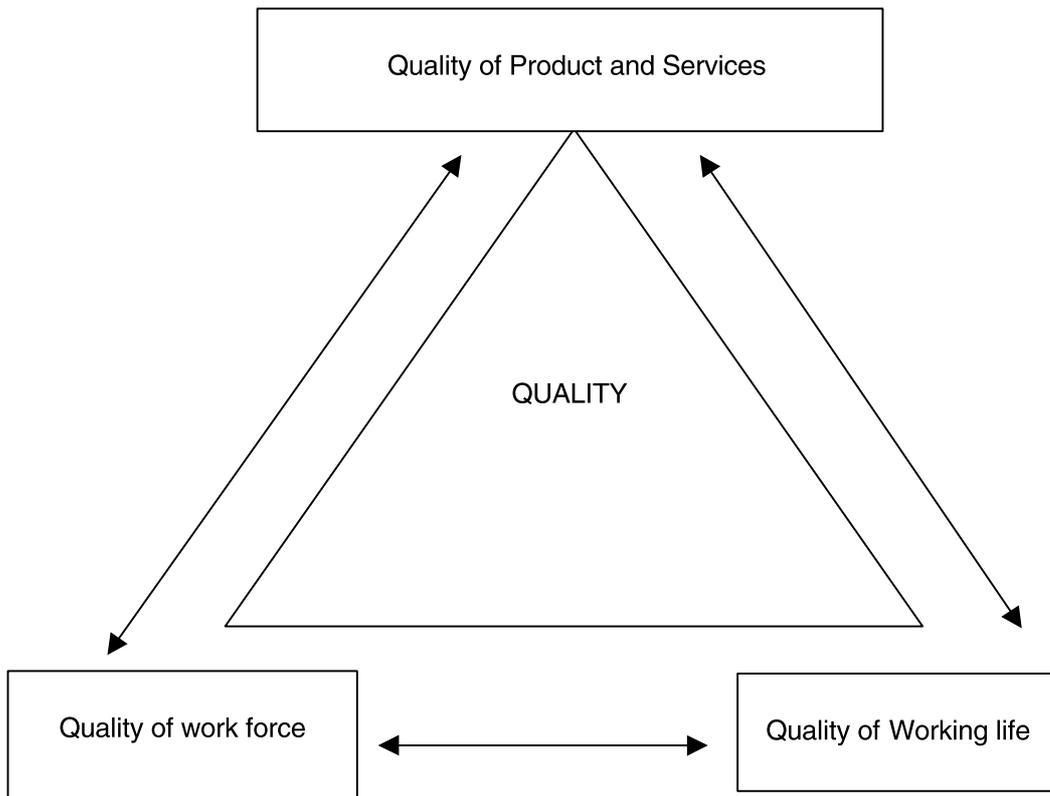

Figure 5. Three interrelated aspects of quality (modified from Carayon *et al.* 1999).

Figure 6. Relationships between TQM, work design and QWL (modified from Carayon *et al.* 1999).

Table 1. Traditional approach to quality, safety and ergonomics.

Safety	Quality	Ergonomic
Zero accidents	Zero defects	Zero work place defects
Incident analysis	Event analysis	Work site analysis
Written policies procedure and guidelines	Documented policies procedures and work instructions	Written policies and procedure
Safety committee	Quality circles, employee involvement teams	Ergonomic committee
Employee participation	Employee empowerment	Employee involvement
statistical analysis	Control charts, statistical process control etc.	Experts methods including some statistical tools
All accidents are preventable	All non conformers are preventable	All work place defects are preventable
Continuous improvement	Continuous improvement	Continuous improvement

Safety in work environment:
–Potential impendence for life and health, Physiopatological consequences of work (tiredness, diseases, injuries) etc.

human resource management, data collection and management, and participation and teamwork, etc. These elements constitute the main building blocks for quality management, whose fundamental core principles are focusing on the customer, participation and teamwork, effective measurement and continuous improvement. For example, TQM can be used as a suitable management framework for the integration of quality, ergonomic and safety. Thus merging ergonomics and safety efforts (occupational health and natural environment) with quality management will provide a single and coherent system that identifies all elements in relation to quality, ergonomics and safety, and helps to fulfill simultaneously different requirements related to standards, rules and regulations, guidelines (MBNQA), etc.

4. FRAMEWORK OF INTEGRATED QUALITY MANAGEMENT SYSTEM, ERGONOMICS AND SAFETY MODEL

Working conditions influence product quality, while productivity improvement is dependent on quality, macro-ergonomic and safety (occupational and health, natural environmental) management activities. System performance can be improved by minimizing productivity losses, injuries, accidents, environmental disasters and destruction, general well-being of all employee, and minimizing cost and time use for improvement activities.

Table 3 and Figure 7 illustrate the elements and relationships for integrating ergonomics, safety, and QMS. A framework of integration of quality management, ergonomics, and safety is given in Figure 8. This model is essentially an adaptation of the open system model for understanding the interactions between technological changes and organizational processes. Based on the management leadership and proper planning from the variety of perspectives (financial, safety, human resource, etc.), an organization utilizes all resources (information, material, people, etc.) to design

Table 3. Elements of the integrated set.

A
–Inspection activities (Sampling methods)
–Variability reduction methods
–Marketing and delivery strategies

B
–Ergonomic experts analytical methods, Task analysis, occupational safety

C
–Body dimension and structure in relation to work site (Antrhropology)
–Manual lifting, Postures etc.
–Physical pressure that can be endured
–Physical capabilities and limitations
–Accidents and hazards analysis in relation to work

D
–Hazards analysis in relation to the work and natural environment (Chemical, Physical, Biological)
–Machine guards, shield, warning signs
–Disposals (Toxic materials etc.)
–Emergency systems, Protective Clothing etc.

E
–External factors such as Technology (CAD, CIM etc.)

Common point

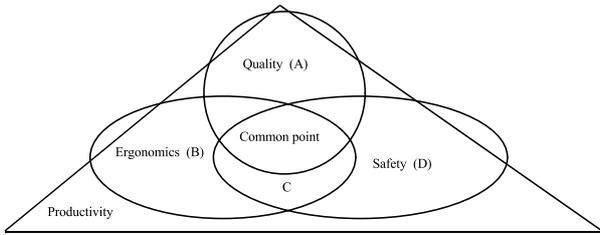
–Leadership, commitment, policies, and values in relation to quality, ergonomics and safety
–Vision priority and direction
–Provision of adequate resources
–Review performance set goals (quality, ergonomic and safety), auditing
–Employee involvement and empowerment
–Effective human resource management
–Continuous improvement activities
–Training and education (quality safety and ergonomic)
–Auditing and documentation
–Effective maintenance and installation practices
–Product and process development
–Equipment and material purchase
–Calibration and metrology services
–Statistical methods
–Defects and problem investigations
–Work instructions in relation to quality, ergonomic and safety
–Task analysis in relation to quality ergonomics and safety
–Cost benefit analysis
–Customer complaints and return product analysis
–Customer needs and expectations


Figure 7. Relationship between quality, ergonomic, safety and productivity.

the process and produce the product in a desired way. Organization also uses all of the internal (ergonomics surveillance, process defects identification etc.) and external (ISO9000, government regulation, etc.) information to perform continuous improvement activities.

Figure 9 presents the inter-relationships between the corporate growth and integrated ergonomics, safety, and quality management. This integrated model is made up of the inputs, planning, processes, continuous improvement activities, interventions, auditing, and outputs. The overall goal of the model is the combination of the goals of Quality, Ergonomic and Safety subsystems. From the early studies and observations, it is noted that these goals interact in several areas. Consequently, the quality, ergonomics and safety related problems must be solved simultaneously to attain these goals by adjusting certain variables or changing some conditions.

Figure 8. Framework of the integrated ergonomics, safety and quality management.

A. Quality deficiency analysis B. Ergonomic (work condition) defect analysis C. Safety (occupational and health and natural environmental) defect analysis

*OHSM (Occupational Health and Safety Management)
**EMS (Environmental Management System)

**Figure 9. Integration of ergonomics, safety and quality management in organizational development.**

In view of the above, the integrated continuous improvement system can be described as:

- Attaching equal importance to quality, ergonomic and safety related problems.
- Identifying the relationship between quality, ergonomic and safety related characteristics for simultaneous improvement.
- Minimizing system procedures by performing common functions and solving common problems simultaneously.
- Combining quality, ergonomics and safety activities in all system operations

5. CONCLUSIONS

The concepts of quality, ergonomic and safety (natural environmental, occupational and health) reveal several dimensions of corporate performance that interact with each other, thereby suggesting a need for the integrated system focused on the continuous system improvements.

Integration of Risk Management into Complex Management Systems

J. Sinay

Department of Transport Machines and Logistics, Technical University of Kosice, Kosice, Slovakia

1. INTRODUCTION

A high level of complexity is a typical feature of new technologies and new machine design. New machines and new machine technologies are more and more complicated. Their influence on the environment, ergonomics and human factors must be taken into consideration.

New development trends in the area of engineering also demands new technologies, new machine design, reliable control systems and new materials. Safety in the man–machine–environment system is a very important decision criterion for the correct exploitation of new technological systems. It is necessary to create conditions for the safe operation already in the phase of design of new machines or new machine technologies. These aspects of machine safety are not only important questions for designers but also they are integrated into the legislation of many countries throughout the world. It is the expression of national priorities in the area of work safety and health protection in the working process.

2. RELATION BETWEEN SAFETY AND TECHNICAL RISK

Technical safety is a very important function, i.e. the subject (machine, technology, operation) must perform its functions without any hazardous situations to persons or the environment. A hazardous situation is one in which a person is exposed to a hazard. A hazard is a potential source of harm. Harm is physical injury or damage to the health of people either directly or indirectly as a result of damage to property or to the environment.

All used methods for the analysis of global safety must take into account not only technical aspects of the safety of machines and devices, but also the protection of health and the environment.

Technical risk is defined as a combination of the probability of occurrence of harm and the severity of that harm (weight factor). For the computation of risk level, one must know real values for the probability of occurrence of harm and the values of severity of harm. If the final computed risk is greater then an acceptable level, the necessary measures for risk reduction or elimination must be performed. This process is risk management (RM), being one subsystem of global management of work safety. Safety here is a freedom from unacceptable risk.

RM (or "control of risk") is based on the three points: identification analysis, reduction and elimination of the risk. Europe has a new legislation framework for RM via the Directions of Council of European Union (EU), i.e. 89/391/EU, 89/392/EU, 93/44/EU and 93/68/EU on machine safety and health protection in the working environment.

89/391/EU is concerned with safety and protection of employees during the working process. According to it, an employer is obligated to evaluate the technical and human risks and to perform all necessary protective measures. To prevent risks, working conditions, social relations, environment, working organization and technical influences must be taken into account.

The most important Direction for machine safety is 89/392/EU (along with its supplements 91/368/EU, 93/44/EU and 93/68/EU). It legislates member countries about the safety of machines and machine devices; and its main purpose is to determine the requirements for safety and health protection during machine operation and also the creation of conditions for the free movement of commodities in the framework of the common European market.

An integrated part of International Standard ISO 14001 is the area of RM. Chapter 4.4.7 from this standard is devoted to the problematic of accident situations.

It can be stated that, according to ISO 9001, Part I, the employer has full responsibility for the activities of all managers at all management levels in the organization. After 89/392/EU the employer must integrate such activities like identification, analysis and evaluation of risks into one complex. (Everybody is also subjected to many risks at work and at home.) For this reason the employer, designer, operator, safety engineer and quality expert are obliged to identify, analyze, evaluate risks and perform the necessary measures for the reduction or elimination of them, i.e. to perform all activities within the framework of RM.

It is usually known that if there are often failures in the system, there will also be conflicts between safety and quality. Therefore, so-called "weak points" must be eliminated from complex systems

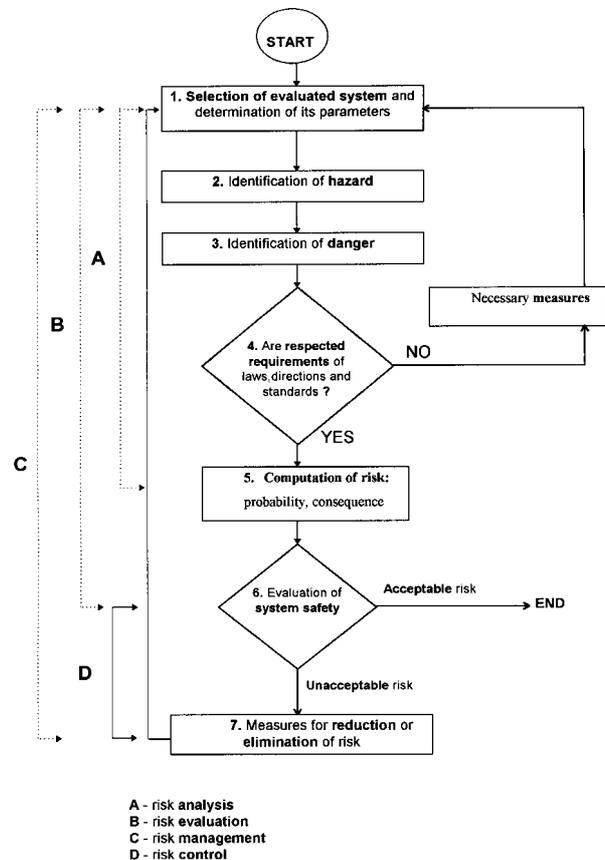

Figure 1. Activities of risk management.

to increase reliability. Accordingly, an increase of reliability means also the elimination of these weak points, and the elimination of the weak points means the minimization of risk.

The final efficiency and success of the working systems depends on the interaction of the quality of various components: technical means, organizational activities, people and social aspects.

The most important task is the control of the risk level in man–machine–environment systems, i.e. to reduce the final risk level and to obtain the so-called acceptable risk level. It is necessary from this to analyze and classify risks for the next minimization and for the realization of the whole complex of RM activities (figure 1) (Sinay 1997).

3. INTEGRATED MANAGEMENT SYSTEMS

ISO 8402 explains "quality" as a complex of properties of the subject that fulfills all determined and supposed requirements. Safety is one of very important components of quality. There are many common aspects and connections among the systems of quality management (QM), technical safety management and work safety, i.e. among the components of RM, which also includes the area of environment (Pischon and Liesegang 1997). Therefore, it is possible – like the first step – to integrate components of QM and the environment management system (EMS) into one complex system of QM by means of the total quality management (TQM) methods, and – like the second step – also to integrate the components of safety and health protection, e.g. in accordance with BS 8800/1996 (Guide to Occupational Health and Safety Management Systems). All three components of TQM are defined separately in the individual regulations, e.g. in ISO 9001, ISO 14001, EU 89/391 or EU/392. At present, there is no international or national standard that can define all three TQM components – quality, environment and safety, i.e. QM, EMS and RM – like one common base of properties of the final product.

QM, safety of technical systems, safety of work and environmental measures were separated from the organizational point of view in the past. There are many new international rules and

regulations for the technical safety and health protection that are integrated into the internal laws of countries. But it is not possible (or not so easy) to elaborate one common international standard for application in all industrial areas.

3.1. Purposes of the Integrated Management System

The main purpose of the integrated management system (figure 2) is the analysis of all partial goals in the company, the minimization of redundances and the exploitation of synergetic effect (Sinay 1997). This integrated system has many advantages, for example:

- A high level of quality.
- An increase insafety for technical devices and health protection.
- A better social acceptance of company.
- A better acceptance of environmental and safety legislation.
- The possibility of avoiding conflicts between companies and offices of state inspection.

3.2. Activities of the Integrated Management System

After creation of the integrated management system the main question is if all required aims have been achieved. There are three main categories of aims in connection with the newly created integrated management system: quality of production, safety of work and environment.

For the first category – quality – it is necessary to determine the criterion for the evaluation of quality of the final product. For the second category – safety – one must create the possibility of reducing the risk level and, above all, to define the residual risks. For the third category – environment – the question of used materials, storage systems and recycling processes is important.

Processes and technologies in man–machine–environment systems and also the final products are the subjects of an analysis in the framework of the RM (Leist 1997).

3.3. An Example of Management System Activities

An example of the integration of QM, RM and EMS activities into one complex management system (from the area of the pipeline transport systems) is shown.

During the transport of various material mediums in the pipeline system, the quality of the transported medium/material must be secured in accordance with the given specifications and requirements, i.e. this is the area of QM.

Next, a very important question is the possibility of the material leakage into the environment. From this point of view are defined the conditions for proper dimensioning of the pipeline, for the right choice of the pipe material, for protection of the pipe surface and for the surface protection paints. In such a way technical safety and the environment are joined.

Both the assembly and maintenance works demand performance of activities of the RM and environment management.

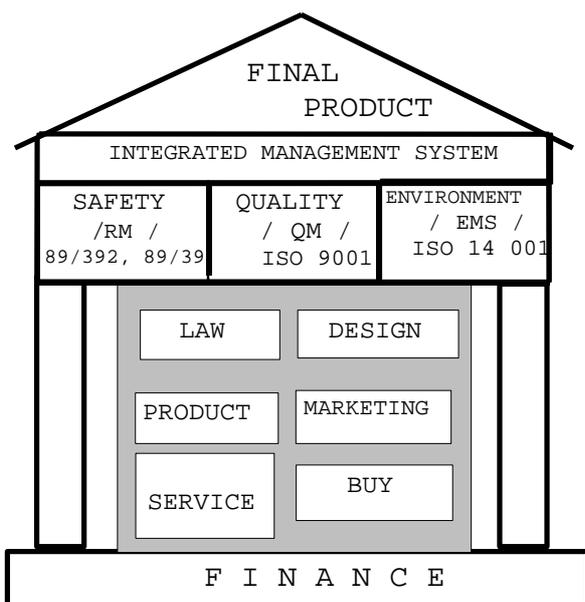
There is described a distribution of the individual activities in the framework of the integrated management system in the relation to several functions of organization in table 1 (Leist 1997).


Figure 2. Integrated management system.

Table 1. Distribution of risk management functions.

Function	Quality management tasks	Risk management tasks	Management of the environment tasks
Research and development of devices	Research, development of new conception of quality management	Research, development of new methods of risk evaluation	Research, development of environmentally friendly products
Projection, planning	Conditions for quality requirements of products	Information about required safety	Determination of environmental requirements
Production, means, maintenance	Maintenance for high level of quality and durability	Identification of failures and elimination of them New safety devices	Usage of environmentally friendly production means
Material flows	To ensure the quality of articles during transport of material	To ensure the safety during transport of material	The choice of environmentally friendly transport methods

Intelligent Transportation Systems

P.A. Hancock

Human Factors Research Laboratory, 141 Mariucci Arena, 1901 Fourth St, SE, University of Minnesota, Minneapolis, MN 55455

1. INTRODUCTION

In many countries of the world, the problems of crashes and congestion associated with ground transportation have reached unsupportable levels. In the traditionally "developed" nations of the world, there is no longer the space or land to continually build new roadways to deal with the congestion problem. Similar strictures are placed upon developing nations who are also experiencing an explosive growth in the number of vehicles on their roads. If information superhighways are important to sustained growth and development, how much more so are physical highways that carry people, goods, and vital services? The result of these trends is that we have overcrowded and dangerous highways upon which vehicles travel at progressively slower speeds as the transportation infrastructure spirals downward in decline. What can be done about this problem? The answer in many regions of the world is to turn to innovative and advanced technologies to solve the problems of congestion and safety. Across the globe this endeavor has had several labels: in Europe it has been referred to as Transportation Telematics; in Japan Advanced Transportation; but the phrase used here is the consensus term used in the United States — Intelligent Transportation Systems (ITS). The National ITS Program Plan (1995) refers to its function as follows:

> ITS applies a broad range of advanced and emerging technologies to the needs of our surface transportation system, drawing from such fields as information processing, communications, control, and electronics. Effectively integrated and deployed ITS technologies could lead to significant improvements in safety. Mobility, accessibility, and productivity.

The reasoning behind ITS is clear. If technology can find ever more efficient ways to pack an increasing number of vehicles safely on to existing roadways, then politicians and administrators can avoid the unwelcome and unworkable alternative of ever more road-building programs. ITS seeks to accomplish this goal through the identification of user services which have been bundled according to specific domains (see Table 1). Many of these services are building blocks that can be combined for deployment in a number of different ways. For example, ITS provides an excellent opportunity to improve the dissemination of real-time weather information (RWIS) to the travelling public but also to decision-makers routing aircraft, ground commercial transport, or emergency management. Such services can be expected to change over time as different supportive technologies mature and different forms of inter-modal linkage are developed.

In addition to these user services, if innovative technologies, such as telecommuting, can replace the need for physical travel, it is possible that the problem of congestion may be solved. In

Table 1. Identified bundles and associate user services

Bundle	User Services
1. Travel and transportation management	1. En-route driver information 2. Route guidance 3. Traveler services information 4. Traffic control 5. Incident management 6. Emissions test and mitigation
2. Travel demand management	1. Demand management and operation 2. Pre-trip travel information 3. Ride matching and reservations
3. Public transportation operations	1. Public transportation management 2. En-route transit information 3. Personalized public transit 4. Public travel safety
4. Electronic payment	1. Electronic payment services
5. Commercial vehicle operations	1. Commercial vehicle electronic clearance 2. Automated roadside safety inspection 3. On-board safety monitoring 4. Vehicle administrative processes 5. Hazardous material incident reports 6. Freight mobility
6. Emergency management	1. Emergency notification and security 2. Emergency vehicle management
7. Advanced vehicle control and safety systems	1. Longitudinal collision avoidance 2. Lateral collision avoidance 3. Intersection collision avoidance 4. Vision enhancement and crash avoidance 5. Safety readiness 6. Pre-crash restraint deployment 7. Automated highway system

From the National ITS Program Plan (1995)

the near term this is unlikely. In the United States in the two decades between 1977 and 1997, the amount of drivable road increased by 2% while the number of registered vehicles increased by 50% and the number of journeys increased by an incredible 70%. Clearly, the demand is increasing and there is at present no obvious indication of any decline. Not unnaturally, administrators turn to those who created the roadways to solve the contemporary problems and since these individuals have largely been trained in the engineering sciences, it is again unsurprising that they themselves turn to their parent discipline for solutions.

2. ENGINEERING SOLUTIONS TO ADVANCED TRANSPORTATION

The marriage of engineering solutions with advanced technologies could not seem a more natural one. Since the problem is essentially one of controlling a large number of vehicles on a relatively small amount of roadway, the obvious solution is to concentrate a greater number of vehicles into a smaller space. However, there is a barrier to this which is the unpredictability associated with human drivers. Therefore, from an engineering perspective, it would appear best to circumvent this unpredictable

component and to generate automatic control over all vehicles. In the US, this effort was labeled the Automated Highway System or AHS. AHS was certainly well-intentioned and in some ways, there were signs that such a system could be successful. After all, when a complete system can be regulated, automated vehicles do quite well. For example, there are many shuttles which run at airports in the United States with no driver aboard and they perform to a tolerable level of success. What defeated the general idea of fully automated vehicles was the same stumbling block which has retarded progress in the area of Artificial Intelligence (AI), namely the conundrum of *context*. Where the problem of concern can be bounded, then computer-mediated systems do very well. For example, in the airport shuttle case, all stops and their locations are known. It is certain that there will be no other traffic on the line, etc. Similarly, in chess, AI programs have been successful since they are able to survey a bounded space of possibilities (despite the apparent enormity of that space of potential moves to us humans as individual chess players). Unfortunately, real-world problems are not so easily bounded in that same formal way. Thus, to be successful, automated vehicle systems would have to possess a wealth of "world" knowledge which appears so facile to human performers yet so difficult for their machine surrogate.

If we are unable to have a completely automated system the engineering argument ran, then let us develop a limited "world" in which some automated vehicles could operate. This was the idea behind levels of automation that could use "automated" lanes as used in the automated highway demonstration. To gain entry into this privileged world, the vehicle would have to undergo an electronic "check" to ensure that it had sufficient "intelligence" to operate within such a world. This conception seemed feasible, especially since many congested urban areas had already begun to construct or designate high occupancy vehicle (HOV) lanes in initial attempts to increase passenger-to-vehicle ratios. In order to maximize the effect of such automated lanes, the concept of "platooning" was adopted in which a group of vehicles, all travelling at the same uniform velocity, joined together in close proximity (essentially 1–2 feet apart from bumper to bumper). The technical feasibility of platooning was shown in several impressive demonstrations. However, some major problems have beset the platooning version of automated transportation. First, there is the problem of entry into automated lanes when large platoons can suddenly appear and the choice of entering the lane is at the discretion of the individual driver. Second, there is the problem of assembling platoons as they travel along well in excess of 60–70 mph. Third, there is the problem of egress from platoons or platoon dispersal as all cars reach their downtown destination at one time. This is not to say that such problems are insuperable, and indeed much progress was made on these issues culminating in a series of demonstrations of automated vehicle control in California in 1997, as had been mandated in the original Intermodal Surface Transportation Efficiency Act (ISTEA) of 1991.

Despite these successes, however, it became apparent that fully automated vehicles were not the way that Intelligent Transportation Systems (ITS) were heading. Rather than one single reason, there were a collection of influences which militated against such developments. There were questions of infrastructure. For example, if vehicle were to be guided by magnetic strips in the road, who was responsible for laying and maintaining these strips? What would happen in the event of a crash if these failed? Would car manufacturers construct vehicles that needed such external forms of support to operate efficiently and would the costs of these added features be supported by buyers in the market? In addition, how would automated and non-automated vehicles be integrated on the roadway and how would such dedicated lanes serve all road users? This is not to say that such problems of legislation, infrastructure, and responsibility — like those of a more technical nature — could not have been overcome. Rather, it is that ITS chose a different direction for progress and the vital conception in this new thrust is human-centered transportation.

3. HUMAN–CENTERED TRANSPORTATION

In actuality, human-centered transportation is an initiative of the US Government that extends well beyond ground transport to include aviation, marine, and space operations. Human-centered approaches to ground transportation can vary widely, depending upon what the specific institution or agency means by the term. In ITS, human-centered approaches have been founded upon user-services of which 29 were indicated in the 1995 ITS plan (see table 1), while some others have since begun to emerge. The purpose of ITS is to deliver these services. This is not what we mean by human-centered approaches in human factors and ergonomics (see Barfield and Dingus 1998). Our vision concerns itself with user-centered interactions with technical systems in which the human provides both the intention (either at the stage of design or at the stage of operation) and the control. Thus users in the ITS realm are largely passive consumers to be satisfied whereas in the human factors realm they are self-intention beings to be designed for. Despite this difference, I shall deal with users in the latter sense, and thus will focus largely on users as drivers of vehicles that are envisaged as including many advanced technical systems in the near future. A first question is how to structure a brief review of such a vast and growing area of research and applications? Here, I have decided to use response time as the defining characteristic. In so doing, I shall focus on some forms of current technology, mostly those in the vehicle, while necessarily giving less attention to other innovations, such as those being implemented in advanced traffic management centers. In general, the three categories I shall deal with are (1) communications, (2) navigation, and (3) collision-avoidance.

3.1. Communications Technologies

The first forms of advanced in-vehicle systems to penetrate the mass market have essentially to do with communication. In this, the cellular phone is pre-eminent. Cellular phones first appeared in the US in 1983 and were installed in vehicles closely thereafter. Although still somewhat rare in rural areas, it is difficult to drive down a major road of any urban region of the US without seeing someone telephoning from their car. Although there may be some users for whom a phone is a vital piece of operational equipment (e.g. emergency services), most car phones are discretionary technology which it may be useful to have, but not impossible to live without. A natural question that has surfaced is whether it is safe to drive and phone at the same time. It turns out that this question is not simple to answer (Goodman, Tijerina, Bents, and Wierwille 1999; Hancock and Scallen 1999) and the National Highway Transportation Safety Administration (NHTSA) has

recently conducted an extensive study of just this issue. In Japan, a breakdown of accidents involving car phone use reveals that 42% occurred when the driver was answering the phone, 31% took place when the driver was dialing and 16% resulted when the driver was simply conversing on the phone. However, as Hancock and Scallen (1999) noted, the simple act of phoning and driving together may, in themselves, not be dangerous, rather it is the context in which such actions are performed that cause them to be more or less safe activities. In view of this contextual dependency, the present safety effect of cellular phone use on driving is still largely to be determined.

Now that we have a communications channel into the vehicle there is, in principle, nothing to stop the whole of the electronic world being introduced into the driving environment. Already it is possible to receive fax and email. There are also plans for an auto-PC in which the car can become a travelling office accessing the World Wide Web and unlimited electronic information, all while travelling at 70 mph down a crowded freeway. There are already great concerns over drivers reading newspapers, applying make-up, shaving, and the like while driving. This concern must surely grow if distractions such as email, TV, and video games are placed in everyday vehicles. Many such commercial products are already being installed and operated. How and where limitations are put upon these in-vehicle systems appears, at this time of writing, yet to be determined. Of course, we can all think of ways of locking drivers out from use while the vehicle is in motion; however, for some services such communication capabilities are vital. Cellular communications have already given rise to mayday and automatic collision notification systems (e.g. OnStar, RESCU, etc.) and promise several other critical advances such as emergency notification upon airbag deployment, route assistance, real-time traffic data, and stolen vehicle recovery. What can and what should be available for operation while the vehicle is in motion is clearly a human factors question and one which many of our community is now investigating.

3.2. Navigation Technologies

If mobile phones are among the first advanced electronic systems to enter the vehicle, map navigation systems are fast following. Global positioning technologies (e.g. GPS) enable the immediate and accurate positioning of the vehicle, which can be immediately displayed on an electronic map. Some professionals, such as taxi drivers and delivery personnel, are in constant need of direction from their origin to a destination with which they are not familiar, and there is an advantage for emergency services to have information upon locations to which they are being summoned. However, is there such a strong demand from the ordinary driver? We know that the vast majority of driven miles occur on routes with which the driver is intimately familiar. Further, we know that with the increasing use of cars for commuting there is a slow but clear decrease in car use as a source of recreation. Therefore, we must ask, what advantage is it to the regular driver to possess such a capability as in-car, dynamic map-navigation systems? The answer to this seems to be bound up in the question as to how much the average driver would be willing to pay for this as a vehicle option. As of the present the answer does not seem to be a lot.

Manufacturers of such systems point to some forthcoming additional advantages. For example, when linked to information broadcast from central traffic management centers (TMCs), map systems can also display congestion. With this information drivers can choose to re-route themselves or request that the navigation system does this for them and provide a more efficient route. In saving the driver time, such systems may save the driver more money than their cost and so prove sound investments. However, this assumes that there are always viable alternative routes, but in many urban areas this simply is not so. Often, there may be only one or two routes possible between, say, downtown and a given suburban region and, if one way is blocked, virtually all drivers on the road are aware of the alternative. The optimistic advertising scenario of the powerful vehicle roaring though empty urban backstreets is likely to be misleading and counter-productive. Further, since many current map systems are downloaded from large-scale military or civilian sources, such as the USGA, they provide birds' eye views of areas from a perspective vertically above the area of interest. In reality, however, individuals do not navigate well using this perspective, but are much better at landmark recognition from the viewpoint of the human eye. Thus, turn-by-turn advisory systems are more closely allied to actual driver navigation behavior, and a number of these have begun to come to market. Perhaps integration of such understanding of human preferences and behavior will facilitate market penetration.

From a safety standpoint, navigation systems have the potential for causing significant driver distraction or increased workload. In Japan, where 12% of all new passenger vehicles come equipped with such systems, they resulted in one fatality and 93 injuries in the first half of 1998. The majority of these accidents (73%) occurred while drivers were looking at the navigation systems. This is not surprising given that driver inattention is a primary or contributing factor in a majority of all crashes in the US — even without such in-vehicle navigation systems. Thus, the challenge for designers and manufacturers is to make these devices safe and easy to operate. For example, the seemingly simple issue of deciding when to present turn instructions depends not only on the timing of the route instruction, but also on the traffic conditions and road geometry. On a positive note, standards and design guidelines are being developed for limiting access to input information to navigation systems while the vehicle is moving, as well as ensuring message uniformity, prioritization of functions for in-vehicle messages.

3.3. Collision-warning and Collision-avoidance Systems

While congestion is certainly a significant economic problem, it is the improvement of safety that stands out as the main goal of ITS. In the US alone, vehicle crashes take the lives of 42 000 people per year and millions more are injured. Adding together both the direct and indirect costs of vehicle accidents, the financial detriment alone runs into the hundreds of billions of dollars. However, road traffic accidents do more than this. Figures show that young people are far more likely to die as a result of road traffic crashes than from any other cause. Thus, road traffic accidents rob individuals, families, and society of more useful years of life than any other source of societal harm. Given this, there is a strong moral and financial impetus for us to seek ways in which technology can successfully reduce the accident toll. ITS collision warning and avoidance services

promise this increased safety and efficiency through computer-based decision and automation in the form of driver assistance or warning systems. These devices are expected to reduce both the occurrence and the severity of crashes, as well as property damage losses and crash-caused traffic delays that lead to lost work, wages, or productivity. The National Highway Traffic Safety Administration estimates that over 1 178 000 crashes could be avoided if only three systems — rear-end, lane change/merge, and road departure systems — are implemented (NHTSA 1996). To help achieve commercialization of effective collision warning and avoidance systems, NHTSA has undertaken a program of research to develop safety-based performance specifications for a number of these systems, including those for preventing rear-end, road departure, lane change and merge, and backing crashes. The automotive industry envisions such collision warning/avoidance safety services will be available within the next five to ten years.

Although collision-warning and collision-avoidance are terms that are used synonymously, there is an important distinction. Collision-warning systems are used to focus the driver's attention upon a source of threat and thus provide advanced notice of an impending collision. Collision-avoidance systems initiate some form of active intervention by the system to circumvent imminent collision.

We deal first with collision-avoidance systems. Drivers have finite capabilities and among these are restrictions upon the time it takes them to perceive and respond to stimulation in the environment. For changes that can be anticipated, humans respond relatively quickly, but their responses can be quite slow for unexpected changes. In addition, there are some events which occur with such a short latency that even the most attentive and skillful individual is unable to respond, and these are the conditions in which engineering solutions must step to the forefront. For example, an incursion into the path of progress of the driver some 250 milliseconds into the future (the equivalent of a child stepping out, from between two parked cars, 11 feet in front of a vehicle travelling at 30mph), is not amenable to significant driver response. In this case, a purely automated system could be responsible for engaging in evasive action such as swerving and/or immediate application of full braking. More complicated questions are raised when the driver and the automated system have to work together to achieve the goal of collision-avoidance. Many human factors questions are immediately evident (see Hancock, Parasuraman, and Byrne 1996). Who has control? How and when is control passed from one entity (the driver) to the other (the automation)? How and when is that control returned? Should automation ever usurp the driver's right of control? Under what circumstances might this be envisaged?

Collision-warning systems, unlike collision-avoidance systems, provide information further in advance of incipient collision. One obvious question is how far? The further off in time and space that warning about a potential collision is given, the greater the propensity for false alarms. Even with virtually flawless detection systems, there is a significant false alarm problem anyway since the probability of collision on the road is actually so low (Parasuraman, Hancock, and Olofinboba 1997). In addition, how are we to warn drivers? Is a four-dimensional auditory warning, necessarily competing for visual attentional resources, the best form of localization? How are we to calibrate different systems to different drivers' styles? Another concern is that drivers may compensate for each of the safety improvements afforded by collision-warning and avoidance technologies to gain what they perceive as the best advantage for themselves. Over-reliance on these systems may therefore lead drivers to assume additional risks and compromise any gains in safety. Drivers with forward collision-warning or night-vision systems, for example, may have a tendency to drive faster or exercise less caution than they otherwise would under degraded conditions. Product standardization and consistency is also paramount among safety critical warning systems. All these and a multitude of other questions have yet to be resolved as we endeavor to assist drivers in a task which, we must recognize, they do very well on a day-by-day basis anyway. These are part of the future challenges of ITS.

4. SUMMARY

Intelligent transportation systems using human-centered views are currently being built and implemented. However, progress in this area is moving so rapidly that it is likely that by the time this work is published some, if not all, of the developments described in this article will be either outdated or obsolete. While there have been significant and sincere attempts to bring human factors and ergonomics professionals into the development of standards, guidelines, and many specific designs, it is clear that not all such burgeoning technologies are likely to have benefited from human factors input; unfortunately, in a litigation-laden society, there will be many opportunities for forensic human factors professionals to comment and speculate upon the impact of designs of varying utility. If, however, we have contributed to the reduction of crash frequency and can demonstrate that human-centered approaches are effective in the protection of pedestrians, drivers, and passengers, we will have made a contribution that our students and followers can take into the future.

Operator Testing and Non-destructive Evaluation Performance

D. H. Harris

Anacapa Sciences, Inc., 301 E Carrilo St, PO Box 519, Santa Barbara, CA 93102, USA

1. INTRODUCTION

Non-destructive evaluation (NDE) is a critical activity in assuring the structural and functional integrity of components in power plants, production facilities, aircraft, ships, submarines and numerous other types of vehicles and facilities. NDE systems employ ultrasonic, radiographic, electromagnetic (eddy-current) and other techniques to detect and characterize flaws in materials. In these techniques probes return signals from the materials examined and operators interpret the signals (within the signal context) to assess the condition of the material. Since these techniques depend on operator proficiency for their effectiveness, operator testing can contribute to the effectiveness of system performance through: the early identification and selection of personnel who are most likely to benefit from training and experience in the application of NDE techniques; and the identification and qualification of personnel whose capabilities meet the standards required for specific NDE applications in the field.

Potential contributions of aptitude testing to the selection of candidates for NDE jobs is illustrated by the development and validation of the Dynamic Inspection Aptitude Test (DIAT). It was designed to predict success in the application of NDE techniques (such as ultrasonic and eddy-current) that require the combined aptitudes of general cognitive ability, abstract reasoning and spatial visualization. Validation studies showed that the DIAT was highly reliable, correlated with other measures of these key aptitudes and was predictive of the job performance of NDE operators.

Performance testing can provide valid, reliable, practical methods for the identification and qualification of personnel whose capabilities meet the standards required for specific NDE applications. A notable example is the performance testing that serves as the principal basis for qualifying operators for the eddy-current examination of steam generator tubes in nuclear power plants. However, while providing a valid basis for the qualification of operators, performance test results may not necessarily predict performance in the field. Various performance-shaping factors (such as alertness, work habits, environmental conditions, job preparation and motivation) might operate to degrade performance under field conditions.

2. APTITUDE TESTING

Attempts to predict job performance from scores on aptitude tests are based on the assumption that individuals who have certain innate human capacities (aptitudes) will be able to develop and apply job skills requiring those aptitudes more effectively than those who do not. An additional assumption is that higher-aptitude individuals will be able to learn the required job knowledge and skills more quickly and will be more likely to pass performance tests required by operator qualification programs. Under these assumptions the use of aptitude testing is appealing because the investments in testing are typically very small relative to the costs of operator training and qualification and to the costs incurred as the result of poor operator performance on the job. As a consequence, substantial returns on investments might be anticipated.

A computer-based test was designed to measure the dynamic combination of aptitudes required for the effective application of NDE. By measuring the requisite combination of aptitudes simultaneously, the approach employed for this test differed from the more traditional and more commonly used aptitude-testing methods in which aptitudes are measured one at a time by static tests administered either in paper-and-pencil form or by computer.

A computer-based test was developed in which scoring well on the test involved the simultaneous application of multiple aptitudes in performing a series of inspection-like tasks. It was expected that an individual's test score would reflect both the individual's aptitude levels and the dynamic interaction among these aptitudes. That is, the combined effect on task performance of the interaction among aptitudes of one individual could be greater than the combined effect of the interaction among the aptitudes of another, even when the levels of individual aptitudes were about the same.

2.1. Task Analyses

The specific job selected for the development and validation of the test was the ultrasonic detection of intergranular stress-corrosion cracking in the piping of nuclear power plants. This specific task was selected because, due to its scope and complexity, it encompassed the components of a wide range of ultrasonic NDE tasks performed in nuclear power plants and elsewhere. Task analyses were completed to identify the specific aptitudes required for the performance of this job. The detailed results of these analyses were reported previously (Harris 1990, Harris and McCloskey 1990). The aptitudes are defined briefly:

- General cognitive ability — the general ability to learn, to understand instructions and to solve problems.
- Abstract reasoning — the specific ability to determine an underlying principle, or logical rule, and apply it in understanding relationships.
- Spatial visualization — the specific ability to visualize operations conducted in three-dimensional space.

2.2. Description of the Test

The DIAT consisted of 36 items, each administered and automatically scored by computer. The test taker had 36 min to complete the items. Test files automatically maintained records of test scores and individual responses to each test item. Access to the test and to testing records was controlled by a password. In each of the 36 test items the objective was to locate a target box in an array of 20 boxes. One point was scored for each item in which the target box was correctly reported, providing for a maximum test score of 36. A two-step approach to locating the target box was required to score well on the test. Step 1 consisted of narrowing the number of possibilities to just a few boxes by identifying the characteristics of the target box through the use of analytical reasoning — determining the characteristics of the

last box in a five-box series. Step 2 consisted of applying three tests to the remaining boxes to determine which box responded with the prescribed pattern of audio signals. The item was completed by reporting the box selected as the target.

2.3. Assessments of Test Reliability

Two separate studies demonstrated that the DIAT had a very high level of reliability. Reliability is the extent to which variability among test scores reflects true differences among the aptitudes of the individuals tested rather error introduced by the testing process. The reliability of the test calculated from test scores of 46 students at Piedmont Virginia Community College was 0.94. The reliability of the test calculated from test scores of a sample of 32 experienced ultrasonic NDE operators currently employee by utilities and inspection service organizations in the nuclear power industry was 0.91.

2.4. Assessments of Test Validity

The DIAT demonstrated both content and predictive validity. As a consequence, the test is likely to be useful for the selection of personnel for jobs requiring the application of ultrasonic NDE methods. Content validity refers to the linkage between what a test measures and the tasks, behaviors, knowledge and skills required by a particular job. Predictive validity refers to the correlation between scores on a test and measures of job performance.

2.4.1. Content validity

The DIAT was shown to correlate significantly with widely used measures of the three aptitudes, as discussed earlier, that were linked to ultrasonic NDE tasks. A sample of 46 community college students completed the DIAT, the Wonderlic Personnel Test (a test of general cognitive ability) published by Wonderlic Personnel Test, Inc. (1992) and the Abstract Reasoning and Space Relations tests from the Differential Aptitude Tests (DAT) battery published by The Psychological Corp. (Bennett *et al.* 1991). These particular tests were selected for the study because of the extensive validity data that existed for them in a wide variety of jobs and tasks. Significant ($p < 0.05$) positive correlations, ranging from 0.36 to 0.65, were found between the DIAT and these other aptitude measures. These results indicated that the DIAT scores reflected each of these aptitudes.

2.4.2. Predictive validity

The predictive validity of the DIAT was assessed by correlating test scores with measures of ultrasonic NDE performance. The percentage of flaws correctly reported was calculated for each of 32 ultrasonic operators from their individual examinations of a sample of 45 piping specimens, both flawed and unflawed, which were representative of the flaw types, materials, examination limitations and component sizes encountered in nuclear plants.

