About the Editor

Waldemar Karwowski, Ph.D., P.E. is Professor of Industrial Engineering and Director of the Center for Industrial Ergonomics at the University of Louisville, Louisville, Kentucky, USA. He holds an M.S. (1978) in Production Engineering and Management from the Technical University of Wroclaw, Poland, and a Ph.D. (1982) in Industrial Engineering from Texas Tech University. He is also a Board Certified Professional Ergonomist (BCPE). His research, teaching and consulting activities focus on prevention of work-related musculoskeletal disorders, workplace and equipment design, human and safety aspects of advanced manufacturing, and theoretical aspects of ergonomics science.

Dr Karwowski is currently (2000-2003) President of the *International Ergonomics Association* (IEA), and is past President of the *International Foundation for Industrial Ergonomics and Safety Research*, as well as past Chair of the US TAG to the ISO TC159: Ergonomics/SC3 *Anthropometry and Biomechanics*. He is the author or co-author of over 200 scientific publications in the area of human factors engineering, industrial ergonomics and safety, mathematical modeling in human factors, and fuzzy systems, and has edited 25 books.

Dr Karwowski serves as Editor of the *Human Factors and Ergonomics in Manufacturing* international journal, Co-Editor of the *International Journal of Occupational Safety and Ergonomics*, and Consulting Editor of the *Ergonomics* journal. He is also a board member for *Human Factors, Applied Ergonomics, International Journal of Human-Computer Interaction, Universal Access to the Information Society: An International Interdisciplinary Journal, Occupational Ergonomics, Industrial Engineering Research: An International Journal of IE Theory and Application* (Hong Kong).

Dr Karwowski is also the Editor-in-Chief of the new journal *Theoretical Issues in Ergonomics Science* (TIES), launched in 2000, and designed to stimulate and develop a theoretical basis for the unique science of ergonomics.

Dr Karwowski is Fellow Member of the Human Factors and Ergonomics Society and recipient of the highest recognition in occupational safety and health in Poland, *Pro Labore Securo* (2000). He received the University of Louisville Presidential Award for Outstanding Scholarship, Research and Creative Activity in the Category of Basic and Applied Science (1995), and the W. Jastrzebowski Medal from the Polish Ergonomics Society (1995). He served as Fulbright Scholar, Tampere University of Technology, Finland (1990-1991), and was named an Outstanding Young Engineer of the Year by the Institute of Industrial Engineers (1989).

Foreword

Ergonomics is the discipline concerned with interactions among humans and other elements of a system (the term 'system' is intentionally vague and ranges from simple tools to complex sociotechnical structures). As a science, ergonomics is relatively young; however, the underlying ideal, human-centred technology, has played a pivotal role in the evolution of human society from its very start. The use of stone tools by *homo habilis*, over two million years ago, represents the dawn of ergonomics as an artform. Throughout the history of civilization, technological innovations were motivated by fundamental human aspirations for security, prevalence and self worth, and by problems arising from human-system interactions. In the 20th century, ergonomics emerged as a formal science in its own right, though it continues to be taught as part of other faculties such as engineering or psychology. Although it has been referred to as the science of work, ergonomics, in its broadest sense, is concerned with all forms of human activity. The application of the scientific method to the development of theory, principles and data relevant to design has had enormous impact on the reduction of user error, improved performance, reduction of occupational injuries and worker discomfort, increased usability and safety of computer systems and consumer products.

Today, profound changes are taking place that touch all aspects of our society: changes in the nature of work and play; changes in global commerce and communication; changes in science and technology; and changes in population migration and world demographics. These changes cannot but influence the future course of ergonomics since they relate to how people interact with technology in an increasingly dynamic and complex world. More importantly, they beckon ergonomics to play a more direct and vital role in shaping the society of the future.

An encyclopedia of ergonomics and human factors is crucial to the further development of the science and its applications. It serves to inform practitioners, educators, students and researchers in the field. As well, it is a useful resource for those not directly involved with ergonomics, but who want to understand one or more aspects of human–system interactions. It is a foundation of knowledge that serves all who have an interest in the field.

Preparing an encyclopedia in any discipline is a daunting task; preparing one in ergonomics and human factors is heroic. Part of the reason is that ergonomics is a very broad field, whose scope includes physical, cognitive, and organizational topics. Moreover, although the science of ergonomics is differentiated from other disciplines by the fact that it is concerned exclusively with the design of human–system interactions, it relies heavily on knowledge from related fields such as psychology, physiology, engineering, medicine, sociology, anthropology and kinesiology. That is, in addition to knowledge content unique to ergonomics, researchers and practitioners routinely apply knowledge from the relevant biological, behavioural and engineering sciences. It is clearly not possible for an encyclopedia of ergonomics to cover all of the related disciplines whose theories and data it borrows, adapts, and extends. Yet, it is similarly not practicable to exclude content from related sciences that is central to an understanding of human interactions with technology. The editors have, therefore, had to make difficult decisions about what to include and what to exclude in their effort to make the encyclopedia as comprehensive and informative as possible. They have clearly attained this goal in this unprecedented volume.