Each operator required about 2 work weeks (80 h) to examine all specimens and to report the conditions found. These measures were obtained as part of an ongoing performance–demonstration process used to qualify operators to perform ultrasonic NDE tasks in nuclear power plants. A flaw detection rate of 80% was the established standard for operator qualification.

The correlation coefficient between the DIAT scores and the ultrasonic NDE performance measures obtained from the sample

DIAT Score	Percentage qualified for ultrasonic NDE tasks (demonstrated flaw detection • 80%)
• 25	92
Š24	25

Figure 1. Relationship between DIAT score and ultrasonic NDE performance.

of 32 operators was 0.51. The practical significance of this degree of correlation is illustrated in the expectancy chart of Figure 1, which relates DIAT test score to the percentage of operators who qualified for NDE jobs. As shown, 92% of those with DIAT scores of ≥ 25 qualified while only 25% of those with DIAT scores of £ 24 qualified.

2.5. Test Utility

Use of the test can result in cost savings from reductions in the amounts of training and experience required by selected candidates to meet standards of satisfactory ultrasonic NDE performance, and/or from the greater qualification rates of participants in ultrasonic NDE qualification programs. Currently < 60% of candidates qualify to perform ultrasonic NDE jobs in nuclear power plants. At this rate, it would take 167 candidates entering the qualification process (including those who choose to repeat the process) to produce 100 qualified ultrasonic NDE operators. At a cost of ~$6000 per candidate for salary, travel, lodging and subsistence, these costs alone for qualifying 100 operators would be $1 002 000 (i.e. 167 operators at $6000).

Based on the validation results, using a DIAT cut-off score of 25 to select candidates, 92% of those selected would be expected to qualify. Thus, among those scoring ≥ 25 on the DIAT, it would take only 109 candidates to produce 100 qualified operators, at a total cost of $654 000. The estimated cost savings, per 100 qualified operators, would be $348 000.

3. PERFORMANCE TESTING

Performance testing can provide valid, reliable, practical methods for measuring the capability of NDE techniques and personnel. The principal advantage of this approach is that measures can be obtained under controlled conditions that serve to eliminate potential sources of bias, subjectivity, and measurement error. Moreover, the extent of any error introduced by the measurement process can, itself, be measured and employed in establishing lower-bound confidence limits for the performance measures obtained. The standard error of measurement statistic computed for this purpose is a function of the reliability of the measurement process and the variability among the obtained measures.

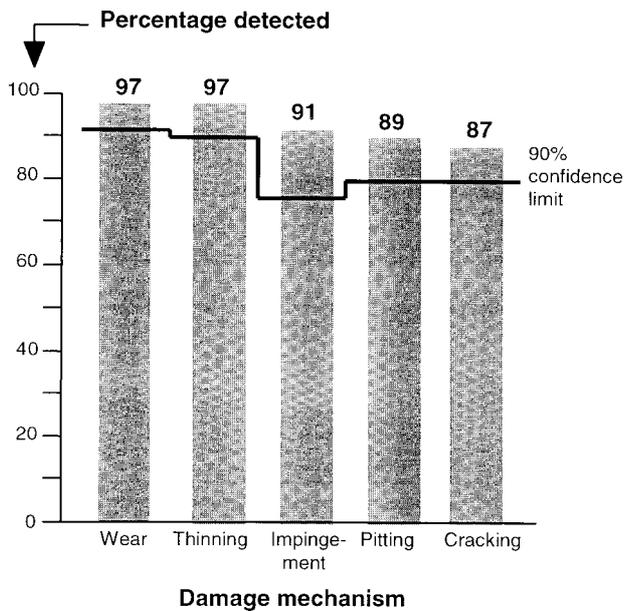
Assessment of NDE capabilities is illustrated here by measures obtained from the performance of the first 286 eddy-current data-analyst candidates in the industry's qualification program (Harris 1996). On average, each candidate analyzed > 2000 tube locations containing ~400 reportable indications. Percentages of indications correctly reported (and associated 90% confidence limits) were calculated for indications attributable to the different possible damage mechanisms — thinning, wear, impingement, cracking, pitting. Thinning is the reduction in wall thickness due to the corrosive effect of water and steam over time; wear is the loss of


Figure 2. Percentages detected of indications attributable to wear, thinning, impingement, pitting and cracking.

tube material from the abrasive effect of another object (such as a support bar); impingement is damage caused by another object striking the tube; cracking is tube-wall reduction from a combination of stress and corrosion; and pitting is the loss of tube material due to corrosive effects of chemicals in the water. These results are shown in Figure 2.

As shown from these results, performance may differ as a function of the conditions under which an examination is conducted. For example, Figure 2 indicates differences in capabilities to analyze indications attributable to different damage mechanisms. Such findings suggest that the use of generic performance measures (those which have been averaged over various examination conditions) may lead to inadequacies in planning and conducting NDE. Other conditions which have been shown to influence operator capability for the detection of flaws of this type include: material, structural configuration, location, sizes of discontinuities and associated signal strengths, guidelines employed and specific NDE techniques employed.

3.1. Performance-shaping Factors

Measures of NDE capabilities obtained from performance testing may not necessarily be totally predictive of the levels of performance to be expected under field conditions. They would be highly predictive if field examinations were conducted under conditions equivalent to those of performance testing. However, there may be various performance-shaping factors that operate under field conditions to influence performance levels. Thus, the potential influence of performance-shaping factors must be addressed in arriving at the performance parameters to be employed in inspection planning and in assessing structural integrity based on NDE results.

There are numerous factors on the job that might degrade NDE performance from levels at which a specific technique–operator combination is capable of performing. Some factors might affect the hardware and software employed for the acquisition and analysis of data, such as less than optimal

calibration of the system, probe deterioration, variations in the probe-tube interface and so on. Other factors, such as the following, might affect the operator.

Alertness:
● Physical condition.
● Time on duty.
● Time since last break from work.
● Time since last reportable indication.
● Distractions (family, financial).

Environmental conditions:
● Temperature, ventilation, noise, lighting, interruptions.

Job preparation:
● Job-specific training and testing.

Motivation:
● Recognition, opportunities, feedback on performance, supervisory practices.

Unfortunately, relatively little is presently known about how these variables might operate, individually and in combination, to influence different aspects of NDE performance under different circumstances. As a consequence, any approach to predicting the degradation of performance by addressing each of the individual effects of specific performance-shaping factors would probably prove to be impractical.

A more reasonable alternative would be to compare measures obtained from performance testing with performance measures obtained under field conditions for the same or equivalent technique-operator systems. Data from comparisons of this type, reflecting the combined effects of the more influential factors, could then be used as the basis for developing algorithms for estimating field performance from measures obtained from performance tests.

3.3. Comparison of Performance Testing Results with Field Performance Measures

A recent study illustrated the comparison of measures made during performance testing to measures obtained under field-inspection conditions. A sample of 818 steam generator tubes was examined by 12 qualified operators under performance testing conditions and, separately, by two other qualified operators under field conditions. The sample contained 1363 reportable indications over a wide range of signal strengths (voltages). All operators, under both conditions, worked independently of other operators. A comparison of the mean percentages detected under the two conditions is provided in Figure 3. Each data point represents the average indications correctly reported within one of seven categories of signal voltages.

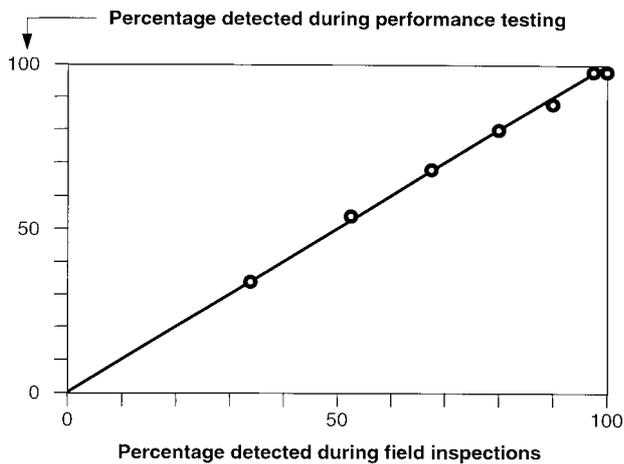
The results showed a very high positive correlation between performance-testing detection rates and field detection rates ($r = 0.999$), even though performance measures were obtained from two separate groups of analysts rather than from the same analysts under each of the two conditions. Thus, in this single, limited assessment, performance-shaping factors did not significantly degrade NDE capabilities under field conditions, and field performance could have been accurately predicted from measures


Figure 3. Relationship between testing performance and field performance.

obtained from performance testing. On the other hand, the signal voltages of the crack indications greatly influenced detection performance. Based on these results, one could not expect detection rates ≥ 90% unless signal voltages were ≥ 1.00.

4. SUMMARY AND CONCLUSIONS

Potential contributions of aptitude testing to the selection of candidates for NDE jobs was illustrated by the development and validation of the DIAT. This test was designed to predict success in the application of ultrasonic NDE techniques that require the combined aptitudes of general cognitive ability, abstract reasoning and spatial visualization. Validation studies showed that the DIAT was highly reliable, correlated with other measures of these key aptitudes, and was predictive of the job performance of NDE operators. Moreover, they demonstrated that use of the test could result in considerable cost savings in the training and qualification of NDE personnel.

Effective NDE planning requires accurate measures of the capabilities of NDE systems, the combinations of techniques and operators to be employed. To this end, performance tests have been developed and shown to be valid, reliable, practical methods for measuring the capability of NDE techniques and personnel.

However, measures of capabilities may not necessarily predict performance under field conditions, particularly if field conditions differ significantly from those under which performance testing is conducted. Numerous factors in the field environment can operate to degrade system performance. Consequently, research is required to compare the extent to which performance-shaping factors degrade NDE capabilities when they are applied under field conditions.

One recent, but limited, study indicated that capabilities for the eddy-current detection of indications in steam generator tubes was hardly degraded at all under field conditions. However, more comprehensive studies of this type are required to provide a definitive basis for the prediction of field performance from measures obtained from performance testing. The goal of the recommended research would be to develop algorithms that can be applied to performance test results to predict NDE performance in the field.

Process Control

N. Moray

DERA Professor of Applied Cognitive Psychology, Department of Psychology, University of Surrey, Guildford GU2 5XH, UK

1. INTRODUCTION

Process control systems involve industrial operations for the manufacture or transformation of energy and chemical products in a continuous stream through the interaction of mass and energy. They include, on the large scale, operations such as the manufacture of chemicals, oil refining and electrical power production, whether using fossil or nuclear energy; and on the small scale processes such as pasteurization and domestic heating and air conditioning. Processes that bear some similarities to process control but which are sufficiently different include discrete manufacturing, transportation systems and systems such as hospitals, although under certain conditions and assumptions aspects of the human factors of process control can be applied to these latter. For general descriptions of the human factors of process control see Rasmussen (1986), Woods (1986), Rasmussen *et al.* (1995) and Moray (1997a, b)

2. CHARACTERISTICS OF PROCESS CONTROL PLANTS

Process control systems have characteristics in common which cause difficulties for operators and other personnel. Typically they involve the interchange of large volumes or masses of physical substance, the feedstock, and the exchange of large quantities of energy. These exchanges are frequently on a scale which, if uncontrolled, give rise to considerable hazard, to which the events at Bhopal and Chernobyl bear witness. Control of rates of reaction, and mass–energy balances are central to process control operations. Frequently the products, by-products, or waste products include materials which are toxic, and which therefore must be controlled.

Process control operations are governed by the laws of Newtonian physics and related chemical laws. If a valve is opened, pressures are transmitted through the system almost instantaneously. Flows are proportional to pressures, and relations between pressures and temperatures obey the gas laws. Many processes can be described and modeled by mathematical equations, and transfer function descriptions of operations may be available. But while formal quantitative descriptions are often available, they are not always complete, and there is much uncertainty and risk under some operating conditions due to instabilities or imperfect quantitative models of process. The time constants of significant events in process control systems can be both very long and very short. It takes several days of complex operations involving teams of many people to start up a nuclear power plant or an oil refinery from cold shut-down; but the chain of events that destroyed Chernobyl occurred over minutes, and the final transient within seconds.

Process control plants are among the largest and most complex industrial systems constructed by mankind. They may occupy sites of many hectares, and the number of components in a plant may number hundreds of thousands. Nuclear power plants have ~50 degrees of freedom, implying that to control the plant an operator would need at all times to know the value of at least 50 variables. Older nuclear power plant control rooms have between 1000 and 2000 displays and controls, and modern ones several hundred pages of computerized displays. Furthermore, there is often tight coupling between different parts of the plant, so that events in one part may propagate rapidly to affect other parts. On the other hand, because of the inertia of the masses and energies involved, there may be lags of many hours in response to changes in controls. In general, except for abnormal transients, the bandwidth of events tends to the very low end of the spectrum, at which continuous perceptual motor control of closed loops is not performed by humans, who instead intervene from time to time to correct divergence from required set-points by discrete actions. Despite this there has been some success in modeling the operator using control theory (Baron *et al.* 1990).

Continual process control plants are bounded by physical constraints. Operators must ensure that temperatures, pressures, etc. do not exceed values defined by designers, mandated by regulators, or which would cause the failure of components or result in the release of toxic products to the environment. Operations are "real time": that is, a rapid response is required to divergences from designed operating conditions. Often there are no readily identifiable discrete events other than alarms for long periods. However, when a process has been shut down there is often a need to control the state of the system for many hours or days because of the presence of exothermic chemical reactions, radioactive decay, etc. Thus plants must be maintained in safe states even when they are not operating and when perhaps power to usual control systems has been lost.

Because of the complexity of process control systems widespread use is made of automatic control systems using closed-loop negative feedback, and increasingly of sophisticated automation. Dynamic allocation of function is therefore central. Process control systems may run under automation for many months, but operators should intervene from time to time to compensate for disturbances that cause drifts from set-points, to perform tests on equipment, and to manage any faults which may occur. Such activities require that operators know the state of the system, and this in turn may require coordination and communication with other personnel, management, and maintenance personnel both in the control room and at widely dispersed locations about the plant. Process control is essentially a team operation, even though manning levels have declined precipitously in recent decades with the development of automation and computerization.

It is easy to show from empirical data that operators cannot possibly keep track of all displayed information. Given known physiological limitations on eye movements and the dynamics of attention and the limitations of working memory, operators must construct their knowledge of system state from samples of a relatively small number of state variables. However, these, if chosen appropriately, can suffice to identify the overall system state because of the correlation (coupling) among variables within subsystems. Such sampling has been shown empirically by Iosif (1968, 1969a, b) and has been discussed theoretically by several writers (Moray 1986). It is widely believed that operators form mental models of the causal structures of the systems with which they work, and that these models are used as surrogates for a complete real time knowledge of all state variables.

To summarize, the characteristics of industrial systems which are of most relevance to human factors are system size, complexity, system dynamics (time constraints, bandwidth), system decomposition into subsystems and components, intrasystem coupling, closed loop and open loop control characteristics, degree of automation, style of automation, observability, modelability, bases for function allocation, modes of human–machine coupling, and the quality of the human–machine interface.

Typical tasks include start-up and shut down operations, maintaining variables at their set points, fault detection, diagnosis and management, and maintenance, which may occur during operations or during a previous planned system outage.

A major change from manual to supervisory control has occurred during the last thirty years due to increasing automation. Excellent summaries of the human factors of manual process control are provided by Edwards and Lees (1974a, b), who provide many hundreds of references to relevant laboratory and field studies. Such work is important, because when operators intervene during fault management they become elements in closed-loop negative feedback loops, and the early research discusses their properties in such conditions. Novice controllers in manual control behave as closed-loop controllers, lagging the plant state, but as they acquire expertise they become open-loop, predictive controllers, implying the acquisition of mental models which allow them, consciously or unconsciously, to extrapolate from present to future plant states, and thus achieve much more efficient reduction of system state error.

Automation has changed the job of operators from manual to supervisory control (Sheridan 1992, 1997). The main task is now to monitor the system, and intervene only when abnormal conditions arise, whether due to drifts from set points of due to faults. The combination of human and automated control can take many forms. For example, the automation may require confirmation from operators before carrying out actions, may carry them out unless countermanded, or may carry them out and inform the operator. Surprisingly little is known about the relative merits of different styles of human–machine cooperation. Bainbridge (1983) notes that one effect of automation is to make operators' work harder, since engineers automate what they understand well, leaving the remaining tasks to human control. Thus one effect of supervisory control is to place increasing emphasis on the role off the human as a fault manager. Various attempts have been made to use expert systems to embody the knowledge and wisdom of human operators, in effect to automate intelligence, but few of these have been successful, and currently there is little emphasis on the use of expert systems in process control.

3. PSYCHOLOGICAL CHARACTERISTICS OF PROCESS CONTROL TASKS

Sheridan (1997) defines the main tasks in supervisory control as being to monitor the system, intervene when necessary, learn about the properties of the system, reprogram the controls and automation when necessary, and to plan for future actions both in the short- and the long-term. From this list one may identify psychological functions and characteristics which are demanded of expert controllers. All require high-quality human–machine interfaces, with display controls designed in the light of human information processing and cognitive abilities.

Efficient monitoring requires an accurate appreciation of the dynamics of the components of the system, so that limited attention can be efficiently deployed. When monitoring conventional control panels eye movements (which approximate to the direction of attention) seldom exceed two per second, and when pages of computer information must be accessed, the rate of switching may fall well below this rate, although the resulting displays can be richer, and may make it easier to identify system state (Vicente 1999). Several models of attention dynamics are available (Moray 1986). It is important to realize that in a very large system, even optimal distribution of attention cannot guarantee that all abnormal signals will be detected. Efficient and reliable alarms must be provided, and their reliability should be considerably higher than the processes they monitor.

The data acquired by the observer serve to allow the latter to identify system state, and hence support diagnosis and the detection of faults. Although much research has concentrated on how operators reason when performing fault diagnosis, direct perception of patterns of displays, in particular patterns of illuminated annunciators, often provide potent diagnostic ability without reasoning (Rasmussen 1986). Hence, the design of displays is extremely important, and recent research has provided new insights into how to design displays for complex systems (Moray 1997, Vicente 1999). Monitoring and pattern perception together provide the basis in process control for system state identification, which in other domains may be called "situation awareness."

A major difference between novices and experts in process control is the extent to which they possess well-developed and accurate mental models of the plant. Having a mental model is more than merely having knowledge about the plant. It implies that the operator has learned how to choose a subset of state information which is practical to monitor and which suffices under normal conditions to deduce causal relations among plant components, and thence to make appropriate diagnoses and take appropriate actions. It also supports predictive behavior. Operator mental models can take many forms, from unconsciously embodied transfer functions in closed- and open-loop control to complex verbal or mental images of how the plant works (Moray 1997b, 1999). Training should aim to provide accurate mental models and support their use.

4. FAULT MANAGEMENT AND ALLOCATION OF FUNCTION

Although allocation of function between human and machine is not restricted to periods of fault management, it is convenient to consider them together because of the way operators decide when to intervene in plant operation. Since modern plants are usually optimized for automated control, operators should not intervene unless they believe that the automation is malfunctioning. It is therefore necessary that they should trust the automation. Characteristically, it is during fault conditions that trust fails, and operators take manual control. While this is desirable, they should be prepared to return control to the automation when conditions change. One problem is that when reasoning about faults operators tend to show certain characteristics which hinders dynamic allocation. When faced with abnormal conditions in a complex system, operators tend to choose a hypothesis to explain the fault as rapidly as possible, and are then unwilling to change

the hypothesis. This "cognitive lock up" as it has been called, results in their collecting evidence in favor of the hypothesis and neglecting alternatives. (The most well known example of this was the failure to diagnose the correct cause of the accident at Three Mile Island, where operators decided early on that they had too great an inventory of coolant, whereas in fact they had a loss of coolant.) A different kind of rigidity may be seen in what has been called "complacency" (Parasuraman and Riley 1997). If trust in automation is too great, operators may cease to monitor the automation, and hence fail to notice the need to intervene. It is not known to what extent complacency is a real problem: the mere fact that part of a plant that is highly reliable is not monitored often is not a sign of miscalibrated trust, but may be a correct strategy given the past history of high reliability. Our understanding of the psychological relations between humans and the systems they supervise is still relatively poor, and it is not clear to what extent research can be transferred between domains, for example, from studies in aviation to those in process control. (Compare, for example, Parasuraman and Riley 1997 with Lee and Moray 1994.) To understand the psychology of this kind of behavior it is most important to rely as much on field research in industrial settings as on laboratory studies. Field studies in process control have a long history, from work such as that of Bainbridge (1974) to more recent work particularly in Europe (De Keyser 1981, De Keyser *et al.* 1987, for example).

5. CONCLUSION

Process control provides an environment in which people are required to work in the most complex systems ever designed and built by humans. The transfer of knowledge from basic research in cognitive and social psychology provides an opportunity for human factors to play a major role in the development of safer and more productive socio-technical systems, and to improve the working conditions of personnel. At the same time, the remarkable skill of experienced operators in process control provides important data about human cognition, and a challenge to laboratory research to explain the abilities of humans who, despite progress in automation, it is now accepted must remain an essential component in the operation of such plants. Since the books by Edwards and Lees (1974) there have been great advances in the human factors of process control, and currently human factors can provide important insights into the role of humans in automated systems and how they should be designed for process control.

Rail Transport

I. Grabarek

Faculty of Transport, Warsaw University of Technology, Poland

1. INTRODUCTION

The basic element of rail transport system is rolling stock, which can be divided into traction vehicles, passenger coaches, and freight wagons. Traction vehicles include locomotives with electric or internal-combustion engines. The rapid development of electric traction in many countries and a large number of electric locomotives concentrates the subject of this article on problems of ergonomics in that area of transportation.

From the point of view of ergonomics the most important issue is the place where the train driver works — that is, the cab. The work of a train driver is typical operator work in a moving technical object. Basic functions of a driver-operator are the processes of orientation, decision-taking, and execution. The main equipment in each cab is the control desk with steering and signaling devices. The optimization of the driver–locomotive–environment system depends on the degree in which the rules of ergonomics are applied in the phase of designing the vehicle, and then in maintaining the state during the usage.

That is why ergonomic examination is part of concept or correction ergonomics. Safety and economy of transportation enforces the designers to develop more advanced solutions of cab design. The concepts are presented in the later part of this article. In correction ergonomics, the most important factor is the method of ergonomic diagnosis, the aim of which is not only to establish the actual level of ergonomics in a locomotive cab, but first of all to formulate conclusions for its modernization, which would make driver's job more comfortable. The tools for simplifying and accelerating the diagnosis are computer-aided expert systems, whose usefulness has been proved in research.

2. CHARACTERISTICS OF DRIVER'S WORK

The function of a driver of an electric locomotive is not only to integrate received information, but also to steer the vehicle. The signals received from the environment (the track, high and low signals, obstacles, etc.) and information from indication devices in the control desk are continuously analyzed and processed. The effect of these procedures is the making of an executive decision, performed via steering devices. The operator is, first of all, the moderator of data processing. It does not change the fact that he is to a large extent a receptive element in the system, registering data from both the track and the control desk. The steering functions are accomplished by relatively small movements that do not require great precision and speed. The necessity of quick decision-taking arises in situations of possible collisions (e.g. unexpected obstacle on the track), driving at night or in bad weather conditions. It is combined with the necessity of correct judgement of the situation and correct reaction.

The structure of a driver's working place in a locomotive cab, from the point of view of its design, is subordinate to general rules of ergonomics that apply to:

i. the spatial structure;
ii. the arrangement of elements of equipment in the working field;
iii. material working environment.

The spatial structure of the place should be adjusted to:

i. dimensions of a user and his dominating body position at work;
ii. the scope of movements, visionary field;
iii. the planned equipment of the working place, providing optimum comfort and safety;
iv. projected scope of user's manipulative movements.

The ergonomics of the control desk and arrangement of steering devices and the seat, which are adjusted to the anthropometric dimensions and visionary field of a man, decide about the optimization of spatial structure of a cab.

The arrangement of elements of equipment in a cab must be subordinate to the visibility of a track and of signaling and steering devices. The angle of windscreen inclination is very important. It has to protect the driver against dazzling and disable mirror reflections while driving at night. Signaling and steering elements in a locomotive cab are arranged to make them visible from the driver's seat in natural and artificial light. Ergonomic arrangement of signaling and steering elements requires:

i. maintaining the agreement of directions of movements of steering elements with the direction of movements of indication and control elements;
ii. positioning of seldom used steering elements outside the control desk;
iii. positioning of damage control steering elements outside the control desk;
iv. grouping signaling and steering elements in the control desk in the following function blocks: basic signaling block, diagnostic block and preparatory block.

Quick and precise reception of information, being the prerequisite for safe driving, is not only dependent on the arrangement of signaling devices, but also on their shapes and types. The arrangement of signaling devices is dependent on the visual field of a man, in which we can distinguish three spheres. Sphere A includes elements requiring easy and quick perception or continuous observation; in sphere B there are elements requiring periodic control; sphere C includes elements that do not have principal meaning for the steering process.

Strict adjustment to the requirements of ergonomics has particular meaning in the positioning of the seat. It should provide the possibility of vertical and horizontal adjustment, and above all comfort (according to anthropometric requirements), that would lessen the fatigue connected with train driving.

Material work environment in the cab is created by physical and chemical factors like noise, vibrations, microclimate, lighting, air pollution, and electromagnetic field.

It is very important to keep the values of the factors above according to the requirements of appropriate norms. The values should be controlled during the usage of a vehicle and corrected if necessary.

3. NEW TENDENCIES IN ERGONOMIC SHAPING OF A WORKING PLACE

In rail vehicles designed today there are various technological developments introduced according to individual needs of long-

distance or local transport. The projects must take into account some needs connected with higher speeds of driving. From the point of view of the man–machine system, the most interesting are solutions concerning the driver's cab, the spatial structure and equipment of which provide the driver with the possibility of performing his operator actions in comfort. Modern ergonomic solutions of the cab concern first of all the spatial structure, features of signaling, and steering devices. A characteristic feature of those solutions is assisting the driver with computer systems. While driving a vehicle, the man can always evaluate and identify received information on the basis of the data he has, and then make correct decision. The higher the speed of a vehicle, the faster is the sequence of the processes described, as there is less time for their realization. A higher degree of automation of the working post simplifies the work process itself and lowers the participation of cognitive functions in completing the tasks. This is why the introduction of computer systems assisting the driver requires research and the forming of ergonomics rules that would provide:

i. increasing the speed and capacity of transmitted information as a basis for safety;

ii. early warning of the driver about approaching signals and limitations of speed;

iii. increasing the feeling of safety connected with the impossibility of passing a semaphore with a STOP signal on it;

iv. a possibility of objective evaluation of a situation in emergency situations (lessening the number of decisions made by the driver in probable situations).

One of the first systems meeting those requirements was EBICAB 700, which is used in Sweden, Portugal, France, Bulgaria, Australia, and Taiwan. It is built on the basis of a transmission device installed between rails, which sends encoded signals to a receiver on a locomotive. The new generation of the system, called EBICAB 900, which has bigger transmitting capability, enables the speed to be increased above 140 km/h. The system registers all events. It also meets the demands of speed increase and the volume of information transmission. The transmitters, located between rails, send data from signaler devices and traffic management systems as constant information to the antenna of a locomotive. The transmission lasts for several milliseconds. Quick data transmission concerning approaching signals and speed limitations enables early warning of the driver and gives him enough time for braking. The devices in the cab control the speed all the time (calculating braking curves) and immediately reacting to any deviations from the pre-programmed drive.

The modernization of the method of data transmission and reception results in some changes in the spatial structure and the whole equipment of a cab. The control desk of the new type of cab usually separates information and executive areas. The executive elements are usually placed in two consoles encircling the driver's seat. In ABB Henschel–"Eco 2000" locomotives, the console is situated inside the cab and can be half-opened to let the driver leave his seat in emergency situations. Opening of the console activates emergency braking. In the new generation of locomotives the steering of propulsion and braking is done by a deck computer, which also has control and diagnostic functions. The usage of 32-bit computers enables extension of diagnostic function (location of damage, operating instructions, data storage) and additional functions such as the energy saving drive program

or drawing the actual course characteristics. As a rule, deck microcomputers enable access to their data from a PC computer and send the data by radio to a dispatcher.

In the control desk there should be the following steering devices: a pulling power control lever, a set speed control lever, a supplementary air brake valve lever, and an automatic air brake valve lever. Other indicator devices include, first of all, a deck monitor, voltage indicators, current, pulling and braking power indicators, and indicators of pressure in the braking system. An example of an ergonomic solution is the control desk in the locomotive ABB-Re 460, from the group of ABB locomotives (in cooperation with SLM). The control desk consists of two consoles, one of which can be drawn aside. An example of a different solution is the control desk in the : "Euro-Sprinter" electric locomotive, jointly manufactured by Siemens and Krauss-Maffei. Both control desks represent the same generation of technological solutions. They perform the same functions, but differ in the ergonomic conception of the shape, equipment, and arrangement of signaling and steering devices, and finally, in color. For example, in the central and left parts of the desk we have some necessary indicators of the brake system control. As advised by the rules of ergonomics, the indicators are round. The levers of the air and regeneration brakes, which are used most often in driving, are separated from each other but installed on one panel. In the control desk there are two different colored areas: a white panel which contains the black steering devices, and the area of the upper part of the desk, containing indication devices, which is black. All the instruments have white scales, marks and pointers to simplify reading. The monitor of the deck computer is located on the right side of the desk in the central field of vision. Less important devices, and those indication and steering devices that are not used so often, are arranged in the left- and right-side fields of vision. Equipping the cab with a computer creates the necessity of taking into account many rules of ergonomics concerned with human–computer work, which is a new problem in locomotive cab design. It is worth mentioning the "Thalys" locomotive, which was designed cooperatively by French, Belgian, German, and Dutch firms, is an example of the usage of leading solutions in the construction of drivers' cabs.

4. AN EXAMPLE SOLUTION OF A CONTROL DESK IN THE DRIVER'S CAB

All new solutions of cabs in electric locomotives are usually widely tested by their manufacturers. It is the basis for the introduction of many improvements and modernization in successive versions. The research involves not only the technical efficiency of a vehicle, but also the need to increase driver's reliability and optimization of his physical and mental load. First of all, it is very important to reduce a load that results in "sharp" fatigue; this is the reaction to short bursts of effort, which causes a serious loss of efficiency and which ceases after some rest. Chronic fatigue is also important; it appears as a sum of other types of fatigue, resulting from incorrect adjustment of the cab and material working environment to a man. Negative reactions include both physical and mental fatigue. Physical fatigue affects efficiency of movement, whereas mental fatigue manifests as incorrect reaction during the reception and processing of information.

The monotony of the work process leads to boredom and sleepiness. Optimization of the driver's physical and mental loads

is a prerequisite for the optimization of the whole man–machine–environment system; it becomes a priority in the search for new ergonomic solutions which will guarantee working comfort for users from a range of populations, driving vehicles in a range of climates. Work in this direction is being conducted by European Rail Traffic Management System (ERTMS). They use the experience of European Train Control System (ETCS) in control-desk design, assuming the use of only one monitor in a cab, the operation of which should be simple for every European driver. That is why ERTMS have adopted a uniform method of presenting basic parameters to a driver, such as current maximum speed, target speed (the closest speed limit), and distance to that target. ERTMS takes into account differences in signaling in the countries that are supposed to cooperate with the ECTS system.

The control desk suggested by ETCS was created on the basis of research and experiments in simulators, which were conducted by specialists in vehicle driving and ergonomics. Having gathered usage and experimental data, they suggested the ultimate solution, which reflects drivers' and experts' opinions about the location of fields in the monitor. The monitor is divided, according to requirements of ergonomics, into six fields:

A. brake details
B. speed control
C. speed maintenance
D. planning
E. monitoring
F. driver input

The fields represent main tasks in driving a train:

A.   Brake details:
the field displays time to brake activation, distance to an area of lowered speed, projected speed in the target in relation to applied braking intensity. From the point of view of ergonomics, the most important parameter was the choice of colors: green denotes that the train will stop before the target, gray denotes that the train will stop at the target, and orange denotes that the train will stop past the target.

B.   Speed control:
the field shows basic parameters concerning the speed when the train is moving: the speedometer shows current and target speeds and the change of colors of the information on display when the train starts braking. Colors are used to attract the driver's attention. In the case of exceeding the speed limit, the driver is warned by the change of color of the speedometer's pointer and its border to orange. Further exceeding the limit causes the color to change to red and simultaneously starts the braking.

C.   Speed maintenance:
data is displayed in graphics format. It is possible to display timetables and information about suggested and target speeds.

D.   Planning, and E. Monitoring:
these fields display information about the profile of the track and all information about traffic safety.

F.   Driver input:
in this field there are some continuously lit touch keys, enabling the driver to switch the screen to maneuver position, cancel some system warnings, input train and driver data, and conduct diagnostic tests.

From the point of view of ergonomics, a correct solution in the field of speed control is a device that does complex calculations and reduces the outcome to one figure and one gray arrow, and gives the driver ready-made information — "slow down" or "accelerate". The technology reduces the mental load, as it presents information in its most coherent form. The arrow pointing upwards shows the need to increase speed, while the arrow pointing downwards shows the need to decrease speed (the movement of the arrow matches the expected result). The length of the arrow expresses the value of difference between actual and suggested speeds.

In the "planning" field the designers facilitated projecting the progress of driving by:
i.   confronting various data on the route chart;
ii. separating information concerning safety (maximum speed limit) from current information.

The driver can decide on the size of a field. Touching the upper part of the screen extends the scale, touching the lower part contracts it. The whole screen in the driver's cab is sensitive to touch and in this way every information sphere has its equivalent touch key that enables the driver to obtain other pictures. It is also used for accepting the information received. During the driving period, the pictures in the fields "brake details", "speed control", and "driver input" are always displayed, and the driver can decide himself what type of information should be displayed at any particular moment. There is also a possibility of supplying additional information in the form of electronically generated sounds. The monitor is able to transmit a wide scope of such sounds, including artificial speech in several languages, which lessens the danger of confusing these sounds with others used in the cab.

The following are the rules for color usage:
i.   white is used as a basic color that does not require special attention or action;
ii.   white changes into yellow in order to signal the need for taking an action in the immediate future;
iii. a higher degree of urgency is indicated by orange, denoting the necessity of immediate execution of an action, otherwise the system intervenes automatically;
iv.   red indicates dangerous situations, and the system intervenes automatically.

The presented solutions of the control desk in the driver's cab prove that the scope of ergonomic actions includes the need for the unification of projects to make them comply with the demands of European users.

5. SUMMARY

This article shows the main directions of ergonomics in the cabs of electric locomotives. It also presents some results of leading European research; it underlines the specific meaning of ergonomics in rail transport, in which the integral part of the optimization of the driver–locomotive–environment system is the safety of passengers. The International Union of Railways is the coordinator of unification efforts (including ergonomics), which currently boasts a membership of 140 companies in 82 countries: 59 active members (the railways of all Europe, North Africa, the Middle East, India, and East Japan), 49 associate members (railways in Asia, Africa, America, and Australia) and 32 affiliate members (companies providing public transport, sleeping car and railway catering services, etc.).

1. INTRODUCTION

A model of a system is a representation, or abstraction, of the real world being studied. System models can be used to gain an understanding of real-world complexities and can be the basis for development of support systems, such as decision aids, user interfaces, and training systems. Models can help predict performance of a system and can aid in identifying the information needed for decision-making processes concerned with system operation and design. Models are critical in the system design phase, and often valuable for system management. Models can be either descriptive (e.g. simulations that predict values of performance measures for a given input specification) or prescriptive (e.g. linear programming methods that specify the values of the decision variables that provide the normative solution for a given problem).

Irrespective of the modeling methods adopted, one of the first steps an analyst must perform is to describe the system in a manner amenable to analysis. This description leads to the abstraction of the real-world problem through the use of a modeling framework. The model results can then facilitate informed decision-making. Techniques such as Entity–Relationship diagrams help an analyst in describing a system (Chen 1983). While these techniques are generic and have been found useful in applications such as database development, they are at a very high level and are difficult to operationalize for developing dynamic system models.

For modeling dynamic and complex real-world systems, a physical/control/information (PCI) decomposition provides analysts with a better means for describing system characteristics and along with traditional diagramming techniques such as flow charts, can be powerful in identifying areas of improvements during analysis. This chapter provides an overview of the PCI approach and illustrates its application in analyzing a real-world warehouse system.

2. THE PCI APPROACH

The PCI approach is based on the premise that most complex dynamic systems have three major components: a physical part, a control part, and an information part. The physical part is the actual visible manifestation of the entities in the system. The control part embodies decision-making processes that drive the physical entities in the system. The information aspect represents data or parameters used by the physical entities or control processes during the system execution. The physical-control decomposition method has been in vogue since the early control theoretic approaches, but adding the information dimension has gained popularity with the increasing interest in the object-oriented simulation community. The PCI approach has been coupled with object-oriented programming concepts in developing reusable simulation architectures for various domains, including airbase logistics (Narayanan *et al.* 1997) and manufacturing (Narayanan *et al.* 1998; Pratt *et al.* 1994).

The PCI decomposition in systems modeling is useful because it readily separates the decision-making aspects of the system from the physical and information dimensions in analyzing complex time-varying behaviors exhibited in most real-world systems. The separation of control processes, when implemented in a computer simulation, is particularly useful in conducting what-if analysis. To test alternate control policies, for example, only the control processes need to be modified. Similarly, the explicit identification of information flow and content facilitate the development of support systems for informed decision-making. Good decision-making, in turn, is fundamentally important to efficient and effective system performance. System performance, in turn, relates to cost and customer satisfaction in most industries.

The PCI approach, along with traditional diagramming techniques, can be powerful in describing an operational system and can be used for multiple purposes. These include: (1) describing and documenting current procedures (needed for quality certification), (2) identifying the critical information needs (to improve decision-making), and (3) specifying the role of decision aids and other support systems (to aid human operators). These purposes are of great benefit to the analysis of industrial systems (e.g. factories, warehouses, distribution systems). These types of systems are complex, with a variety of operations that must be performed. They require extensive decision-making in design and operation, and increasingly information availability and quality certification are becoming major issues. The PCI approach of decomposing a warehouse system and its utility in describing current procedures and support systems needed are outlined below.

3. CASE STUDY: A WAREHOUSE SYSTEMS ANALYSIS

3.1. Elements of a Generic Warehouse System

In a broad sense, a warehouse can be viewed as a system that receives shipped material from a surrounding environment, and then ships that material, or some transformation of that material, out into the surrounding environment. During the time the material is in the warehouse, it is handled in different ways. Material may come into the warehouse in bulk units, be stored in bulk units, and be shipped out in bulk units. Alternately, a

warehouse may receive bulk units, break down these units, package the smaller units, store the smaller units, pick the smaller units, and ship the smaller units. Similarly, the warehouse may receive smaller units, package several different units together, store these consolidated units, and then ship out the consolidated units. Other combinations exist, and a warehouse may perform any number of these activities simultaneously (Bartholdi and Hackman 1998). Numerous performance measures are used in warehouse systems analysis. These include the following:

- *Cycle time.* The time needed to perform an operation or a set of activities (e.g. unload a truck).
- *Lead time.* The time needed to satisfy a customer order after it has been received.
- *Fill rate.* The percentage of an order that has been filled when shipped.
- *Error rate.* The percentage of items incorrectly included or excluded in an order.
- *Utilization.* The percentage of time spent by a resource performing operations. A resource can be either equipment or labor. Other ways that resources may spend time include being idle, being in a failed state, being on break, or undergoing maintenance.

We recently modeled a real-world warehouse using the PCI approach and developed a transaction documentation system to help document current procedures for quality certification purposes and to increase warehouse efficiency, aesthetics, and effectiveness. The case study is described below.

3.2. A Specific Example

The specific case study is referred to as Warehouse ABC. Warehouse ABC is a complex, dynamic warehouse, which handles products for a large automotive manufacturing company, and sells separate automotive products to its own customers. Warehouse ABC receives shipments from suppliers in trucks in the form of individual items, or as pallets, which are cases stacked on a wooden skid, and are moved by a forklift or pallet-jack. These shipments are manually transported from the dock to the appropriate storage area. The materials are stored for some period of time until they are removed from storage to be transformed into the customer-defined product, or transported to the dock to be shipped out. An initial analysis based on real-world observation reveals three broad scenarios that describe the warehouse operations. These scenarios are: (1) unloading and storage of incoming material, (2) retrieval and shipping of outgoing material, and (3) value added transformations of material inside the warehouse (e.g. kitting, assembly, repackaging, etc.).

3.3. PCI Decomposition

The analysis methodology consists of two major components: (1) development of a warehouse model using the PCI decomposition and (2) analysis and development of decision support systems using the model. The model is represented using flowcharts of the three scenarios described above.

The modeling goals are twofold. The first goal is to identify areas for improvement, both for short-term operations and for longer-term planning. The second goal is to catalog the existing set of operations, and any proposed changes to them, in anticipation of the system documentation required for ISO certification (i.e. quality certification needed in many industries).

The PCI decomposition for the scenarios consists of abstracting the warehouse system into physical, control, and information elements, and tying these to the necessary performance measures. These elements are united by two significant concepts: the flow of material in the system and the flow of information in the system.

3.3.1 Physical activities

The physical element of decomposition involves physical activities, which consist of the operations performed in the warehouse. These include, but are not limited to, loading items, unloading items, moving items, inspecting items, assembling or repackaging items, storing items and retrieving items. Physical activities require the use of limited resources, including space, time, equipment and labor. Activities also require procedures to be performed effectively and efficiently.

3.3.2 Control (decision-making)

The control element of decomposition captures the decision-making of the warehouse operators performing the physical activities. During the operation of a warehouse, decisions have a major impact on performance. A decision may consist of selecting a procedure to perform operations. It may also consist of prescribing a sequence of operations to perform. Making "good decisions" is important not only for operational efficiency, but also for quality assurance and customer satisfaction.

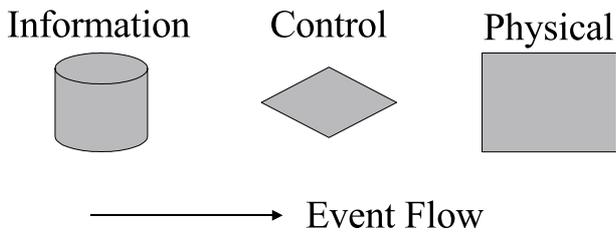
3.3.3 Information

System abstraction of information elements reveals the data used to describe the warehouse system. This data includes the system state information, as well as requirements, procedures and structure information. Good decisions depend heavily on having the right information at the right time. Information consists of a variety of data and exists in a number of formats. For example, information consists of procedures used to perform an activity. It also consists of the set of orders to be filled at any point in time, or the set of people and equipment available to perform an activity. In terms of format, information can be stored in a computer database or as a set of instructions in paper form. An *information system* is a well-defined set of procedures and data that provides information for decisions. Much of it may be computerized, although computerization of all information is not necessary. It must be designed to supply the right information at the right time to support effective decision-making.

3.4. Flow Charts

The PCI decomposition and event flow can be represented through the use of flow charts. The convention used in the flow charts is shown in figure 1.

The cylindrical shape represents information entities, the diamond represents decision-making control, and the rectangle represents physical activities. The arrows represent flow of events from one entity to the next, however, the represented flow does not hold true for all real-world situations within the three scenarios.

Figure 2 shows a portion of the flow chart created for scenario 1, in which material comes into the warehouse on a truck. There is a vertical flow from top to bottom, representing the order of the physical activities and the decision-making that precedes those actions, or is required of the operator because of those


Information   Control   Physical

Event Flow

Figure 1. Notations used in flow charts.

actions or some other action or requirement. For example, the human and equipment resources are allocated before the truck can be unloaded. On the other hand, a dock can be allocated to a truck only after the truck has arrived. The flow chart also shows a horizontal flow from left to right, representing the flow of information elements of the PCI decomposition. For example, information on dock status is required to make the decision of which dock the truck will enter. Once that decision is made and the truck docks, then the dock status information is updated to reflect this. This decision will affect future dock-related decisions, and will in turn change the system state as well as the information element of the PCI decomposition. This is represented in the flow chart as a cylinder on the left representing utilized information and a cylinder on the right representing the updated information that will be utilized later. The arrows show this transition. Flow charts are similarly specified for all the operations in each scenario.

3.5. Application

The flow charts provide the basis for specific analyses and for the development of a computer-based system to document and analyze warehouse operations (i.e. a transaction documentation system). Through analysis and identification of decision points and the information and resources needed, recommendations for operational improvement were identified. These include procedures to be used for staging outgoing orders prior to shipment, procedures for scheduling weekly workload for the warehouse, and tracking of orders that need to be filled to enable effective expediting of orders that are late. Each of these recommendations focuses on improving decisions on the shop floor to improve performance in terms of efficiency (e.g. shorter operation cycle times) or effectiveness (e.g. increased number of orders shipped on time).

At the same time, the PCI approach enabled the design of a transaction documentation system for the warehouse operations. The purpose of this application is to aid an operator in tracking and documenting warehouse activities. While this is a necessary step in quality certification, it also provides a database of historical information that can be used for further analysis for improvement. Documentation of procedures is a time-consuming and tedious task. It is rarely done (or done well) by operators. A computer-based application should be designed to automate the tedious tasks associated with data entry and to reduce the time needed for data management (thus freeing the operator for other tasks in the warehouse). The application is developed using Microsoft

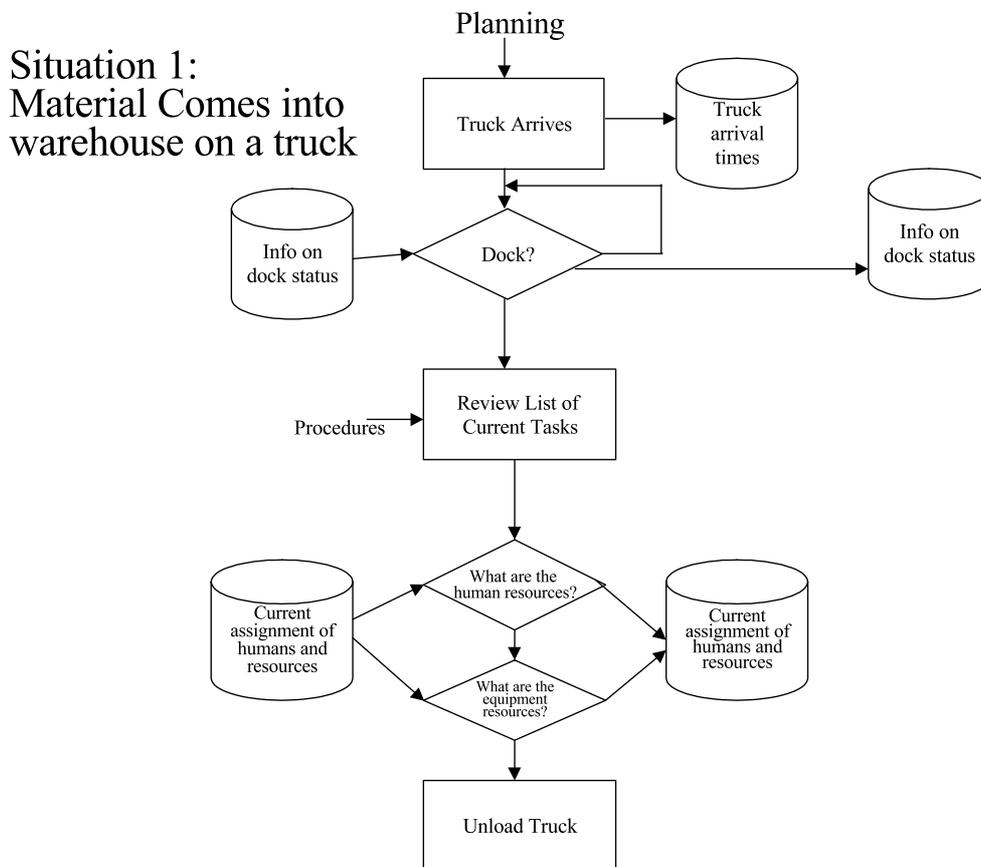


Figure 2. Flow chart for scenario 1.
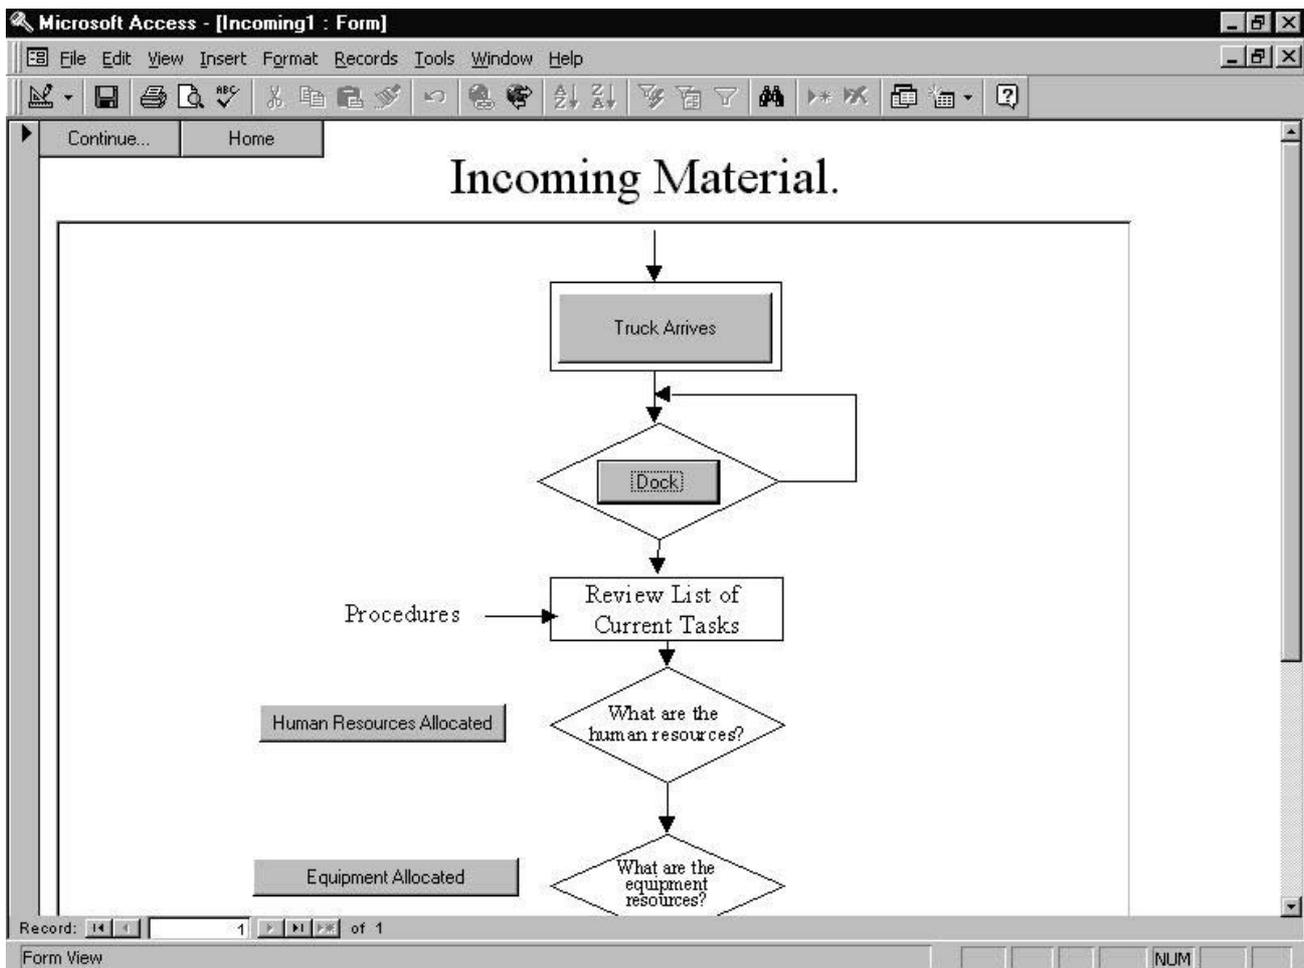

Figure 3. Screen-shot of the transaction documentation system.

Access 97, due to its database capabilities, availability, user-interface design tools, and ease of programming/re-programming. Figure 3 depicts a screen shot from the system.

The transaction documentation system allows operators to enter data into the database by following a user interface based on the flowcharts for the three scenarios. Figure 2 shows a portion of the application environment designed based on the flow chart of figure 1. Operators enter the program, select the scenario for which they will be entering data, and then point and click on the appropriate button embedded in the flow chart. For example, in figure 2, the button 'Truck Arrives' is clicked on when a truck arrives at the warehouse. The operator enters data such as the trucking company, the type of customer, the truck arrival time, and any other significant notes. The system provides a transaction number for tracking purposes.

The database is then updated, and the system analyst can review this data at a later time. For example, performance measures, such as cycle time and fill rate, can be calculated by reviewing the database. The database can also be queried to compile the procedures necessary for ISO certification and to identify potential improvements to effectiveness and efficiency of system operations. Future design improvements can be made through analyzing the databases, and interviewing warehouse operators. Regular use and analysis of the application can promote ongoing systems management, and can be a useful tool in training, decision-making, and planning for future company growth.

1. INTRODUCTION

The ISO 9241-11 definition of usability is "The effectiveness, efficiency and satisfaction with which specified users achieve specified goals in particular environments." In general, two factors should be included in a complete evaluation of human–computer interaction: the user and the computer system. Whitefield *et al.* (1991) classify the different usability evaluation methods according to how the user and the computer components of the system to be evaluated are presented in the evaluation process (Figure 1). These two components of the system can be real or representational.

For the component "users," "real" means actual users or approximations of them, such as students. The "representational user" means descriptions or models of the user. For the component "computer," "real" means the physical presence of the computer and software system or an approximation of it. The system, prototypes and simulations all count as a real computer presence in the usability evaluation. "Representational computer" refers to the notational models or the user's mental representation of the computer. In questionnaires and interviews or during code inspection, users work with their symbolic mental representations of the computer. Based on this classification, the evaluation methods are divided into four categories: analytic methods, specialist reports, user reports and observational methods.

2. ANALYTIC METHODS

When analytic usability evaluation methods are used, both the computer and user are representational. Typical methods include the Goals, Operators, Methods, Selections model (GOMS); the Task Action Grammar (TAG) method; the Systems Analysis of Integrated Networks of Tasks (SAINT); and Queuing Network

Figure 1. Classes of usability evaluation methods (Whitefield *et al.* 1991).

Models. All the methods presented here are cognitive modeling methods that can be used to make predictions about the usability of products.

The GOMS model analyzes cognitive tasks in terms of operators and methods for achieving the goals of the tasks and rules for choosing among different possible methods. The goal defines the end-state that the user is trying to achieve (e.g. saving a changed file). The operators are the basic actions available to the user for performing a task. This includes motor, perceptual, or cognitive primitives (e.g. click a mouse button, search a menu item, remember a file name). Methods are sequences of operators, or procedures, for accomplishing goal (e.g. saving a file is accomplished by moving the cursor to the File menu, clicking the left mouse button, moving the cursor to the Save menu item, and clicking the left mouse button). Selection rules are invoked when there is a choice of methods (e.g. the user could also save the file by clicking the save button on the toolbar). The GOMS model can be used to describe the methods that a user employs to carry out a set of tasks, and to estimate the time it takes to complete those tasks.

The Natural GOMS Language (NGOMSL) was developed to enable the task analysis using a GOMS-like model to be more specific. NGOMSL is an attempt to define a language that will allow GOMS models to be written down with a high degree of precision. The purpose of the language is to describe idealized, error-free behavior in terms of those four concepts (goals, operators, methods, selection rules), and to predict the time needed to execute given tasks. NGOMSL can also be used to estimate minimal learning time and to quantify different aspects of mental workload.

Task Action Grammar is a method of describing interfaces in terms of the linguistic structure of the commands. TAG requires an existing interface specification for evaluation and has little to say about non-expert performance. It is focused mainly on revealing internal inconsistency existing in the interface mechanisms rather than on evaluating user performance.

The Systems Analysis of Integrated Networks of Tasks models human interaction with the task environment as a sequence of tasks. Alternative sequences to accomplish a goal may exist and form a network. Queuing network models integrates the considerations of queuing theory and discrete network models, and supports modeling a broader range of possible mental structures that can be subjected to empirical testing. The SAINT model allows processes on the same path to be active at the same time. It supports modeling of both alternative and concurrent processes as well as sequential and parallel processes.

The principal advantages of analytic methods are that they can be used early in development (before any real computers exist), require few resources to apply, and are potentially fast. The disadvantages are that suitable modeling techniques are still under investigation and development and, consequently, the validity and reliability of the methods are uncertain.

3. SPECIALIST REPORTS

This category of usability evaluation involves one or more people who are not real users assessing a version of the real computer. The evaluators could be human factors specialists evaluating the design of a prototype version using relevant handbooks, guidelines, or their own experiences. Typical evaluation methods

are checklists, guidelines, walkthroughs or heuristic evaluations by specialists.

There are many user interface guidelines available in the literature. Some guidelines are used for a specific platform or software, such as those from Microsoft, Apple, OSF/Motif Style Guide. There are also many general guidelines designed by individual usability engineers. ISO 9241 also has guidelines for specifying and measuring usability.

The advantages of using guidelines are that they are relatively fast, use few resources, provide an integrated view and can address a wide range of behavior. The disadvantages of using guidelines are that their reliability will vary between specialists and, because their assessments are inevitably somewhat subjective, their reports are likely to be incomplete, biased and difficult to validate.

Since user interface guidelines have the disadvantage of being hard to follow (some of them have > 1000 rules), specialists proposed another method: the heuristic evaluation, which is easier to follow. Heuristic evaluation involves having a small set of evaluators examine the interface and judge its compliance with recognized usability principles such as those defined by Nielsen (1993), provide simple and natural dialogue; speak the user's language; minimize user memory load; be consist; provide feedback; clearly marked exits; provide shortcuts; provide good error messages; prevent errors; provide help; and provide documentation. Three more heuristics were extended and validated later: respect the user and her/his skills; provide a pleasurable experience with the system; and support quality work.

The advantages of heuristic evaluation include: low cost in comparison with other methods; that it is intuitive to perform; that no advance planning is required because the evaluations can be conducted by team members in isolation; and that it is suitable for use early in the development process. But because it does not involve real users, it has some degree of subjectivity. Heuristic evaluation often focuses on problems rather than solutions. Also, it requires several usability specialists to perform the evaluation, which limits its application power.

Cognitive walkthrough provides a method of analyzing designs in terms of exploratory learning. It can be applied to designs for systems that will be used by people without any prior training, perhaps in a "walk-up-and-use manner." Analysis by cognitive walkthrough involves simulating the way users explore and become familiar with interactive systems. The evaluator starts with a rough plan of what s/he wants to achieve; for example, a task to be performed. By simulating the process of a user's interaction, the evaluator asks the following questions: Will the correct action be sufficiently evident to the user? Will the user connect the correct action's description with what he or she is trying to do? Will the user interpret the system's response to the chosen action correctly; that is, will the user know if he or she has made a right or a wrong choice? The problems found by this method are focused mainly on these three areas.

The cognitive walkthrough method can help define the user's goals and assumptions and can be used by software developers. The disadvantage is that it requires task definition methodology, which is tedious for evaluators and which may miss general and recurring problems.

4. USER REPORTS

User reports involve real users and their mental representations of computers. Methods typically include the use of interviews, focus groups, and questionnaires. The methods are used to obtain data or opinions from the users on some aspect of the system.

Interviews provide a particularly rapid and congenial way of gathering data. They require less prior planning and preparation than other formal methods of analysis. Interviews may be structured or unstructured. This method can also be used in the beginning of the design process to conduct user studies. Because interview data are subjective, they are open to a number of inaccuracies.

Focus groups provide another way to assess users' needs and feelings. In a focus group, about six to nine users are brought together to discuss new concepts and identify issues. The session is completed in about two hours. Each group is run by a moderator who is responsible for maintaining the focus of the group on the issues of interest. The moderator usually needs to prepare a plan outlining issues to be discussed. Focus groups often bring out users' spontaneous reactions and ideas through the interaction between the participants.

In general, a user satisfaction questionnaire measures an individual's feeling about some aspect of a computer system. If a system meets users' needs in an easy and efficient manner, it will be used and user productivity will increase. A user satisfaction questionnaire indirectly provides information that may be used to improve the system. Ideally, a user satisfaction measure provides evaluations of the hardware components, system capabilities, screen design, the quality of the information flow, instruction manuals and technical support.

There are several questionnaires available, such as User Satisfaction Scale, Computer User Satisfaction Inventory (CUSI), Questionnaire for User Interaction Satisfaction (QUIS), Software Usability Measurement Inventory (SUMI), Purdue Usability Testing Questionnaire (PUTQ), After Scenario Questionnaire (ASQ), Post-Study System Usability Questionnaire (PSSUQ), and Computer System Usability Questionnaire (CSUQ).

The User Satisfaction Scale is also referred as the Pearson–Bailey scale, which defines satisfaction on the basis of positive and negative attitudes toward different components of the computer system. The questionnaire has 39 items that comprehensively cover the computer system, such as accuracy, error recovery, attitude of staff support, documentation and security of data. Each item is rated on six scales. Four are used for evaluation responses and include adjectives like good/bad, simple/complex, useful/useless and fast/slow. A fifth scale directly assesses the user's feelings about the item, and is anchored with satisfactory/unsatisfactory. Studies showed an acceptable reliability and validity with a modified Pearson–Bailey Scale.

The Computer User Satisfaction Inventory is a short questionnaire of 22 items. Two subscales of usability were established, called Affect (the degree to which users like the computer system) and Competence (the degree to which users felt supported by the computer system). These subscales were developed by the analysis of intercorrelations of responses to individual questions in a large initial item pool. This item pool was gathered from literature searches and discussion with end users about their reactions when carrying out their normal tasks

on their usual system. The range of systems sampled was large and heterogeneous. CUSI has an overall reliability of 0.94, with two separate scales showing individual reliability of 0.91 for Affect, and 0.88 for Competence.

The Questionnaire for User Interaction Satisfaction is a commercially available questionnaire. QUIS v.5.5 consists of one introductory section, which is an overall reaction to the software scale, and four other sections, each consisting of between four and six items. These sections are screen, terminology and system information, learning, and system capabilities. The current version has two forms: a long form with 80 items, and a short form with 27 items. The long item version was reported to have a high reliability coefficient of 0.94 for the entire scale.

The Software Usability Measurement Inventory was developed on the basis of CUSI by examining the CUSI Competence scale, expanding it, and extracting further subscales. The final version has 50 items. It provides three types of measures: an overall assessment, a usability profile and an item consensus analysis. In the usability profile, five subscales are included: affect, efficiency, helpfulness, control and learnability.

PUTQ, Purdue Usability Testing Questionnaire, was developed on the basis of information processing theory. Eight human factors are identified: compatibility, consistency, flexibility, learnability, minimal action, minimal memory load, perceptual limitation and user guidance. It was reported to have a reliability of 0.77.

The ASQ, After Scenario Questionnaire, was developed especially for scenario-based usability study. Participants use a product to do a series of realistic tasks. The ASQ can then be used to assess participant satisfaction after the completion of each scenario. The three items of the questionnaire address three important aspects of user satisfaction with system usability: ease of task completion, time to complete a task, and adequacy of support information. An average reliability of 0.93 was reported. The moderate correlation between the ASQ score and scenario failure or success provides evidence of concurrent validity to the questionnaire.

Both the Post-Study System Usability Questionnaire and Computer System Usability Questionnaire are overall satisfaction questionnaires. The PSSUQ items are appropriate for a usability testing situation, and the CSUQ items are appropriate for a field study situation. Otherwise, the questionnaires are identical, and each contains 19 items. Factor analysis identified three main factors that were measured in the questionnaires, namely, system usefulness, information quality and interface quality. High reliability, validity and sensitivity of the questionnaires were reported.

Generally speaking, questionnaires provide a means to gather enough data to perform statistical analyses. Questionnaires demand very careful design to produce reliable data and to avoid the problem of misleading questions. They may also be conducted via the Internet by using e-mails and Web pages. Relatively formal techniques for data collection and analysis are available. The methods can be applied relatively quickly, and they involve real users.

5. OBSERVATIONAL METHODS

This category involves a real system and real users interacting with a real computer. The set of such methods is very large,

ranging from informal observation of a single user to full-scale experimentation with appropriate numbers of subjects and control of variables. The observation can be conducted in the real working environment or in usability laboratories.

Usability laboratories generally have two rooms, one for the experiment, the other for observation (Figure 2). There are soundproof, one-way mirrors separating the observation room from the test room. This allows the experimenters to monitor users' actions without disturbing them. In laboratories, the evaluation methods such as user performance measurement, think aloud protocol collection, and logging actual use can be used.

For user performance measurement, usability testing can be conducted to get information on user execution time, accuracy, user's satisfaction, and cognitive workload. Generally such a test involves one test administrator and one data logger. Additional observers might also be used to gather more observational data. The test administrator is responsible for controlling the test flow and interacting with the test subject. The data logger is responsible for recording the user's comments and task performance time, sometimes with data logging software. The following performance data is helpful in identifying usability problems and can be collected during the test: failure to complete the task; task and subtask time with high variability; deviation from optimal task path as perceived by usability test administrators; long "seek" time, or the time it takes the user to find the right place in the software to accomplish a task; requests for help during the task; and verbal expression of confusion, discomfort, irritation, and so forth. From those data, usability problems could be identified. If necessary, audiotaping and videotaping can also be used to record voice and image information. Some usability practitioners also do retrospective usability testing by reviewing the videotapes with usability test subjects.

In an industrial setting, usability testing can be very costly. Based on several published budgets, Nielsen (1993) estimated that for a representative, medium-sized usability test, fixed cost was US$3000 and variable cost was $1000 per test user. The pay-off ratio between the benefits and the costs changed with various numbers of test users. The highest ratio was achieved with three test users for a typical medium-sized project. For a user number over three, the pay-off ratio began to decrease. To identify 85% of the usability problems exist in a system, about five subjects are needed for the test.

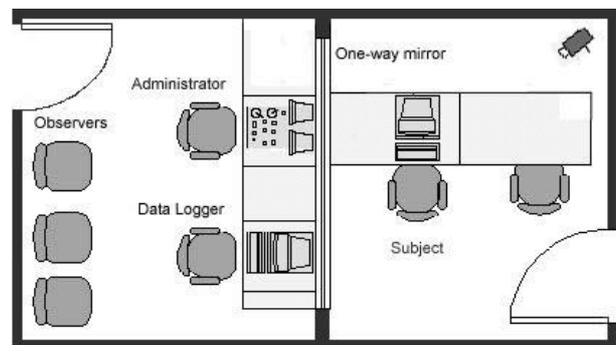
Think-Aloud evaluation can also be used in a usability test. This basically involves having a test subject use the system while continuously "thinking out loud." By verbalizing their thoughts,


Figure 2. Usability laboratory layout sample.

test users enable an observer to understand how they view the computer system. This makes it easy to identify systems major design flaws. This method also provides process information about the human–computer interaction.

Logging actual use involves having the computer automatically collect statistics about the detailed use of the system. Normally, logging is used to collect information about field use of a system after release, but logging can also be used as a supplementary method during user testing to collect more detailed data. Typically, an interface log will contain statistics about how frequently each user has used each feature in the program and how frequently various events of interest occurs; for example, how frequently error messages are called. This method is especially useful in evaluating Web site usability.

Together, observational methods of usability evaluation have the major advantage of investigating the performance of the real system and, therefore, ought to reflect the performance more accurately than the other methods. Disadvantages of these methods are that they tend to be slow to conduct, use many resources, and require expertise in experimental design and interface issues.

6. CONCLUSION

There are many usability evaluation methods available, and each has its own advantages and disadvantages. Some scientists argue that there is no single "best" evaluation method. All of the methods examined have some disadvantages or consider only a limited number of the factors influencing an evaluation, but many of them contain useful ideas or are very appropriate for the evaluation of a specific factor. In practice, deciding which is the optimal usability evaluation method for a specific interface is a fairly complex matter, and depends on the goal of the evaluation and the resources available.

Utility Analysis

N. A. Stanton and M. S. Young

Department of Psychology, University of Southampton, SO17 1BJ, UK

1. EVALUATING DESIGN

The concept of *usability* is common parlance in design, and terms such as *user friendly* and *ergonomically designed* are becoming the ad-man's by-line. Evaluation of the design of everyday objects in terms of their likely impact on human performance would seem to make good sense. Indeed, which product manufacturers would not like to make their devices easy and pleasurable to use? Methods are available which attempt to predict good or bad designs, and thus save manufacturers' time and money. Such methods are taught on every undergraduate and postgraduate program in Human Factors and Ergonomics (Sanders and McCormick 1993), and are undertaken by ergonomics groups in commercial organizations (Jordan *et al.* 1996). However, despite the proliferation of ergonomics methods in research, teaching, and industrial practice, there is little substantive empirical evidence that these methods actually work. This is most likely due to the way in which the methods have evolved and developed over this century. Interest began in the early 1900s with the examination of physical activity, looking at what people did in performing tasks and breaking these activities down into task units (Gilbreth 1911). The analysis led researchers to identify optimal task activity sequences and to prescribe performance times (Taylor 1911). Around the middle of the century, theorists began to link covert, internal, cognitive processes with observable behavior to develop theories of skilled performance (Miller *et al* 1960; Welford 1968). These theories led to the development of methods for representing both internal and external activity with the aim of assisting the development of skills and predicting performance of skilled persons in the execution of activities. From the research and development activities of many dedicated researchers spanning the past ninety years reported in substantial academic journals (e.g. *Ergonomics*; *Human Factors*) and books, modern-day techniques have begun to assume their own validity. These methods are so entrenched in the *modus operandi* of researchers and so well established in the literature that everyone, quite naturally, assumes that they are valid. Indeed, it is difficult enough to get funding to conduct research and consultancy projects without having to ask sponsors for additional funds to prove that the conclusions drawn are valid ones. This argument would be counter-productive to the initial intervention — who is going to fund the work if you have to admit that you cannot be sure that your findings have any sound basis? With this in mind, let us consider in more detail what ergonomics methods do.

2. ERGONOMICS METHODS

People use ergonomics methods with the aim to improve design by: reducing device interaction time, reducing user errors, improving user satisfaction, and generally improving device usability. Each of the methods considers different aspects of human interaction with artifacts. The methods can be broadly classified as either quantitative or qualitative. The quantitative methods predict either speed of performance (e.g. Keystroke Level Model: KLM), errors (e.g. Systematic Human Error Reduction and Prediction Approach: SHERPA), or both speed and errors (e.g. observation). The qualitative methods predict user satisfaction (e.g. questionnaires and repertory grids), device optimization (e.g. checklists, link analysis, and layout analysis), and user-device interaction (e.g. heuristics, Hierarchical Task Analysis (HTA), and interviews). Thus a fairly wide range of human activity with devices is considered using methods that have a pedigree of up to 50 years in ergonomics research.

3. COSTS AND BENEFITS OF ERGONOMICS METHODS

Claims have been made regarding the benefits of ergonomics methods in the design of devices. These normally center around cost–benefit analyses. Many researchers have made brave attempts to quantify the benefits. This usually works by calculating the cost of applying the method (in terms of person-hours, materials, etc.) and subtracting this from the estimated savings generated by the consequently improved design. The net figure is proposed as the benefit brought about by using the ergonomics methods. However, this fails to take account of the accuracy of the methods being used — potential benefits will be reduced if the method is not wholly accurate. For example, the costs associated with a major usability engineering program (Bias and Meyhew 1994) include setting up a laboratory ($20,000), conducting interviews ($4,850), task analysis ($21,900), checklists ($16,800), development of prototype 1 ($39,860), observation ($18,600), modification of prototype 1 ($5,600), observation ($18,600), modification of prototype 2 ($5,600), and final evaluation comprising questionnaires ($6,000), interviews ($7,275), and observation ($6,220). This makes the total costs of conducting the ergonomics study $171,445. The benefits arising from the improved design are expressed as profit from increased sales ($62,500), decreased training ($280,000), decreased support ($233,335), and the savings associated with making the design changes early rather than late ($16,800). This makes the total benefits $592,635. The benefits are justified on the basis that well-designed products (e.g. TVs, VCRs, software applications) are more likely to sell in greater numbers, less likely to require support, and more likely to reduce the need for training a support team, as well as reducing the need for corrections to the design. Subtracting $171,445 from $592,635 leaves $421,190. Who could fail to be impressed? However, the researchers of this work do qualify the figures by noting that the assumptions are estimated, and that they are not proven benefits as proof does not exist (Bias and Meyhew 1994). In addition, the ease of use of a device or product is not the only factor influencing its purchase; factors such as cost, functionality, aesthetics, and perceived usefulness may figure as high, or higher, in the mind of the purchaser.

Our contention with such figures is that the likely dollar benefits do not attempt to take the accuracy of the ergonomics methods into account. The application of ergonomics methods (if inaccurate) could fail to predict true problems with device design or, worse still, identify problems that do not exist. The extent to which methods do this can be calculated using Signal Detection Theory, which determines both the hit rate (the rate at which the method generates correct data, expressed as a ratio of hits to misses) and the false alarm rate (the rate at which the method generates incorrect data, expressed as a ratio of false alarms to correct rejections). Combining these two ratios will

give an overall sensitivity value for the method. We argue that the degree to which the financial benefits will be realized will depend upon the accuracy of the methods used.

4. UTILITY ANALYSIS

In order to consider utility of ergonomics methods, we must factor reliability and validity into the cost–benefit equation. A study was conducted to investigate the reliability and validity of these ergonomics methods to test their stability across analysts (reliability) and their ability to predict behavior (validity). The reliability and validity data are presented together because the two concepts are interrelated: while a method might be reliable, it might not be valid; however, if a method is not reliable it cannot be valid. The data for reliability and validity for each of the ergonomics methods, based on our studies, are presented in table 1. As shown in Table 1, five of the methods achieved acceptable levels of inter-rater reliability (i.e. the reliability statistic above 0.5: this means that there was a reasonable degree of agreement between analysts) and eight of the methods reach acceptable levels of validity (i.e. the validity statistic is above 0.5: this means that the sensitivity of the methods in discriminating between hits and false alarms was satisfactory). Only five methods (indicated with asterisk) performed at an acceptable level for both criteria. We recommend that all of the other methods are treated with caution until further studies have established their reliability and validity.

For the purpose of critiquing conventional cost–benefit wisdom, we have applied our data to the figures taken from the analysis conducted in our previous example. For this analysis we have assumed that the amount of potential benefit to be reaped from the analysis will be comparable to the effort expended on the method (based on person-hours which is expressed in terms of dollars — this is a fairly arbitrary approximation, but perhaps the fairest way of treating the data). Assessing the impact of accuracy of the methods on the potential dollar benefits is worked out using the formula:

(reliability $\times$ validity $\times$ potential benefit) $-$ cost of method $=$ net benefit

A reworking of the cost–benefit analysis for each method first assumes that the maximum potential benefit will be $592,635. From this is subtracted the cost of setting up a laboratory ($20,000), development of prototype 1 ($39,860), modification of prototype 1 ($5,600) and modification of prototype 2 ($5,600). This leaves $521,575, percentages of which are allocated as

potential dollar benefits to interviews (12%), task analysis (22%), checklists (17%), observation (43%), and questionnaires (6%). The formula for each of the methods showing credit (or debit) are illustrated below:

Interview = (0.449 x 0.446 x $62,589) - $12,125 = $409

Task Analysis = (0.226 x 0.591 x $114,746) - $21,920 = (-$6,594)

Checklists = (0.307 x 0.589 x $88,668) - $16,800 = (-$767)

Observation = (0.89 x 0.729 x $224,278) - $43,540 = $101,974

Questionnaires = (0.578 x 0.615 x $31,394) - $6,000 = $5,160

Therefore, the overall net benefit is more likely to be in the region of $100,182 (the sum of the credits and debits for the five methods above), which is less than 25% of the estimated benefit before the reliability and validity of the methods was taken into account. The utility analysis shows that some methods are likely to have greater payback than others. The take-home message of this analysis is that ergonomists need to be realistic in showing the value of their approach, and make credible claims about the payoffs. The analysis can also be used to assess the relative (financial) merits of using one method over another.

5. ENHANCING ARTIFACT DESIGN

In conclusion, we have begun to show that it is possible to collect evidence to strengthen, or weaken, the confidence that may be placed in ergonomics methods in the design of devices. The picture painted in our studies might represent a worst-case scenario, and further studies could lead to a more optimistic picture. However, in the absence of substantive evidence to the contrary, we would rather caution was exercised. There is still little reported evidence in the literature on reliability or validity of ergonomics methods. The use of reliable and valid methods would indeed enhance product design. This would be an attractive situation for ergonomists (who could use their methods with justified confidence), manufacturers (who could make their products easier to use and therefore more attractive to purchasers), and consumers (who would reap the benefits of better-designed products). Therefore, establishing the reliability and validity of ergonomics methods is to the general benefit of everyone. We suspect that, independently of academic debate, there is likely to be an increase in the use of ergonomics methods in the next century. This makes it even more important to establish the reliability and validity of methods as soon as possible.

Work Design and Organization

Air Traffic Management

K. Corker

NASA Ames Research Center, Moffett Field, Ca. & San Jose State University, San Jose, CA 95192, USA

1. INTRODUCTION

Air traffic management (ATM) can be defined as the control of aircraft and airspace system assets to assure safe, efficient and flexible movement of aircraft and passengers through international airspace. The process of ATM is fundamentally a coordination of vehicle and airspace control. The process is mediated by three primary instrumentalities: (1) the air traffic service provider (air traffic control), (2) the airlines and air transportation service operations, and (3) the commercial flight deck and the general aviation cockpit. In addition to these primary constituents, there is a very large number of ancillary service organizations that provide maintenance, communications, weather information, scheduling, training and infrastructure to support ATM. It is a dynamic and distributed control. The system is managed in time frames that extend from seconds to months. The system operates in a physical range from surface movements at tens of miles per hour to *en route* operations with a range to 60 000 feet altitude and Mach 1.8 velocities. Air traffic management is, by the nature of its service, global in extent.

The human factors issues associated with so complex a system are similarly complex and diverse. Human factors research is performed in broad categories as follows: training and selection of personnel, design and development of controls and displays for human use, development of automation and optimization decision-support tools for the operators, and human performance contribution to safety, human–system error propagation, and human response to psycho-physiological stressors, situation awareness, vigilance, crew and team coordination, and system dynamics and stability. The research paradigms brought to bear to address the issues are similarly broad, extending from computational analyses and simulation through empirical studies in the laboratory and simulation to field studies, and large-scale institutional demographic and ethnographic studies. The following sections will describe the evolution of ATM, identify the human factors issues associated with current and future operations, and discuss the methodological implications of these issues.

2. AIR TRAFFIC MANAGEMENT OPERATIONS SCOPE AND HUMAN FACTORS

Research in ATM human factors has tended to be focused on training and selection of air traffic controllers and pilots, on technology for presentation of information to human operators in the system, and on technology for transmission of control input to appropriate parts of the system. However, the drive to efficiency and flexibility has provided technologies to make the process of ATM distributed and de-centralized. In response the foci in human factors, research has shifted to include considera-tion of collaborative decision-making, distributed control, and coordination of roles and responsibilities in dynamic systems.

2.1. Schedule and Planning

Airline operations schedules are established months in advance of flight operations. The schedules are based on market demographics and on the particular operations being scheduled (e.g. optimal cargo airline schedules from those of passenger/revenue operations). In addition to market demands, human factors issues associated with fatigue, vigilance and duty-cycle play a significant role in mediating operations duration and frequency, and in determining crew complement. The performance impact of circadian de-synchronization are the focus of a significant body of research in aviation/ATM human factors (Aviation Space and Environmental Medicine 1998). The issues of duty time and cycle are being extended from flight crew to maintenance and air traffic controller schedules.

2.2. Flow and Facility Optimization

The national and international airspace and the airports that serve commercial and general aviation operations are a constrained resource. Human operators are called on to manage these scarce assets to provide predictable and timely performance while maintaining a margin of safety to assure system robustness in response to environmental or other sources of operational disturbance. Within the US national airspace, 50 000 flights per day operate. The issues of large-scale optimization and decision-making come quickly to the fore. Automation and information aids are needed to assure all factors are accounted for in the decision-making process. Automated checks for information integrity and currency are critical to the air traffic service providers and to the operators. Appropriate resolution of human factors issues associated with human/automation integration and distributed decision-making are fundamental to effective operations.

2.3. Air Traffic Control

Air traffic service providers seek to ensure efficient passage of aircraft through the airspace and while assuring that safe separation is maintained among aircraft. An international collaboration in ATM, the International Civil Aviation Organization (ICAO), partitioned the type of management and decision-making required of the human operators in the system. Air traffic operations are delegated to distinct facilities and different services are provided by those facilities. For a review of the structure of ATM and its evolution, see Federal Aviation Administration (1995). The operations on the surface of airport facilities and the management of operations at gates are delegated to ramp control and airport surface tower operations. Arrival and departure traffic management is delegated to tower and approach/departure control operations. These transition airspace in departure and arrival are handled by the Terminal Radar Approach Control (TRACON). Finally cruise, *en route* operations are managed both over continental and oceanic operations by controllers in Air-Route Traffic Control Centers (ATRCC).

There is a range of specific human factors issues motivated by the kind of service provided and the types of tools provided to the controllers to manage those services. These services are provided by the delivery of clearance and advisory information from the ground to the aircraft and by the provision of opera-

tional state information from the aircraft to the ground service providers. Human/automation integration, training for operation, interface development, procedure development, coordination in strategic decision-making, and communication processes are the key areas of concern for human factors in air traffic control.

2.4. Flight Management

The final common path for ATM is the coordinated movement of aircraft through the airspace. The process of flight management seeks to assure safe timely and efficient operation of aircraft. The human factor attendant the evolution of flight control and flight management as the integration of human and machine is well documented in the Billings (1997). The management of flight has evolved from simple manual control with augmentation to a nearly fully automated operation. The development and evolution of flight deck automation has compelled significant development in the theory and practice of human factors (Weiner and Nagel 1988. This fundamental research in human automation integration in flight deck operations serves as an excellent precursor for similar automation integration issues in ground-based air traffic control.

2.5. Integrated Flight Deck and Air Traffic Management

There are crucial and far-reaching changes in the process of ATM that provide significant challenge to human factors theorists and practitioners. The world community of aviation operations is engaged in a vast, system-wide evolution to integrated airborne and ground-based ATM, NASA, the FAA and Eurocontrol have initiated programs of research and development to provide flight crew, airline operations and air traffic managers with automation aids to increase capacity in *en route* and terminal areas. The aiding technologies support exploitation of timely and dynamic information on atmospheric hazards, traffic fluctuations and airspace utilization. However, the human operators retain the authority and responsibility for safe, efficient operation. The integration of human decision and performance parameters with those of the automation-aiding systems offers a significant challenge to human factors and cognitive engineering in the extent and dynamics of information and control exchanged among the participants across a global aviation network (Kahne and Frolow 1996).

3. AIR TRAFFIC MANAGEMENT HUMAN FACTORS RESEARCH

The complexity of current ATM challenges human factors practice. The potentially revolutionary impact of operational changes in advanced ATM requires fundamental and extensive research agenda to assure: operational integration, management of automation, assurance of appropriate situation awareness, safety assurance and interface optimization (FAA Human Factors Team 1996, Wickens *et al*. 1997, 1998). In addition to these human–technology interactions, the context of operations for these technologies is international in scope. Language and culture will have a significant impact on the integration and operation of technologies for worldwide use. Research in the interaction of automation and culture is in its infancy in terms of theory and method.

3.1. Relaxation of Constraints and Crew–Team Coordination

Technologies have being developed to relax system constraints and integrate flight deck and ground-based operation. These impact human performance research in two ways. First, the decision-making process becomes distributed. This distributed decision process differs from current operations in the number of participants, in the timing of their communication, in their situational awareness and in the span of their authority which has direct impact on crew and team resource management processes. Second, the dynamic concept of operations provides a new coordination challenges for the human operators of that system. In current operations, the roles of the constituents in airspace operations are relatively fixed. However, through implementation of technologies to share information and authority in ATM relax that stability. The human operators (pilots, air traffic controllers, airline operations personnel) must monitor and predict any change in the distribution of authority or control that might result as a function of the airspace configuration, aircraft state or equipage, and other operational constraints. The operators are making decisions and sharing information not only about the management of the airspace, but also about the operating state of that airspace.

3.2. Automation Integration

Automation of flight management operations has had a 20-year development history and the human factors issues associated with increasingly sophisticated multi-modal control operation has received extensive research (Weiner 1989, Billings 1997). The issues of automation bias and over-reliance, lack of adequate feedback as to operating mode, workload, vigilance decrements and primary/secondary task inversion need to be investigated in the development of ground-based automation for air traffic control. These issues become even more critical as the link in control tightens between the ground and the air.

3.3. Workload, Situation Awareness and Vigilance Factors

In addition to workload issues associated with automation management, ATM human factors research will need to address dynamic shifts in workload distribution between air and ground. As automation and information systems for the participants increase in sophistication, situation awareness will need to be maintained among multiple participants in the system. As aircraft development provides for more fuel-efficient extended range operation, crew complement and crew fatigue factors will need to be re-investigated.

3.4. Control–Display Interface Integration

The promise of increased safety and efficiency in the international airspace is based in large part on improved automation aiding and information presentation to the multiple players in the system. These improvements rest on a research requirement in the human factors of controls and displays. The use of virtual environments, new color-coding and immersive technologies for information retrieval and communication are areas for significant new redevelopment. Integration of new display and communication process into the ATM requires a human factors focus on transition from current practice to near-term future improvements (e.g.

data link that moves transactions from an essentially verbal/auditory to a visual/spatial representation). Research is required to assure effective transition (operator training and interface design) and to assure safety (human reliability studies and system design for error–tolerance).