Another challenge that faced the editors was the fact the ergonomics is continually evolving. As an applied science, ergonomics evolves with technology and economic diversification. By necessity, an encyclopedia such as this reflects current directions and state-of-knowledge. Brian Shackle has identified the major thrusts of ergonomics applications in the 20th century as: military ergonomics, industrial ergonomics, consumer product ergonomics, human–computer interaction and software ergonomics, and cognitive ergonomics and organizational ergonomics. To this, Martin Helander has suggested adding eco-ergonomics as the main thrust of the first decade of the 21st century. The editors of this encyclopedia, have, therefore, had to strike a balance between covering the theoretical and methodological underpinnings of the field and elaborating topics closely aligned with major applications. Again, the balance achieved provides a rich scientific and technical resource yet one that retains strong relevance to practitioners.

Producing the first edition of an encyclopedia is unquestionably the most challenging for obvious reasons. Future editions will undoubtedly build on this work, update it and add significant new knowledge. However, the first edition represents a landmark, signifying the true coming of age of ergonomics. It is thus a timely and notable contribution to the field.

The editor, authors and the publisher are to be commended for undertaking the arduous task of producing such a fine resource. It will serve the discipline and profession well into the future.

Y. Ian Noy
President (1997–2000)

1. INTRODUCTION

The purpose of this chapter is to transfer the human factor design related criteria developed by US government agencies to non-government personnel. While many readers are familiar with ISO (International Standards Organisation), ANSI (American National Standards Institute) and SAE (Society of Automotive Engineers) standards, they are not familiar with design standards developed primarily by military agencies or agencies with a specific focus, such as the FAA (Federal Aviation Administration) and NASA (National Aeronautics and Aerospace Administration). Readers seeking design criteria, principles and practices for use in the design and development of systems, equipment and facilities will find these standards useful. Please note that since we have focused on design-related criteria we did not include guidelines or regulations developed by agencies such as NIOSH (National Institute of Occupational Health and Safety) or OSHA (Occupational Health and Safety Agency).

How are these criteria developed? Essentially, these standards were developed by committee and represent (1) the best of what was known at the time of their development and (2) the consensus arrived at by the committee. In some cases, an arbitrary decision is required. For example, luminance contrast (C) can be defined as either $(L_{max} - L_{min})/L_{min}$ or $(L_{max} - L_{min})/L_{max}$. The former formula produces whole numbers, while the latter formula produces values between 0 and 1.0. If luminance contrast is to be specified as design criteria then only one definition is acceptable, and DoD representatives elected to use the former definition.

The five major documents described here are:
- MIL-HDBK 46855: Human Engineering Program Processes and Procedures.
- MILSTD 1472: Human Engineering design criteria for military systems, equipment and facilities.
- Department of Defense (DoD) Human Computer Interface Style Guide.
- Federal Aviation Administration (FAA) Human Factors Design Guide (HFDG) for Acquisition of Commercial-off-the-Shelf-Subsystems, Non-developmental Items and Developmental Systems.
- NASA-STD-3000: Man–Systems Integration Standards.

Readers may also wish to consult the excellent British Defence Standard 00-25: Human Factors for Designers of Equipment. Defence Standard 00-25, is comprised of 13 parts and designed to "be viewed as a permissive guideline, rather than a mandatory piece of technological law" (vol. 1, p. 1). The text, written for designers with a variety of technical backgrounds, includes both general background information and human factors data. Most parts include definitions of terms relevant to that specific part, references and/or related documents, and sources for obtaining related documents. The 13 parts of this standard were issued over a period of more than ten years. Interested readers can download BDS STD 00-25 from the WWW site provided in the references.

2. MIL–HDBK 46855: HUMAN ENGINEERING PROGRAM PROCESSES AND PROCEDURES

MIL-HDBK 46855 is a DoD guidance document that describes the analysis, design and development, and test and evaluation considerations expected in a Human Engineering (HE) Program. It describes: (1) the program tasks, (2) the procedures and preferred practices useful in implementing the guidance and (3) selected HE methods. The handbook of approximately 300 pages consists of eight sections.

- 1. Scope: describes both the document in general and its applicability and tailoring (using selected portions in developing the HE program for a system under development).
- 2. Applicable Documents: lists relevant DoD standards, specifications, and handbooks as well as other pertinent government documents.
- 3. Definitions: defines the acronyms used in this HDBK.
- 4. Program Tasks: provides general program task guidance that the system developer can incorporate into the HE Program Plan. Issues addressed include, among others, risk management, non-duplication, analyses options, procedure development, and failure and error analysis.
- 5. Significance of HE for Program Acquisition: describes the role of HE in systems acquisition, including Human System Integration (HSI) and Manpower, Personnel and Training (MPT) implications. The range of HE activities are described, as well as the value of HE (descriptions of benefits and problems resulting from the lack of HE are provided).
- 6. HE Procedures for DoD Organizations: describes the HE responsibilities of the DoD organization acquiring the system. Descriptions of implementations unique to each service are provided. Details on program planning, budgeting and scheduling; preparing the Request for Proposal (RFP); proposal evaluation; and contract monitoring are also provided.
- 7. HE Procedures for Contractors: describes the HE responsibilities of the contractor developing the system. A listing of HE design standards and guidelines is provided. Descriptions of documentation (e.g. HE Test Plan, HE System Analysis Report) required by the acquiring agency are provided.
- 8. HE Methods and Tools: being of ~100 pages, provides details and references to a wide variety of time-tested methods. The methods described include mission, timeline, and workload analysis; diagrams (operational sequence, decision/action); and checklists, mockups, and mannequin usage. HE Test and Evaluation methodologies described include: HEDGE (Human Factors Engineering Design Guide

for Evaluation), interviewing and questionnaire techniques), physiological instrumentation, and physical measurement.

- Appendix A, Application and Tailoring.
- Appendix B, Task Analysis.
- Appendix C, Data Item Descriptors (DID).
- Appendix D, a matrix that cross-references sections of this HDBK with relevant DoD documents.

3. MIL-STD-1472 HUMAN ENGINEERING

MIL-STD-1472, provides design criteria, principles and practices for use in the design and development of military systems, equipment and facilities. It was originally developed in 1968 and has been periodically reviewed and updated since. It is currently undergoing technical revision, and the new version, revision F, should be available some time in 2000.

This standard is supported by two additional documents: MIL-HDBK-1908A, *Definitions of Human Factors Terms* (MIL-HDBK 1908 is currently undergoing revision) and MIL-HDBK-759C, *Human Engineering Design Guidelines*. These two documents provide important supplementary information for practitioners using MIL-STD-1472. MIL-HDBK-1908A provides standard definitions for human factors terms to supersede conflicting definitions in the literature and to eliminate unnecessary overlap. MIL-HDBK-759C provides additional guidelines and data that may be useful when designing military systems, equipment, and facilities. It is organized in sections that correspond with the top three levels of headings in MIL-STD-1472.

The body of MIL-STD-1472 is structured in five sections: (1) Scope, (2) Applicable Documents, (3) Definitions, (4) General Requirements and (5) Detailed Requirements. There is also a detailed index. Most of the substantive content of MIL-STD-1472 occurs in Sections 4 and 5.

- Section 4: provides high-level guidance about a variety of topics including functional allocation, human engineering design, fail safe design, simplicity of design, safety, ruggedness, nuclear/biological/ chemical (NBC) survivability and electromagnetic pulse (EMP) hardening. The 16 subsections of Section 5 in MIL-STD-1472E provide detailed requirements (principles, practices, criteria) concerning the topic areas described below.
- Section 5.1. Control/display integration: provides guidance concerning integration issues such as position and movement relationship, grouping, consistency, and control/display movement ratios.
- Section 5.2. Visual displays: much of the information about displays in MIL-STD-1472E concerns displays that are presented using technologies such as trans-illuminated displays, legend lights, and signal lights. Only limited information is provided about displays that are presented using computer technology. Human factors issues considered in Section 5.2 include display illumination; information content, precision, and format; location and arrangement; coding; scale types and designs; counters; and pointers.
- Section 5.3. Audio displays; includes information about topics including audio warning signals, verbal warning signals, speech transmission equipment, speech reception equipment, and speech intelligibility.
- Section 5.4. Controls: includes information about rotary and linear controls, about discrete and continuous controls, and

about keyboards, joysticks, trackballs, touch screens and mice. It also addresses human factors issues including direction of movement; arrangement and grouping; coding; and accidental actuation.