3.5. Communication

Improved information exchange, coordination of its use and assurance of its integrity are all key issues in human factors for the advanced ATM process. Group coordination and distributed decision-making research is beginning to explore the impact of shared data on aviation operations. Research needs to be undertaken to explore the impact of shifting roles and responsibilities in a complex dynamic system. Communications contribution to system safety and reliability in distributed operations needs to be characterized. The appropriate coordination of information services on the flight deck and on the ground also needs to be explored. The technology "push" tendency to overwhelm the operator because information is available should be countered by study of information requirement and information utility based on roles and responsibilities in the advanced ATM.

3.6. Methodological Developments

In addition to the research agenda based on the emerging issues of complex dynamic systems, there is shift in methodologies required to meet that research agenda. Prior paradigms used an incremental increase in testing complexity, fidelity and cost from empirical results, to prototype, to full mission simulation and then to field-testing. Such a process is still a valid paradigm. However, the rate of development of ATM systems, the tremendous economic pressure to implement and reap immediate benefits from technologies, and the significant complexity and cost of large-scale distributed air–ground tests suggest the development of other, more cost effective, methods of human factors research. Prominent among these is computational human performance modeling (Laughery and Corker 1997). In this paradigm the human and the system elements of interest are represented as computational entities (or agents). These agents interact as the system elements would in actual field operations and behaviors can be observed. The benefit accrued (assuming well-developed and validated models) is that system and human characteristics can be quickly varied (e.g. based on an assumed technology change) and the impact of that change identified in the full-system context. Such models help focus the expensive and complex simulation and field tests. In addition, performance at the edge of system safety can be explored in the computational human performance-modeling paradigm.

4. CONCLUSION

Human factors research in advanced ATM is a challenging mix of well-established human factors practice (e.g. display and control development and evaluation, training and selection processes) and more edge-of-the-art research (e.g. virtual and immersive environment development, automation, shared initiative, and decision-aiding in distributed control). These techniques are made more challenging by the size, dynamic complexity and safety–criticality of an evolving international system. The methodology and the theory of human factors are challenged by the scale of technology and the global extent of its implementation. Fundamental research is needed in the process of scaling-up basic human factors practice to global technology implementation for real-time control of such a dynamic and critical operation as advanced ATM.

Air Traffic Management System Design

K. Kerns

The MITRE Corporation, Center for Advanced Aviation System Development, 1820 Dolley Madison Boulevard, McLean, VA 22102-3481, USA

1. INTRODUCTION

In the USA, the air traffic management (ATM) system, operated by the Federal Aviation Administration (FAA), is composed of two subsystems. The air traffic control (ATC) system assures safe separation of aircraft and an orderly flow of traffic. Air traffic specialists or controllers provide the ATC system's direct service to pilots, aircrews and passengers on board aircraft being controlled by the system, during takeoff, while en route and upon landing. The traffic flow management (TFM) system works to simplify and expedite traffic flows, ensuring that the operational environment is compatible with the capabilities of the controllers and pilots responsible for conducting flight operations. Traffic flow management specialists issue system-wide, regional and local restrictions on aircraft flight paths and schedules to ensure that traffic demand does not exceed the traffic handling capacity of the ATC system. Figure 1 depicts the hierarchical structure of the ATM system that has evolved as the demand for aviation services has grown.

Increases in traffic demand are projected to continue for a long time. The next evolutionary steps for the ATM system focus on the introduction of new technologies, decision-support tools and traffic management strategies better to utilize capacity and to accommodate user needs without compromising safety. Even as the ATM system evolves becoming more highly automated, the role and contribution of the human element to the system's performance remains significant. The interactions and interdependencies among the human operators, their equipment and their procedures present a broad and diverse set of human factors challenges. An examination of the changing role of controllers in the evolving ATC system and in the future ATM system illustrates many of these challenges.

2. THE ATC SYSTEM AND CONTROLLER TASKS

To receive air traffic services, pilots file a flight plan, obtain a clearance and maintain radio communication with controllers as they fly through airspace controlled by the ATC system. Controllers monitor flights within the specific airspace (sectors) that they are in charge of and issue instructions to pilots to ensure safe separation and efficient use of the airspace.

Controllers in terminal and en route facilities handle active flights operating under the control of the ATC system. Figure 2 shows the role of the terminal and en route controllers (Mundra 1989). In the terminal area, controllers working in airport traffic control towers (or towers) control the surface movement of aircraft and their landings and takeoffs. Once the aircraft takes off and before it lands, the aircraft is controlled by controllers working in terminal approach control facilities. Outside of this region,

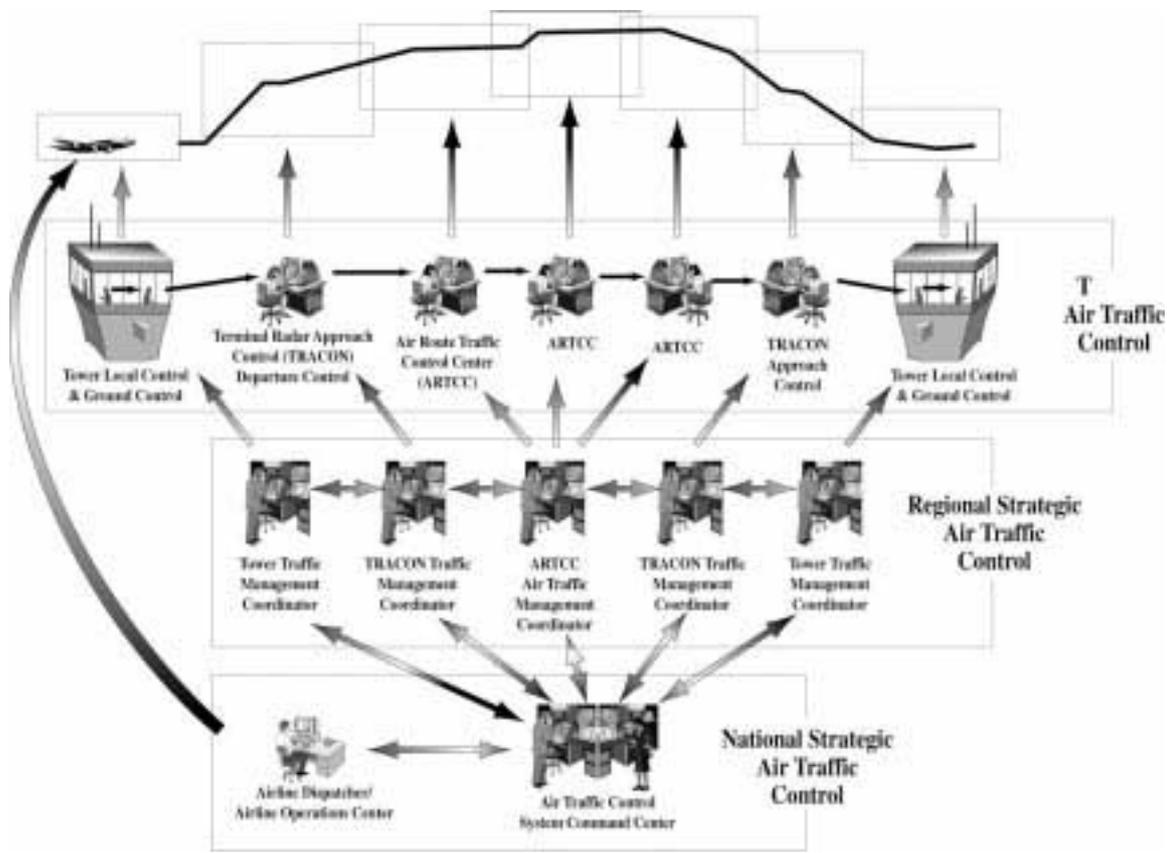

Figure 1. The air traffic management system organizational structure from Kerns *et al.* (1999), with permission.

Type of Facility	Terminal Area Facilities		En Route Facilities	
Controlling Facility	Airport Traffic Control Towers	Approach Control Facilities	Air Route Traffic Control Centers (ARTCCs)	
Type of Control	Ground Traffic Control Takeoff and Landing Control	Approach and Departure Control	ATC during Transition and Cruise	
Airspace	Airport Traffic Area Typically 5 nmi and 3,000 ft AGL	Approach Control (Tracon Area) Typically Extending Up to 40 nmi and 10,000 ft msl from the Airport	En Route Airspace Transitional Phase Typically 50-150 nmi from Airport	Cruise Phase Up to 60,000 ft
Typical Flight Time	Typical Ground Time 5-10 min	Typical FlightTime 10-20 min	Typical FlightTime 10-20 min	Typical FlightTime 20 min to Several Hours
Flight Profile				

Figure 2. Role of terminal and en route facilities in air traffic control from Mundra (1989), with permission.

controllers working in en route centers have responsibility for the flight. While en route, aircraft may pass through one or more centers, into oceanic airspace, and be transferred to an international control facility.

2.1. The Airport Traffic Control Tower

Controllers working in towers spend much of their time visually tracking aircraft movements outside the tower. The glass-enclosed tower cab is physically oriented relative to the runways to provide an unobstructed view of the airport's primary movement areas (taxiways and runways). To keep track of aircraft movements, tower controllers must move around the tower cab and interact with other controllers who are responsible for aircraft during different segments of the takeoff and landing phases of flight. Reduced visibility at night or because of weather conditions, can leave tower controllers and pilots vulnerable to errors resulting in runway incursions and other surface incidents between aircraft taking off and landing. In addition, the responsibility to monitor traffic by continuously looking out the tower cab window, makes it difficult read display information or enter data without disrupting visual scanning tasks.

A voice communication link allows the tower controller to direct aircraft movements to and from the gate and issue clearances for take off and landing. During busy periods, tower controllers must accomplish time-critical communications at a rate only marginally ahead of air traffic movements around the airport. The tempo of the operation means that controllers must speak rapidly to transmit complex messages. Moreover,

radiofrequency congestion during these busy periods often prevents pilots from verifying the communication by reading back their instructions. Dropping the readbacks or other procedural steps that are intended to assure communication can leave controllers and pilots vulnerable to communication errors.

2.2. Terminal Radar Approach Control

Once the aircraft takes off and before it lands it is monitored by the terminal radar controllers. Arrival and departure controllers rely on a radar display to keep track of the traffic situation and plan efficient traffic flows. The arriving traffic in the terminal area funnels in from higher altitudes and speeds for landing. The arrival controllers sequence and space the aircraft. The departing traffic fans out to higher altitudes and speeds for the cruise phase. Departure controllers establish the aircraft on headings to their planned routes of flight.

In this environment, there is a high frequency of aircraft maneuvering and rapid convergence of many traffic streams. Within the terminal airspace aircraft do not follow a predefined route, instead control is exercised through heading, altitude and speed instructions. Controllers must extrapolate aircraft positions to visualize the paths to be flown by the traffic and issue instructions to execute these paths. A two dimensional radar display depicts each aircraft's position, identity, altitude, and speed. The controller's performance depends on an ability to visualize the three-dimensional traffic situation and keep track of the situation and the required actions under high workload conditions.

The high rate maneuvering results in frequent communications with pilots and frequent coordination with other controllers handling nearby sectors of airspace. As in the tower, terminal controller workload and frequency congestion can result in procedural short cuts and miscommunications.

2.3. The En Route Center

Once an aircraft is established on its route of flight, en route controllers monitor the flight and ensure separation. Over the continental USA, en route ATC is predominantly based on radar information. However, the FAA also provides ATC service within a large area of non-radar airspace over the Atlantic and Pacific Oceans and the Gulf of Mexico. Oceanic ATC is based on flight plan and aircraft position information provided by pilots. This section focuses on controller tasks and procedures in the en route radar environment.

The en route center airspace is divided into sectors with various characteristics. Controllers working high altitude sectors handle departure traffic climbing to cruise altitude, en route traffic flying level and traffic descending to a lower level in preparation for arrival. Controllers working low altitude sectors handle a mixture of aircraft which fly at lower altitudes, slower speed arrival and departure traffic, and higher performance aircraft climbing to the high altitude sectors.

Characteristics of the traffic and sector airspace contribute to sector complexity and controller workload. Factors such as the type of traffic flows and the service that must be provided each aircraft account for routine tasks that are known in advance and performed for every aircraft or for a specific subset of the traffic such as a particular flow. For example, en route controllers currently have a major responsibility to routinely issue predetermined routing and altitude clearances that establish an orderly flow of traffic within the airspace. Factors such as the size and shape of the airspace delegated to the sector, the number and characteristics of aircraft within the airspace, and the nature and frequency of requests by pilots to alter their flight plans account for additional tasks that depend on the situation. For example, one factor thought to be an important determinant of complexity involves the number and pattern of potential conflicts that can occur within the sector airspace for a given period of time. The decision-making process associated with the detection and resolution of conflicts has a great impact on determining controller workload and sector capacity.

During busy periods, two or three controllers may staff en route sectors. When multiple controllers work a sector, their tasks must be closely coordinated. Typically, a radar (R) controller is in charge of the sector operation. This controller uses the radar situation display and voice communications to apply radar separation procedures and separate the aircraft from all others within the sector. A radar associate or data (D) controller is responsible for separation planning activities. The D controller uses paper flight strips which provide advance information on the aircraft's planned route and communicates with other controllers to identify potential problems and coordinate preventative control actions. When the sector is too busy for the R and D controllers to handle, a radar coordinator (tracker) or handoff controller may share the R controller's load, serving as a redundant "set of eyes and ears" to support situation monitoring and as a second pair of hands to perform data entry and coordinate actions with other sectors.

In contrast to the tower and terminal environments, the en route operations and computer system support a more structured traffic organization. Manual data entry tasks that make up a large part of the en route controller's workload can be demanding and time-consuming. The en route computer system stores maintains the ground system's flight plan data for each aircraft throughout its flight. To support ground-based flight planning, en route controllers are required to keep the computer's data up to date by entering control instructions and flight amendments as they are issued.

During busy periods, communication with pilot makes up a significant portion of the R controller's workload. Moreover, the addition of other team members does not redistribute the sector's communication workload. In fact, the R controller's heavy involvement with air–ground communication tasks tends to hinder the verbal interactions required for team direction and coordination when multiple controllers are working. As in the tower and terminal radar environments, miscommunications can occur when controller workload and frequency congestion increase.

3. HUMAN FACTORS ISSUES IN THE EVOLVING ATC SYSTEM

The ATC system is evolving to address human factors challenges that relate to the mental demands and uncertainties imposed by the ATC process and the environments in which the controllers are embedded. Fundamental human factors challenges are to manage mental demands and complexity while improving the efficiency of controller strategies. Another broad set challenges relate to the cooperative nature of the ATC activity and the need to manage communications demands and improve information transfer.

3.1. Complexity Management

Because the air traffic control system is functioning near, at or even beyond its planned maximum traffic handling capacity, there has been a long-standing interest in understanding and quantifying the controller's traffic handling capacity and in predicting when this capacity breaks down. However, despite years of research on controller workload, sector complexity, and operational errors, the measurement and management of complexity in the current system is rudimentary.

Today, a mix of procedural techniques and automated capabilities is used to anticipate and manage complexity problems. On a scheduled basis, controller positions are opened and closed and responsibility for sector airspace is divided and combined under the positions. During busy rush periods throughout the day, en route sectors are staffed with one, two, or three controllers. When traffic volume is expected to exceed a sector's capacity for an extended period, TFM is alerted by an automated function and procedures are activated to limit the volume of traffic handled by the sector. Currently, the automated function uses the predicted aircraft count to estimate sector complexity. Operational decisions on alerting thresholds and complexity management actions are made from human experience and judgment.

Operational errors and deviations have been used to study the factors that contribute to sector complexity and controller

workload giving rise to system breakdowns . Although controller workload has been analyzed extensively to derive traffic and airspace characteristics beyond traffic count that predict controller workload, this approach seems to be most applicable to measurements of the observable, motor and manual components of workload. Research on the mental and cognitive components of workload has shown that successful controllers use adaptive strategies to handle more aircraft without error or excessive workload. For example, the controller may handle an unexpected increase in traffic load by structuring the traffic so that all of the flights are in-trail and traveling at a uniform speed, thereby reducing the difficulty of monitoring for conflicts. As a result the controller spends less time on each flight during periods of high demand. In part, this adaptability may explain why studies of operational errors reveal that errors are not only uniquely associated with high complexity and workload, but also occur under low-to-moderate complexity and workload.

Because there are no normative data indicating relative frequencies of the levels of traffic volume and complexity in the operational environment, it is difficult to determine whether the reported frequencies of errors in these levels are disproportionately related to chance. A better understanding of the relationship between complexity and errors and techniques for managing complexity depends on more complete baseline data on human and system performance under normal and abnormal conditions.

Even though researchers do not fully understand the relationship between complexity, workload, and errors, there is general agreement that controllers need information on current and predicted sector complexity. Decision-support tools for conflict prediction and resolution may help to address controller needs for sector complexity information (Kerns 1999a). With these tools, an indicator of sector complexity is available in the form of display data on the number of predicted conflicts and their temporal distribution. Advance information on conflict resolution workload is expected to improve situation awareness and allow the sector team to better schedule and manage conflict resolution tasks.

3.2. Control Strategies and Efficiency

As mentioned earlier, controllers cope with increasing traffic demand and complexity by employing adaptive strategies. Research on controller strategies indicates that specific adaptations tend to lower the efficiency of individual flights and the overall traffic flow when demand is high. In general, strategies that are economical for the controller are those that preserve the primary objective of safety but take less account of secondary objectives such as flight efficiency, user-preferred paths, and fuel economy.

Another way controllers adapt their strategies is to focus on the immediate tactical situation and abandon planned strategies. To plan and execute control strategies that are more flight efficient, controllers must coordinate with each other. Under high workload, a shift from cooperative toward individual work has been observed in both the terminal and en route environments. In the terminal environment controllers may shed coordination tasks under high demand, resulting in less efficient sequencing of arrival aircraft. While in the en route environment, both sector controllers focus attention on the current tactical situation, reacting quickly and employing less efficient tactical control techniques. In many traffic situations, reactive strategies are also

communications-intensive, with the controller assuming greater responsibility for flight paths and making continuous tactical adjustments.

To preserve flight efficiency, a more proactive approach to ATC is desirable. Decision-support tools for tactical planning and selection of control strategies are being introduced in the en route and terminal environments. The preceding section mentioned the en route decision-support tools being developed to provide early detection of conflicts. This conflict probe capability will reduce the mental calculations and extrapolations involved in separation monitoring and afford a longer lead-time to plan resolution maneuvers that are less disruptive to the user's flight intent. Team performance will be aided by providing the D controller with more powerful tools for visualizing the future traffic situation and evaluating proposed maneuvers. In addition, an automated coordination aid will also allow controllers to share and approve plans electronically.

In the terminal environment, controller aids for merging flows and sequencing aircraft for approach are already in use or under test at field facilities. These tools provide advance information on the predicted sequence of arrival aircraft. One tool, the converging runway display aid (CRDA), is designed to assist the controller in conducting staggered approaches (Mundra and Levin 1990). Staggered approaches require specific separations between aircraft landing on adjacent runways as well as between in-trail aircraft. Staggered approaches are more complicated than simultaneous approaches that have only in-trail spacing requirements. The CRDA reduces the complex mental calculations and extrapolations involved in staggered approaches by projecting false targets or ghosts for aircraft arriving in one of two converging streams onto the other stream, thus allowing the controller to visualize and manage simple in-trail spacing on a single approach.

Another tool, the final approach spacing tool (FAST) provides the controller with landing sequence numbers and runway assignments to achieve an accurately spaced flow of traffic onto the final approach course (Lee and Davis 1995). Based on the displayed sequence, the controller formulates appropriate instructions for merging and spacing the arrivals. FAST advisories should improve the runway delivery precision and reduce controller workload by reducing the number of vectors issued to each aircraft and reducing the need for (verbal) coordination between controllers.

3.3. Communications and Information Transfer

There is ample evidence in the research literature that controller–pilot communications are a common and persistent problem in today's operations (Kerns 1999b). Some of the primary factors that contribute to communications problems arise from the use of spoken language to transfer information. Controllers and pilots have adopted a standardized phraseology, language conventions, and procedures which define the process for conducting the dialogue, including the cues that tell a listener when a transaction has been completed and whether a readback is required. However, despite years of refining the language and procedures, research confirms the intractable nature of many of the problems inherent in the exclusive use of spoken language for controller–pilot communications. Grayson and Billings (1981) analyzed aspects of human speech processing and conversational behavior that mediate communication performance. Their analysis found that

a tendency to fill-in information, the expectancy factor, and timing problems were implicated in many types of controller–pilot communication problems. The expectation factor contributes to misinterpretations and inaccuracies because controllers and pilots sometimes hear what they expect to hear. This generates what have been called "readback and hearback" errors in which, respectively, a pilot perceives what he expected to hear in the instruction transmitted by the controller and a controller perceives what he expected to hear in the readback transmitted by the pilot.

Congestion on the voice radiofrequency has also been implicated in communications problems. During busy periods, controllers issue longer, more complex messages in an attempt to minimize use of the radiofrequency. Analyses of routine communications (Cardosi 1993, Morrow *et al.* 1993) have highlighted the contribution of message complexity and the resulting memory burden to miscommunications. In both the terminal and en route environments, errors and procedural deviations increased as clearances increased in complexity. In response to these problems, data link communications have already been introduced as an alternate means of information transfer in the tower environment and a controller–pilot data link capability for the en route environment will be field tested soon.

In addition to reducing frequency congestion, data link technology offers several advantages for transfer of lengthy, repetitive ATC messages. The data link has capabilities for message storage and retrieval that reduce the controller's burden when preparing messages and the pilot's memory burden when receiving them. Data link also allows controllers and pilots to pace the transmission and processing of the information, thus avoiding conflicts between communications and other higher priority tasks.

Although the experience and results to date indicate that these initial applications of data link offer important operational benefits at little or no cost to the human operators, future applications of data link must be selected carefully, addressing key human factors challenges. Visual display and manual control of transmitted information may not be appropriate in environments where the controller or pilot visual and manual resources are already reaching an overload state. Delay factors associated with message composition may limit the utility of data link in rapidly changing conditions while transmission delays may limit its utility for time-critical transmissions. Finally, new procedures will be needed to maintain team performance when the communication medium is silent and may be less readily observable by multiple operators.

4. HUMAN FACTORS ISSUES IN THE DESIGN OF THE FUTURE ATM SYSTEM

Recently, the FAA and the aviation industry reached general consensus on a strategic direction for the ATM system in the USA called "Free Flight" (RTCA 1995). The goal of free flight is an ATM system based on two fundamental premises:

- The FAA retains and strengthens its safety mandate for separation of aircraft.
- The users of the system are given the flexibility to make decisions that allow them to extract the maximum economic benefit from the ATM system.

Among other characteristics, free flight assumes a shift way from the current ground-based, tactical ATC operations toward a more cooperative arrangement in which users have greater flexibility to select and manage their flight paths and to participate routinely in airspace management decisions. The new decision-support tools and data link communications technology discussed in the preceding section represent the initial phase of ATM system evolution toward free flight. As the ATM system continues to evolve, further human factors challenges will emerge in response to changes in operating philosophies, the design of new functional architectures which reallocate system functions, and the introduction of more advanced tools and technologies to support ATM operations.

4.1. New Philosophies and Procedures

Currently in ATC, the basic rule of separation is that every controller is responsible for separation of participating aircraft for the duration of time the aircraft is within the controller's sector of responsibility (Nolan 1990). In future ATC, the free flight goal is to evolve toward a more strategic operation that better accommodates user preferences. Under this philosophy, controllers may assume more responsibility for solving each other's problems as strategic predictions allow for early ATC interventions. In addition, as new technologies provide pilots with traffic information and conflict prediction capabilities commensurate with or surpassing those of the controller, they may also be called upon to participate in solving ATC problems.

A team perspective is likely to be a major focus in addressing human factors issues in future ATM. Considerable research and analysis has addressed the controller's role (often as a single operator) within an ATC domain. There is much less work that addresses the multi-operator perspective. Today team training is less formal in ATC than on the flight deck, but teamwork is likely to be a critical component of ATM for the foreseeable future. Definition, prediction and management of team performance will be an important human factors challenge in the future system.

4.2. Functional Architecture

Already, new ATM decision-support systems cut across traditional divisions of responsibility between en route and terminal controllers. While strategic planning tools such as conflict probe tend to blur the distinction between ATC and TFM responsibilities. It is also likely that the current workload concentrations in the tower environment will motivate further reallocation of tasks across ATC environments and development of capabilities for smoothing workload through greater human control over the tasks, their timescales, their scheduling, and their sequencing (Laios and Giannacourou 1995). At the same time, imbalances in air and ground system capabilities will motivate exploration of alternative allocations of functions between controllers and pilots which may increase the pilot's role in ATC. These forces, taken together with the new operating philosophies envisioned under free flight, will drive a progression toward new relationships among system participants.

In ATC, human factors can help evaluate the allocation of responsibility between controllers and pilots in all of the operational environments. And within the ATM organization, human factors can help analyze and evaluate the allocation of responsibility between controller team members and between controllers and traffic managers. For example, laboratory simulations can be used to explore the feasibility and effectiveness

of new roles, such as a planner/coordinator controller role that uses automated tools to support multiple sector controllers. Such a role might combine functions currently performed by a D controller and a traffic flow manager.

4.3. Advanced Tools and Technologies

Advanced concepts for ATC in the USA envision higher levels of automation in controller decision-support. In the terminal environment, the next version of FAST will provide automated advisories for final approach spacing while in the en route environment automated conflict resolution advisories will be provided. This level of automation will have a profound impact on the way ATC is performed. Not surprisingly, there is considerable concern in the human factors community over the impact of such automation on the controller's situation awareness and ability to provide back-up for the automation system when necessary environment (Wickens *et al.* 1998).

Automation issues will become increasingly important human factors challenges in the future ATM system. However, before questions on human roles can be addressed, more fundamental questions must be answered regarding the efficiency of the alternatives in different task environments and the nature of the back-up mechanisms. Laboratory simulations can help answer questions regarding the efficiency of controller tools under various traffic scenarios. Requirements for maintaining situation awareness and controller skills will vary according to the need for manual back-up in the future. Human factors analyses can help specify these requirements under various back-up mechanisms.

5. Conclusion

There are major challenges ahead in analyzing functional requirements and the allocation of functions between human and automated elements of the future ATM system. At this point, there is an opportunity for proactive research in human factors to gain insight and perspective on issues surrounding the evolution of ATM. Multiple research approaches, including the review and application of existing data and knowledge, will make it possible to prove the value of new concepts regarding human roles and interrelationships and their impact on the quality and efficiency of the ATM system. During the development and introduction of new ATM capabilities, human factors specialists should be involved to help define new functionality and procedures.

As the discussion above indicates, however, this is a system that has historically attempted to match the capabilities of the people with the demands of the system by distributing roles and responsibilities, and by introducing new tools and technology. Efforts to enhance efficiency through increased flexibility and shifts in the locus of control need to be based on an understanding of the complexity inherent in this system, and on a realistic assessment of the strengths and limitations of the technologies being considered to support controllers and pilots.

Aircraft Inspection: Computer Based Training Program

G. M. Nickles, A. K. Gramopadhye, B. Melloy, and J. Marshall*
Department of Industrial Engineering, Clemson University, USA and
*Lockheed Martin Aircraft Center, Greenville, South Carolina, USA

1. INTRODUCTION

Aircraft inspection and maintenance are an essential part of a safe, reliable air transportation system. Training has been identified as the primary intervention strategy in improving inspection performance. If training is to be successful, it is clear that we need to provide inspectors with training tools to help enhance their inspection skills. This article outlines recent efforts being pursued by the Training System Laboratory at Clemson University focused on the development of a computer-based inspection training program, automated system of self-instruction for specialized training (ASSIST). The ASSIST program was developed using a task analytic methodology.

Existing training for inspectors in the aircraft maintenance environment tends to be mostly on-the-job (OJT). Nevertheless, this may not be the best method of instruction (FAA 1991, Gordon 1994). For example, OJT feedback may be infrequent, unmethodical, and/or delayed. Moreover, in certain instances feedback is economically prohibitive or infeasible due to the nature of the task. Thus, because the benefits of feedback in training have been well documented (Weiner 1975), and for other reasons as well, alternatives to OJT are sought. Furthermore, training for improving visual inspection skills of aircraft inspectors is generally lacking at aircraft repair centers and aircraft maintenance facilities. However, the application of training knowledge to enhance visual inspection skills has been well documented in the manufacturing industry. Training improves the performance of both novice and experienced inspectors (Weiner 1975, Drury and Gramopadhye 1990). Visual inspection skills can be taught effectively using representative photographic images showing a wide range of conditions with immediate feedback on the trainee's decision (Weiner 1975). Training with realistic photographic images, in controlled practice and with appropriate feedback, appears to be superior to OJT training on its own (Latorella *et al*. 1992).

Thus, off-line training/retraining with feedback has a role to play in aircraft inspection training. One of the most viable approaches for delivering training given the many constraints and requirements imposed by the aircraft maintenance environment is computer-based training. Computer-based training offers several advantages relative to traditional training approaches; for example, computer-based training is more efficient, facilitates standardization, and supports distance learning. With computer technology becoming cheaper, the future will bring an increased application of advanced technology in training. Over the past decade, instructional technologists have offered numerous technology-based training devices with the promise of improved efficiency and effectiveness. These training devices are being applied to a variety of technical training

applications. Examples include computer-based simulation, interactive video disks, and other derivatives of computer-based applications. CD-ROMs and digital video interactive (DVI) technology will also provide us with the multimedia training systems of the future. Many of these training delivery systems, such as computer-aided instruction, computer-based multimedia training, and intelligent tutoring systems, are already being used today, ushering in a training revolution.

In the domain of visual inspection, the earliest efforts to use computers for off-line inspection training were reported by Czaja and Drury (1981). They used keyboard characters to develop a computer simulation of a visual inspection task. Similar simulations have also been used by other researchers to study inspection performance in a laboratory setting. Since these early efforts, Latorella *et al*. (1992) and Gramopadhye *et al*. (1993) have used low fidelity inspection simulators using computer-generated images to develop off-line inspection training programs for inspection tasks. Similarly, Drury and Chi (1995) studied human performance using a high fidelity computer simulation of a printed circuit board inspection. Another domain which has seen the application of advanced technology is the inspection of X-rays for medical practice.

It seems that most of the relevant work has focused on developing low fidelity simulators for running controlled studies in a laboratory environment. Thus, research efforts need to be extended in order to take full advantage of today's computer technology. Moreover, advanced technology has found limited application for inspection training in the aircraft maintenance environment. Presently, most of the applications of computer technology to training have been restricted to the defense and aviation industries for complex diagnostic tasks. The message is clear: we need more examples of advanced technology applied to training for inspection tasks, examples that draw on proven principles of training. This article describes a university/industry collaborative research effort to develop an off-line computer-based inspection training system for aircraft inspectors. The specific objective of this research was to develop an inspection training system that would help improve the visual search and decision-making skills of aircraft inspectors. ASSIST was developed in cooperation with Lockheed Martin Aircraft Center and Delta Air Lines (figure 1). Here is a brief description.

2. TRAINING FOR INSPECTION

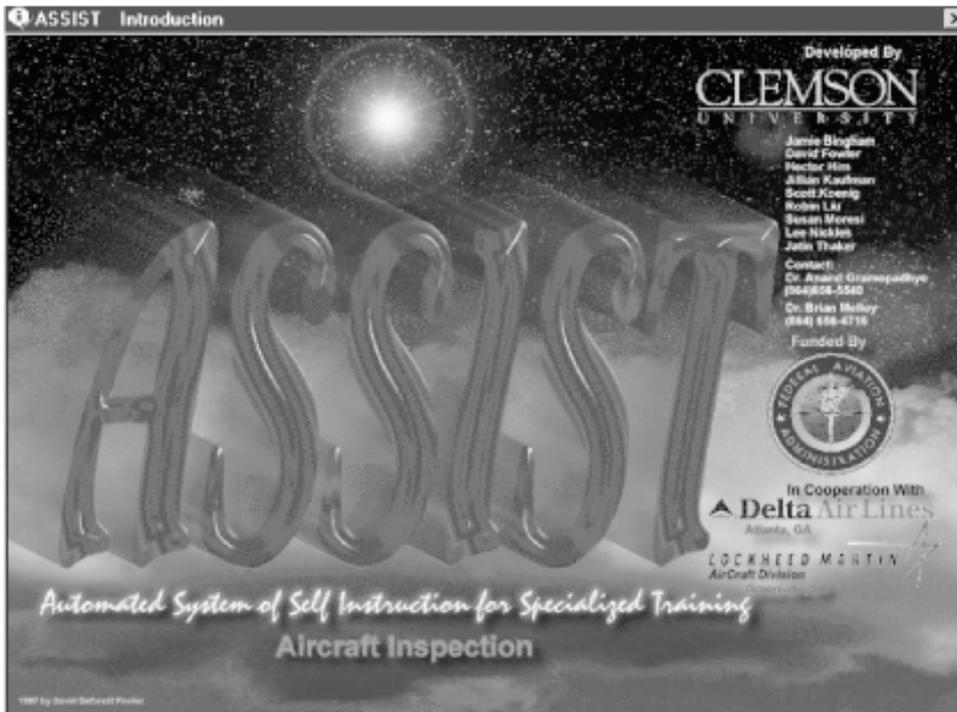
The task analysis is the subject of another article. Along with the trainee analysis, it was used to compare the knowledge and skills required by the task with those of the inspector, in order to determine any gaps which needed to be addressed. Patrick (1992) has identified the training content, the training methods, and the trainee as the important constituents of the training program. Drury (1992) includes the training delivery system as another component of the training program. Although a considerable amount has been written about designing training systems (Patrick 1992, Gordon 1994), very little focuses directly on enhancement of visual inspection skills. Embrey (1979) states that for any training program to be effective, it should address the following three issues: attitude of the trainee at work, knowledge required to perform the job, and the specific skills required to perform the task. Specific training methods which can be used for inspection training (Drury and Gramopadhye 1990, Gramopadhye *et al*. 1997) are described below.


Figure 1. ASSIST title screen.

2.1 Pretraining

Pretraining provides the trainee with information concerning the objectives and scope of the training program. During pretraining, pretests can be used to measure (a) the level at which trainees are entering the program and (b) cognitive or perceptual abilities that can later be used to gauge training performance or progress. Advanced organizers or overviews have proven useful; they are designed to provide the trainee with the basics needed to start the training program. The elaboration theory of instruction proposes that training should be imparted in a top-down manner, wherein a general level is taught first before proceeding to specifics. Overviews can fulfill this objective by giving the trainee an introduction to the training program and facilitating assimilation of new material.

2.2 Feedback

A trainee needs rapid, accurate feedback in order to know whether a defect was classified correctly or a search pattern was effective. Feedback with knowledge of results, coupled with some attempt of performing the task, provides a universal method of improving task performance (Wiener 1975). This applies to learning facts, concepts, procedures, problem solving, cognitive strategies, and motor skills. The training program should start with rapid feedback, which should be gradually delayed until the "operational level" is reached. Providing regular feedback beyond the training session will help to keep the inspector calibrated. Gramopadhye *et al*. (1997) classify feedback as performance feedback and process feedback. Performance feedback on inspection typically consists of information on search times, search errors, and decision errors. Process feedback, on the other hand, informs the trainee about the search process, such as areas missed. Another type of feedback, called cognitive feedback, has emerged from the area of social judgement theory. Cognitive feedback is

the information provided to the trainee about some measure of the output of their cognitive processes. For inspection tasks, process feedback is the same as cognitive feedback.

2.3. Active Training

In order to keep the trainee involved and to help with internalizing the material, an active approach is preferred. In active training, the trainee makes an active response after each piece of new material is presented, e.g., identifying a fault type. Czaja and Drury (1981) used an active training approach and demonstrated its effectiveness for a complex inspection task.

2.4. Progressive Parts Training

Salvendy and Seymour (1973) successfully applied progressive parts training methodology to training industrial skills. In the progressive parts methodology, parts of the job are taught to criterion and then successively larger sequences of parts are taught. If a task consisted of elements E1, E2, E3, and E4, the training would be like this:

- Train E1, E2, E3, and E4 separately to criterion.
- Train E1 and E2, E3 and E4 to criterion.
- Train E1, E2, E3 to criterion and E2, E3, E4 to criterion.
- Train the entire task to criterion.

This method allows the trainee to understand each element separately as well as the links between the various elementsælinks which represent a higher level of skill. On the other hand, reviews of the literature reveal that parts task training is not always superior. The choice between parts task training and whole task training depends on "cognitive resources" imposed by task elements and the "level of interaction" between individual task elements (Gordon 1994). Thus, there could be situations in which one type of task training is more appropriate than the other. Naylor and Briggs (1963) have postulated that for tasks of

relatively high organization or complexity, whole task training should be more efficient than parts task training.

2.5. Schema Training

The trainee must be able to generalize the training to new experiences and situations. For example, it is impossible to train the inspector on every site and extent of corrosion in an airframe so they can detect and classify corrosion wherever it occurs. Thus, the inspector will need to develop a schema which will allows a correct response in novel situations. The key to developing schema is to expose the trainee to controlled variability in training.

2.6. Feedforward Training

It is often necessary to cue the trainee as to what should be perceived. When a novice inspector tries to find defects in an airframe, the indications may not be obvious. The trainee must know what to look for and where to look. Specific techniques within cueing include match-to-sample and delayed match-to-sample. Feedforward information can take different forms, such as physical guidance, demonstrations, and verbal guidance. Feedforward should provide the trainee with clear and unambiguous information which can be translated into improved performance.

3. AUTOMATED SELF-INSTRUCTION FOR AIRCRAFT INSPECTORS

3.1. System Specifications

The computer-based training program was developed using Visual C++, Visual Basic and Microsoft Access. The development work was conducted on a Pentium 120 MHz platform with a 17-inch high resolution monitor (0.28 mm dot pitch, noninterlaced), 32 MB RAM, 2 MB video RAM, ATI Mach 32 VLB advanced graphics accelerator card, 810 MB hard drive, multispeed CD drive, 210 MB Bernoulli drive and a Reveal multimedia kit. The training program uses text, graphics, animation, and audio. The inputs to the system are entered through a keyboard and a two-button mouse.

3.2. System Structure

ASSIST consists of three major modules: (1) general inspection module, (2) inspection simulation training module, and (3) instructor's utilities module. All system users interact through a user-friendly interface. The user interface capitalizes on graphical user interface technologies and human factors research on information presentation (color, formatting, layout, etc.), ease of use, and information utilization.

3.3. General Module

The objective of the general module is to provide the inspectors with a basic overview on the following topics: (1) role of the inspector, (2) safety, (3) types of aircraft, (4) factors affecting inspection performance, and (5) inspection procedure. The module incorporates multimedia (sound, graphic, text, pictures, and video) with interaction opportunities between the user and the computer. Figure 2 shows a prototypical screen of the general inspection module.

3.4. Inspection Simulation Training Module

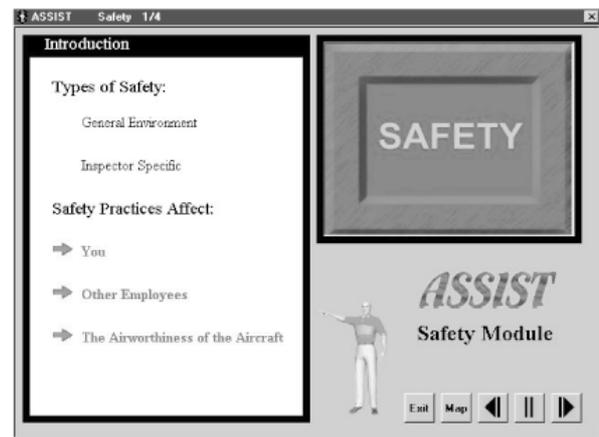
This module of the training program provides inspection training on a simulated aircraft inspection taskæthe aft cargo bin of a Lockheed Martin L-1011 (figure 3). By manipulating the various


Figure 2. The safety topic of the general module.

task complexity factors, the inspector can simulate different inspection scenarios. The simulation module uses actual photographs of the airframe structure with computer-generated defects.

3.4.1 Introduction

The introduction provides the trainee with an overview of the various facets of the program, the workcard for the inspection assignment, and a graphical representation of various faults. It introduces the trainee to the search and decision-making aspects of the visual inspection task.

3.4.2 Testing

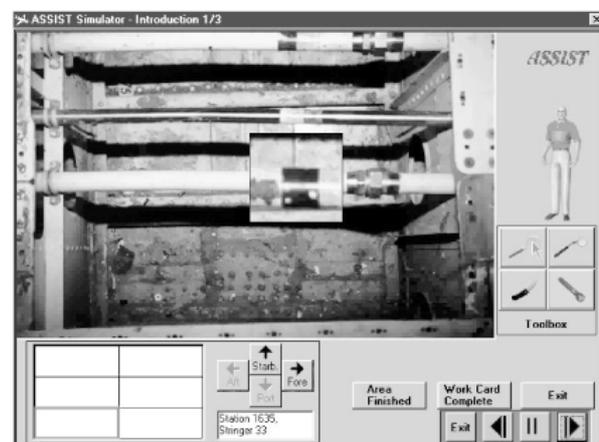
The testing module is designed to operate in two separate modes, with and without feedback. The nonfeedback mode simulates the actual visual inspection task as it would take place on a hangar floor. In either mode, the inspector first locates the defect and indicates this by clicking on the fault. Subsequently, the inspector classifies the defect. In the feedback mode, the inspector is provided with feedback about their own performance on the search and decision-making components of the inspection task. The trainee is also provided with end-of-session performance feedback. The program also features paced and unpaced modes.


Figure 3. The inspection simulator showing the use of the magnifying glass.

Paced mode allows the inspection to continue for only a specified period of time, whereas unpaced mode allows the inspection task to be unbounded by time.

3.5. Instructor's Utilites Module

This module allows the supervisor or instructor to access the results database, the image database, and the inspection parameter modules. The module is designed as a separate stand-alone tool that is linked to the other modules of the system. The results database allows the instructors to review the performance of a trainee who has taken several training and/or testing sessions. Performance data is stored on an individual image basis and summarized over the entire session so that results can be retrieved at either level. The utility allows the instructor to print or save the results to a file. The objective of the image database module is to provide the instructor with a utility wherein a specific image along with its associated information can be viewed on the computer screen. By manipulating the inspection parameters, the instructor can create different inspection scenarios. The inspection parameter module allows the instructor to change the probability of defects, the defect mix, the complexity of the inspection task, the information provided in the workcard (thereby varying the feedforward information provided), whether the inspection will work in feedback mode or nonfeedback mode, and whether the inspection task is paced or unpaced.

3.6. Inspection Training Session

The training program was designed to use the general principles listed earlier, as derived by the task analysis. A major prerequisite was that it should be a progressive parts training scheme which enabled the inspectors to build their repertoire of knowledge and skills in an orderly manner. A typical training session proceeds as follows.

3.6.1 Initial overview

Initially the subjects use the introduction module, wherein they are introduced to the navigation map, and are familiarized with the operational aspects of the computer program.

3.6.2 General module training

In the general module the subjects are given information on the following five topics relevant to an inspector: role of the inspector, safety, aircraft review, factors affecting inspection, and inspection procedures. Using the navigation map, the subjects can either go directly to a particular topic or subtopic, or follow the default path through the topics. At the end of each topic, a brief quiz is administered to review the subject's understanding of the material. The subjects are given feedback and the correct answers. On completion of the topics in the general module, the subjects take the final test. The final test consists of questions selected from a database and covers material from each topic within the general module.

3.6.3 Simulation module

In the simulation module, subjects are initially introduced to the workings of the simulator. Then they are presented with a workcard containing the instructions for the inspection assignment. Next comes information on defect standards; this includes images of the defects, descriptions, likely locations for particular defects, and possible indicators. After this the subjects conduct inspection using representative images of airframe structures, wherein they must first search for the defect and then classify it as needing maintenance or not. The simulator allows the subject to use various inspection tools: mirror, flashlight, scraping knife, and magnifying glass.

Following inspection, the subjects complete a discrepancy report. They are then given feedback on their overall performance. Feedback is provided on the subject's search and decision-making performance (time to complete inspection, defect detection, defect classification performance, etc). The simulator can be operated in various modes (e.g., with or without feedback, paced or unpaced) and it also allows the instructor to set various inspection parameters (e.g., mix of defects, defect probability, workcard instructions), helping to create different inspection scenarios.

CONCLUSION

The high degree of control that ASSIST affords will create the opportunity to systematize the training. In addition, there are several other inherent advantages that will alleviate the problems characteristic of OJT:

- *Completeness*: Inspectors can be exposed to a wide variety of defects, with varying degrees of severity and at different locations, through the use of a library of defect images. Inspectors can also be trained on less frequently occurring critical defects.
- *Adaptability*: ASSIST can be modified to meet the needs of individual inspectors. Batch files of images can be created to train inspectors on particular aspects of the inspection task with which they have the greatest difficulty. Thus, the program can be tailored to accommodate individual differences in inspection abilities.
- *Efficiency*: Since the training will be more intensive, the trainees will be able to become more skilled within a shorter period of time.
- *Integration*: The training system will integrate different training methods (e.g., feedback training, feedforward training, and active training) into a single comprehensive training program.
- *Certification*: ASSIST can be used as part of the certification process. Since the record-keeping process can be automated, instructors can more easily monitor and track an individual's performance, initially for training and later for retraining.
- *Instruction*: ASSIST could be used by instructors in FAA-certified A&P schools for training. In this manner, aircraft maintenance technicians could gain exposure to defects on wide-bodied aircraft that they might not otherwise have acquired.

This article has described research in the area of aviation maintenance and inspection currently underway at Clemson University. Through the development and systematic application of human factors techniques, the research aims at improving the effectiveness and efficiency of aircraft visual inspection. The results of the research effort have been made available to the aviation maintenance community as deliverable products in the form of usable CD-ROMs. It is anticipated that the use of these products would lead to improved airworthiness of the US domestic aircraft fleet. Subsequent phases of this research will evaluate the utility of ASSIST in an operational setting. As to future implications, human performance models could potentially be used in

conjunction with ASSIST for a wide range of controlled studies: (1) to evaluate the effect of various task and subject factors on aircraft inspection performance, and (2) to identify specific interventions to enhance performance.

Balance Theory of Job Design

M. J. Smith and P. Carayon
University of Wisconsin-Madison, USA

1. INTRODUCTION

In 1989 Smith and Carayon-Sainfort introduced a holistic concept of job design that went beyond traditional psychological and ergonomic theories. This concept was elaborated in 1995 to address the issue of new technologies and job design (Smith and Carayon 1995). Smith and Cohen (1997) and Smith et al. (1998) further developed it. Through a general examination of prior work organization, job design and ergonomic theories, an understanding of how work can have psychosocial and psychophysiological effects on the individual was developed. These effects can directly and indirectly influence health, mood state, motivation and performance. In addition, this theory integrated the psychological concepts with physical ergonomic considerations.

In general, micro-ergonomics does not address the complexity of the organizational environment. In the "balance theory" the model of the work system takes into account the multiple aspects of work which can influence employees' performance, safety and health. From a practical point of view many theories of design seem limited because of their narrow focus and their prescriptive guidelines. They lack a "holistic" perspective and flexibility. For instance, the job characteristics theory (Hackman and Oldham 1976) specifies a set of job features necessary for good job design such as task identity, feedback, significance, variety and autonomy. The job strain model of Karasek (1979) proposes two main job characteristics that affect job stress, workload and decision latitude. Our experiences as industrial engineers have led us to question the wisdom of such prescriptive approaches. The approaches fail to address the unique characteristics of particular organizations, their unique workforce, their products and their customers. We have found that in many situations, rigid, prescriptive approaches to job design are not effective and are often not accepted by managers or employees. For instance, how can variety in work be increased when there is only a limited number of tasks to perform? How can decision latitude be increased when management is autocratic and will not share power, or when the employees do not have the knowledge of skills to manage? These real-life experiences convinced us that a job design model needs to be holistic and flexible.

2. THE BALANCE MODEL

The following is a concept about job design that integrates the psychosocial and biological aspects of employee behavior within an ergonomic framework. This model proposes that working conditions (and other environmental features) produce "loads" on the person that challenges biological resources (energy expenditure, biomechanical strain, stress responses) and psychological resources (perception, cognition, decision-making, distress). The characteristics of the load produce physiological and psychological consequences such as hormone release, muscular action, perceptions and mood states. Individual's

physical capacity, health status and motivation influence the responses to the load. The psychological responses are the product of personality, past experiences and social situation. These physiological and psychological reactions to the "loads" act as motivation for employee behavior to respond to the "loads." The response could be increased or decreased performance, or "coping" behaviors (adaptive or maladaptive).

In this theory working conditions impose the "loads" that bring about the individual's physiological and psychological reactions. The physiological reactions caused by the load produce a strain on the person if they exceed the available biological resources, such as energy resources or mechanical strength. For instance, a repetitive lifting task with heavy materials being carried out for hours without rest can exhaust energy resources and produce local muscular fatigue. This can diminish strength and affect lifting style. Or shiftwork can disrupt biological rhythms, which increases the demand on the body's energy resources. It can influence behavior such as eating and sleeping, which affect energy resources and fatigue. When both of these load are present the effects are greater and happen sooner.

Working conditions can also cause psychological reactions that have emotional, behavioral and biological consequences. These consequences are primarily determined by the individual's perception of her/his ability to meet the demands imposed, and/or her/his perception of the "acceptability" of the working conditions. In addition, the person's availability of psychological and behavioral resources, such as motivation, cognitive capacity and coping behaviors influence the consequences. However, the physiological and psychological reactions are not independent of each other. They interact and may even reinforce each other. For instance, the repetitive lifting task may cause boredom, which leads to mental fatigue. It may also produce physical fatigue by depleting energy resources. These effects reinforce each other resulting in a systemic response of "general" fatigue (Grandjean 1968).

Physical, psychological and behavioral resources are not a fixed and stable set of individual characteristics but change over time and are influenced by capacity, motivation, stress responses and the demands of the working conditions. For instance, these resources may increase because of on-the-job training or the availability of powered assistance machinery. In the repetitive lifting example the introduction of equipment to do the lifting will reduce the energy requirements and the local muscle fatigue, while training in proper lifting techniques may also reduce these same outcomes. Stress responses can influence the biological and psychological resources available to an individual. Individual personality characteristics, genetic make-up and health status all influence the physical resources available to the individual and the nature of the stress responses.

The load on the individual can be influenced by the physical demand, psychological response to the demand as mediated by perception, or both. When the load becomes too great, the person displays stress responses which are emotions, behaviors and biological reactions that are maladaptive. When these reactions occur frequently over a prolonged period they lead to health disorders. Thus, chronic exposure with cumulative reactions is a hallmark of distress. Cumulative stress responses reduce the available resources for dealing with the loads from the work environment, and a circular effect begins. This repeated circular

cycle leads to a breakdown in individual resources unless external resources are made available or the environmental load is reduced.

According to the balance theory the effects of the work system on the individual are assumed to be mediated by the stress load, which is both physical and psychological. The stress load is the resultant internal effect of the work system on the individual. The physical and psychological dimensions of the stress load are not independent. They interact with each other to produce effects. These effects have influences on the quality of working life, performance, strain and health.

Figure 1 (Smith *et al*. 1998) was developed from the concepts of Smith and Carayon-Sainfort (1989). It illustrates a model for conceptualizing the various elements of a work system and defines categories of loads that working conditions can exert on workers. At the center of this model is the individual with his/her physical characteristics, perceptions, personality and behavior. The individual has technologies available to perform specific job tasks. The capabilities of the technologies affect performance and also the required skills and knowledge needed for its effective use. The task requirements also affect the skills and knowledge needed. Both the tasks and technologies affect the content of the job and the physical demands. The tasks with their technologies are carried out in a worksetting that comprises the physical and the social environment. There is also an organizational structure that defines the nature and level of individual involvement, interaction and control.

This model can be used to establish relationships between job demands and job design factors, and loads. In this model these various elements interact to determine the way in which work is done and the effectiveness of the work in achieving individual and organizational needs and goals. This is a systems concept in that any one element will have an influence(s) on any other element(s). Demands are placed on the individual by the other four elements (environment, technology, organizational design, task) which create loads that can be healthy or harmful (motivating or stressful). Harmful loads lead to stress responses that can produce adverse health effects. Each element in this model and some examples of the potential adverse aspects are described below.

Figure 1 also displays the relationship between the work system and the employee. This can be used to examine the effects of job design factors, such as workload and task content, on employees' behavior, performance and health. In this model the various elements interact to determine the way in which work is

accomplished, and the way the work affects individual and organizational needs and goals. This is a systems concept in that any single element will have influences over any other element. Demands are placed on the individual by the environment, task requirements, the organizational structure and the technology used. These demands can match an employee's capacity and capabilities to produce a positive fit, or exceed the employee's capacity and capabilities and cause misfit. Chronic misfit leads to poor performance and/or ill health. Each element of the model and some examples of the potential effects are described below.

- Environment: various aspects of the physical environment have been implicated as job stressors. Noise is the most well-known environmental stressor that can cause increases in arousal, blood pressure and negative psychological mood. Environmental conditions, general air quality and housekeeping have been shown to affect energy expenditure, heat exchange, stress responses and sensory disruption, which make it more difficult to carry out tasks increase the level of worker stress and emotional irritation.

- Task: aspects of the task have been studied more than any other element in this model. A wide variety of influences have been studied from content considerations such as repetitiveness and meaningfulness, to workload issues such as overload and underload. Low task content, lack of control, high demand and machine-pacing lead to low motivation, stress and diminished performance.

- Technology: lack of adequate skills to use the technology leads to poor motivation, stress and diminished performance. Fear over job loss due to replacement by technology reduces motivation and increases stress. On the other hand when new technology is applied appropriately it can enhance job content and skill use which leads to increased motivation and performance with decreased stress. The physical characteristics of the tools and technology can put physiological loads on the employee. For instance, poor workstation design leads to unhealthy postures and movements and diminished performance.

- Organizational factors: the organizational context in which work tasks are carried out often has considerations that influence worker motivation, stress and performance. The way in which workers are introduced to new technology and the organizational support they receive, such as training and time to acclimate, has been related to stress and performance. The ability to grow in a job and to be promoted (career development) affects motivation and stress. Potential job loss influences motivation, performance and stress. Other organizational considerations such as work schedule (shiftwork) and overtime have been shown to have negative mental and physical health consequences, as does role conflict and role ambiguity.

- Individual: a number of personal considerations determine the physiological and psychological responses that the preceding elements of the balance model will produce. These include personality, physical health status, skills and abilities, physical conditioning, prior experiences and learning, motives, goals and needs.

The five elements of the balance model system work in concert to provide the loads and the resources for achievement of individual and organizational goals. We have described some of

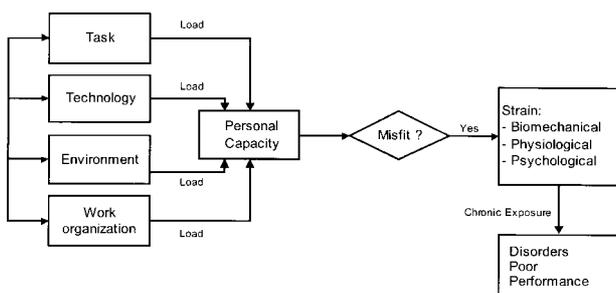

Figure 1. Balance model of misfit (from Smith *et al*. 1998).

the potential negative attributes of the elements in terms of motivation, performance and job stress, but there are also positive aspects of each that can counteract the negative influences. For instance, increased worker training can offset the negative influences of inadequate skill to use new technology. Or the adverse influences of low job content can be balanced by an organizational supervisory structure that promotes employee involvement and control over the tasks. Jobs with many negative elements are jobs that produce the most adverse impact on the employee, whereas jobs that have better balance are less stressful (Carayon 1994).

The essence of this theory is to improve motivation and performance and reduce stress and the negative health consequences by "balancing" the various elements of the work system to provide positive aspects to counter the negative ones. The "best" job design can be achieved by providing all characteristics of each element of the model that can meet recognized criteria for worker ego needs fulfillment and that set proper physiological and psychological loads to eliminate stress and strain. In reality such a perfect job is not attainable. Then, this model proposes using good elements to compensate for poor aspects in other elements to balance the "loads" to achieve reduced stress and enhanced motivation and performance.

Various theories of job design can help us define the positive and negative characteristics of the work system. For instance, theories of occupational stress have defined work stressor which are negative characteristics, such as high workload, shiftwork, low job control, high role ambiguity and role conflict (Smith 1987). Theories of job design have also specified positive characteristics such as high task variety, feedback, opportunities for learning, and autonomy (Herzberg 1966, Hackman and Oldham 1976). Ergonomic models have also defined negative characteristics or work, and their interactions with the individual. generic risk factors have been defined, such as repetitiveness of motions, forceful motions and poor postures.

3. ACHIEVING A BALANCED WORK SYSTEM

There are two aspects of "balance" that need to be addressed: (1) the balance of the total system and (2) compensatory balance. System balance is based on the idea that a workplace or process or job is more than the sum of the individual components of the system. The interplay among the various components of the system produce results that are greater (or lesser) than the additive aspects of the individual parts. It is the way in which the system components relate to each other that determines the potential for the system to produce positive results. If an organization concentrates solely on the technological component of the system, then there is an "imbalance" because the personal and psychosocial factors are neglected. Thus, job improvements must take account of and accommodate the entire work system. Our model of the work system can be used to establish relationships between job demands, job design factors and stress.

The second type of balance is "compensatory" in nature. It is seldom possible to eliminate all psychosocial factors that cause stress. This may be due to financial considerations, or it may be because it is impossible to change inherent aspects of job tasks. The essence of this "balance" is to reduce psychological stress by making changes in aspects of work that can be positively changed to help improve those negative aspects that cannot be changed.

In one strategy, proper job design can be achieved by providing all of those characteristics of each work element that meet recognized criteria for physical loads, work cycles, job content, control and socialization, and that provide for individual physiological and psychological needs. With this approach, the best designs will eliminate all sources of stress. However, such a perfect job cannot often be achieved in reality, so a second strategy is to use positive work elements to compensate for poor work elements which can balance the stress by moderating those negative factors to reduce the total demands (loads).

4. ADVANTAGES OF THE BALANCE MODEL

Our model defines the process by which working conditions at different levels (i.e. individual, task, environment, technology, organization) can produce loads that can lead to poor outcomes such as low motivation, diminished performance, increased stress and poorer health. It also proposes a system that helps balance these loads to produce better outcomes. When balance cannot be achieved through changing the negative aspects of an element, then it can be improved by enhancing the positive aspects of other elements of the job. Thus, the good aspects of work can be used to "counter-balance" the bad.

A major advantage of this model is that it does not highlight any one factor such as shiftwork, or a small set of factors such as demand and control. Rather it examines the design of jobs from a holistic perspective to emphasize the potential positive elements in a job that can be used to overcome the adverse aspects. Thus, all aspects of the job must be considered in developing a proper design. This model does not subscribe to only one approach for job design such as content enrichment or participation. Both approaches may have some positive benefits given the right circumstances. In fact, it is likely that there will be circumstances in which both approaches can be used in concert to provide less stressful work. This model is similar to an "organizational development" approach in that it uses one or more aspects or elements from many different theoretical perspectives to solve specific problems. The emphasis differs in that stress and not productivity is the outcome of interest and, therefore, may direct different interventions than an "organizational development" approach.

Another advantage of this model is that it provides a research direction that can be fruitful in defining the causes and cures of occupational stress. Most current job stress research is directed toward one or two critical job factors as the primary elements in producing worker stress. The results of such research have proven connections between specific factors and workers stress responses but in each case have only accounted for a small portion of the total effect. To us this suggests that a multifactor theory will be most fruitful in defining how job conditions influence stress. One simple way to look at multiple factors is to use an engineering analogy to the total load that leads to some level of stress which if sufficiently great can produce strain.

The balance theory is a total systems viewpoint that shows how to integrate the diverse workplace job design factors into a characterization of positive work design. We think that our concept of "load" which is a combination of physical and psychological attributes of the environment does this in a logical way. Much research has to be carried out to define how the various on and off the job factors can be fit together to determine the

"stress load" of a job. Some factors may always have a greater influence in promoting an "unhealthy load", or situational characteristics may influence the specific contribution that a factor makes to the total load. Only research and experience can answer this. But for the time being our approach offers a clear direction for job design.

Changes in Modern Manufacturing Practices

D. Holman, C. Axtell, C. Clegg, K. Pepper, P. Waterson, I. Cantista, and M. Older–Gray

Institute of Work Psychology, University of Sheffield, UK

1. INTRODUCTION

Manufacturing organizations compete in an environment that is characterized by uncertainty, increased global competition, the fragmentation of markets, an increasing dependence on non-price competitiveness, and a high level of technological change (Bessant 1991). To survive and compete in such an environment, there is widespread agreement on the importance of an organization's ability to innovate and manage change (Burnes 1993; Wolfe 1994). Recent research would seem to suggest that UK companies are responding positively to the need for change and innovation. For example, a recent CBI/NatWest survey of innovation in UK companies found that 50% of manufacturing companies had introduced between two and five new processes in the last year, 15% had introduced between six and ten processes, and 20% had introduced over ten processes. Only 8% had introduced one new process, and 3% did not introduce any new processes (CBI/Nat West 1998). Moreover, a recent survey of 564 UK manufacturing companies across 18 sectors, has shown the widespread use of modern manufacturing practices, such as total quality management, team-based work, just-in-time, supply chain partnering, and outsourcing (Waterson *et al.*, in press).

At one level, then, it would appear that UK companies are responding well to the present competitive environment. Yet, although the use of modern manufacturing practices is fairly widespread, the expected improvements in performance have often failed to materialize (Webster and Williams 1993; Wemmerlov and Johnson 1997; Waterson *et al.,* in press). For example, a survey of IT-based practices found that approximately 80% of cases failed to meet their objectives and that 40% of systems failed outright (Clegg *et al.* 1996). There are clearly a number of reasons why an innovation will be successful or not, but it has been argued that one key factor is the effective management of the change and innovation process (Voss 1992; Tidd 1991). The change management literature suggests that there are well-established principles of change that can enable the successful introduction of manufacturing practice innovations (Jaikumar 1986; Voss 1992; Bessant 1991; Tidd 1991; Dawson 1994). They include:

- Conducting a strategic review.
- Considering a variety of objectives and not solely focusing on cost reduction or technical objectives.
- Taking the long-term view and ensuring a sustained level of interest by management.
- Ensuring resources are adequate, particularly with regard to training.
- Communicating and selling the change.
- Using project planning tools and cross-functional teams.
- Using champions of change.

- Considering the systemic effects that an innovation might have, particularly human resource issues.
- Encouraging the participation of all in change.
- Examining the expertise within the firm.
- Evaluating the change process.

However, empirical research on the implementation of modern manufacturing practices has demonstrated that many of these principles are not necessarily practiced (Bessant 1991; Voss 1992; McLoughlin and Harris 1997), and that this can contribute to a considerable reduction in the overall effectiveness of the manufacturing practice being introduced (Kearney 1989; Wemmerlov and Johnson 1997). For example, a lack of planning or project management, a failure to think systemically about the impact of the practice, especially in relation to human resource practices, and a failure to consult and involve end-users have all been shown to reduce the effectiveness of the manufacturing practice (Webster and Williams 1993; Fawcett and Scully 1995; Clegg *et al.* 1996). It is interesting to note that similar results have been found across a range of manufacturing practices, organizational sizes, and sectors.

By showing that the principles of change management may not be widely practiced, the research conducted on UK samples (e.g. Kearney 1989; Clegg *et al.* 1996, clearly calls into question the "change and innovation capabilities" of UK companies with regard to the implementation of modern manufacturing practices. Capabilities are the skills, routines, and ways of doing things that are built up and learnt over time by organizational members (Collis 1994; Bessant *et al.* 1996). Change and innovation capabilities may therefore be thought of as the skills and routines that organizational members have learnt which enable them effectively to manage the change process. While present research provides many important insights, e.g. in establishing principles of change and illuminating the relationship between the change process and the outcomes of change, it does not provide data on the nature of the change process or the change and innovation capabilities of UK companies more generally. This is primarily due to the fact that existing studies have been based on case studies of a small number of firms, and on surveys of one type of manufacturing practice. This limits, to some extent, the generalizability of the findings. Given this limitation of previous research, the main aim of this research was to examine the change and innovation capabilities of UK manufacturing companies across a range of companies in different sectors, and with regard to a variety of modern manufacturing practices.

This article is divided into three further parts: the methodology describes the rationale behind the research design, the experience of the participants, and the range of companies and practices covered. This is followed by the findings of the research and a conclusion.

2. METHOD

To achieve the aims of the research, experts drawn from research, consultancy, professional bodies, and manufacturing companies were interviewed, all of whom had extensive experience of managing or studying the change and innovation process in manufacturing companies. The "expert panel" approach was chosen as it enables the collection of data about a larger number of companies, and across a wider variety of manufacturing practices, than case study approaches, while also enabling

descriptively richer accounts of the change process to be gathered than is possible by a questionnaire survey.

Data was collected by interview using a semi-structured interview schedule that had three main sections. The first part focused on the participants' experience and expertise. In particular, interviewees were asked about the type and number of companies they had worked for or researched in, and what type of manufacturing practices they had most expertise of. Interviewees were asked to indicate from a list of twelve practices (see table 1, which type of practice they had most experience of. (Between them, interviewees had experience of all 12 practices, although less experience was evident in the area of concurrent engineering). This list was based on a detailed evaluation of previous manufacturing surveys in the UK, and on earlier research that classified the variety of modern manufacturing practices (Bolden *et al.* 1997). This list was also used successfully in a previous survey (Waterson *et al.* 1999). Once the interviewees

Table 1 List of modern manufacturing practices used in the study

Practice	Definition
Just-in-time production	Making products in direct response to internal or external customer demands (rather than building in advance to maintain stock levels).
Manufacturing cells	Organising the shop-floor so that one or a group of operators has the resources to produce a whole product (rather than routing the product through different functional areas).
Intergrated computer-based technology	Linking together computerized equipment to enable enhanced integration. (Such as CADCAM, CIM and FMS rather than stand-alone CAD or CNC machinery).
Concurrent Engineering	Simultaneously designing and manufacturing products (rather than keeping design and production as seperate functions).
Total production maintenance	Involving all operators in minor maintenance and repairs (rather than having all maintenance done by engineers).
Team-based work	Placing operators into teams with their own goals and giving the team freedom to allocate work between members (rather than dividing labour according to job title).
Decentralised decision-making (Empowerment)	Passing considerate responsibility for operational management to individuals or teams (rather than keeping all decision-making at the managerial level
Learning culture	Providing a range of development oppurtunities for employees, not merely training them for their present job
Outsourcing	Contracting out certain manufacturing processes and sub-processes to other companies (rather than making everything in-house).
Supply-chain partnering	Developing strategic alliances and long-term relationships with suppliers and customers (rather than negotiating on a short-term basis)
Total quality management	Seeking continous change to improve quality and making all staff responsible for the quality of their work. (Such practices include Kaizen and Continous Improvement).
Business process re-engineering	Radically re-designing or rationalizing production processes to eliminate unnecessary practices and procedures (rather than the more gradual process of continual improvement).

had selected the practices that they had most experience of, they were asked to concentrate on these practices for the rest of the interview. The second part of the interview schedule was based on process models of innovation. These attempt to understand the manner in which innovations (an idea, practice, or artifact, are adopted, implemented, incorporated, and evaluated within organizations (Van de Ven *et al.* 1989; Wolfe 1994). They are also concerned with very similar issues to that in the change management literature — for example, the extent and nature of planning, and the extent and nature of evaluation. Process models of innovation, therefore, provided an appropriate means with which to structure both the interview and generate data useful to the aims of this study. The main topics covered in the second part of the interview were (see Appendix 1 for complete interview schedule):

- the reasons why companies adopt particular manufacturing practices;
- the implementation process;
- the degree to which the practices are successfully incorporated into the organization;
- how companies evaluate the process of implementation.

The third part of the interview focused on the factors that interviewees thought could improve the change and innovation process in UK companies.

Each interview lasted on average 1–1.5 hr. Where possible, all interviews were tape-recorded and fully transcribed. Using NUDIST, a software package that facilitates qualitative analysis, each interview was then coded according to a pre-defined coding scheme. The coding scheme was based on the interview structure. Early analysis of the data indicated that there were variations in response between the different types of interviewee. The analysis therefore started by separating responses according to interviewee type.

Different sampling rationales were chosen for the various types of participant. The researchers, consultants, and members of professional bodies were selected as some of the leading experts in this field in the UK, and to cover the leading groups with expertise in this area. Researchers were selected to reflect various disciplinary backgrounds and expertise in researching different manufacturing practices. Consultants were selected from the leading consultancies as well as from smaller specialists in manufacturing. Professional bodies were chosen to reflect the different interest groups in manufacturing industry. The company practitioners, manufacturing managers, and directors were chosen from a database of participants in an earlier survey (Waterson *et al.* 1999). This database, derived from the Dun and Bradstreet Database of UK companies, covered 15 manufacturing sectors (see Appendix 3, and four sizes (150–249, 250–499, 500–999, 1000+ employees). While we were limited in the number of companies we could select, attempts were made to include one company from each sector, as well as to select companies of varying size.

Forty-eight people were interviewed. By occupation there were 16 researchers, 9 consultants, 17 company practitioners, and 6 representatives from professional bodies. As a group, participants had experience of work in all 15 manufacturing sectors, although we were unable to obtain company practitioners from the "clothing" and "rubber and plastic" sectors. Participants also had experience of working in all sizes of company. However,

participants, particularly the consultants, had less experience of working in small organizations, and some participants had particular expertise in working with small companies. Consultants tended to have worked with more companies than researchers and practitioners. The average number that consultants had worked in was 300. Researchers had researched or consulted in from 20 to 300 companies, the average being about 50. Company practitioners had worked in an average of seven companies. Members of professional bodies had contact with hundreds of companies. In total, interviewees were able to draw on knowledge of approximately 10,000 organizations.

3. FINDINGS

The major findings are described below, and organized into the following five parts:

3.1. Adoption

Interviewees were asked about the reasons why companies adopted new manufacturing practices. The clear message from interviewees was that companies often adopt a new manufacturing practice in reaction to a "significant event" (which some labeled a "crisis", such as declining market share, the loss of a major customer, or poor profits. Another, but less common trigger, is pressure from a major customer, particularly in relation to the introduction of total quality management and supply chain partnering. Less common still are the more proactive approaches to change, and these were thought only to occur in the "better" companies. Proactive approaches involved continuously seeking out new ways of doing things through, for example, scanning the market place, benchmarking, and evaluating the usefulness of new methods.

One researcher posited that, although the pressures for change are common to adopters and non-adopters, what differentiates the two are the forces against change that prevent the innovation process from starting in the non-adopters. All interviewees mentioned that one of the main reasons why change does not occur is that the risks are seen to be too high, especially among senior management. The key risks were generally perceived to be financial (e.g. loss of profits, or personal (e.g. loss of personal credibility). Risks were thought to be higher if the scale of change is large and the practice relatively new (e.g. company-wide BPR). Twelve interviewees with extensive experience of IT-based practices suggested that management seriously underestimated the level of risk involved in their adoption.

Other forces against change are "initiative fatigue", a history of failure and abandonment, a lack of knowledge by management about alternative working practices, and a preoccupation with operational firefighting. Twenty-two respondents commented that a significant barrier to the introduction of new manufacturing practices in the 1990s is middle management. This is especially the case when a new practice challenges middle managers' traditional job roles and calls for new forms of managerial control. Commenting on the introduction of team working one manager noted that:

> there was a perceived risk [by managers] that the more you empowered people the less control you have, and when you are used to having all the control, [losing it] was very much a fear in a lot of their eyes.

By contrast, only two respondents thought that the shop floor, whether unionized or non-unionized, was a significant and consistent inhibitor of change. This may be a reflection of unions' reduced power, but five interviewees actually stressed the positive role that unions can play in promoting change.

Whether a reactive or proactive adoption of a manufacturing practice, the following four factors were regarded as important in the adoption stage, and it can be noted that these are similar to those suggested by the change management literature:

i. *A strategic review*. A strategic review was considered to be fundamental to the success of a new manufacturing practice, although researchers and consultants were particularly skeptical about the extent to which this occurred in UK companies. For example:

What's missing is a real strategic sort of outlook in terms of what is the nature of their business, on what basis are they going to compete [and] what are the drivers of competitiveness. They don't go through that process at all (Researcher).

Concern was expressed by researchers and consultants about the general level of strategic ability in senior managers in the UK More critical comments suggested that managers may only be getting better at telling "strategic tales".

ii. *The consideration and specification of various objectives.* The best adoption practices were believed to be characterized by companies considering a variety of objectives (e.g. cost, quality, customer responsiveness, the environment). The evidence from interviewees suggests that while more and more companies are starting to consider a wider variety of objectives, management's prime objective for the introduction of many practices is cost reduction. Indeed, six interviewees suggested that there is a pervasive obsession with cost-cutting, even in the more strategically thought-through implementations. Such an obsession was seen to obscure the alternative ways in which competitive advantage might be achieved. Consultants and researchers cited many examples of strategic reviews in which they had been involved where companies realized that cost-cutting was not such an important driver of competitive advantage as they had first thought.

iii. *Participation in the strategic and operational review*. Strategic and operational reviews were seen by some fifteen respondents to be improved by the involvement of middle management and other members of the organization (e.g. unions). When middle management are involved, two main benefits were thought to accrue. First, operational issues are better considered in strategy formulation. Second, there is less chance of middle management being unsure of the strategic objectives of change, and configuring the change process to suit purely operational objectives.

iv. *A long-term view*. There was a common consensus that senior management needed to take a long-term view of the introduction of new manufacturing practices. There was much criticism about "short-termism' and the pressure for quick fixes and quick returns. In some instances, the pressure for quick returns, particularly on cost, was seen to negate the value of any strategic planning. In most cases though, short-termism was seen to be symptomatic of a lack of strategic thought and a mechanistic view of organizations in which practices could be simply plugged in and made to work almost immediately. About two-thirds thought that

manufacturing practices often took three or four years to fully realize their potential, and that this was especially the case with team work, empowerment, learning culture and total production maintenance. For example:

In Total Production Maintenance . . . you won't get much under three to five years, and people are hoping that TPM will be paying for itself within a year or two. I think in many cases it has been a forlorn hope . . . I think it's all pressure to get a pay back on whatever investment you've put into the work (Practitioner).

The desire for quick fixes was believed to lead managers to fail to realize that symbolic and material resources would be required beyond the initial adoption and implementation phases. Forty-six respondents, nearly the whole sample, noted that the pressure for quick fixes was intense in the current economic climate.

Interviewees were asked about whether they thought practices were introduced because they were the latest fad. While about one-third agreed with this statement, the rest, especially company practitioners, were skeptical about the degree to which the implementation of practices could currently be described as faddish, although they did recognize that this may have been more true in the past. What emerged from the interviews was that the problem was not so much with the fads themselves, but how they were adopted and implemented. Thus, a more positive interpretation of "faddism" is that it does bring new ideas and practices to the attention of managers. It gets new practices onto the innovation agenda, which if adopted and implemented well, can be of immense benefit. The willingness of UK companies to adopt new practices is thus an indication of their innovativeness. Organizations such as the Department of Trade and Industry, the Engineering Employers Federation, Higher Education Institutions, and consultancies play an important role in disseminating knowledge of these new innovations. "Fads" are only problematic when they are adopted without careful reflection and attention to strategy, and with the belief that they are a universal panacea which will produce quick returns.

3.2. Implementation.

In response to questions about the process by which manufacturing practices are implemented, the following factors were thought to be some of the most important in successful implementations: participation of all stakeholders; an examination of business processes; flexible project planning; champions of change; a systemic view of change; the use of tools (e.g. soft systems analysis, sociotechnical theory, that facilitate a systemic approach; and, the selling and communication of change. The fact that many of these are well-established "principles" led one-quarter of interviewees, mainly consultants and researchers, to wonder why these well-known principles of change are not widely practiced. The evidence from this study suggests that UK companies are getting better at implementing changes, that "the principles of change" are becoming more widely practiced. In particular the evidence suggests that companies are generally improving at:

- project planning, i.e. the "mechanics" of change;
- using champions of change;
- consulting end users;
- communicating and selling the reasons for change;

- recognizing that change impacts on human resource practices, particularly payment systems;
- choosing and using consultants.

The evidence from interviewees also suggests that, in general, companies could benefit from:

i. *Taking a more systemic view of change.* Interviewees were asked whether a range of topics were considered during the planning of change (see Appendix 2). The evidence from their responses indicates that change tends to be technology or technique led. For example:

Change very much seems a technical matter. So personnel, human resource issues and the personnel function tend not to be playing leading roles [and] get involved after the event to deal with "human" problems (Researcher).

As this quote illustrates, other aspects of the organization, such as human resource practices, job and work design, accounting systems and supply chains are often considered late in the change process, or only when it is clear that a problem has arisen. One result of this is that changes to these systems are rushed through with little consultation and participation. Another outcome is that the resource implications of such changes are not costed in the project plan. A consequence being that such changes are under resourced and inadequately implemented.

ii. *Understanding change as messy, iterative, political and emotional.* Companies are getting better at managing the mechanics of change (project planning, etc., but many tend to see change as linear and mechanistic. This can lead to change being simply cascaded down the organization in an autocratic manner and passed from one level to the next, and a lack of review and reflection. It was also noted that little explicit recognition is given to the fact that change is a political process involving the construction of alliances, and a highly emotional event that can cause anxiety about future work roles and job security.

iii. *Using a range of tools.* A number of interviewees, five in total, suggested that many project planning tools focus too much on the timing and sequencing of change. While this is useful, such tools can encourage mechanistic and linear approaches, and make little or no explicit provision for promoting systemic thought, or for encouraging participative methods.

iv. *Encouraging end user participation rather than just consultation.* The degree of involvement by end-users (e.g. the shop floor , is often limited to consultation towards the end of the implementation process, rather than participation throughout the whole change process. This was mentioned by sixteen respondents, ten of whom were researchers.

v. *Understanding the impact on middle management.* Thirty-three interviewees noted that many new manufacturing initiatives had a significant impact on middle managers' career paths, status, identity, job security, job roles, appraisal, remuneration, and the forms of control that they can exercise. Only a few cases were cited where this had been explicitly considered in the change process.

vi. *Attending to other practices whilst new ones are being introduced.*

My experience tells me that [manufacturing practices] fail in the long term because something else comes along and it's "Let's put that to one side and do this". That's not a sustainable culture, that's a series of projects (Practitioner).

This quote illustrates that existing manufacturing practices were often felt to be ignored while new ones are being introduced. This can lead to the possibility of older practices decaying or being abandoned.

vii. *Attending to the management of learning and expertise*. Nine participants stressed the need for companies to play closer attention to the promotion of learning during the implementation process, e.g. through training and periods of review and reflection. It was also thought that organizations need to play closer attention to the way in which change affects expertise, e.g. the possible disruptive impact of a new manufacturing practice on expertise, or, the degree to which the expertise of external experts is transferred internally.

When asked about the extent to which changes were completed on time and on budget, interviewees found it difficult to provide specific figures as deadlines and budgets were sometimes not set, or set and subsequently revised. Forty-four interviewees thought that projects were nearly always late and rarely within budget. Practitioners tended to perceive higher rates of success, suggesting that 50% of practices were on time and within budget a lot. Researchers, consultants and professional advisors thought that only 20% of practices were on time and within budget a lot.

3.3. Incorporation

The best examples of change were found to be characterized by a sustained effort by management and the shop-floor to ensure that a practice became embedded into everyday organizational life after the "big bang", i.e. when it had gone live. Thirty-five interviewees stated that, in a significant number of cases, adequate and sustained support, particularly by managers, did not occur. The lack of continued support is often compounded by a "quick-fix" mentality which expects large and exciting returns. The best companies were also thought to recognize that setbacks and failures would occur after the initial implementation. Indeed, it was noted that with practices such as TQM and JIT, if problems do not surface, then the practice is not working properly. As one researcher noted: "Our experience with JIT is that it's high risk because you want the system to break down, find out where the problems are [that] you've got to fix."

Furthermore, setbacks and failures are treated as learning events. This, as one member of a professional body posited, differs from the norm in which companies "have a crack at something, fail, then don't say we can learn from our failure. They just simply cut it off there and then."

Many interviewees, thirty-seven in all, believed manufacturing practices often failed to meet their full potential, and that this was rarely due to their inherent technical complexity. Incompatible human resource practices and lack of continued managerial effort were offered as more likely causes. With regard to human resource practices, inappropriate payment schemes were cited the most often. The "classic" example was the continuance of a payment scheme that rewarded individual performance when team work or manufacturing cells had been implemented. Such misalignments were seen to be avoidable if a more systemic approach had been taken earlier in the change process.

Three interviewees stressed that careful attention to learning processes is crucial during the post-implementation period as:

"Users can acquire the technology, they can't acquire the knowhow. And of course, it's the knowhow and the technology that make the innovation" (Researcher).

It was thought that most individual learning about a new practice occurs when employees make it workable and smooth its rough edges. End-users also discuss and disseminate this knowledge developed between them in an informal manner. It was also suggested that companies should facilitate this process so that the effectiveness of the practice may be enhanced. Training and the opportunity in formal settings to discuss problems and communicate what they have learnt were offered as examples of how this could be achieved.

Interviewees were asked about the extent to which newly implemented practices meet their objectives. The most optimistic assessments were given by practitioners. Practitioners stated that, on average, 30% of practices met their objectives entirely and that 40% met their objectives a lot. Consultant and professional advisers, and researchers in particular, were much more pessimistic about success rates. Practices were thought rarely, if ever, to meet their objectives entirely. Only 20% of practices were seen to meet their objectives a lot. The majority of practices were thought to meet their objectives moderately or only a little. Differences in the perception of success probably stem from different criteria of success being used. From the results it would seem that practitioners have lower criteria for judging success. However, and in apparent contradiction to this, many interviewees noted that extremely high objectives are often set at the beginning of the project as a political device to get funding. This either points to official and unofficial objectives being aimed for, or managers going through some form of post hoc rationalization and adjusting the criteria of success downwards. Differences may also be a result of consultants and researchers being called in after a failure; they may therefore see fewer examples of success. The practices that were thought to be the most successful were TQM, JIT, and Concurrent Engineering. The least successful practices were thought to be BPR, team working and IT-based practices.

Interviewees were asked about the extent to which practices were abandoned. Again there were differences between practitioners and other interviewees. Practitioners suggested that very few, if any, practices were totally abandoned. Other interviewees thought that 10% of practices were abandoned. The reason for this discrepancy might be that practices are not necessarily completely abandoned but simply wither away leaving behind some traces of their existence.

3.4. Evaluation

Forty-five interviewees said that nearly all companies do not evaluate new practices against initial objectives. Good practice, the continuous evaluation against well-specified initial objectives, was thought to be extremely rare. The main reasons why evaluation against initial objectives did not occur were thought to be:

- It could not be done, as initial objectives were not specified.
- Political reasons; it may not be in the interests of managers to conduct an evaluation.
- The effort and costs involved are seen to be too high.
- That companies tend to look forward rather than backwards. Evaluation, when it was done, tended to be against current

measures. These were normally quantitative cost or quality measures. Few examples were offered of companies evaluating the impact of change on their employees. Eight participants thought that the lack of evaluation and reflection on the introduction of new practices significantly reduced further capacity for successful change.

3.5. Improvements needed

Interviewees were asked about what needed to occur to improve the process of change in UK manufacturing companies. A large proportion of interviewees, thirty-nine in all, believed that one of the best ways to improve the change process in UK companies would be to disseminate knowledge and expertise more widely. One way of disseminating knowledge was thought to be through using examples of "good practice". However, it was often noted that such examples should not just reinforce the relatively well-known principles of change. Rather, examples of "good practice" should also focus on the practicalities of managing change, particularly the social and political processes involved, and include information about the tools and processes that help companies to think strategically and systemically. Three interviewees wondered whether too active a promotion of "good practice" may be problematic. For example, do examples of "good practice" lead to companies having unduly high expectations about a practice? Does it encourage the following of fads? Thirty-two interviewees thought that while knowledge dissemination was adequate, in many instances other forms of direct intervention were needed. These more direct forms of intervention included Teaching Company Schemes and the creation of learning networks which bring companies with similar problems together to share knowledge and learn from each other.

Ten respondents argued that the dissemination of knowledge and expertise should be targeted at the long tail of "average" companies, and not the small head of excellent companies. It was further suggested that organizations such as the Department of Trade and Industry, the Confederation of British Industry, the Engineering Employers Federation, Business Link, European Community Regional Development Funds and institutions of higher education should play a major and pro-active role in disseminating and delivering knowledge and expertise. A more proactive approach was thought to be needed as knowledge and expertise from the head was not thought to "trickle down" to the tail in an efficient and effective manner.

Just over half of the participants, twenty-five in all, also thought that managers needed more education in management. Yet, one perspective that emerged on this is that, although more and more managers receive some form of management training (witness the phenomenal expansion of business schools and business courses), the problem may not be so much with the extent, but the type of education they are receiving. A clear problem is that while managers may know the theory, they often think it irrelevant or difficult to apply. This implies that management education should focus more on the practicalities of managing through the use of experientially based teaching practices such as action learning (Pedler 1991). Given the lack of strategic planning, twelve of the twenty-five who mentioned management education, thought that particular attention should be given to improving the strategic skills of senior managers.