- Section 5.5. Labeling: includes both general information about labeling and specific information about label orientation and location, label content, qualities of the information presented (e.g. brevity, stated using familiar terms etc.), design of label characters and labeling of equipment.
- Section 5.6. Physical accommodation: generally based on criteria that are generally stated in terms of percentiles.
- Section 5.7. Workspace design: provides information about common working postures, about workspace design for seated and standing operators, and about specific workspace feature such as stairs, stair ladders, fixed ladders, ramps, doors, hatches and surface colors.
- Section 5.8. Environment: provides information about heating, ventilation, air conditioning, illumination, acoustical noise and vibration.
- Section 5.9. Design for maintainer: includes information about mounting, adjustment controls, accessibility, lubrication, cases, covers, access openings and covers, fasteners, conductors, connectors, test points, test equipment, failure indications, fuse requirements, printed circuit boards and designing for efficient handling.
- Section 5.10. Design of equipment for remote handling: includes information about the characteristics of the equipment to be handled remotely, feedback, manipulators, viewing equipment and illumination.
- Section 5.11. Small systems and equipment: provides information about portability and load carrying; tracking; and optical equipment and related equipment (e.g. sights, reticles, binoculars).
- Section 5.12. Operational and maintenance ground/ shipboard vehicles: includes basic information about vehicle design including information about seating; controls; operating instructions; visibility; heating and ventilation; trailers, vans, and intervehicular connections; cranes, materials handling and construction; and automotive subsystems.
- Section 5.13. Hazards and safety: includes information about safety labels and placards; pipe, hose, and tube line identification; general workspace hazards (e.g. emergency exits, illumination, thermal contact hazards); general equipment-related hazards; platforms, electrical, mechanical, fluid, toxic, and radiation hazards; trainers; and stealth and covert operations.
- Section 5.14. Aerospace vehicle compartments: contains limited information about the design of the crew station and passenger compartments, personnel entrance and exit, and emergency evacuation.
- Section 5.15. User–computer interface: include information about data entry, data display, interactive control, feedback, prompts, defaults, error management/data protection, data and message transmission, and system response time. It was not updated during the technical review of MIL-STD-1472E. For more current information, readers should consult the Department of Defense Human Computer Interface Style

Guide, Volume 8 of the Department of Defense Technical Architecture Framework for Information Management (TAFIM see below).

- Section 5.16. Visual display terminals (VDT): directs the user to ANSI/HFS 100 (Human Factors Society) for information about the use of VDT in office environments. However, VDT use in other environments is governed by requirements in this MIL-STD.

4. DEPARTMENT OF DEFENSE (DOD) HUMAN COMPUTER INTERFACE STYLE GUIDE

The DoD Human Computer Interface (HCI) Style Guide is Volume 8 of the DoD Technical Architecture Framework for Information Management (TAFIM). This document, of > 300 pages, is an excellent source for HCI guidelines, which can be traced back to references. Volume 8 consists of 14 sections that are described below:

- Section 1. Introduction: the goal of this document is to provide HCI standardization, i.e. a common framework for HCI design and implementation within the DoD. It is intended for use by individuals who determine system requirements, program managers, system managers, software developers and application HCI designers. The secondary audience includes users, software maintainers, and test and evaluation personnel. The document is applicable in both the operational and the business environments.
- Section 2. Interface Style: written for software developers, this section describes strategies for selecting a user interface style and for re-designing interfaces to improve usability. It also addresses application portability across platforms.
- Section 3. Hardware: focuses on input/output (I/O) devices, displays technologies other than CRT (e.g. liquid crystal, large screen, stereoscopic, etc.), and alternate I/O devices (Braille printers, large keycaps on keyboards, etc.) for individuals with disabilities.
- Section 4. Screen Design: provides guidance concerning screen design, log-on/off procedures and the use of color.
- Section 5. Windows: provides guidance on basic window design including appearance, message areas, scroll bars, labeling and navigation.
- Section 6. Menu Design: provides information about advantages and disadvantages of menus, pull-down and pop-up menus, hierarchical menus, menu labeling and dialog menus.
- Section 7. Direct Manipulation: provides information about screen arrangement by users, and about metaphors and icons (types, use, design, evaluation).
- Section 8. Common Features: provides guidance concerning interface features, functions, and formats that should be used consistently in all DoD applications. It also provides information about on-line Help, user computer dialogs (e.g. interrupts, error management, alarms), and the use of function keys.
- Section 9. Text: addresses the use of text within windows (labeling and updating fields, and the text cursor). It also provides guidelines for form completion (form layout, error management, etc.).
- Section 10. Graphics: provides guidelines for presenting data in graphical formats including tactical graphics (overlays,

symbology, and terrain representation), pictographic representations (digitized maps, pictures, etc.), and presentation graphics (graphs, pictures, and diagrams). Guidelines pertaining to graphical characteristics of the user interface (e.g. screen design, windows, icons, buttons, etc.) are also provided.