4. DISCUSSION

This survey indicates that only a small proportion of UK manufacturing companies are thought to manage consistently the change and innovation process in an effective manner. Such companies can be thought of as having well-developed change and innovation capabilities. The results also indicate that, in the majority of companies, the quality of the change process is variable and that their change and innovation capabilities are not particularly well developed. Thus, companies are generally good at managing the mechanics of change (e.g. project planning), placing more importance on selling and communicating change, consulting end-users more often, and increasingly recognizing that human resource practices often need adjusting to realize the benefits of change. Companies also appear to be less subject to fads. However, this research also shows that in most manufacturing companies:

- manufacturing practices are adopted with relatively little strategic thought;
- change remains technology and technique led;
- the systemic impact of change on employees and human resource practices is generally considered too late;
- user participation is usually limited to consultation;
- rarely evaluate the impact of new practices against initial objectives.

If read optimistically, these findings suggest that some of the lessons of change management are slowly becoming embedded within the change capabilities of UK organizations. From another perspective, the findings make for more pessimistic reading as they fit into similar patterns found by earlier studies (e.g. the lack of strategic thought (Kearney 1989); the lack of systemic thinking (Clegg *et al.* 1996); that change is often technology or technique led (McLoughlin and Harris 1997)), and demonstrate that this is occurring across a large number of organizations and with respect to many different types of modern manufacturing practice.

This study has also found that the principles of change seem to be fairly well known if not widely practiced. Companies, it would appear, experience difficulty in implementing the principles of change; the devil is quite clearly in the detail. An example of this can be seen in the fact that while managers may realize the need to think strategically or systemically, they often lack the tools that enable them to do this in a detailed and practical manner. A lack of tools, therefore, goes some way toward explaining the difficulty of using the recommended principles of change. But, as case studies of successful change have shown, change is not simply a matter of following the "correct" prescriptions or using the "right" tools. Rather, change is also a social and political process that involves the interactions of different interest groups with different aims (Mintzberg 1973; Bessant *et al.* 1996; Thomas 1996). Recognizing and attending to the social and political aspects of change is as important as attending to its technical, strategic, and systemic aspects. That the political aspects of change were not particularly well highlighted in this study points to one of the limitations of the expert panel approach.

A further interesting theme to have emerged from this study is the importance of using techniques that develop learning and expertise, and this is in keeping with concepts such as

"organizational learning" and the "learning organization" (Argyris 1996; Cohen and Sproull 1991; Pedler 1991). Techniques that are thought to promote learning and expertise include end-user participation, cross functional teams, periods of review and reflection, action learning, evaluation of the practice, and evaluation of the change process. With regard to the change and innovation process, these techniques appear to have three benefits. First, they aid the creation and dissemination of knowledge about an innovation, its systemic implications, and how to enhance its effectiveness once implemented (Nonaka 1995). (It can be noted that improving the knowledge base and expertise of organizations was implicit in the recommendations made by interviewees, see section 4.5., Second, techniques such as action learning and cross-functional teams can provide an important means with which to examine, reflect on, and manage the social, political, and technical practicalities of change (McLoughlin and Thorpe 1993). Third, evaluating, reviewing, and reflecting throughout the process of change, and at the "end" on the effectiveness of the practice and the change process itself, can help organizational members to learn from their experiences. Indeed, reflecting on experience is one of the critical tasks of learning and development (Schon 1981; Kolb 1984, What is perhaps worrying is that although evaluation and reflection appear to be so critical to the development of change and innovation capabilities, they rarely happen in any systematic manner. Overall, it can be suggested that techniques that focus on learning and expertise can contribute not only to a successful change process, but also to the development of change and innovation capabilities (Bessant 1996; Tidd *et al.* 1997).

One criticism of this study that could be made is that, due to the relatively small number of participants, the picture drawn is not representative of UK companies as a whole and it is therefore difficult to be confident in the claims made. In defense, it can be argued that although the number of participants was small, the actual sample of companies drawn on was relatively large in comparison to other examples of research in this area. Moreover, the interviewees responses indicated that the sample drawn on represented a wide range of company sizes and sectors.

Another criticism is that the interviewees may be biased in the picture they present. Company practitioners may be too positive due to their personal investment in the change process. Researchers and consultants might be too negative on account of witnessing more "failures" or higher standards of success. However, such biases are likely to be a problem for any methodology. The fact that the expert panel draws on a range of perspectives may go some way in providing a more balanced account. Further confidence can also be drawn from the fact that the results are similar to those found in other studies which we commented on earlier (e.g. Kearney 1989; Clegg *et al.* 1996).

5. CONCLUSION

The aim of this survey was to gather information, based on the experience of experts, about the change capabilities of UK manufacturing companies with respect to a range of twelve common modern manufacturing practices. It indicates that in the UK there are a small number companies that have good change capabilities, while the majority of companies have change capabilities that are more variable in quality. With regard to the latter group, there are optimistic signs for believing that companies are slowly learning the lessons of change and developing their

change capabilities. Indeed, many of the principles of change appear to be widely known and companies do seem to be getting better at aspects of change such as project planning, selling and communicating change, and consulting end-users. This survey also indicates that companies could develop their change capabilities further and that they are poor at learning from their experiences of managing change and innovation. In order to rectify this situation there are a number of factors that companies need to pay close attention to. These include: examining the strategic and systemic (e.g. human, organizational, aspects of change; using tools that help manage the practicalities of change; increasing end-user participation; using practices that promote learning and expertise; evaluating against initial objectives; and evaluating change projects. Organizations, such as governmental agencies, higher education institutions, consultancies and professional bodies can also play an important role in facilitating the development of change capabilities by providing examples of "good practice" and through schemes that promote the transfer of knowledge and expertise more directly.

Future research on this topic will need to examine and explore a number of different areas. Given the relatively small number of participants and the methodological approach, further survey work is needed to confirm the whether this survey's results have a wider validity, and examine more closely the similarities and differences between company sizes and industrial sectors. In addition to this, detailed case studies should be conducted that examine the development of change and innovation capabilities over time. Of particular importance in these studies would be an examination of the role and nature of learning and expertise, how they affect the change and innovation process, how they affect the subsequent effectiveness of the manufacturing practice, and how they affect the long-term development of change and innovation capabilities.

APPENDIX 1
MAIN BODY OF INTERVIEW SCHEDULE
1.   Adoption of innovation
1.1 When companies decide to adopt the practices you have just identified to what extent are these choices: strategically led; business-led; customer driven; because it is the latest fad; seen as a quick fix?
1.2 What are the objectives of selecting these practices?
1.3. How risky are these practices perceived to be? and what are the key risks?

2.   Management of change/planning and implementation
2.1 Can you please summarize how the implementation process is/was usually managed?
2.2 To what extent did the plan consider the impact of the new practice on other organizational systems and practices? *Respondent shown Appendix 2.*
2.3 What was the extent of end user involvement (including managers, in the redesign process?
2.4. Do companies use "champions of change" either in the form of individuals or groups?
2.5. To what extent have new practices been delivered on time and within budget?
     entirely   _____%

a lot	_____%
moderately	_____%
a little	_____%
not at all	_____%
Total	_____%

3.   Incorporation of new practices

3.1 To what extent do you estimate that these practices have met the company's objectives for which they were introduced? For example: what percentage have:

met company objectives entirely	_____%
met company objectives a lot	_____%
met company objectives moderately	_____%
met company objectives a little	_____%
not met company objectives at all	_____%
Total	_____%

3.2 What percentage of investments in these areas have been abandoned? _____%

3.3 To what extent have the practices given value for money? and/ or made an acceptable return on investment? (financial performance measures?)

3.4 Where practices have not succeeded, why has this been the case?

3.5 Did the new practice have the intended impact on other organizational practices? *Respondent shown Appendix 2.*

3.6 Did the new practice have unforeseen consequences in relation to other organizational practices? *Respondent shown Appendix 2.*

4.   Evaluation

4.1 To what extent do companies evaluate new practices against initial objectives?

4.2 How have companies done it (financial audits, surveys, benchmarking)?

4.3 Were any of the new practices evaluated against "emergent objectives"? (i.e. did a company take on a practice for one reason, but find it particularly effective in relation to another important objective).

4.4 To what extent have these new practices had an effect on the firms financial performance?

APPENDIX 2
EXAMPLES OF ORGANIZATIONAL PRACTICES

1. Human resource practices
   Payment systems
   Appraisal/development practices
   Levels and type of training needed
   Employment contracts
2. Other manufacturing practices and technologies
3. Job design/work organization
4. Organizational structures
5. Traffic across organizational boundaries (e.g. contractual relationships between firms, particularly in relation to outsourcing and supply chain partnering)
6. Culture (communication patterns, power)

7. Others?

APPENDIX 3
STANDARD INDUSTRIAL CLASSIFICATION OF MANUFACTURING ORGANIZATIONS

20/21 Food products, beverages and tobacco
22 Textiles
23 Apparel and clothing
24/25 Lumber, wood, furniture and fixtures
26 Paper and allied products
27 Printing and publishing
28/29 Chemicals and petroleum
30/31 Rubber, plastic and leather products
32 Stone, clay glass and concrete
33 Primary metal industries
34 Fabricated metal products, except machinery and equipment
35 Industrial and commercial machinery
36 Electronic/electrical equipment
37 Transportation equipment
38 Measuring and analyzing equipment

1. INTRODUCTION

Interest in change and innovation dates back to antiquity, yet
what has now come to be called change management has mainly
developed as an explicit area of action and inquiry in the post-
World War II period. The dominant view of *change management*
is a prescriptive model of planned organizational innovation in
an environment that is making organizational change more rapid
and more complex yet more essential for survival. Planned
organizational change initiatives may take a number of different
forms and occur at a number of different levels. In 1974,
Friedlander and Brown (1974) made a classic distinction between
planned human processual and techno-structural changes, which
was extended into a four-fold typology in McMahan and
Woodman's (1992) survey of organizational change initiatives in
Fortune 500 industrial firms. The types of change initiatives
observed were: *human processual*, i.e. an emphasis on human
relationships, team building, work team interaction, process
consulting or conflict resolution; *techno-structural*, i.e. emphasis
on socio-technical systems, task and technology, work designs,
or organization and group structure; *strategic planning*, i.e.
emphasis on strategic business planning processes, strategic
change or visioning; primarily top management involvement; and
systemwide, i.e. emphasis on organization-wide improvement
activities; leadership, culture, quality improvement, and trans-
formation type organizational change projects. It is now
commonly argued that organizations are increasingly required
to undertake more strategic and systemwide changes in the face
of increasing rates of change in external environments. This broad
"managerial" or strategic planning model stands in sharp con-
trast to more "reflective" research on *organizational change* that
seeks to understand and describe the full complexity of change
processes.

2. CHANGE MANAGEMENT AS PLANNED INNOVATION

As a prescriptive model for managing change, change manage-
ment has traditionally been dominated by "project management"
and "organizational development" approaches that date back to
the periods of World Wars I and II.

2.1. Project Management

The project management model views all change as projects
involving people working within a fixed time frame to achieve
particular goals, balancing parameters of cost, time and
specification. The focus is on the technical content of projects,
rational planning and control. Project management control tech-
niques stem from the work of the American Henry Gantt who
designed the bar chart ("Gantt chart") as a planning and control
aid in World War I. They were further developed in the 1950s in
methods seeking to calculate and coordinate the relationship
between different sets of activities, such as the US Navy's Program
Evaluation and Review Technique (PERT) and Remington Rand
Vac's Critical Path Method (CPM). More recently, the Project
Management Institute in the US and other countries certifies
project managers who combine experience with tested compe-
tence in the Project Management Body of Knowledge in the eight
areas of: managing scope, managing time, managing money,
managing quality, managing communications, managing human
resources, managing contracts and supply, and managing risk.
Project management consultancy firms and practices within firms
normally present different stage models of projects, from initial
problem definition to implementation and improvement. These
stage models have been continued in many equally linear staged
models of the information system development lifecycle
(Buchanan and Badham 1999). This general project management
approach has been widely criticized as a change management
model for its overly simplistic view of the linear course of projects,
rationalistic assumption of clear and unitary goals to be followed,
artificial separation of formal projects from ongoing informal
processes of change (or failure to change), and failure to
adequately consider the central importance of involvement and
participation as means of orienting projects and preventing as
well as overcoming resistance.

2.2. Organizational Development

The "organizational development" model has its origins in Lewin"s
(1951) classic three stage model of change, as "unfreezing,"
"changing" and "refreezing," as well as the commitment of
organizational development practitioners to addressing the "soft"
or "human" side of change processes. Unfreezing is the initial
stage in which a recognition develops of a need for change, and
action is taken to unfreeze traditional attitudes and behavior.
Changing is the second stage as the implementation of new
patterns of behavior and modes of operation occurs. Refreezing
is the third and final stage, where positive reinforcement of the
change is provided and the internalization and institutionaliza-
tion of new attitudes and behaviors is achieved. Lewin's (1951)
classic "force field" analysis examines two types of forces operating
in a change environment, driving forces promoting change and
restraining forces that act to maintain the status quo. To bring
about change, Lewin argues, driving forces must be strengthened
and resisting forces weakened.

Many organizational development specialists that adopt this
general approach seek to provide data that would unfreeze the
existing system by reducing resisting forces rather than increas-
ing the driving forces (Dawson 1994). The classic experiments
of Coch and French (1948) in a US pajama factory, identified
participative approaches to change as a key factor in overcoming
resistance and mobilizing support for change. This has led to
organizational development practitioners advocating what
Pettigrew (1985) characterizes as the "truth, trust, love and
collaboration" approach to change management. A key orienta-
tion is to establish "ownership" of change, with change consultants

providing process expertise to the "real" owners of change processes, helping them to incrementally improve their own problem solving, communication and learning capabilities in an open and honest change process rather than providing expert solutions to be implemented.

Approaches to the project management approach vary within the organizational development approach. Some emphasize the need for a "soft" organizational development accompaniment to "hard" project management in a total project management approach, others support the idea that organizations need to create resources, structures and cultures to support a thriving "shadow organization" or "adhocracy" of project groups or "skunk works," while others criticize the rationalist attempt to divide change into goal oriented project-based chunks, preferring a more diffuse approach that uses projects as participative vehicles for organizational learning and culture change.(Buchanan and Badham 1999). More recently, however, there has been a critical backlash against long-term loosely defined culture change projects, advocating a return to more focused "results oriented" change strategies (Schaffer and Thompson 1992).

Since Lewin's classic work, there have been a multiplicity of refinements to the three stage change model, with numerous recipes developed offering more complex and refined views of stages of change and the type of activities and "change roles" that occur, or need to be played out, at the different stages (Buchanan and Badham 1999). More critically, there has been increasing skepticism about the degree to which existing, and often rapidly changing, organizational structures are usefully seen as "frozen," or the extent to which a new ideal structure should be "refrozen" into something difficult to change. Organizational development practitioners have also been criticized for offering a universalistic model of "one best way" of change, and for their sometime naive commitment to incremental participative change as a change model appropriate for all circumstances (Dunphy and Stace 1990). Two new models of change that are critical of both the project management and organizational development models, yet committed to achieving planned change are the "contingency-design" and "political-processual" models.

2.3. Contingency Design Approach

Contingency-design approaches to organizations argue that organizations need to rationally adapt their structure to "fit" environmental demands. Contingency-design approaches to change management apply the same principles to organizational change, emphasizing the need for planned change actions and strategies to be adapted to internal or external organizational contingencies (Dawson 1994). Contingency approaches to organizational change have identified a number of such contingencies ranging from the internal life cycle of organizations and the type of organizational culture that an organization possesses to the nature of the inter-organizational context within which an organization operates and the nature of the intended or required change. They have also drawn on participative management literature to classify more or less participative or authoritarian set of change management approaches. Dunphy and Stace (1990) provide a classic analysis. They explore the appropriateness of particular styles of change management (collaborative, consultative, directive or coercive) for different scales of change (fine tuning, incremental adjustment, modular transformation, corporate transformation)

in different types of circumstances (time available for change, degree of institutionalized opposition to change). They present four ideal strategies: participative evolution; charismatic transformation; forced evolution; and dictatorial transformation. These strategies center around Dunphy and Stace's argument that organizational development approaches may be more appropriate to incremental changes where there is little opposition and time is available, whereas in conditions of high conflict and time pressure and a need for radical change, a more coercive style of change may be required. The central argument of contingency theories that change management strategies should be tailored to different circumstances is a valid and important one. Contingency models may, however, degenerate into mechanistic prescriptions providing over-simplified and deterministic views of the environment and over-generalized and unhelpful views of change strategies.

2.4. Political–Processual Approach

Political approaches to change management have their roots in views of organizations as sets of competing individuals and coalitions making choices in conditions of uncertainty in line with their own interests, perceptions and bounded rationality. Drawing on "strategic choice" models of organizations, change strategies are seen as being influenced by dominant coalitions of senior managers, and mediated by middle management and other groups pursuing their own goals and interests. In contrast to simplistic recipes for organizational change, a "processual" model has been developed by Pettigrew (1985) and others viewing change as an "untidy cocktail" of rational plans, managerial visions and numerous power plays in different and changing internal and external contexts. As Buchanan and Badham (1999) argue, this view informs an approach to change management in which politics needs to be understood in all its complexity, and "managed" by change agents who recognize that it cannot be "managed away." While the processual approach has traditionally only offered limited prescriptions for planned change, Buchanan and Badham (1999) have further developed the implications of this approach for the self-understanding and training of change agents as *political entrepreneurs*. They detail the political *skills and knowledge* required by the change agent, the *behavioral repertoire* needed by change drivers that attempt to address the political dimension of change, and the manner in which effective change agents adopt a *reflexive practitioner's perspective* toward learning and improving on their ability to diagnose and act politically.

3. REFLECTIVE APPROACHES TO ORGANIZATIONAL CHANGE

In contrast to managerial models of planned organizational change, more reflective analysts of organizational change are highly critical of what they view as the simplistic change recipes of "snake oil salesmen" (Czarniawska and Sevon 1996). Influenced by ethnographic and post-modernist research traditions, many of these analyses adopt what Martin (1992) has described as a "fragmentationist" view of organizational change, i.e. they focus on the lack of certainty, inherent ambiguity and contradictory nature of cultures and change processes. In addition, many of the advocates of this general approach are critical of simple assumptions of an overlap of interest between management and workers, and point to the intended and unintended

coercive and disciplinary dimensions of many change initiatives and processes.

While managers and other actors are performing the necessary acts of simplifying and stylizing reality to assist action, the role of reflexive researchers is seen as complementing such activities by encouraging systematic reflection on the complexity of organizational life and the change processes in which practitioners are involved. While the contingency-design and political role models have helped to introduce a more complex view of change and change management, the more reflective approaches tend to go further in being highly sensitive to the danger of research being directed or used to oversimplify or reinforce a restricted managerialist view of change processes.

4. CONCLUSION

Change management literature has traditionally been prescriptive in character, as it has been intended to provide advice on how to improve the management of organizational change. In contrast to radical approaches to organizations that criticize the dominance of managerial interests in change initiatives, change management approaches have primarily provided advice to assist managers in their formal change initiatives. Despite this orientation, there is now a greater awareness of the complex, situational, and political nature of all change initiatives. This has been enhanced by the contribution of more reflective analysts of organizational change. In future, there may be a blending of the different approaches as more traditional project management and organizational development approaches attempt to improve their success rates in complex and changing organizational circumstances. In particular, it is likely that future approaches to change management will increasingly incorporate a blend of insights from contingency, political and reflective approaches to organizational change.

Collaborative Engineering: Spanning Time and Space

C. M. Harvey

School of Industrial Engineering, University of Oklahoma, 202 West Boyd, Norman, OK 73019-0631, USA

1. INTRODUCTION

A new paradigm of competition is facing businesses today. This new environment requires companies to market, design, manufacture and sell a product within shorter time periods than ever before. Likewise, companies must be able to respond to and collaborate with global competitors to compete in the world economy. Companies can not afford simply to react to the market in the development of new products. Instead, they must understand the potential future of the market. More flexible companies that embrace change are replacing mass production. Companies must create new opportunities for profit and growth and establish an entire new competitive environment.

Competitive factors are those that deal directly with a firms survival. Competition can create an environment in which a company must collaborate for survival, resource sharing or to reduce uncertainty to increase the predictability of the environment. As well, competition can force companies not to collaborate. For example, in a market of zero growth with resource scarcity, firms are less likely to collaborate. Several factors can create the need to collaborate. Included in these are rapid economic and technological change, declining productivity growth, increasing competitive pressures and global interdependence.

In this new environment, people's skills, knowledge and access to information become more important. With the emergence of information technology and the convergence of computer networking and telecommunication technologies, it is no longer a requirement for people or cooperative companies to be located in the same place to communicate. Instead, people or companies that are geographically dispersed can and are engaging in collaborative arrangements. However, with a transition from the traditional face-to-face (FTF) meetings to other forms of interaction, the way teams accomplish tasks has to be rethought from formal design meetings to the informal gatherings that occur in the hallways.

This chapter intends to provide an overview of the factors that affect people when collaborating across time and space. To begin, it will first discuss the collaboration process and how engineers collaborate. This is followed by a discussion of what technologies must provide to bridge distance and time for engineers.

2. FUNDAMENTALS OF ENGINEERING COLLABORATION

2.1. What is Collaboration?

The term *collaboration* is derived from the Latin verb *collaborare*, which means "to labor together." *Webster's Ninth New Collegiate Dictionary* (1983) first definition of collaboration is: "to work jointly with others or together esp. in an intellectual endeavor." Several definitions of collaboration exist within the literature. Wood and Gray (1991) have consolidated many of them:

- A process through which parties who see different aspects of a problem can constructively explore their differences and search for solutions that go beyond their own limited vision of what is possible.
- A process of joint decision-making among key stakeholders of a problem domain about the future of that domain.
- A group of stakeholders who work together to make joint decisions about the future of their problem domain.
- An interactive process having shared transmutational purpose and characterized by explicit voluntary membership, joint decision-making, agreed-upon rules, and a temporary structure.
- The formal or informal institutions, rules and decision-making procedures shaped by prevailing principles and norms by relevant actors about acceptable behavior in a given issue area.

Using these definitions of collaboration as a background, Wood and Gray provided a complete definition of collaboration:

- Collaboration occurs when a group of autonomous stakeholders of a problem domain engage in an interactive process, using shared rules, norms and structures, to act or decide on issues related to that domain.
- Collaboration requires members to share a common goal, participate in a social environment, plan and coordinate task-specialized activities necessitating joint decision-making based on an agreed-upon set of norms and rules, and complete a task within a given time frame. The question is raised then as to how engineers collaborate in traditional FTF settings.

2.2. How do Engineers Collaborate?

It is important to understand how engineers collaborate and some of the conditions that may influence the success of the collaboration.

2.3. Design Task

Engineers are trained from their very introduction to the profession that design problems are a well-ordered transformation from the formulation of the design problem to the selection of a solution. Engineers are taught early models of design that typically consist of three-to-seven stages by which a problem is transitioned from a problem to a solution. As they advance through their education, engineers are taught that problems do not simply follow a well-ordered process and most problems generally consist of many different and interrelated problems.

Design could then be viewed just as simply a composite of problems. However, as Malhotra *et al.* (1980) state, problem solving occurs "when moving from a problem state to a non-problem state." The design process is much more complex. In design, usually a person has no defined initial state and generally the means of accomplishing the design problem are only limited by imposed design constraints. In real world design problems, the requirements are generally fuzzy and poorly articulated. In addition, there is no exact final state.

Elements of the design task that could affect its accomplishment in the distributed environment include its scope, structurability and uncertainty (Harvey 1997). Task scope is the breadth, extent, range, reach or general size of a task. Task structurability indicates how well defined is the sequence and relationships

between subtasks. How structured the task is could affect its analyzability, number of alternative solutions and amount of coordination needed between the subtask team members. Task uncertainty is the degree of predictability or confidence associated with a task. The combination of a task's scope, structurability and uncertainty determine how simple or difficult a task's accomplishment.

2.4. Design Team Interaction

In practice, most design work is done by teams of engineers and the problems follow anything but a well-ordered process. The frequency of group interaction cycles is a key aspect of decision development with more frequent interactions increasing decision quality (Poole and Hirokawa 1986). Team member interaction may be different depending on the requirements of the work domain (Figure 1). For example, the work may be *individual work* (e.g. work assigned to a single individual based on expertise); *cooperative work* (e.g. work that is pooled based on each individuals' work); or *collective work* (e.g. people work together, pooling their resources and knowledge to solve a task) (Rasmussen 1991). This work can be both formal and informal in nature.

In today's world of virtual collaborative teams, interaction may be accomplished through many different media from conference calls to chat sessions to video conferencing. Whatever the medium, one of the fundamental elements of groups is the requirement to coordinate activities. Malone and Crowston (1994) define coordination as "managing dependencies between activities." Dependencies between groups would include such items as shared resources (money, space, time) or the transfer of the product one activity produces to another activity. Coordination can be concurrent as when members of a design team work in

parallel on different aspects of the same product or sequential as when one design team must provide the other team a work product before their task can begin. Processes have been developed to facilitate these dependencies in the coordination process. For example, in managing shared resources, heuristics such as first-come/first-served and priorities have been developed to attempt to mediate the coordination of resources needed by more than one activity (Malone and Crowston 1994). Cooperative work tools have also been developed to support the coordination process. For example, electronic mail acts as a message transport, whereas group-scheduling tools serve to support synchronization dependencies. The type of coordination necessitated may ultimately depend on the task to be accomplished. Organized sports make this point apparent. While coordination in a basketball team is driven by the mutual adjustment of the players, American football coordination is achieved through planning and hierarchical direction (Keidel 1984). Likewise, a group formed to complete a task in particle physics will likely have different forms of coordination than a design team.

Communication is one of the fundamental elements used by groups to manage the dependencies. A shared common knowledge and/or communicative vocabularies facilitate the communication process (Clark and Marshall 1981). Therefore, as groups start their development process to agree on the task at hand, they are faced with the need to communicate. In this process, they must at minimum begin to establish a common dialog by which they can communicate. One has to be cautious of any bias caused by a reduced bandwidth created by replacing traditional FTF interactions with new technologies. Filtering hypotheses and functional fixedness are two biases that serve to decrease decision quality by limiting the quantity of design alternatives

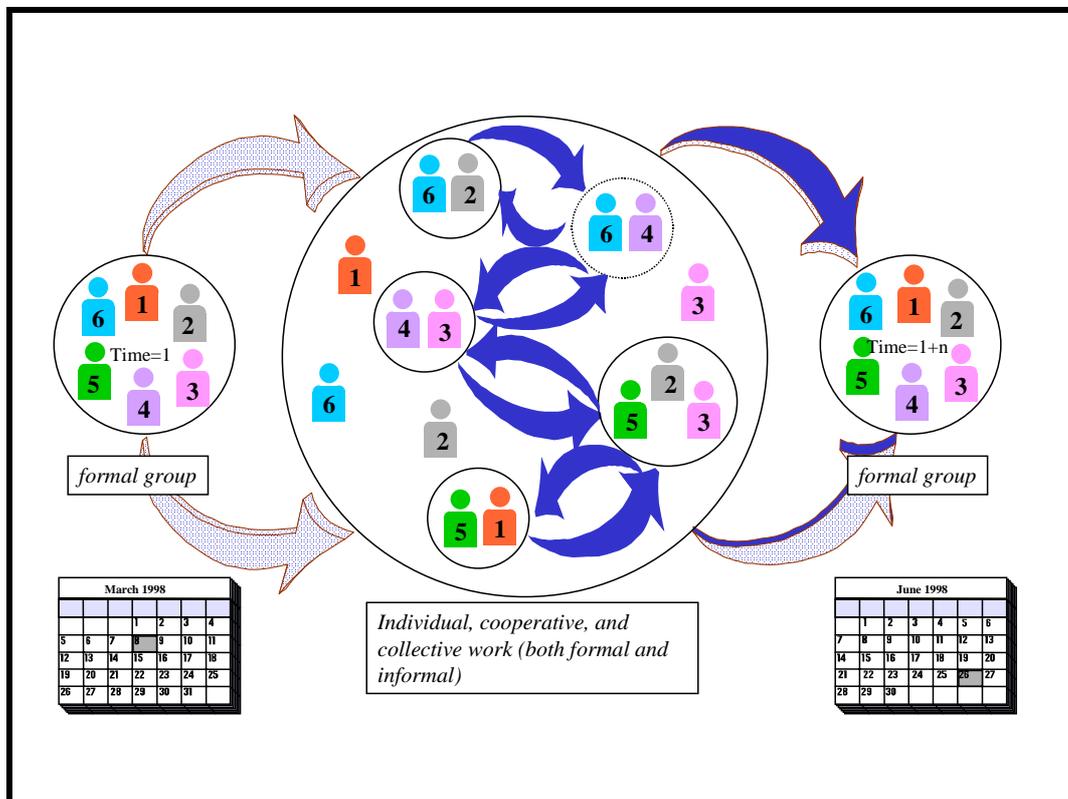

Figure 1. Engineering collaboration process.

considered by the group (Wickens 1992). The potential of these biases existing in the distributed work group could have a profound affect on the technical quality of the design, design time, schedule compliance, resource management, cost management and competition. What is unclear is whether these effects will be positive or negative. Another element that has to be considered in distributed collaboration is the other means by which engineers collaborate.

2.5. Collaborative Tools

Artifacts are one element critical to the engineering collaboration process. Artifacts are how engineers construct a representation of their ideas. Designers are notorious for not being able to think without making a drawing or sketch of rough ideas (i.e. "back-of-the-envelope-sketches") and, hence, require the ability to work within some visual medium. Ullman *et al.* (1987: 64) found six uses for the act of drawing:

- To archive the geometric form of the design.
- To communicate ideas between designers and between the designers and manufacturing personnel.
- To act as an analysis tool. Often missing dimensions and tolerances are calculated on the drawing as it is developed.
- To simulate the design.
- To serve as a completeness checker. As sketches or other drawings are being made, the details left to be designed become apparent to the designer. This in effect helps establish an agenda of design tasks left to accomplish.
- To act as an extension of the designer's short term memory. Designers often unconsciously make sketches to help remember ideas they might otherwise forget.

Dym's (1994) review of design from a broader perspective outlines six knowledge-state layers needed for design: perceived need, function, physical phenomenon, embodiment, artifact type and artifact instance. In describing these six layers, Dym outlines five representation languages as needed:

- Textual (e.g. document(s) used to articulate design projects and to communicate between design and manufacturing teams).
- Numerical-discrete (e.g. attribute values such as constraints, costs, or dimensions).
- Numerical-continuous (e.g. graphical representation of numbers which represent some element of a design).
- Graphical (e.g. visual descriptions such as sketches and CAD drawings).
- Physical (e.g. mathematical, analytical or physical models derived from the physical properties of a design that can be used to describe a function or behavior).

Dym states that "the knowledge-states and their representations are not likely to be entirely independent because the more abstract the layer, the more likely that it is rather vague knowledge expressed in text. At the other end of this spectrum, artifact types and artifact instances are increasingly specific descriptors." Hence, the designer needs different types of representation to express the design as the level of abstraction changes when moving from the initial design to the final design state.

2.6. Cognitive Workload

The distributed collaborative environment places a great strain on individual cognitive resources. Interaction within the distri-

buted collaborative engineering environment contains potentially many different input sources (e.g. video conferencing, voice communications, individual/shared computer screens) for the individual to contend with as s/he participates in the group effort.

Research has found that problem-solving is affected by the load on working memory (Sweller 1988). Likewise, some initial work looking at cognitive workload in the distributed work environment has found interesting results (Storck and Sproull 1995, Harvey 1997). In these initial findings, there appears to be an increased workload using video communication while no increase in audio communication. The video increase could be caused by the fact that social information is harder to obtain, yet there is a sense of obligation to work harder given individuals can see one another. Likewise, the non-increase in audio groups could be because it is too difficult to maintain the needed level of cognitive resources and/or the incapability between the task and the media. In either case, the distributed environment tends to impact the individuals use of cognitive resources and thereby could affect the collaboration process.

2.7. Task Cohesion

Why some groups succeed while others fail is still somewhat a mystery, yet one concept, *group cohesiveness*, is thought to impact on groups and their interaction. Cohesiveness is a complex concept to define; yet, most people can recognize whether it exists in groups in which they are participating. Three types of cohesion exist: interpersonal attraction, task cohesion and group pride. Interpersonal cohesion is viewed as the socio-emotional connection among group members (Festinger *et al.* 1950), whereas task cohesion consists of the group having a shared commitment to a task (Hackman 1976). Group pride suggests a bond between the individual and the group (Piper *et al.* 1983). Among these, task cohesion emerges as a critical component to be considered in groups of all types (Mullen and Cooper 1994).

3. SUPPORTING COLLABORATION ACROSS TIME AND SPACE

3.1. What Needs to be Supported?

A basic understanding of the engineering collaboration process allows one to start to envision the needs of engineers that are working at a distance spanning both time and space. In discussing distributive collaboration, it seems important to look at supporting technologies that support either *tele-presence* or *tele-data* (Greenberg *et al.* 1992). Technologies that support tele-presence would attempt to provide the participants participating in distributed communication with the necessary explicit and subtle dynamics that occur between participants including body language, voice cues, hand gestures, eye contact, focusing attention, etc. Tele-data is instead concerned with allowing participants at a meeting to present and access physical materials that would normally be inaccessible to distributed groups. These include notes, documents, plans and drawings, as well as a common work surface that allows each person to annotate, draw, brainstorm, record and convey ideas. These definitions provide a method of classifying technologies that support collaboration.

3.2. Supporting Technologies

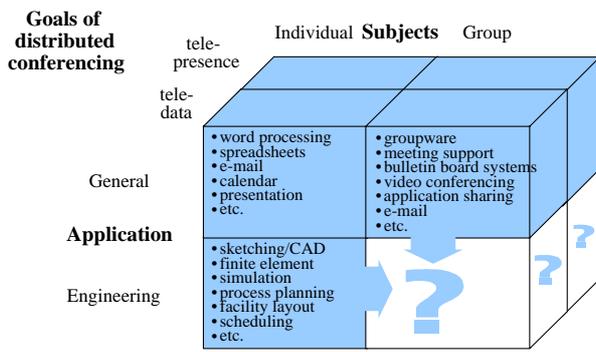
Several supporting technologies exist that can be used to support distributed collaboration (Figure 2). Tools to support


Figure 2. Engineering collaboration tools.

engineers working at a distance are still in development although research in this area is expanding. Today, engineers are taking advantage of the tools that are available to businesses for conducting distributed group work while research continues to meet specific engineering needs. Stanford's Center for Design Research (SHARE project), Carnegie Mellon's Engineering Design Research Center, Purdue's Center for Collaborative Manufacturing as well as on-going research at the University of Oklahoma's Human–Technology Interaction Center are just some of the places working on the improvement of the engineering collaboration process through the understanding of the engineering collaboration process and development of tools and technologies.

4. RECOMMENDATIONS

If an engineering group is considering the use of distributed collaboration or currently using other forms of media to communicate, the following recommendations should be considered:

- Allow team members to interact initially in a FTF environment to establish goals and work tasks before instituting distance technology. This will foster good relationships between group members.
- Ensure that the technology can support the engineering task(s) being accomplished at a distance.
- Assess design teams to ensure they are as effective at a distance as traditional FTF teams.
- Do not overuse the technology. Allow teams to reform in a FTF atmosphere from time to time.
- Train people so they can take full advantage of the collaboration tool(s).

1. INTRODUCTION

Community Ergonomics was originally developed as an approach and a tool for applying ergonomics to 'dysfunctional' community settings (Cohen 1996; Cohen and Smith 1994; Smith and Smith 1994; Smith *et al.* 1994). The objective of Community Ergonomics is to improve the quality in communities using ergonomic principles and methods. Community Ergonomics relies on micro- and macro-ergonomics principles and methods to design and develop communities that are healthy, safe and productive. Different levels and types of community can be examined. The community can be comprised of individuals (e.g. students (Newman 1997)), of groups (e.g. a neighborhood with different stakeholders (Cohen 1996)) or of organizations (e.g. enterprises in an industrial zone (Carayon, Coujard, and Tarbes 1997)). In this article, we discuss various applications of Community Ergonomics. See the article by William J. Cohen on the concepts and methods of Community Ergonomics.

2. COMMUNITY ERGONOMICS PROJECTS IN THE USA

2.1. The Milwaukee Project

The plan to develop the Milwaukee Community Investment Partnership (MCIP) was the framework for pursuing a strategy and specifying and presenting solutions to specific issues of concerns and aspirations of community residents. The strategy pursued (based on industrial engineering theory and techniques) was a process to create the framework to:

- establish a purpose to be achieved;
- organize a strategy to be pursued;
- specify and present solutions;
- involve people critical to planning and implementing the solution;
- develop and use information and knowledge appropriately;
- arrange for changes and improvements to the solution and the solution finding process.

This search was not some ultimate solution to the initial issues of concern, but instead was a proposal to organize a framework in which solutions develop over time and to increase the participant's ability to use the framework repeatedly for their unique needs. The search for solutions is to decide what is needed, why it is needed,

who is needed, when things are needed, and where they will be needed. MCIP consisted of local community advocacy groups, community learning centers, special homes and shelters, large local industry, business development groups, housing development agencies, religious groups, public and private banking institutions, employee unions, and local, city, state, and federal political agencies. The result was a comprehensive plan to generate economic and social results in the form of a community investment bank acting as an intermediary between traditional banking facilities and community residents who are typically rejected by those facilities.

The planning group spent several meetings delineating the issues of concern based on the planning and design matrix work of Gerald Nadler and his concept of "Breakthrough Thinking" (Nadler and Hibino 1998). The discussions of problems that generate the purposes for which solutions are needed, are framed as substantive questions, situations, phenomenon, and issues which concern members of the partnership. Such concerns, reflected in needs, uncertainty, aspirations, obstacles, desires, difficulties, or doubts are values motivating the aim for change and improvement. The specific locus of "what, where, when, and who" unique to each type of problem and issue is also defined. The purpose of this section was to define the "Something(s) That Cause Concern" within the Milwaukee inner city as defined by the Planning Committee.

The challenge was to diagnose and remedy the substantive issues in Milwaukee inner city communities. Although these inner city areas are severely affected and in need of significant attention, inner city communities are not devoid of economic or social potential. These potentials must be sought in a manner that does not promote gentrification of the area, but rather the improvement of quality of life for current residents. The potential can be identified for individuals who have an entrepreneurial attitude but no means to achieve their intentions, and for those who desire to own homes but lack both credit and capital, among others.

The purposeful activities of MCIP recognized the problems that occur during the life process of individuals or groups of individuals in terms of the need for fair and legal access to credit and capital as one way to improve community environment relations. The interactions between people and groups with institutions, agencies, other individuals, or procedures in the banking and lending domain typically do not complement personal life requirements and developmental needs for self-sufficiency and independence. The community ergonomics process helped to discern both the need for a new interface design and the opportunity for community improvement through access to systems of credit and capital. This is not to say that a community bank was the be-all-and-end-all solution to community problems. It was the process of people and resources interacting in a structured manner over a period of time that led to this one logical alternative. The partnership itself was one preliminary solution to address issues of concern, while the bank was only an alternative to do so and, as such, represents one solution in a holistic approach to inner city problems.

2.2. Improving the Educational System for Minority Students

The institution of education has been one of many institutions that has been negligent in the nurturing and development of underrepresented groups in society. Spanning decades, African

Americans, Latino Americans and Native Americans have been experiencing poor public school education. This particular research study concentrated on the under-represented population of students (African American and Latino American) currently enrolled in the University of Wisconsin-Madison College of Engineering (COE), as well as those students who were once enrolled, but who chose to leave the COE.

A qualitative research approach was used to help extract information regarding student success and/or failure. The aim was on determining those factors associated with academic success or well-being for students of under-represented populations, particularly those majoring in engineering. This research integrates principles of Total Quality Management (TQM) and systems design in an effort to identify those factors which hinder or enhance the educational performance and success of under-represented student populations pursuing higher education in engineering and science.

The findings indicated a level of misfit between the students from under-represented populations and the academic environment. Elements such as better development of advising/mentoring programs, education as a life process, pre-college preparation, more faculty–student interaction, more awareness of cultural diversity and the overall classroom environment were identified as necessary components for student success. Other elements such as alienation and isolation, miscommunication between students and faculty, administrators, as well as other students, expectations of professors, lack of financial and social support, lack of cultural diversity, lack of training, and organizational climate were identifies as factors depriving students of a rich and successful educational experience. How does one work to correct such issues? One suggestion spoke of the need to evaluate the faculty and staff on a regular basis (beyond those currently completed by students at the end of the semester). The students also indicated a need and a desire to interact with more faculty (professors, teaching assistants, etc.) of diverse backgrounds. The students indicated that the classroom environment is crucial to the model of academic learning life, because it brings with it so many other issues that link, directly, to a student's success (i.e. preparation, academic skills/foundation, classroom interaction, etc.). All of these issues set the tone of the class from the moment the student enters. They help to determine the climate — which determines a student's willingness and ability to interact or to retreat and which helps to determine whether or not students will survive.

We attempted to develop a better understanding as related to those factors contributing to student academic success. One must realize that in uncovering these negative components, one has, in fact, also stumbled upon those positive components deemed necessary to promote retention and success. The analysis performed by the community ergonomist allowed the identification of solutions aimed at improving the educational system for minority students at the COE.

2.3. Quality Improvement at the City of Madison

The objective of Community Ergonomics is to improve the quality of life in communities. Local government organizations play an important role in any community. Therefore, improving the quality of the management and organization of these organizations is an important element of Community Ergonomics. In the USA, we have worked closely with the City of Madison on their quality improvement program. In France, we have accompanied the quality management program at the City of Nancy (see below).

The City of Madison has been a pioneer among public sector organizations in adopting and implementing Total Quality Management (TQM) principles. This effort began in 1983 through collaboration between the Mayor's office and the Center for Quality and Productivity Improvement (CQPI) of the University of Wisconsin-Madison (Box et al. 1989). In its early stages, Madison's quality improvement program was strongly influenced by the Deming approach. After the initial success of applying TQM principles and methods in the City's Motor Equipment Division, the quality improvement program was spread to other divisions of the City (Sainfort and Carayon 1997). During the summer of 1994, a research team at the CQPI of the University of Wisconsin-Madison started a new partnership with the City of Madison.[1] This partnership led to an evaluation of the quality improvement program at the City of Madison, as well as active participation of the university researchers in the development of new quality improvement activities. The evaluation of the quality improvement program was based on the following methods:

- archival analysis of all documents related to quality efforts from 1984 to 1994;
- administration of an employee survey at two different times;
- in-depth assessment of quality improvement projects;
- semi-structured interviews with selected managers, union representatives and other key personnel at the City of Madison.