- Section 11. Decision Aids: describes when to use decision aids and expert systems, and offers guidance concerning requirements definition for decision aids, features of decision aids, decision aid interfaces and displays, and user training.
- Section 12. Query: deals with accessing data from Database Management Systems. This Section describes the types of database queries and database storage methods. It focuses on user-oriented database design and provides specific guidance on query screen designs, user requirements, user-friendliness, search options, and differing design requirements for novice and expert users.
- Section 13. Embedded Training: deals with *on-line training* that focuses on the learning process, as opposed to on-line help which provides assistance with specific functions, commands, etc. It provides guidance on embedded training including components of embedded training, instructional structure, and presentation. Guidance is also provided on screen design, navigation within embedded training, error feedback, and the ability to modify embedded training.
- Section 14. Emerging Technology: is divided into two sections: (1) personalization of the user interface to meet the skill levels and characteristics of different users (this includes adaptive modeling and workgroup situations) and (2) multimedia (including authoring systems and navigating within multimedia).
- Appendices: an 18-page glossary and 31 pages of references are provided.

5. FEDERAL AVIATION ADMINISTRATION HUMAN FACTORS DESIGN GUIDE FOR ACQUISITION OF COMMERCIAL–OFF–THE–SHELF–SUBSYSTEMS, NON–DEVELOPMENTAL ITEMS AND DEVELOPMENTAL SYSTEMS

The FAA Human Factors Design Guide (HFDG) provides referenced information to assist in the selection, analysis, design, development, and evaluation of new and modified FAA systems, facilities and equipment. This 1996, 2-inch loose-leaf binder document (also available on CD-ROM) combines guidance from other sources into one "human factored, user friendly" document. The document contains 14 sections, four appendices and an index that are described below:

- Section 1. Introduction: describes the purpose, scope and format of the document.
- Section 2. Complementary Documents: describes the sources from which data were integrated into this document. The sources cited include 32 Government Specifications, Handbooks and Orders, 10 federal regulations (including OSHA), and 20 non-government documents (ANSI/HFS, ASME (American Society of Mechanical Engineers), etc.).
- Section 3. Definitions: provides ~275 definitions of terms used in the text.
- Section 4. General Design Requirements: provides general

principles for designing or selecting systems and equipment, and discusses human performance and human–system interactions at the top level.

- Section 5. Maintenance Automation: primarily tutorial in nature. It provides general principles, as well as guidance, on human-centered automation; process control lessons; command, control and communications; systems engineering; monitoring; interfaces; remote maintenance; and maintenance management information.
- Section 6. Designing Equipment For Maintenance: provides criteria and guidelines related to designing equipment for handling; packaging, arrangement and mounting of equipment; access openings; covers and shields; cases; fasteners; connectors; lines and cables; packaging, layout, and mounting of internal components; adjustment controls; failure detection and isolation; fuses and circuit breakers; test points and service points; test equipment; and tools.
- Section 7. Human–Equipment Interfaces: addresses display–control integration. It also provides specific guidance concerning the following topics:
  - Visual displays (principles, trans-illuminated displays, scale indicators, CRT, large screen displays, light emitting diodes, flatpanel displays, liquid crystal displays, plasma, electroluminescent displays, stereoscopic displays, and touch panels);
  - Audio Displays (warnings and signals, controls, and voice communication);
  - Controls (selection of, movement, arrangement and grouping, coding, compatibility with hardware, accidental activation, foot operated, hand operated, keys, thumbwheels, knobs, cranks, pushbuttons. keyboards, levers, joysticks, ball controls, stylus devices, etc.);
  - Labeling and Marking (general guidance, location and orientation, typographic matters, designing label characteristics, wording, and information); and
  - Accommodating People with Disabilities (controls and displays for people with disabilities, telecommunications, and safety for people with disabilities).
- Section 8. Human–Computer Interfaces: provides guidance concerning user computer interaction, basic screen design and operation, windowing, data entry, data display, user guidance, data communication, input devices, and accommodating people with disabilities.
- Section 9. Workplace Design: describes workplace layout, designing of passageways, common working positions, standard console design, visual display terminals (VDT), and accommodating people with disabilities.
- Section 10. User Documentation: provides guidance on writing user documentation, layout and format, components of documents (cover pages, figures, tables, etc.), specific user document contents (proceduralized instructions, interactive electronic technical manuals), and accommodating people with disabilities.
- Section 11. System Security: describes general design practice, physical security and access control, identification and authentication, auditing, information and data protection, documentation of security safeguards, and security training.
- Section 12. Personnel Security: provides guidance on,

workspace safety, safety labels and placards. It also sets limits/specifies protection for the following types of hazards: liquid and gas, toxic, radiation, special chemicals, temperature, fire, noise, explosion and implosion, radiant energy and lasers.

- Section 13. Environment: provides guidelines on ventilation, temperature and humidity, illumination, and noise.
- Section 14. Anthropometry and Biomechanics: provides information about the application of anthropometric and biomechanical data and about anthropometric variability as well as anthropometric and biomechanical data on reach, human strength, and handling capacity. It concludes with a section on designing for physical comfort.
- Appendix A. References: 13 pages of references are provided.
- Appendix B. Sources: sources of the data contained in each section are specified.
- Appendix C. Standard Actions — Pushbuttons: provides definitions of functions that are performed with pushbuttons in windows (e.g. back, close, clear, cut, compile, etc.).
- Appendix D. Standard Verbs: provides definitions of verbs for use in task analysis and in writing procedural instruction (e.g. accomplish, align, find, clamp, etc.).
- Index: the 81-page index allows the reader to locate information that may be located in several sections.

6. NASA–STD–3000: MAN–SYSTEMS INTEGRATION STANDARDS

The NASA *Man–Systems Integration Standards* (NASA-STD-3000) is a multi-volume set of documents that specifies generic requirements for space facilities and equipment that interface directly with crewmembers is applicable to all manned space programs. Of primary interest are Volume 1, *Man Systems Integration Standards* (NASA-STD-3000, Revision B) and Volume 2, *Man–System Integration Standards: Appendices.*

Volume 1 is divided into 14 sections. In general, each section contains three, and sometimes four, kinds of information: (1) an overview of the section's content, (2) design considerations (background information that can help a user understand the rational behind specific requirements), (3) design requirements (contractually binding standards) and (4) design examples (sometimes included to illustrate important information). Although written for application in the space environment, with the exception of microgravity concerns, much of the information contained in the NASA-STD-3000 can be applied to comparable human interface/engineering problems in other environments.

- Section 1. Introduction: includes a statement of purpose; an overview of the entire set of Man–System Integration Standards; a statement of scope, precedence, and limitations; and general instructions on how to use the documents.
- Section 2. General Requirements: focuses on basic design information related to simplicity and standardization.
- Section 3. Anthropometry and Biomechanics: presents quantitative information about human body size, joint motion, reach, neutral body posture, body surface area, body volume, and body mass properties.
- Section 4. Human Performance Capabilities: documents the significant ways that the performance capabilities of humans may change when they go into space. It includes information about vision; the auditory system; olfaction and taste;

kinesthesia; reaction time; motor skills/coordination; strength; and physical workload.

- Section 5. Natural and Induced Environments: indicates the kinds of conditions to which a crewmember will be exposed during space flight including information about the effects of the composition of the atmosphere, microgravity, and acceleration, and specification of acceptable noise, vibrations, radiation, and thermal levels.
- Section 6. Crew Safety: deals with general safety concerns such as mechanical hazards; electrical hazards, fire protection and control, and decompression as they relate directly to crewmembers.
- Section 7. Health Management: discusses measures that must be taken to maintain crewmember health including both preventive care and medical care.
- Section 8. Architecture: provides information about the placement, arrangement and grouping of compartments and crew stations in space modules, including design data for concerning traffic flow, translation paths, location coding, orientation of workstations especially in microgravity, physical body envelopes for essential crew functions, hatches, doors, windows, lighting, and mobility aids and restraints.
- Section 9. Workstations: covers basic workstation design, including layout, controls, displays, labeling, coding and user/computer interaction design.
- Section 10. Activity Centers: discusses design and layout requirements for off-duty crew stations in the space module including facilities for personal hygiene, body waste management, trash management, crew quarters, recreation and meeting facilities, exercise and medical facilities, laundry facilities, and storage.
- Section 11. Hardware and Equipment: offers general equipment design guidance for tools; drawers and racks; closures and covers; mounting hardware; handles and grasp areas for portable items; restraints; mobility aids; fasteners; connectors; windows; packaging; crew personal equipment including clothing; and cable management.
- Section 12. Design for Maintainability: provides general guidance concerning maintainability and specific requirements concerning design; physical access; visual access; removal, replacement, and modularity; fault detection and isolation; test points; and requirements for a maintenance data management system.
- Section 13. Facility Management: addresses issues associated with housekeeping, inventory control, and information management.
- Section 14. Extravehicular Activity (EVA): establishes guidelines for extravehicular activity.