For more details on all of these data-collection efforts, see Sainfort et al. (1998). The data collected was used for two purposes: (1) diagnostic of quality improvement activities at the City of Madison and identification of solutions, and (2) research studies. Data was fed back to the City of Madison and identified opportunities for improvement in quality-related activities. The partnership established between the City of Madison and the university set the ground for useful contributions from the university researchers. For instance, the researchers participated in the development of quality-related activities, such as the administration of a citizen satisfaction assessment survey. Different solutions have been implemented to improve the overall quality improvement program, therefore, leading to increased quality of working life for the city employees and higher quality of services for the community members.

3. COMMUNITY ERGONOMICS PROJECTS IN FRANCE

3.1. Developing a Network of Enterprises

Community Ergonomics can also be used to improve the overall quality of life for a group of enterprises. The first French Community Ergonomics project is taking place in the industrial zone of Ludres-Fléville, located south of Nancy, France. Since its creation in 1996, the industrial zone of Ludres-Fléville (ZLF) has always tried to create optimal conditions for facilitating the implementation of new companies in the zone and for encouraging the development of companies already implanted in the zone. The ZLF is composed of about 200 small- and medium-sized enterprises.

In 1995, a group of political and economic actors of the region

decided to create an association for industrial excellence in Ludres-Fléville ('Association Excellence Industrielle Ludres-Fléville' — AEILF) in order to achieve the following objectives:

- To support and help companies of the ZLF in their own quality improvement program;
- To improve the well-being, the image and the environment and to stimulate job creation in the ZLF;
- To create a dynamic process for continuous quality improvement in the ZLF.

In practice, two types of action are put in place by the association:

- Implementation of quality improvement programs in the companies of the ZLF;
- Work groups comprised of various actors (including companies of the ZLF) on different topics related to community quality.

A total of 24 companies have started quality improvement programs. Different activities are organized by the AEILF for supporting and helping those companies: quality audits, training programs, exchange of experience and working groups. The association promotes and organizes activities of benefit to the largest number of companies. These activities foster the development of significant interactions between the companies.

In order to help establish synergies between the ZLF companies, six work groups were formed in order to study and solve problems experienced by a large number of ZLF companies: (1) traffic-transportation, (2) communication, (3) safety, (4) environment-recycling, (5) relationship with educational system, and (6) mail-multimedia-telecommunications. The work groups are comprised of ZLF companies which either have a problem related to the issue or which have a solution for the problems studied by the work group. In addition, actors outside of the ZLF also belong to the groups. For instance, representatives of the local government (cities of Ludres and Fléville) are involved in various work groups.

Quality management methods are used in the management of the association's activities and the running of the various actions. The AEILF does not implement actual solutions: it manages the entire problem-solving process, but relies on outside organizations for implementing actual solutions. The functioning of the work groups relies heavily on various problem-solving tools borrowed from the quality management literature and practice.

The community ergonomics researchers are involved in the project. They participate in some of the work groups, and provide conceptual and methodological advice to the president and the project manager of the association. Under the guidance of senior researchers, engineering students of the Ecole des Mines de Nancy, France, are regularly involved in specific projects of importance to the association.

The association has been quite effective in its various actions. Over a period of two years, the association accomplished quite a large number of projects (total of 17 realizations). The association has a total of 25 projects currently under study by the different work groups. This data shows that the association is quite effective in solving problems experienced by the ZLF companies.

3.2. Quality Management at the City of Nancy

The quality management program at the City of Nancy began in 1996 in the form of a collaboration between the mayor and the top manager (called 'secrétaire général'), on one hand, and the Ecole des Mines de Nancy, on the other hand. The quality program relies heavily on process improvement and organizational functioning in selected divisions of the City of Nancy.

The transformation process started with awareness of the top manager. Following initial contacts between the city's top manager and researchers at the Ecole des Mines de Nancy, quality management was identified as a potential solution for improving the functioning of the city organization, under tight financial conditions. In addition, quality management was seen as a useful complement to an existing project of decentralizing services throughout the city.

The implementation process involved the following phases:

- involve volunteer departments
- form an informal quality committee
- hire engineering trainees to accompany volunteer departments
- start ad-hoc training of selected employees and managers
- organize seminars on quality (examples from the private and public sectors)
- inform employees and managers
- involve more volunteer departments
- establish a small formal structure for supporting and coordinating quality efforts (quality coordinator and quality liaison persons in the volunteer departments)
- communicate on the quality management program (both internally and externally).

The quality management program at the City of Nancy in volunteer departments includes two directions: (1) clarification and improvement of the functioning of the department, and (2) process improvement. First, the volunteer departments use different methods and concepts of quality management to identify the main missions of their departments, to define the corresponding organizational structure, and to clarify the positions in their departments. A second type of actions engaged in the volunteer departments is process improvement. Key processes are first identified, then analyzed, and finally improved. Initially, the main focus of the quality management program was on internal functioning of the departments. Later on, the needs of external customers, i.e. the community members, have been taken into account and better, more appropriate, services are now offered.

4. CONCLUSION

In this chapter, we have described applications of Community Ergonomics in the USA and in France. The projects covered a range of problems and situations:

- economic problems in the Milwaukee project and in the French industrial zone;
- educational problems for minority students at an engineering college in the USA;
- quality management in local government organizations in the USA and in France.

NOTE

1. Funding for this research was provided by the 'Total Quality Organizations' program of the National Science Foundation [Grant number: SBR-9529900, PI: F. Sainfort].

Cross-cultural Factors in Macroergonomics

1. INTRODUCTION

New knowledge and understanding on cross-cultural issues in macroergonomics is necessary better to take into account cultural characteristics in the (re)design of work systems, in particular in the context of the development of global companies. Globalization of business has become a statement of success for companies in the international market. In this paper, globalization has a twofold meaning: (1) a company with international activities and operations and (2) a company with a true and deep understanding of the international business environment and the cultural characteristics of the countries where it conducts business (Järvenpää *et al.* 1997). Global companies need to understand different cultures and the effects of cultural factors on employees, and thus on organizational effectiveness and functioning. For instance, leadership styles and organizational structures suitable for a given national culture may not necessarily be applicable to the context of another national culture (Järvenpää and Immonen 1996).

In contrast with the concepts of hardware ergonomics, environmental ergonomics and software ergonomics, macroergonomics refers to an approach in which the organizational design and context are taken into account. Macroergonomics is a top-down, socio-technical systems approach to organizational and work systems design, and the design of related human–machine, human–environment and user–system interfaces (Hendrick 1991). In organizational redesign and development, organizational factors, such as organizational structure, communication, responsibilities and the functions of different operational units should be taken into account. Hendrick (1997) emphasizes the importance of cultural diversity in the macroergonomic design of organizations. This paper deals with cross-cultural issues in the management of organizations and people from the viewpoint of macroergonomics.

2. CROSS-CULTURAL MODELS

The most popular cross-cultural model of management was developed by Hofstede (1997). According to him, culture is the collective programming of the mind that distinguishes one group or category of people from another. He developed a model for understanding cultural differences at the country or national level. His original model included four dimensions of national cultures (Hofstede 1983): 1, power–distance; 2, uncertainty–avoidance; 3, individualism–collectivism; and 4, masculinity–femininity. Based on a study by Hofstede and Bond (1988) carried out in Asian countries, a fifth dimension was added later: Long- versus short-term orientation. Power–distance has been defined as the degree of inequality among people that the population of a

country considers as normal, from relatively equal (small power–distance) to extremely unequal (large power–distance). The dimension of power–distance represents the dependence on the superior, centralization of authority and autocratic leadership. Uncertainty–avoidance has been defined as the degree to which people in a country prefer structured over unstructured situations. Structured situations are those in which there are clear rules about how one should behave. In countries with high score on uncertainty–avoidance, people tend to show more nervous energy, while in countries that score low, people are more easy going. Individualism–collectivism has been defined as the degree to which people in a country prefer to act as individuals rather than as members of groups. In individualist countries, people attach importance to personal time, freedom and challenge, and relative unimportance to training, use of skills, physical conditions and benefits. The dimension of individualism–collectivism represents one's loyalty to the group and dependence on the organization. Masculinity–femininity has been defined as the degree to which tough values like assertiveness, performance, success and competition prevail over tender values like the quality of life, maintaining warm personal relationships, service, care for the weak and solidarity. Long- versus short-term orientation is a dimension that was added later in a 23-country study of the values of students (Hofstede and Bond 1988, Hofstede 1994). Long-term orientation represents values oriented towards the future, like thrift (saving) and persistence, whereas short-term orientation represents values rather oriented towards the past and present, like respect for tradition and fulfilling social obligations.

Hofstede's model was developed using data collected in a large questionnaire survey. The 1968 survey was distributed to 116 000 IBM employees in 67 countries and included 150 questions; it was also translated in 20 different language versions and was aimed at understanding how people in different countries perceive and interpret their world. Based on the survey and subsequent ones, each country is assigned a score from 0 to 100 for each of the five dimensions. The scores represent relative positions of the countries on the different dimensions. Scores for 50 countries and three regions are available in Hofstede (1997).

Hickson and Pugh (1995) have linked the five dimensions of Hofstede's model to five primary management-related features. First, power–distance is related to managing authority. Power–distance shows how removed subordinates feel from superiors in a social meaning of the word "distance". In high power–distance societies, subordinates look for directions from superiors, and usually accept those instructions without question. In low power–distance countries, subordinates are more likely to initiate discussions with their superiors and even challenge what comes from above. Second, uncertainty–avoidance is related to managing uncertainty. A way of dealing with (managing) uncertainty is through rules and regulations in organizations that give people some sense of certainty. In high uncertainty–avoidance countries, rules and regulations are plentiful. However, these countries may differ on the way rules are treated. In Germany, for instance, the rules tend to be abided by, whereas in other high uncertainty–avoidance countries, like many of the Latin countries (e.g. France and South/Central America), the rules tend to be treated lightly. In those countries, there is a conflict between a demand for rules and regulations and a tendency to go around them in practice. In low uncertainty–avoidance country, there are fewer and more

ambiguous rules. Third, individualism–collectivism is related to managing relationships. Management in an individualist country is management of individuals, whereas management in a collectivist country is management of groups. In individualist countries, employees can be moved around individually, and incentives and bonuses should be linked to an individual's performance. In collectivist countries, management decisions should take into account the groups that people belong to and feel attached to. In individualist countries, the relationship between an employer and an employee is a contract supposed to be based on mutual advantage. In collectivist countries, that relationship is perceived in moral terms, like a family link. Fourth, masculinity–femininity is related to managing oneself. In masculine countries like North America, organizations offer achievement-linked rewards, like bonuses, pay rises and promotions. In feminine countries, quality of life matters, people and environment are to be considered, and to be of service is important. Fifth, long- versus short-term orientation is related to managing time. Some cultures are more concerned with time past, others with time present or future. Short-term oriented cultures are more oriented towards the past and present, and tend to be more static. Long-term oriented cultures are more oriented towards the future (especially perseverance and thrift), and tend to be more dynamic. In short-term oriented countries, quick results are expected, whereas in long-term oriented countries, perseverance towards slow results is valued.

Hofstede *et al.* conducted the same survey twice, once in 1968 and a second time in 1972. Comparison of the 1968 and 1972 data showed no convergence of the scores obtained by the countries on the four original dimensions. Over time, there seemed to be divergence for power–distance and masculinity–femininity. There seemed to be some change in individualism–collectivism towards the more individualist side; however, the cultures shift together, so that the differences between them remain intact. Hofstede (1997) argues that national cultures have historical roots that make them highly stable and unlikely to change, at least for some centuries.

More recently, another Dutch researcher, Fons Trompenaars, has proposed a different set of dimensions for characterizing national cultures (Trompenaars and Hampden-Turner 1998):

1. Universalism–particularism: focus on rules versus focus on relationships.
2. Communitarianism–individualism: the group versus the individual.
3. Neutral–emotional: the range of feelings expressed.
4. Diffuse–specific: the range of involvement.
5. Achievement–ascription: how status is accorded.

The dimension of universalism–particularism is similar to Hofstede's power–distance. The dimension of communitarianism–individualism is similar to Hofstede's individualism–collectivism dimension. The dimension of neutral–emotional is similar to Hofstede's uncertainty–avoidance. The other two dimensions proposed by Trompenaars and Hampden-Turner do not overlap with Hofstede's model and, therefore, provides additional information on national cultures. The dimension of specific–diffuse cultures is related to the degree to which we engage others in specific areas of life or diffusely in multiple areas of our lives. In specific-oriented cultures, a manager separates out his/her task relationships with subordinates and insulates this from other dealings. The aim of management is to achieve objectives and standards with rewards attached. In diffuse-oriented cultures, management is a continuously improving process by which quality improves. The dimension of achievement–ascription specifies how we accord status: achieved status refers to doing (e.g. performance and knowledge), and ascribed status refers to being (e.g. title).

3. CROSS-CULTURAL ISSUES IN MACROERGONOMICS

Table 1 lists the cross-cultural characteristics of Hoftsede's and Trompenaars' models, and, for each cross-cultural characteristic, selected macroergonomic issues.

3.1. Participatory Ergonomics

Participation is a key method for the design and implementation of ergonomic changes and programs. Participatory ergonomics has been defined as "the involvement of people in planning and controlling a significant amount of their own work activities, with sufficient knowledge and power to influence both processes and outcomes in order to achieve desirable goals" (Wilson and Haines 1997). Participatory ergonomics has been applied in many different countries, such as Japan (Noro 1991), the USA (Imada 1994, Smith 1994, Haims and Carayon 1998), The Netherlands (Vink *et al.* 1995), Germany (Zink 1996) and Finland (Järvenpää and Eloranta 1997). These applications have provided empirical support for the use of participatory strategies for implementing ergonomic changes.

The type and methods of participation may vary considerably on different dimensions, as defined by Wilson and Haines (1998): extent/level, purpose, continuity, involvement, formality, requirement for participation, decision-making structures, and coupling. Participatory ergonomics is a complex concept within which a multiplicity of tools and methods are used. We argue that the design and implementation of participatory ergonomics should also take into account characteristics of the national cultures.

According to cross-cultural models, participation has different meanings in different cultures. Even though employees in most countries desire and prefer a participative style of management, the amount and type of employee participation seem strongly based on cultural background. In a study of right countries, it was found that Germany and The Netherlands preferred participative management style to a higher degree than the UK and Canada. The cross-cultural differences in participation can be explained by the dimensions of power–distance and individualism–collectivism of Hofstede's model (Hofstede 1997). According to Hickson and Pugh (1995), power–distance is related to managing authority, whereas individualism–collectivism is related to managing relationships. Participation is a management style that requires sharing of decision-making power and close relationships among people (e.g. project teams). Participation may be easier to implement in countries with low power–distance and high collectivism. In countries with low power–distance, management style is usually more informal and employees are used and even encouraged to express their opinions openly to their superiors. Low power–distance indicates rather equal rights for all individuals. This may facilitate participation. Every member of the organization is expected to take his/her responsibilities

Table 1. Cross-cultural characteristics and selected macroergonomic issues.

Characteristics of national culture		Selected macroergonomic issues
Hofstede's model	Trompenaars' model	
Power distance: degree of inequality among people which the population of a country considers as normal	Universalism-particularism: focus on rules versus focus on relationships	• managing authority (Hickson and Pugh 1995) • participatory ergonomics • organizational design • management style
Uncertainty avoidance: degree to which people in a country prefer structured over unstructured situations	Neutral-emotional: the range of feelings expressed	• managing uncertainty (Hickson and Pugh 1995) • design of work systems: psycho-social work factors and job stress • organizational design • management style
Individualism-collectivism: degree to which people in a country prefer to act as individuals rather than as members of groups	Communitarianism-individualism the group versus the individual	• managing relationships (Hickson and Pugh) • participatory ergonomics • organizational design • management style
Masculinity-femininity: degree to which tough values like assertiveness, performance, success and competition prevail over tender values like the quality of life, maintaining warm personal relationships, service, care for the weak and solidarity		• managing oneself (Hickson and Pugh 1995) • design of work systems: psycho-social work factors and job stress • organizational design • management style
Long-versus short-term orientation: values oriented towards the future, like thrift and persistence versus values oriented towards the past and present, like respect for tradition and fulfilling social obligations		• managing time (Hickson and Pugh 1995) • organizational design • management style • management of change
	Diffuse-specific: the degree to which we engage others in specific areas of life or diffusely in multiple areas of life	• organizational design • management style • management of change
	Achievement-ascription: how status is accorded; accorded to performance and knowledge versus accorded to one's title	• participatory ergonomics • organizational design • management of change

and participate in decision making. Because power–distance is low, employees in different levels of the organization and in different positions are able and used openly to discuss with each other. Participatory ergonomics often means that people work together in groups. Individualism–collectivism is related to managing relationships, and may therefore impact the effectiveness of participatory ergonomics in different countries. In individualist countries, it may be more difficult to implement group-based participatory ergonomics programs because the individual's performance is more important than the group's performance.

Finally, participatory ergonomics programs may challenge the existing status structure of an organization. Trompenaars' dimension of achievement–ascription should therefore be taken into account. In some cultures, status depends on what one does (i.e. performance and knowledge), whereas in other cultures, status depends on what one is (i.e. title). In cultures where status is ascribed, managers and/or supervisors may resist participatory programs because of the threat to their status, i.e. their position/title in the organization.

3.2. Design of Work Systems and Organizations

According to the balance theory of job design, a work system is comprised of the following elements: the individual, tasks, tools and technologies, and environment and organizational factors. Various factors of the work system influence the quality of working

life of employees, e.g. psychosocial work factors. Psychosocial work factors are 'perceived' characteristics of the work environment that have an emotional connotation for workers and managers, and that can result in stress and strain (Hagberg *et al*. 1995). According to cross-cultural models, the psychosocial work factors of importance to people may vary from country to country: stress and strain of employees in different countries may be influenced by different psychosocial work factors. Studies by Järvenpää and Carayon have shown that the relationship between psychosocial work factors and strain was slightly different for Finnish and American office workers. In a study of Finnish and American computer users, Järvenpää *et al*. (1993) found that high workload and low variety were related to high strain in both Finnish and American workers. However, in the American sample, high strain was also related to high job future ambiguity, frequent computer-related problems and lack of feedback; whereas in the Finnish sample, lack of participation and low co-worker social support were related to high strain. These results may be explained by the cultural differences between the USA and Finland on the characteristics of uncertainty–avoidance and masculinity–femininity. The USA has a higher score of uncertainty–avoidance than Finland, therefore psychosocial work factors related to uncertainty (e.g. job future ambiguity, frequency of computer-related problems and lack of feedback) may be more stressful for Americans than for Finnish people. Finland is a feminine country, whereas the USA is a masculine country: in a feminine country,

social support may be more important than in a masculine country, therefore Finnish people may be more stressed by lack of co-worker social support than Americans.

The design of organizations needs to fit the characteristics of the national culture. Trompenaars and Hampden-Turner (1998) proposed a mapping of national cultures onto corporate cultures. They define four types of corporate culture: (1) the family (person-oriented culture), (2) the Eiffel tower (role-oriented culture), (3) the guided missile (project-oriented culture) and (4) the incubator (fulfillment-oriented culture). They found the following patterns between corporate and national cultures:

- family companies — France and Spain
- Eiffel tower companies — Germany
- guided missile companies — USA and UK
- incubator companies — Sweden.

Other models of the fit between national cultures and corporate cultures have been proposed (e.g. Hofstede *et al.* (1990).

3.3. Management in a Cross-cultural Context

Management style, that is the way managers behave and act in leading employees and organizations, may differ across cultures. Highson and Pugh (1995) showed that in individualist countries, management is management of individuals, whereas in collectivist countries it is the management of groups. Power–distance is another cultural characteristic that affects management style. Expectations for management in countries with low power–distance differ from those in high power–distance countries, as Highson and Pugh (1995) show. These findings have implications for management in a cross-cultural context. Multinational companies need to understand the cultural context of the countries where they run some operations. The managers responsible for these operations and the employees involved need to adapt their management style to the country's culture. In product development, teams can work in several countries designing different parts of the same product. Managing cross-cultural product development teams is a big challenge, especially when the cultural characteristics of the team members' countries differ. Team members have different expectations of management. This may affect communication, knowledge sharing, responsibilities and job roles.

Management of change is another important macroergonomic issue that should take into account cultural characteristics, in particular Hofstede's short- versus long-term orientation and Trompenaars' characteristics of diffuse-specific involvement and achievement–ascription. In long-term oriented cultures, change may be easier to implement because these cultures are more dynamic and perseverance towards slow results is valued. In short-term oriented cultures, quick results are expected, therefore putting pressure on organizations and their employees to change fast. In managing change in specific-oriented cultures, specific objectives with specific deadlines should be put forward, whereas in diffuse-oriented cultures, continuous improvement approaches are more valued. Management of change should also take into account the status of those involved in the change process. For instance, project managers may be chosen according to their title in ascribed-oriented cultures and according to their performance and knowledge in achieved-oriented cultures. Korunka and Carayon (1998) confirm these cultural differences in the management of change: there were significant differences in the

way technological change was managed in Austria and in the USA. For instance, stronger negative effects on employees, such as high reduction in personnel, were found in the American cases: this finding confirms the short-orientation of US culture as compared with that in Austria, as well as the specific characteristic of the American culture as compared with the more diffuse characteristic of the Austrian culture.

4. CONCLUSION

Cross-cultural issues are extremely important today because of the globalization of businesses. Understanding and managing cross-cultural aspects in organizations not only has, therefore, become important for the competitiveness of companies, but also for the well-being of employees. This paper has presented cross-cultural models of management that define important cross-cultural characteristics that should be taken into account in macroergonomics. The importance of these cross-cultural characteristics for participatory ergonomics, work design and management has been emphasized.

Design of Shift Systems for Shiftwork

P. Knauth

Department of Ergonomics, Institute for Industrial Production, University of Karlsruhe, Hertzstraße 16, D-76187 Karlsruhe, Germany

1. INTRODUCTION

In contrast with "normal" daywork, shiftwork means either work at varying times of day (e.g. morning shift, afternoon shift and night shift) or work at constant but unusual times of day (e.g. permanent afternoon shift or permanent night shift). However, with increasing flexibility of daywork the borderline between daywork and shiftwork is difficult to define. The various features of any given shift system, such as the timing and duration of shifts, and the direction and speed of rotation of the shift system may result in various problems for the shiftworkers.

The sleep–wake cycle and body rhythms of shiftworkers may be disrupted. Furthermore, shiftworkers live at least partly disconnected from their social environment. Therefore, the individual shiftworker's problems can range from disturbed sleep to impaired well-being, health and performance, as well as to impoverished family and social life. As a consequence, their employers may be faced with increased labor turnover and absenteeism, as well as reduced safety and productivity. Therefore it is necessary to seek solutions to reduce these problems.

2. PROBLEMS OF SHIFTWORKERS

The human body is mainly 'programmed' for daytime work performance and for night-time recreation and rest. The disruption of daily variations in physiological functions caused by having to be at work at biologically unusual hours as well as by having to sleep during the day is one of the major points of stress associated with shiftwork. Many shiftworkers have the subjective impression that they feel better adjusted to nightwork after two or three night shifts. However, most authors who have studied short-term adjustment to nightwork using objective measures have found that even after 1 week of continuous nightwork the physiological rhythms of most shiftworkers are only partly adjusted.

Furthermore, a variety of workplace hazards such as noise, unfavorable climatic conditions, unfavorable lighting conditions, vibrations and a combination of these can sometimes occur more often in three-shift systems, irregular systems and night shift systems than in two-shift systems or daywork.

Although the stress of a group of shiftworkers with the same shift system is the same for each member of the group, the magnitude of individual disturbances is modified both by individual differences in age, experience, personality, capacity to cope, gender, physical fitness, etc. and by situational differences, e.g. related to domestic circumstances, environmental noise levels at home, commuting time, etc. Nevertheless, in many studies on the effects of shiftwork (Colquhoun *et al.* 1996) some general trends have been observed.

Sleeping difficulties are a major concern in the life of shiftworkers, particularly for those who have to work night shifts.

Table 1. Potential negative effects of shiftwork (Knauth 1996). Shaded areas are potential problems.

On an average day sleep after a night shift has a reduced duration (~6 h) and the quality is less good compared with normal night sleep. Therefore, in a week of night shifts an accumulation of sleep deficits has to be expected. In addition, the sleep before morning shifts is shorter, the earlier the morning shift starts. A week of morning shifts, all starting very early, results also in an accumulation of sleep deficits. Therefore, shiftworkers may be very tired at the end of a week of such morning shifts or of night shifts.

Nightwork leads to a change in the sequence and timing of meals. During the night, the body cannot adequately cope with the composition and the quantity of a typical daytime meal, because the activities of stomach, liver and kidney are very much reduced at night. Some nightworkers suffer more from disturbances of appetite than dayworkers or shiftworkers not on night shift.

In the long run, irregular food intake can lead to gastrointestinal complaints or even to disorders. However, the reasons for complex gastrointestinal symptoms are surely manifold. Some longitudinal studies have shown that those shiftworkers who transferred to daywork out of shifts because of medical problems had a higher frequency of gastrointestinal disorders than the remaining shiftworkers.

Similarly an increase in cardiovascular disorders, particular among those who transferred away from shiftwork, has been observed. Altogether, nightwork is regarded as a risk factor for health, i.e. not every nightworker will develop illnesses. However, if nightwork is combined with aggregative factors (e.g. individual and situational factors from private life) the probability for disorders may be increased.

Shiftwork may have adverse effects on family life, contacts with friends and relatives, attendance at meetings of organizations, such as sports clubs, political parties or civic groups, or participation in evening classes. Most of the activities are bound to evening hours or the weekend. If a shiftworker works in evening shifts, night shifts or at weekends, he is desynchronized from the 'normal' social environment. Women on shiftwork may have more problems with domestic duties and sleep, since household responsibilities are not equally shared by the partners.

'Headline' incidents such as the chemical/gas leak at Bhopal, the nuclear accidents both at Three Mile Island and Chernobyl, and the *Exxon Valdez* tanker wreck, all of which occurred at night, have drawn attention to the potential cost of impaired performance and safety in shift systems. It seems probable that the potential loss of efficiency and impaired safety on abnormal work

routines reflects the combined influence of a number of factors. These may include the relatively indirect influences of social factors and impaired health, as well as the more direct influences of disturbed circadian rhythms in sleepiness/alertness and performance capabilities. However, more detailed studies or 'real job' measures of safety and efficiency in different shift systems are needed before adequate recommendations can be made (for a review, see Colquhoun *et al.* 1996).

There are several possibilities for reducing the problems of shiftworkers such as special health measures (Colquhoun *et al.* 1996), guidelines for shiftworkers (Wedderburn 1991) or most effectively the design of shift systems according to ergonomic recommendations.

3. ERGONOMIC RECOMMENDATIONS FOR THE DESIGN OF SHIFT SYSTEMS

If shiftworkers are asked which shift system they feel is the best, very often – irrespective of the type of shift system – they name their roster, i.e. the one to which they are accustomed. Therefore, it seems more sensible to assess the advantages and drawbacks of a shift system on the basis of objective criteria, such as adjustment of physiological functions to nightwork, level of well-being (e.g. sleep, fatigue, appetite), health problems, disturbances in personal and social life, performance efficiency and accident rates (allowing for time of day and particular type of shift system in operation). The most important ergonomic recommendations for the design of shift systems are summarized in Table 2.

4. PERMANENT NIGHTWORK

The permanent night shift is the most disruptive of all shifts in terms of physiological adjustment, sleep and well-being. The daily variations of the physiological rhythms of most shiftworkers may require > 1 week for complete adjustment to nightwork. Any partial adjustment will be lost during the days off after consecutive night shifts. Thus, the body rhythms of permanent nightworkers are constantly in a state of disruption, whereas the least distortion of rhythms has been observed to occur after a single night shift. In

Table 2. Recommendations for the design of working time arrangements (Knauth 1993).

1. Nightwork should be reduced as much as possible. If this is not possible quickly rotating shift systems are preferable to slowly rotating ones. Permanent nightwork does not seem advisable for the majority of shiftworkers.

2. Extended workdays (9–12h) should be contemplated only if: the nature of work and the workload are suitable; the shift system is designed to minimize the accumulation of fatigue; there are adequate arrangements to assure that a complete recovery after work and a high acceptance of the working time arrangement are possible.

3. An early start for the morning shift should be avoided. In all shift systems flexible working time arrangements are realisable. The highest flexibility is possible in 'time autonomous groups'.

4. Quick changeovers (e.g. from night to afternoon shift on the same day or from afternoon to morning shift) must be avoided. The number of consecutive working days should be limited to 5–7 days. Every shift system should include some free weekends with at least 2 successive full days off.

5. The forward rotation of shifts (morning shift, evening shift, night shift) would seem to be recommendable at least in continuous shift systems.

contrast with our view that the physiological rhythms of shiftworkers should remain as near as possible to the 'normal state', i.e. should be disturbed as little as possible, some authors recommend accelerating adjustment to nightwork with the help of bright light. However, up to now not enough is known about the optimal light–work–sleep schedule for shiftworkers in terms of their ability to shift biological rhythms, improve sleep and reduce fatigue, as well as in terms of their social feasibility. Furthermore, no controlled long-term studies on the effects of such a bright light treatment have been carried out.

As detailed studies of sleep protocols of permanent nightworkers over several weeks have shown, in most cases an accumulation of sleep deficit was observed. Furthermore, former nightworkers, who transferred to daywork after many years of permanent nightwork, had more sleep problems than their colleagues, who had previously worked in alternating shift systems.

In comparison with other shift systems, permanent night shifts also have more negative effects on families, who must adapt their lifestyle to this schedule, on sexual relations and on a worker's ability to fulfil family roles.

Permanent nightwork also has some advantages. Nightworkers report a greater feeling of independence and less supervision at night. Very often nightwork is chosen because of the increase in income due to the night shift allowance. Some female nurses prefer permanent nightwork, because this represents the only way of better arranging domestic responsibilities and employment outside the home.

Although, there is insufficient knowledge about the long-term health effects of permanent nightwork and about optimal bright light–work–sleep schedules, it is known that night shifts are the most disruptive of all shifts in terms of physiological adjustment, sleep and well-being. Therefore, until results from further research are available, it will be assumed for the moment that permanent nightwork is not recommendable for the majority of shiftworkers.

5. QUICKLY ROTATING VERSUS SLOWLY ROTATING SHIFT SYSTEMS

More rapidly rotating shift systems are more advantageous compared with weekly shift rotation for the following reasons:

- Biological rhythms are not in a constant state of disruption from partial adjustment to different day and night orientations, but are kept nearer to a daytime orientation.
- The bigger accumulation of sleep deficit such as during a week of night shifts and during a week of morning shifts (starting early) are avoided.
- Shiftworkers have free evenings in every week and, thus, more regular contact with friends is possible than with weekly rotating shift systems.
- The relative risk of accidents increases during (several) consecutive night shifts.

In several longitudinal studies, the majority of shiftworkers who had experienced weekly and quicker rotating shift systems always voted in favor of quicker rotating shifts after a trial period.

6. DURATION OF SHIFTS

The potential drawbacks and advantages of 12-h shifts have been extensively discussed (Rosa 1995). According to our experience an

extended workday of 9-12 h should be contemplated only in the cases mentioned in Table 2. In particular, this means that 12-h shifts are not compatible with high physical, mental or emotional demands of a job. Furthermore, if there are many extended work shifts in a row, an accumulation of fatigue has to be expected. Similarly if there are no adequate arrangements for the cover of absentees and if overtime is added, the shiftworkers may become exhausted. As our knowledge is very limited about toxic exposure and toxic clearance during the time off work in connection with extended working hours, it is recommend that one limit toxic exposure as far as possible or not to introduce extended working hours.

7. TIMING OF SHIFTS

An early start of the morning shift seems unfavorable because it may reduce sleep duration before the morning shift, increase fatigue during the morning shift and increase the risk of errors and accidents in the morning shift. On the other hand, a late start of the morning shift means (assuming there is a constant shift length of 8 h) that the evening shift and the night shift will also start and end later.

Other factors, such as availability of public transport, opening hours of shops, main time of social contacts in the evening, meal times together with the family or particular requirements of the job, have to be taken into consideration when fixing starting and finishing times of shifts.

Flexible working time arrangements are also possible even in three-shift systems, where employees can choose their working hours in agreement with their colleagues.

8. DISTRIBUTION OF LEISURE TIME WITHIN THE SHIFT SYSTEM

When the interval of time off between two shifts is too short (e.g. 7, 8 or 10 h only) sleep is reduced, well-being impaired and fatigue increased. Too many working days in succession can lead to an accumulation of fatigue. Although it is not easy to define a limit for the maximum number of consecutive working days — because the workload, the organization of breaks, and exposure to unfavorable conditions vary from workplace to workplace — it is recommend that one limit the number of consecutive working days to between 5 and 7.

Free weekends are of particular social importance for the majority of workers. Instead of only 1 or 1.5 days off (after night shifts), every shift system should include some free weekends with at least 2 consecutive days off.

9. DIRECTION OF ROTATION

A shift system that first moves from the morning shift to the evening shift, and then to the night shift, has a 'forward rotation' (phase delay, clockwise rotation). An anti-clockwise or 'backward rotation' has a phase advance that moves from night to evening to morning shifts. The forward rotation appears preferable because it corresponds more closely to the human biological rhythm. A comparison of shiftworkers with forward and backward rotating shift systems revealed more digestive troubles, more cardiovascular complaints, more chronic fatigue and more disturbances of family and social life in the latter group. The worst case comprises backward rotating shift systems, which include several short intervals of time off between two shifts.

The only advantage of a backward rotation may be a long period off work between the end of the last morning and the start of the first night shift, in particular when this period includes a weekend.

10. EXAMPLE OF A FAVORABLE SHIFT SYSTEM

It is not always possible to adhere to all recommendations mentioned above simultaneously. However, the shorter the weekly working hours the easier it is to follow them. In Figure 1 an example of a continuous shift system is shown that corresponds quite closely to the recommendations. This shift system is operated by five teams, i.e. the basic schedule has a mean weekly working time of 33.6 h. Depending on the agreed weekly working time, additional shifts have to be worked, which may be used for continuation training, maintenance or, in a limited number of cases, to provide cover for absentees.

The shift system has short periods of morning shifts, evening shifts and night shifts, and a forward rotation of the shifts. There are longer blocks of free weekends, a regular pattern and > 48 h off between the end of the last night shift and the start of the following morning shift.

11. INTRODUCTION OF A NEW SHIFT SYSTEM

Besides the design of a favorable shift system, the implementation strategy is of particular importance. Shiftworkers who have worked for many years in one shift system have become accustomed to it and know all the drawbacks and advantages. If the employer wants to implement a new shift system this causes doubts, fear or even resistance of the shiftworkers and often also skepticism of the middle managers. To achieve a high acceptance of a new shift system, an adequate strategy is necessary which includes:

- early dissemination of this information to everybody concerned;
- participation of the shiftworkers in the planning phase, i.e. in the finding of a solution that is a good compromise between the demands of the company and the wishes of the workers;
- regular discussions during the trial period; and
- a ballot after the trial period. (If the shiftworkers know that they may vote after the trial period, their fear will be reduced and their willingness to try something new is increased.)

Week	Mo	Tu	We	Th	Fr	Sa	Su	Mo	Tu	We	Th	Fr	Sa	Su
A	M	M	E	E	N	N					M	M	E	E
B	N	N						M	M	E	E	N	N	
C			M	M	E	E	N	N					M	M
D	E	E	N	N					M	M	E	E	N	N
E					M	M	E	E	N	N				

Average weekly working hours

Men

Day off
Morning shift   33.6 h/week without additional shift
Evening shift   35.2 h/week with two additional shifts/10 weeks
Night shift   36.8 h/week with four additional shifts/10 weeks
38.4 h/week with six additional shifts/10 weeks
40.0 h/week with eight additional shifts/10 weeks

Distributed Mission Training

D. H. Andrews

United States Air Force Research Laboratory, Human Effectiveness Directorate, Warfighter Training Research Division, 6030 S. Kent, Mesa, AZ. 85212-0904.

1. MISSION TRAINING CHALLENGES FACING MILITARY PILOTS

Today's military pilots face significant challenges in their attempt to "train as they intend to fight" (Andrews 1988). A variety of constraints makes it difficult to provide realistic training environments on a consistent basis so that new skills can be learned and existing skills can be refined. Some of these constraints include:

- reductions in flying hours that can be used for training;
- training range restrictions;
- aging aircraft that makes it more difficult to use them for training hours versus operational hours;
- safety constraints such as altitude floors below which trainees cannot fly in peacetime but below which they would fly during combat; and
- security constraints that will not allow pilots to use their full range of tactics and electronic warfare gear on training ranges.

These constraints make it difficult for pilots to maintain the readiness that will be required in combat. These constraints promise to grow more challenging and, thus, will make it more difficult to conduct mission training only in actual equipment on existing training ranges (Andrews *et al.* 1995).

Mission training is aimed at teaching pilots higher-order skills necessary to conduct tactical missions. This type of training usually involves training with team members who may be on board one aircraft, and it often involves training with team members who are in other aircraft and on the ground. For example, many air forces typically have their fighter pilots fly in four ship formations when they undergo a tactical mission task. Not only will mission training involve the four pilots learning and practicing team skills together, but also it will also involve radar operators in other aircraft and on the ground.

Mission training differs from procedures training in that it is designed to train higher-order skills such as advanced problem solving in tactical settings rather than information and skills required simply to fly the aircraft safely. Examples of normal procedures training are training a pilot to land an undamaged aircraft or training a pilot to handle an emergency procedure like handling an aircraft with an engine fire. Aircraft procedures must be well learned before mission training can begin. Mission training includes such functions as suppression of enemy air defenses, defensive counter air and air–ground attack.

2. USE OF SYNTHETIC ENVIRONMENTS TO MEET TRAINING CHALLENGES

Fortunately, modeling and simulation technologies have been developed that can be of great assistance in meeting the training challenges discussed above (Hays and Singer 1989, Leplat 1989). These technologies take many different forms, and when used together allow military pilot instructors to conduct mission training on a distributed basis. Affordability is a major advantage of simulation when compared with actual live-fly training (Orlansky and Chatelier 1983). The term "distributed" means that simulators at multiple sites, often in geographically dispersed locations, are linked together via wide-area computer networks. In addition to virtual simulators, live assets such as aircraft and tanks on training ranges, as well as constructive computer models such as digital war games, can be linked into the simulated training engagement for added realism (Alluisi 1991).

This "synthetic battlefield" can consist of as few as two networked sites or many dozens or hundreds. As the networking technology matures it is feasible to think of thousands of sites representing all manner of weapons systems and military units, not just aircraft. A key engineering issue is making sure that temporal latency does not exceed tight tolerances (less than a few milliseconds) lest the pilot trainees detect non-realistic update rates in their simulators and actual weapon system. Thus far, the latency issue has not proven too great a difficulty as dozens of sites have been networked in early versions of DMT; however, it will be a concern when hundreds or thousands of sites are linked (Bell and Waag 1998). Figure 1 is a graphic representation of DMT showing the virtual (simulation), live and constructive model assets that are joined together to create the synthetic battlefield.

The following are examples of engineering technologies that have allowed militaries to provide distributed mission training to their combat pilots:

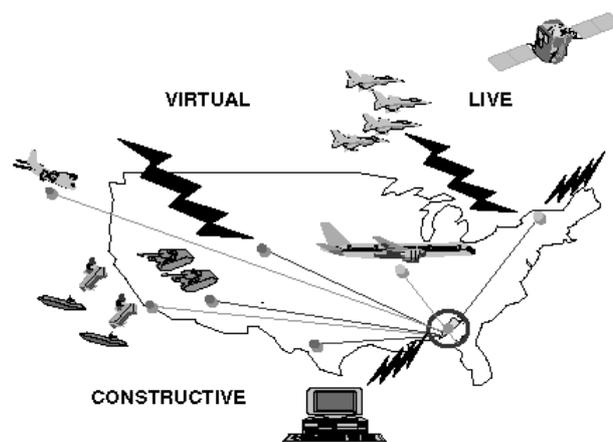
- Simulation visual systems (image generators that produce computer-generated imagery, visual displays such as domes and helmet-mounted displays, and database development tools that allow simulation developers to produce realistic visual and sensor (e.g. infrared and radar) terrain and multi-spectral environments).
- Networking technology for connecting simulated and live entities via wide area networks.
- Representation technologies that allow development realistic of computer-generated models of both friendly and enemy weapon systems and personnel.
- Instructional technologies, such as instructor–operator


Figure 1. Graphical depiction of distributed mission training, including virtual, live and constructive assets
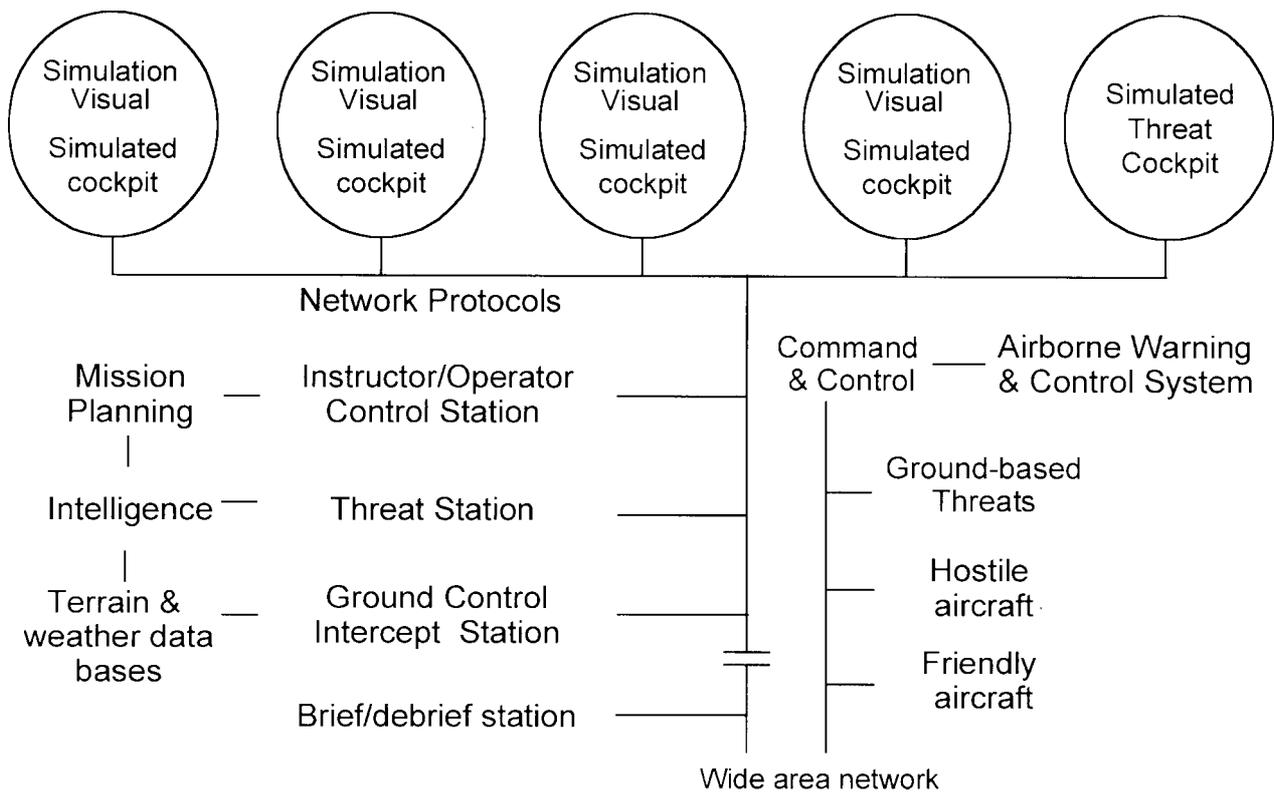

Figure 2. Typical networking schematic of distributed mission training.

stations and sophisticated debrief tools, that aid instructors in providing the necessary training help to trainees.