Volume 2, *Man–Systems Integration Standards*: *Appendices*, contains the appendices which pertain to the Man–System Integration Standards. These appendices include a bibliography, list of sources used to develop specific paragraphs, glossary, abbreviations and acronyms, units of measure and conversion factors and index/keywords listing. Volume 3, *Man–Systems Integration Standards: Design Handbook*, provides a condensed version of quantitative data from Volume 1. However, this volume currently reflects of contents of Revision A, rather than Revision B, of Volume 1.

7. OBTAINING THESE DOCUMENTS

The Internet has profoundly changed our ways of acquiring technical information — so much so that most of the documents described in this section can be viewed on-line and/or downloaded directly from the web.

The two US Department of Defense documents described in this section, MIL-STD-1472, *Human Engineering*, and MIL-HDBK-46855, *Human Engineering Program Processes and Procedures*, can be acquired from the Department of Defense Single Stock Point (DODSSP) using the following information: DODSSP Customer Service, Defense Printing Service Detachment Office, Building 4D, 700 Robbins Avenue, Philadelphia, PA 19111-5094, USA; Tel.: +1 (215) 697 2179; URL: http://www.dodssp.daps.mil/

The DODSSP URL provided above allows access to the Acquisition Streamlining and Standardization Information System (ASSIST) which provides electronic access to some military standards and handbooks.

The remaining documents described here can be accessed directly on the Web (either viewed on-line and/or downloaded) using the information the Reference section. In addition, the "NSSN: A National Resource for Global Standards" web site (URL: http://www.nssn.org/) allows one to search for standards documents produced by > 600 organizations. Their search engine is an excellent source for locating most international civilian and military standards.

ACKNOWLEDGEMENT

Australia: Ergonomics Society of Australia

M. I. Bullock

PO Box 371, Indooroopilly 4068, Brisbane, Australia

1. INTRODUCTION

The Ergonomics Society of Australia and New Zealand (ESANZ) was established in 1964 and separate Ergonomics Societies for New Zealand and Australia (New Zealand Ergonomics Society and the Ergonomics Society of Australia, ESA) were formed in 1986.

The ESA is an active and thriving society with representation from many disciplines. It has branches in each State and Territory, which report to the National Committee. The Society's business is directed by its Strategic Plan, the responsibilities for which are shared by branches. An annual national conference, a bimonthly newsletter and State symposia and workshops provide a means of communication for members. A major initiative of the ESA in 1996 was the organization of a conference entirely on the Internet: the Cyberg Conference, to offer conference opportunities for those unable to attend international conferences through travel. The Cyberg Conference will be held triennially. Several Special Interest Groups (such as in Computer–Human Interaction, Ergonomics Education and Product Ergonomics, Cognitive Ergonomics, Occupational Health and Safety, together with a group for the assistance of developing countries) offer a focus for specialist interests.

The Society has evolved since its formation, reflecting changing ergonomic interests and evolving responsibilities for ergonomists. The early history of ergonomics in Australia centers around individual and collaborative research projects concerned with the enhancement of operator comfort, safety and performance and a recognition of the importance of multidisciplinary activity. Only later, as knowledge of ergonomics grew and the value of its application was acknowledged, did opportunities become available for ergonomics consultants to analyze and solve work-related problems.

2. EARLY RESEARCH FOCUS ON ERGONOMICS

The importance of considering worker capacities and limitations in the design of work and working environments which would ensure effective integration of man and machine was recognized in Australia quite early in the 20th century, and a wide range of ergonomics-related research studies was undertaken.

In the 1930s the aviation industry was the focus of much of the early ergonomics-related research. Factors relating to visual standards, changes in atmospheric pressure with altitude, the problems of blackout in aircrew and the problems of noise in aircraft were areas for particular interest. Later, the Director of Aviation Medicine, Dr John Lane, was the catalyst for many developments, and through his efforts Australia led the world in many features of air safety. The design of air traffic control systems, navigational aids to assist aircraft landing, and visual displays to eliminate irrelevant information and assist the operator to organize incoming data all attracted attention.

Working in association with Flying Personnel Research Units were government instrumentalities such as the National Standards Laboratories, the CSIRO, the Acoustic Laboratory, the National Health and Medical Research Council and the Fatigue and Tropical Unit of the University of Queensland. This collaboration demonstrates an early concern about human performance by a range of scientific disciplines. A Human Engineering Research Group was established within the Aeronautical Research Laboratories of the Australian Defence Scientific Service in the Department of Supply, in about 1957. This represented the first formally constituted research group in ergonomics as such in Australia. Three of the principal researchers associated with this group, Dr Colin Cameron, Professor Ron Cumming and Lane, were to become instrumental in the later formation of the Ergonomics Society.