Figure 2 shows a typical DMT network diagram.

3. HUMAN FACTORS AND INSTRUCTIONAL ISSUES ASSOCIATED WITH DISTRIBUTED MISSION TRAINING

There are a variety of human factor and instructional issues that must be addressed if DMT training capabilities are to reach their full potential. Major examples include:

- Instructional tools for helping instructors train with trainees at distributed locations must be improved. Currently instruction, including briefs and debriefs are carried out over long-distance telephone or video conferencing. What is missing are validated tools that allow instructors at different locations automatically to see and share all the performance data collected at all the sites in a synthesized manner. Briefings (including mission planning) and debriefings are difficult enough to conduct properly when all the team members are in the same location. The task difficulty increases greatly over long distances and effective tools for the task are critical.
- Regardless of how many virtual or live training assets that are available for training, it will probably never be possible fully to represent an entire theater of battle with just human in the loop systems. Constructive models that accurately represent synthetic friends and foes are crucial if DMT is to reach its full potential. Currently constructive models either do not represent key human behaviors, or if they are represented they are not realistic. For example, current models do not represent the human trait of fear. The conse-

quence is that synthetic humans are usually fearless regardless of the situation. A human construct that is now being represented more often in wargame constructive models, but which is seldom represented very accurately is fatigue. Most model builders now recognize that warfighter effectiveness will degrade over time in battle, but the fatigue models presently in use are not based on any scientific data, but rather a degradation model that degrades at a steady rate over time. The consequence of no or poor human representation in constructive models may well be negative learning (Allesi 1988, Baker and Marshall 1989) where trainees learn to expect one behavior from a friend or foe but are surprised in the real world by a new behavior or a behavior that is different than expected.

- Visual resolution in simulator visual displays must be improved. The goal is to achieve eye-limiting (20/20) resolution. Currently, tasks such as air–ground attack mission training and formation flying training are difficult to train in DMT because of visual resolution limitations. Pilots' ability to fly in formation and to identify and attack enemy is dependent upon accurate visual representations.
- Fighter pilots must learn to distinguish key cues from a host of stimuli presented to them in the cockpit. Visual stimuli from outside the cockpit (including night vision goggle images), infrared, radar and other sensor stimuli all must be sorted and interpreted by the pilot to make proper tactical decisions. It is vital that the simulations, which present these different stimuli, be correlated so that the pilot is presented with a realistic picture. The engineering community has still not entirely solved this challenge and trainees might see

visual cues outside the cockpit that represent outside stimuli differently than a radar or forward-looking infrared sensor simulation of the same stimuli. Negative learning cannot take place if visual and sensor stimuli are not well correlated. This correlation issue is present whenever tactical aircraft flight simulators are used, but it becomes even more critical when there are multiple pilots in the loop because a synthesized picture is crucial for team tactics training.

DMT combines virtual, live and constructive assets. Experiments with DMT so far have shown that it is difficult optimally to merge this combination for maximum training effectiveness. Most of the engineering technical hurdles for combining these assets have been overcome, but the instructors who make use of these asset types often have difficulty in knowing how best to make use of the training capabilities from the other asset types. For example, constructive wargames may involve hundreds of trainees who are learning to conduct a combat operation across an entire theater. These trainees are principally concerned with large-scale command and control issues. Consequently, instructors in these settings are not very interested in particular actions of individual pilots or small teams of pilots who might be flying in the training exercises via simulators or aircraft. Therefore, the constructive instructors may ignore important training information that could be learned from the training experience of the individual pilots and small teams.

4. KEY INSTRUCTIONAL GUIDELINES FOR MAKING DISTRIBUTED MISSION TRAINING EFFECTIVE

Although DMT is relatively new and much empirical and analytical research remains to be done, a fair amount has been learned from training effectiveness studies and practical experience about how best conduct DMT training. Following are some guidelines that have emerged:

- It is critical that those who conduct DMT develop systematic instructional programs with clearly defined instructional objectives, performance measures, instructional syllabi and evaluation methods. Too often pilots are happy merely to have a synthetic battlefield environment that nearly replicates their training ranges. Once that goal is achieved, pilots have been happy merely to practice in a freeplay environment that is not well structured from an instructional standpoint. There is no doubt that learning occurs with such an approach, but it is not systematic and not very efficient. Learning to work in well-coordinated teams is a difficult process and it is best done using proven instructional systems approaches and not by mere practice.
- Owing to visual resolution limitations in current flight simulators, it is often necessary to enhance or augment visual cues so that pilots can see and react to these important cues. For example, in the real world a pilot can see the aspect angle (i.e. which direction the aircraft is pointing) of a wingman in formation out to ~15 000 feet depending upon visibility conditions. Beyond that range the pilot can see an aircraft but cannot tell the aspect angle. In current simulators a pilot can tell aspect angle only out to ~5000 feet. This limitation makes it difficult to perform many tasks that tactical teams must perform. This same limitation impacts pilots' abilities to perform tactical dogfights with simulated enemy fighters. These visual resolution limitations can be somewhat overcome by enhancing the simulated representation of friendly and enemy aircraft. For example, an aircraft's image might be made artificially larger at distances > 5000 feet. Another approach is to put artificial colored lights on the wings, fuselage and tail of a simulator aircraft better to help distinguish the aspect angle.

- Instructors who use DMT must be given clear training about how best to use the instructional capabilities that can only come from a synthetic environment learning environment. Instructional features such as freeze replay, performance measurement, and enhanced cues may be familiar to some instructors from their use of these features in traditional non-networked simulators. However, the use of these features differs in DMT, and DMT instructional designers must provide "train the trainer" sessions concerning the most effective use of these features.

5. FUTURE OF DISTRIBUTED MISSION TRAINING AND ITS APPLICATION TO NON-MILITARY ENVIRONMENTS

DMT will continue to grow in importance. New simulation technologies will allow ever more realistic training (Bolton *et al.* 1984). The affordability of synthetic environments when compared with using only expensive flying training hours will have great appeal as training budgets shrink. Currently, a simulator hour of training costs ~20% of a flying hour, and that percentage will shrink as these technologies drop in price. Already these same technologies are having an effect on mission training outside of pilot training such as: armor training, naval surface training and security police training.

Wherever large teams need to train and practice together, especially when the trainees are geographically dispersed, DMT will be of use including non-military training settings such as industrial and transportation training. An example of DMT use in industrial training might be a virtual factory training environment for industrial workers from different locations, who all work on different assemblies that are to be integrated to make the final product (e.g. an automobile that is assembled from parts made around the world). It may be that the parts production employees would have a better shared mental model of how their parts impact production workers at other locations in the assembly process if they all could assemble a virtual car together using representations of the parts they produce. Since it may well be cost prohibitive to have all the workers assemble at a central location for this training, DMT could be an efficient means for producing shared mental models.

An example of DMT training for transportation might be airline aircrews training with air traffic controllers for landing at an airport to which they have never been. Specific and peculiar conditions for landing at that airport could be depicted in the simulated visual and radar representations for the aircrew and the aircrew members could interact by voice with the air traffic controllers in that particular airport.

The key to the ultimate success of DMT is not whether the technology improves or whether it is affordable, but rather whether it fulfills training requirements. In other words, does it satisfy the basic human factors issues described in this entry by providing quality training that cannot be provided with traditional

training methods and technologies? Merely providing practice opportunities will ultimately not allow DMT to fulfill its full potential. Only when new and measurable mission skills and information are learned by trainees will DMT be a major training institution in the military.

The Ergonomic Buddy System

L. T. Ostrom, C. A. Wilhelmsen and T. Lango
INEEL, PO Box 1525, Idaho Falls, ID 83415-3855, USA

1. INTRODUCTION

Currently, there are > 6000 employees at the Idaho National Engineering and Environmental Laboratory (INEEL). Of these, ~4000 work in an office environment to one degree or another. As of Spring 1999, ~3500 of these employees have had an ergonomic assessment of their offices and corrections made. This is quite an accomplishment given that just 3 years ago there were < 1000 employees who had an ergonomic assessment of their offices performed. Two thousand five hundred ergonomic assessments being performed in 3 years take a great effort, yet the INEEL had less than five individuals who have the training and expertise to perform a proper and adequate ergonomic assessment before 1997 and not much funding to support a program. An innovative process called the Ergonomic Buddy System (EBS) was used to accomplish this feat. This chapter will discuss that process.

2. HISTORY OF ERGONOMICS AT THE INEEL

The Human Factors unit was established at the Idaho National Engineering Laboratory (now INEEL) in the early 1980s. Its focus was to develop and test technologies designed to improve the operability of nuclear power plants and military systems. In June 1989 they hired me. My job was to work in the Human Factors Unit, but my focus was to be risk assessment and ergonomics. I immediately was also asked to head up the safety efforts for the Engineering Department. In December of that year I met Cheryl Wilhelmsen. She was in a support role at the time and was working on a degree in corporate training. I began working ergonomic issues in Spring 1990. At that time we conducted an initial survey of all the major worksites and performed initial assessments. This was under the direction of the industrial hygienist unit (Ostrom *et al*. 1991). The team set up to do this work was Gay Gilbert, Cheryl Wilhelmsen and myself. Cheryl was in a support role and helped prepare the report. As a part of the report an ergonomic checklist was developed and a rating scale for workplace design issues. In January 1991 Cheryl and I began a project to analyze the safety culture at the INEEL and found that we had similar goals for improving the working conditions of the employees at the INEEL and from that time we have been partners in crime.

From the ergonomic survey and the safety culture survey we realized that ergonomics was one of the least implemented parts of the safety and health program. We did not have support for performing ergonomics from the medical department right off the bat. In fact, the medical director did not believe there was a condition called carpal tunnel syndrome (CTS), though he claimed to experience symptoms from guiding his horses. So, during this time assessments were only performed if a person was experiencing pain and referred by medical. We were performing about one-to-two per month. It came to my attention that Cheryl was experiencing pain in her wrist and elbow. She was using a Macintosh computer and doing graphics for a book for another individual in the group. Upon reviewing the workstation I found that she was mousing a great deal and using it at a different height than the keyboard. Changes were made to her workstation and Henry Romero, a new ergonomist to the group at that time, designed a platform for Cheryl to use while doing intensive mouse work. This was installed and it helped her. Cheryl also developed a strategy to "listen to her body." Meaning, when she felt fatigued, she would take a fatigue break. This was consistent with both Grandjean's (1980) and Putz-Anderson's (1988) philosophies. Cheryl was committed not to experience an injury, as much to avoid needles as to avoid the injury itself. From this time Cheryl became committed to helping others avoid injuries because she knew what one goes through after developing a cumulative trauma disorder (CTD). Not just the pain, but the probing questions by workman's compensation insurance investigators and the medical procedures used to diagnose CTS. She was very committed not to have the CTS surgery. Cheryl also began to study ergonomics on her own so she could answer employee questions.

After this experience we began to advertise our services to the employees, in spite of the medical director. We performed numerous informational and formal training sessions on ergonomics and, as project work allowed, we performed ergonomic assessments. These were "free" assessments, meaning we had no formal budget to do them. One of the attributes of our training that was unique and helped drive the information home was Cheryl's testimony to the benefits of ergonomics and the need to listen to one's body. She would discuss her own case and how the changes to the workstation benefited her. At the end of 1993 we had performed ~200 clandestine ergonomic assessments.

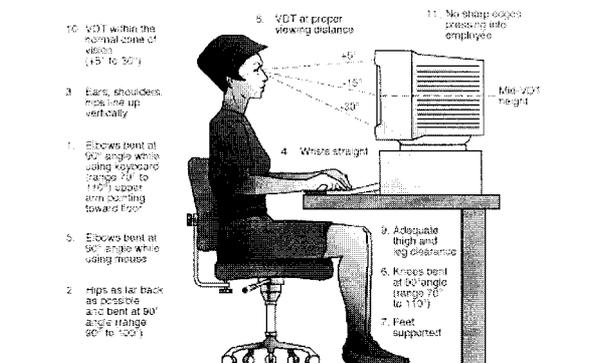
In Spring 1994 Eloise Hayes asked us if we could help perform ~800 assessments at an INEEL facility run by another company. We agreed to this. This mass number of assessments set the stage for the development of the future ergonomics program. One reason being, though this facility was run by another company, they had very close ties to the one we worked for. So, employees on our side of the fence began to ask for assessments more. In addition, since we had a common medical department, medical could not deny that they were seeing benefit from the introduction of ergonomics. About this same time we began an ergonomic's committee to review office ergonomic equipment because managers were buying equipment based on sales people's recommendations or using the "looks good" principle. Again, this committee had no official sanction, but the results were widely used by managers as the basis of their purchases.

Our history of ergonomics sometimes parallel's the introduction of technology at the INEEL. In the early 1990s 1500 drop-keyboard desks were purchased. These desks had a recessed platform 21 inches long, and were non-adjustable. The desk itself was 29 inches tall and the keyboard platform was 26 inches high. These were bought because they, supposedly, were "ergonomically correct" because the keyboard height was 26 inches from the floor. However, they obviously were not designed to fit most individuals. One of the common findings of the ergonomic assessments was that a new desk was needed because the keyboard was not right and there was no room for a mouse. Management balked at the cost of the new desks, but could not deny they were needed to fix the problems. Therefore, we came up with an

idea to level the top of the desks and add an articulating keyboard platform. We estimated that our solution would save the company ~US$900,000 over the cost of new desks, not to mention the savings in human terms. We began a program to retrofit these desks. When we approached management about the fact that we could save them money as we improve the health of employees they began to buy into the ergonomic concept. This helped gain our first management champion, Derek Moore who was the Chief Engineer.

With the introduction of Windows 95 in 1996 employees began to use the mouse to a much higher degree and we began to see a much higher number of employees reporting to medical for evaluations. Managers began to see the need for ergonomic assessments due to the awareness training that had been conducted, as well as employee requests. We began to get swamped and could not keep up with the great number of assessments. We needed a scheme to help us perform more assessments because we did not have funding to hire more help. We came upon the idea of the self-assessment.

The first attempt at implementing the a self-assessment system was a behavioral-based safety project we developed where employees were asked to take a fatigue break and go to an ergonomic information kiosk and receive a Hersey's Kiss. "Take a fatigue break and get a kiss" was the obvious theme. This little program worked very well. At the kiosk there were informational flyers and a self-assessment checklist. This effort demonstrated that properly motivated employees would seek ergonomic information and would perform a self-check.

Next, we distributed self-assessment cards to employees. The self-assessment card contained questions and a diagram showing a person in a correct ergonomic position for a computer workstation (Ostrom 1994). Figure 1 shows the representation


Questions:
Are my feet flat on the floor?
Are my wrists straight?
Are my elbows at a 90 degree angle?
Are my knees at a 90 degree angle?
Is my back support by the chair?
Is the monitor about arm's length away?
Is the mid-monitor height about four inches below eye height?
Do I feel comfortable?

If you answer No to any of these questions contact the ergonomic staff.

Figure 1. Self-assessment card.

of the card. The employees turned in these cards to a designated employee or us and received an award.

In conjunction with the self-assessment card, ergonomic demonstration offices were setup in three different locations on the INEEL. If the employees had questions concerning a piece of equipment (i.e. an "ergonomic" keyboard), s/he could go to the demonstration office and try one out before buying it to ensure it worked. The concept of having employees perform a self-assessment is very consistent with the principles of the Voluntary Protection Program (VPP) that the Department of Energy was beginning to promote. In mid-1996 we did a written survey and found that up to 30% of the employees were experiencing some symptoms of a CTD. Also, the demand for ergonomic assessments was so great we needed more help than just the self-assessment.

3. BIRTH OF THE ERGONOMIC BUDDY SYSTEM

Cheryl was the one who conceived of the EBS. In essence, the system involves four elements: 1, hierarchy of individuals who perform ergonomic assessments (self-assessments, ergo-buddies who are trained to do simple assessments industrial hygienists who perform more complex assessments, and ergonomists who perform the most complex assessments); 2, ergonomic committee that approves ergonomic equipment and directs the ergonomic effort; 3, ergonomic demo-offices where employees can try equipment; and 4, ergonomists on staff who serve as consultants to the organization. These are discussed below.

3.1. Ergonomic Assessments

In the EBS there are four groups who do ergonomic assessments: 1, employees who do self-assessments; 2, the ergo-buddies; 3, industrial hygienists; and 4, trained ergonomists. Figure 2 shows this hierarchy. The unique aspects of the EBS are the self-assessment process and the ergo-buddies, so they will be the items discussed here.

3.1.1. Self-assessments

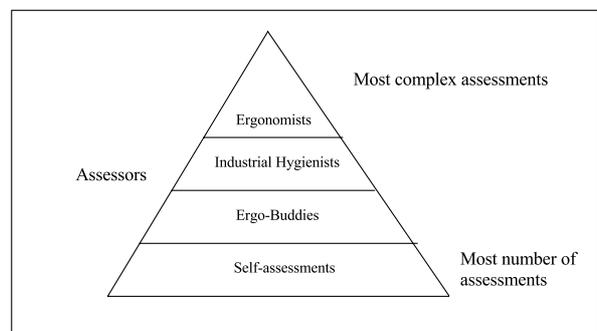
The self-assessment process began as the self-assessment card being given out to employees, but this was found to not be as effective as we would like. To further improve the self-assessment process and the EBS we developed the concept for Buddy Ergonomic Software. Mountain Bluebird Products (Idaho Falls, ID Falls, USA) market it. It is a tool designed to:
- Guide employees through a self-assessment of their offices.
- Remind employees to take fatigue breaks.
- Show employees how to do stretching exercises.
- Show solutions to workplace design problems.


Figure 2. Diagram of ergo-buddy concept.

The primary benefit of Buddy is that it guides employees through a self-assessment of their office. It provides a simple three-step self-assessment process that is designed to be simple and effective. The software is interactive by design and provides the necessary helps to successfully guide the employee through the assessment. One of the unique features of Buddy is that it provides not only information as to what is wrong with the workstation, but also how to fix problems found. In addition, it provides a range of options so you have a choice as to how to fix any problems. For instance, sore neck from telephone usage, then the software says to try a headset phone.

One of the attributes of the Buddy Ergonomic Software is it generates a Move Card. A Move Card (Figure 3) contains the measurements necessary to set someone up in a workstation in the event they get transferred to a new location. The Move Card helps eliminate the need for a new ergonomic assessment every time an employee changes work locations. Their data goes with them and, so, movers can set them up right the first time, rather than setting them up using a general set of measures that do not fit anyone.

3.1.2. Ergo-buddies

Because we could not be everywhere, all the time we developed the concept for an ergo-buddy. Ergo-buddies at the INEEL are volunteers. The purpose of the ergo-buddy is to do ergonomic assessments for individuals who need some extra help or who feel uncomfortable doing their own assessments. The ergo-buddies receive 8 h of training on ergonomics. The training consists of:

- basics of ergonomics;
- the nature of CTD;
- proper workplace design; and
- environmental factors.

The ergo-buddies were selected based on their desire to help and so that there is one in the majority of the sites at the INEEL.

3.1.3. Ergonomic committee

The Ergonomic Committee at the INEEL is made up of employees with an interest in ergonomics, procurement personnel who are responsible for buying ergonomic equipment, ergo-buddies, industrial hygienists, ergonomists and management. The committee meets once per month to discuss issues relating to ergonomics on the site and, on a periodic basis, assess equipment for inclusion as "approved ergonomic items." We have found the ergonomic committee to be an integral part of our program and some of the best ideas have been formulated through the committee efforts.

3.1.4. Ergonomic demo-offices

The ergonomics demo-offices have been in place for almost 2 years. The demo-offices contain all the approved ergonomic furniture and equipment. A need for a mobile demo-office was seen because of the size of the INEEL (840 square miles). In response to this, the ergonomics demo-trailer was born. The ergo-trailer has evolved within the past few months. A trailer was purchased and modified for the purpose of holding office furniture and ergonomic equipment in a stable manner. The distances are great at the INEEL. We could drive 60 miles from our home office to the farthest reaches of the site. The ergo-trailer makes it easier to demonstrate equipment to those located on the desert, at the various facilities. Local vendors of equipment were happy to loan items for the trailer.

The trailer currently visits facilities on a monthly basis. The concept is that a series of ergonomic assessments are planned for a facility, the ergonomist and trailer are at the facility at the same time. The employee and manager then look at equipment in the trailer immediately after the assessment so that the correct items are purchased. This enables the employee to try chairs and other equipment and get what is right for him/her. This avoids the "looks good" syndrome.

Ergonomic Self-Assessment

5/25/99

Item	Initial Measurements		Calc. Measurements	Final Measurements
A	48	*	45	46
B	27	*	18-24 in.	23
C	43		42	43
D	20	*	15	17
E	8	*	5	8
F	15		15	15
G	26	*	23	24
H	30	*	16	30
I	28	*	24	26

* initial measurement was over or under the calculated value by more than 5%

Name: Cheryl Wilhelmsen

Height: 65

Figure 3. Move card diagram.

3.1.5. Trained ergonomists

No ergonomic program can manage without trained individuals. Though a PhD ergonomist is not always needed, someone who has the level of knowledge needed to become a certified ergonomist is needed to ensure the program goes in the right direction. Currently, we have one certified individual and two more individuals are becoming certified in the near future (there are four more certified ergonomists/human factors professionals, but they do not work INEEL ergonomic issues).

4. IMPLEMENTING THE ERGONOMIC BUDDY SYSTEM

The steps for implementing the EBS were:
- Work out the logistics of the program.
- Seek volunteer employees to become ergo-buddies.
- Train the ergo-buddies.
- Develop the database.
- Perform awareness training for all employees.

Table 1. Implementation Steps for the Ergonomic Buddy System

| Element	Description
Workout the Logistics of the Program	The logistics that need to be worked out are: 1) How will and employee notify a buddy that he/she needs an assessment, 2) How will the buddy schedule the assessment, 3) Once performed, how will the data be collected in a central location, 4) Who will maintain the database,
Seek Employee Volunteers	Employees are asked to volunteer to participate in the program. The employees should have expressed interest in the process and are willing to do what it takes to implement it. These employees will be called Ergo-Buddies.
Training	Employees are given training on the basics of ergonomics and how to perform an ergonomic assessment. The training program used at the INEEL comprises two days and includes the priniciples of ergonomics, anthropometry, what are cumulative trauma disorders, workplace design and how to perform a practical ergonomic assessment.
Develop the Database	A database is developed that will contain: 1) The results from assessments, 2) Keep track of who has/hasn't been assessed, 3) Keep track of those who still need solutions, and 4) Keep track of workstation measurements and generate a "move-card." A "move-card" shows a diagram of an employee at a workstation with the measurements for the specific employee. Figure 1 shows the diagram for the move card.
Perform Awareness Training	Awareness training is performed for all employees. This training consists of: 1) What are CTDs, 2) Elements of workstation design, 3) How to report a problem, and 4) How to request an assessment

These steps are discussed in Table 1. The EBS was not implemented all at once in all areas of the INEEL. We began in the in-town facilities and at some of the site facilities. Currently, the program has been implemented in almost all facilities to one degree or another.

5. EFFECTIVENESS OF THE PROGRAM

We feel the EBS is successful. To date, there have been around ~3500 ergonomic assessments performed on site. All employees have received information on ergonomics, if they chose to look at it. Most of the awareness training was performed during 1996 and 1997. Ergonomic assessments are on going, however, a large number were performed during 1997 and 1998. During these assessments a large number of individuals who were experiencing symptoms of a CTD were identified. In fact, ~30% of those assessed were experiencing one or more symptoms. This caused a spike in the accident statistics, which management did not like (Figure 4). This told them the program was not working. However, all it was doing was uncovering employees who had pain and needed help. As with any new program the awareness factor tends to elevate the reporting of problems. In Reason's nomenclature this is called a reporting culture and is an integral part of a VPP (Reason 1990). This, in other words, is a good thing. Our goal is to have employees report their symptoms to medical, the ergo-buddies, or us as soon as they begin to feel them. The earlier one reports an injury, the more ergonomic and medical interventions can be implemented to prevent it from getting worse and to begin the healing process. Our data shows a spike of recordable injuries during the awareness training and initial assessment phase of the EBS. Then it shows a drastic downward trend during the early quarters of 1999. However, we begin to see an increase in first aid cases (Figure 5), which is what we want to see. We feel this is demonstrating that we are developing the reporting culture we want.

6. SUMMARY AND CONCLUSIONS

The EBS appears to have many benefits over the current methods of performing ergonomic assessments. Small battles have bee won in the implementation of an effective ergonomics program, but the war is still being fought. We were lucky to find a champion in management to help fight the battles and get management to understand the importance of providing funding now to invest in healthy employees which in turn elevates productivity. This is a key point to the whole program. Once that battle is won you are on your way to tuning the program to the needs of the employees under any working environment.

Ergonomic Process in Small Industry

C. Stuart-Buttle

Stuart-Buttle Ergonomics, PO Box 18928, Philadelphia, PA 19119, USA

1. INTRODUCTION

An ergonomics process for a small business is different from that of a large corporation. Although the main components of an ergonomics process are similar, the characteristics and limitations related to the size of a business or industry need to be taken into consideration. Several of the issues raised may pertain to a small facility that is part of a large corporation. The main difference between a small company and a small plant of a larger entity is the latter usually has a safety and health process defined or mandated at the corporate level. The small facility may turn to the corporation for guidance and information and perhaps assistance and expertise in ergonomics. This chapter focuses on the issues faced by small businesses.

2. SMALL BUSINESS DEFINITION

In the USA small businesses account for 99.7% of the workplaces and employ 54% of the workforce. About 6.5% of all businesses (20% of the workforce) are in manufacturing, 98.5% of which have £ 500 employees (7.4% of the workforce) (Armstrong 1995). Typically the US Small Business Administration (SBA) defines a small business as having £ 500 employees.

Small businesses make an important contribution to the overall economy. In the USA since 1989 ~100% of new jobs have been created by businesses of less than or equal to five employees (Armstrong 1995). Also, in other industrialized nations, small-to-medium-sized companies are viewed as vitally important to the economic health.

3. SMALL INDUSTRY CHARACTERISTICS

Implementing and evolving an ergonomics process are difficult for any company. Small industries have unique characteristics that carry associated constraints. These constraints impact the decisions that are required to develop the best ergonomics program model to fit the culture and business needs of the company. Small industries often have the following characteristics (Stuart-Buttle 1999):

- Informal.
- Responsible for several positions.
- Responsive.
- Less specific knowledge.
- Greater management involvement.
- Less data-oriented approach.

4. REASONS FOR AN ERGONOMICS PROCESS

Injury and illness costs can be a primary drain on a company's productivity. However, ergonomics offers more to industry than reduced injuries and illnesses. It is a science that applies knowledge about people to the design of the workplace. When the workplace is designed so that people can perform at their best and machines work at their most effective, then productivity is optimized.

4.1. Competitiveness

The increase in the bottom line through production and quality is the greatest return from ergonomics. This may be partly realized by the reduction in injuries and illnesses and related costs or by the increase in work by those no longer in discomfort. However, making the job easier for the worker by improving the work layout or reducing re-handling also improves production.

Quality is part of the productivity equation. Quality is influenced by human performance, and that performance is directly impacted by design of the job and workplace. Insufficient time to perform the task, unsuitable lighting and environment and ineffective training are examples of aspects that can affect quality. Excessive reaching, awkward posture and fatigue increase the time it takes to perform a task, and quality standards may not be met.

4.2. Injury and Illness Costs

Days away from work are expensive for any company, but the burden may be greater on a small industry because there are fewer employees. The hidden or indirect costs, such as training a temporary replacement, that go hand in hand with a workplace injury should also be remembered in the cost–benefit equation.

4.3. Compliance

Compliance to government regulations should not be the sole reason for implementing an ergonomics program. If the workplace is designed well for most people to perform their jobs effectively on a long-term basis, then the workplace will be safe and healthy. If an ergonomics program is implemented with compliance as the only goal then redesigns are likely to fall short of the best solutions to the problems and limit improvements in efficiency. At present in the USA, apart from California, there is no law for implementing an ergonomics program. Management guidelines issued by the Occupational Safety and Health Administration (OSHA) have been adapted for small business in the OSHA Handbook for Small Businesses (OSHA 1992). There are many other sources of guidance for establishing an ergonomics program (NIOSH 1997, Stuart-Buttle 1999).

If a job is improved so that more of the population, including women, can perform it, then costs associated with finding the right people are reduced. Specific accommodation for the disabled also is easier because the workplace is more flexible when designed for a general population. Therefore, there are many benefits to designing well for a wide sector of the population, so compliance in itself need not be a burden to industry.

5. ELEMENTS OF AN ERGONOMICS PROCESS

An ergonomics process sustains the program using methods such as systematic evaluation and revision based on effectiveness. In the long-term, a program without a process is not successful. For success, it is important for a company to find an approach that is the most suitable and effective for the organization's needs and culture. Whatever the model, the ergonomics program goal remains the same: design the workplace so that it is healthy, safe and optimally productive.

5.1. CHOOSING THE APPROACH TO ERGONOMICS

The success of ergonomics in a company depends on how well

the process is structured and carried out. The following factors influence the development of a program and should be taken into consideration.

- Company size.
- Company culture.
- Resources.
- Type of industry.
- Types of ergonomics controls implemented.
- Compatibility with other programs and processes.

The above factors and particularly the characteristics of small industry, determine the appropriate extent of integration of an ergonomics program into existing processes. An ergonomics process is dynamic and regular evaluation and revision are necessary to maintain or improve effectiveness.

5.2. Process Elements

The primary elements of an ergonomics process are:

- Management commitment and employee involvement.
- Medical management.
- Education and training.
- Surveillance.
- Job analyses.
- Controls and improvements.

First, both management commitment and employee involvement are essential for any degree of success with an ergonomics program. If there are many work-related medical cases, quickly establish or enhance medical management. Next, acquire some knowledge about ergonomics and initiate a plan for training. Then having learnt more about what to monitor in the workplace, establish a surveillance system. Conduct job analyses as prioritized by the surveillance system and proactively assess new designs. Finally, implement and measure effectiveness of improvements for a safe, healthy and productive business.

5.2.1. Management commitment and employee involvement

5.2.1.1. Management commitment.

An ergonomics program is easily undermined by lack of management commitment. Management commitment is essential and must be communicated through example. Management should allow for employee involvement, setting clear responsibilities and provide the resources in both time and money for the process.

5.2.1.2. Employee involvement.

Employee involvement should be supported and facilitated by management. Employees are an excellent source of ideas for improvements and are the ones required to work with any implemented changes.

5.2.1.3. Written program.

A written program is often emphasized as essential for a successful program. Although a small business may react to this as "more paper work," there are many advantages to putting down in writing the basics, as it helps to:

- get the program started more efficiently;
- organize thoughts and the best plan of action;
- clearly communicate the process;
- make it easier to introduce the process to a new comer; and

- establish the goals and achievements by which the program can be assessed for success and improvement.

5.2.2. Medical management

A primary responsibility of a company is to respond to work-related medical problems reported by employees. Medical management per se is not in the realm of ergonomics, however, the quality of medical management has a direct bearing on the recorded injuries and illnesses which are often used as a measure in ergonomics. Company personnel have some control over the quality of the services rendered. The following suggestions may help to establish a good working relationship with the medical community.

- Establish close communication.
- Communicate the expertise expected of the medical group.
- Introduce the medical group to the plant's culture and processes.
- Consider the medical community as a training resource.

5.2.3. Education and training

First, some general knowledge in ergonomics is needed by someone in the company so as to plan an ergonomics program. In-depth training is recommended for a specified team, and general awareness training is recommended for managers, supervisors and line workers. The extent of investment in training may depend upon company financial resources and the turnover rate.

5.2.3.1. In-depth training.

In-depth training is recommended for the person or team primarily responsible and involved with ergonomics. The training objectives are to:

- understand the overall program objectives, goals and process;
- understand the injury and illness system for treatment, return to work, and job modifications;
- be able correctly to record and interpret medical records and OSHA logs for surveillance purposes;
- know how to conduct basic problem-solving job analysis for ergonomics issues;
- recognize risk factors for injury and illness in workplace design;
- be able to develop, implement and affirm effectiveness of solutions to basic problems;
- understand basic ergonomics principles to apply to solutions and new designs; and
- be familiar with outside resources and methods for finding resources.

5.2.3.2. Awareness training.

An awareness level of ergonomics training prepares employees to participate in the ergonomics process. The objectives are for the employees to:

- understand generally the ergonomics program;
- appreciate their role and responsibilities in the program;
- recognize the early indicators of physical problems;
- understand the company medical management system;
- understand basic risk factors for injuries and illnesses;
- know basic ergonomics principles; and
- understand their participation in job analyses.

New employees should be trained to maintain the knowledge base in the workforce. It is not unusual to give separate programs for supervisors, management and production workers as there may be differences in educational level and perspectives of each group.

5.2.3.3. Refresher training.
Refresher sessions maintain interest in ergonomics. As with the ergonomics program or process itself, the refresher sessions can be part of other processes in the company, such as continuous improvement or safety and health.

5.2.4. Surveillance
Identifying the areas with problems or the potential for improvement is the first step to improve the workplace. This entails looking at data that have already been collected by the company. Such data include information on injuries and accidents, production and quality measures and personnel records.

5.2.4.1. Data
- Medical information.
- Discomfort surveys.
- Absenteeism and turnover.
- Production and quality data.
- Accident investigation.
- Audits.
- Interview and employee reports.

5.2.4.2. Prioritizing.
Problem areas need to be prioritized to develop an effective action plan. One approach is to develop a spreadsheet with types of indicators or data by departments, areas or jobs. The amount and extent of the indicators can be used to qualitatively rank the problem areas in conference with other team members or employees. Consider factors such as the anticipated scope and difficulty of the project or whether the area or job is about to be changed for production reasons, because these factors also influence the priority.

5.2.5. Job analyses
Job analyses can be conducted from a reactive or proactive stance. A reactive analysis is evaluating a job known to have problems. A proactive analysis is looking at a new design, recent installation or redesign to anticipate problems and ensure that the workstation incorporates ergonomic principles. A proactive approach should be implemented as early as possible in an ergonomics program not only to prevent new problems arising, but also to avoid remaining in a reactive position which is more expensive in the long run, compared with designing well initially.

5.2.5.1. Responsibility for conducting analyses.
A team approach can be used in which the group collects the data, looks at the problem, brainstorms for the root causes and generates potential solutions. It is not uncommon, particularly in a small company, for a process to develop in which one person collects data, analyses it and generates the solutions with informal input from others. Caution should be used when adopting an isolationist approach, as over time, any joint responsibility for ergonomics might lessen and the program might be perceived as one person's responsibility.

Some companies choose not to invest in in-depth education of an employee but rather work with an external expert who gets to know the company process and culture. The approach chosen also depends on the amount and complexity of the issues to be addressed. There may be benefit in having more in-house knowledge if the production process changes frequently. The company needs sufficient understanding of ergonomics to know when assistance is needed, how to find it and where to get further information to address the issues.

5.2.5.2. Problem-solving.
The root causes of poor design are identified through careful analyses. A good problem list helps generate the best possible solutions. The traditionally informal structure of small industry does not preclude good problem-solving, nor does careful, detailed problem-solving always require extensive quantification.

5.2.5.3. Quantification.
Quantification assures that what is perceived as a problem is in fact a problem, and to what extent. Quantification also helps to assess improvements to determine the best alternative, and it provides a measure of effectiveness and cost–benefit. When the situation is more complex, selective quantification assures appropriate design decisions are made and helps prevent the generation of new problems.

5.2.5.4. Analysis.
Discussion of the many analysis methods and tools is outside the scope of this chapter. An overview of the basic steps in an applied analysis is provided as a guide.
- Workstation analysis.
- Clearly define the job function and the tasks, so that they are understood in context with the overall system.
- Collect pertinent job information such as performance rates and quality expectations.
- Interview employees.
- Describe the component actions of each task (possibly videotape them if the task is complex or fast).
- Identify the risk factors and job components that place excessive demand on the worker or that make the job awkward or inefficient.
- Assess the risk factors and job demands quantitatively and qualitatively.
- Determine the root causes of the risk factors, job demands and awkward methods.
- Develop a primary problem list with possible causes.
- Brainstorm for several short and long-term solutions to the problems, especially ones that are inexpensive.
- Assess the cost–benefits of alternative solutions.
- Develop an implementation plan including a trial stage if necessary.
- Reassess the solution after implementation to determine its effectiveness.
- Record the project.
- New design.

Incorporate ergonomics into the process of purchasing new equipment, designing new layouts or redesigning an existing area or workplace in the plant. A checklist may help to consider all the ergonomic aspects, but the interaction of the operators with

the equipment or layout should be especially anticipated and critiqued. Company engineers should have at least basic knowledge of ergonomics and work closely with other personnel to ensure that all safety and quality standards are met.

5.2.6. Controls and improvements

Effective problem-solving usually generates more than one solution, typically long-term and short-term ones of various expense. Engineering solutions are perceived as more permanent and less dependent upon human behavior, but it is common to need an administrative measure to accompany an engineering change.

Follow-through is important. A small company has the advantage of being project focused. Roles must be defined clearly for accountability, particularly if there is a team approach. In a small industry the cost–benefit of an improvement cannot be based on injury and illness alone because usually there are fewer and more scattered incidents throughout the facility. Therefore, gains in productivity and quality become important in the cost–benefit equation.

1. INTRODUCTION

Industrial production may be organized according to a set of principles, or philosophies. Major determinants of the philosophy chosen are the character of the production and the context in which the company operates. New philosophies develop over time. A number of them have gained recognition and spread across the world, but eventually many become fads. The choice of production philosophy has a great impact on the technology, the organization and the personnel policy chosen, and it will have a profound influence on the performance of the company as well as on the working conditions of the employees. Few industrial companies are strictly organized according to a generic philosophy: normally, they constitute a mixture of several philosophies. The purpose of this chapter is to highlight and make a clearer distinction between different production philosophies. The characteristics of four generic production philosophies are summarized and presented in order to offer guidance in the choice and evaluation of production philosophy with regard to the resulting ergonomic consequences.

1.1. Definition of Concepts Used

A production philosophy refers to a generic way of designing technology and the organization in order to achieve specific objectives. A given production philosophy affects a number of components in the manufacturing system: production layout, machine design, work organization, skill requirements and means of managerial control. Not included in the concept as it is used below are the specific elements of human resource and personnel management, such as labor contracts, wage systems, training and career patterns, etc.

Although there is no universally agreed definition of ergonomics, most ergonomists agree that the modern concept of ergonomics includes aspects of humans at work on an individual as well as group and organizational levels. Interactions with technology, the environment and the organization are the focus. The main aims include elimination of accidents and the creation of healthy and comfortable working conditions, from a physical, psychological and social point of view. Recently, emphasis on learning and personal development has been added. In addition, ergonomics aims at improving the performance of the human–machine system, including productivity and quality.

Many attempts have been made to define the term "rewarding work." Motivational theories, socio-technical theory and ergonomics research have proposed a number of criteria for this, some of which are summarized as:

- Meaningful work content.
- Continuous learning at work.
- Decision making possibilities.
- Social interaction and support.
- Work perceived as useful.
- Work leading to a desirable future.
- Obtainable and realistic challenges.
- Recognition.
- Communication and feedback.
- Physical and mental task variety.
- Substantial cycle time.
- Authority and responsibility.
- Freedom to control one's own work.
- A job demanding skills.
- Security of employment.
- A work environment free from the risk of ill-health and accidents.

These criteria may be used as one basis for evaluating the character of a particular production philosophy.

1.2. A Brief Historical View

Both ergonomics and production philosophies are concepts of the 20th century. Before the industrial revolution, physical goods were typically manufactured in two ways:

- In small-scale craft shops, run by independent, highly skilled workers supplying individual customers or middlemen.
- In systems of large-scale production, where large numbers of unskilled workers turned out simple items for military customers or major construction projects. In these systems, high output was achieved through the multiplication of effort rather than the implementation of different manufacturing methods.

The industrial revolution of the late 18th century brought the mechanization of simple operations, and a detailed division of labor. During the following century, elaborated production philosophies emerged on the basis of these advances in the USA. A basic principle in the American System of Manufacture, pioneered by the arms manufacturers, was interchangeability of parts. Another important element was flow production, first introduced in the food industry. Third, Frederic Taylor and his associates fine-tuned systematic time-and-motion studies in the steel industry. A fourth important component was the development of sturdy, easily operated machine tools for high-volume production. Henry Ford brought all these elements together when designing the world's first manufacturing complex for large-scale production of automobiles in 1913. As a result of a long process of trial and error, a new production philosophy, Fordism, emerged. The principal aspects of Fordism were:

- Standardized products composed of standardized parts, eliminating the need for manual fitting.
- Special-purpose machines, operated by unskilled workers, designed according to the principle "one feed, one speed." New safety devices minimized breakdowns in high-volume production.
- Mechanically paced flow systems, feeding assembly workers with materials and minimizing handling time.
- Minute division of labor in the production process, rigid separation between unskilled operatives and skilled tool and die makers, quality inspectors and engineers.
- Fragmented jobs with short cycle times, £ 1 min.

Fordism realized enormous efficiency gains, as well as productive employment for millions of immigrant workers. From an ergonomics point of view, Fordism was a mixed blessing: on

the one hand, there were improvements in physical safety and pay, on the other hand, a proliferation of monotonous and machine-paced jobs resulting in work devoid of any intellectual challenge, with high strains, repetitive tasks, high levels of fatigue and occupational disorders (Hounshell 1984, Ford 1991).

2. SOCIO–TECHNICAL ALTERNATIVE

During the first half of the 20th century, Fordist production principles quickly diffused into every industry producing complex goods in high volumes, from consumer durables to furniture. In the 1960s, the long postwar boom and a tight labor market brought the deficiencies of Fordist jobs from a human point of view to the fore. New socio-technical principles for job design were developed in Britain and rapidly spread in Scandinavia in the 1970s, and later also to other parts of Europe. The socio-technical alternative started from an analysis of psychological job demands in order to arrive at a joint optimization of technical and human requirements. The socio-technical production philosophy consisted of four elements.

- Decoupling of workers from rigid machine pacing through increased use of buffers and new forms of production layout.
- Expansion of "horizontal" work content and variety by lengthening work cycles, job rotation, etc.
- Enriching of "vertical job content" by combining direct and indirect tasks and eliminating indirect and supervisory job roles.
- Delegation of decision-making power by substituting autonomous group work for tightly controlled individual jobs.