The effects of climate provided a special research interest. The extreme temperatures of the tropical and arid regions in Australia led to major studies being carried out within the Tropical and Fatigue Laboratory within the Department of Physiology at The University of Queensland into the physical and psychological effects of tropical service, and the design of clothing for flying in the tropics and at low temperatures. Other studies in the School of Public Health and Tropical Medicine at the University of Sydney investigated the effects of climatic extremes on comfort and performance of people of all ages, whether healthy or sick. Early work of psychologists, principally by Dr Provins in South Australia, was concerned with studying the relationship between environmental conditions, body temperature and the performance of skilled tasks. The results of these studies had application to work at Australia's station at Mawson, in Antarctica and in the mining industry in northern Australia. Engineers became actively involved in designing safety features in the design of load haul dump vehicles (LHD) and underground mining vehicles.

Collaborative research studies by the Departments of Mechanical Engineering and Physiotherapy at the University of Queensland investigated the skills demanded of LHD drivers in coping with vibration. Extensive studies were carried out by physiotherapist Professor Margaret Bullock to determine the optimal worker–pedal relationship to minimize spinal movements, in an attempt to control the prevalent back injuries. The physical stresses associated with manual sugarcane harvesting led engineers to develop an automated system of cane harvesting and bulk storage.

Large-scale surveys of school children allowed collection of data relevant to furniture design for schools, while in the 1960s the influence of seating design, posture and work place layout on the production of musculoskeletal injuries during process work was studied by Dr Peres within a human engineering group of the Division of Occupational Health in New South Wales. In 1963, the name of this group was changed to Ergonomics Group. Thus, an interest in the prevention of musculoskeletal injuries in industry was an important component of ergonomics in Australia from its earliest days.

Demonstrating an early interest in rehabilitation ergonomics, engineers and medical practitioners collaborated in the 1960s to examine upper limb stresses in process work and the design of prosthesis that would enable disabled persons to become productive workers. Dr Patkin also carried out considerable

research during the 1970s and 1980s, in the ergonomic design of surgical instruments, and by Professor David Ferguson in relation to the causation of repetition injuries.

The Australian Road Research Board was influential in supporting the collection of data relevant to Australian design rules for motor vehicle safety, and the driver's work-space. Ergonomics also had an influence on traffic engineering.

The development of ergonomics practice in Australia has been closely associated with interests in occupational health and safety. The excessive amount of lost time from work because of musculoskeletal injury and the subsequent costs forced employers to introduce measures of control. Positive changes in occupational health and safety practices and also in management style were introduced into many work places in Australia during the 1980s, due in part to the major contributions of Professor Ferguson.

The increasing use of computers as part of the new technology and the importance of developing effective user interfaces led to the formation of a Computer–Human Interaction Special Interest Group of the ESA, and this has proved to be of considerable value.

3. EDUCATION IN ERGONOMICS IN AUSTRALIA

Initially in Australia education in ergonomics was offered within relevant professional programs, including Engineering, Psychology, Physiology, Architectural Science, Physiotherapy, Occupational Health and Applied Arts and Industrial Engineering. Today, postgraduate qualifications in ergonomics (at Postgraduate Diploma or Masters Degree level) are offered within some tertiary Institutions. No undergraduate program totally devoted to the preparation of an ergonomist is offered within Australia.

4. PROFESSIONAL CERTIFICATION

The high incidence of work-related musculoskeletal injuries in the 1980s had implications for control of the quality of ergonomics practice in Australia and acted as a catalyst to establish a standard of practice for the ergonomist and to create a register of professional or certified ergonomists.

The criteria that could be used for a program of certification of professionally qualified ergonomists in Australia aroused much debate within the Society and in 1985 a proposal to proceed with developing a professional certification scheme was adopted by the Society. In 1990, 21 Society members were awarded professional certification status at the first ceremony of its kind in Australia. The Professional Affairs Board is active in updating its criteria for membership.

5. COMPETENCIES IN ERGONOMICS

In 1990 the Australian Government moved to introduce competency-based assessment in all occupations and professions. It was realized that definition of ergonomics competencies was vital for the comprehensive review of the certification procedure, as a basis for recertification, and as a resource in planning and accrediting education programs. The ESA has now defined and published its outline of core competencies of an ergonomist.

6. CURRENT ISSUES

An issue uppermost in the mind of the ESA today is quality of practice. The broadened scope of ergonomics, the core competencies required by any person working within the field and the importance of quality practice have led to concerns to define the professional ergonomist more specifically. The issues of professional certification of ergonomists, the specification of optimal educational requirements for an ergonomist and accreditation procedures have generated considerable interest in the ESA.

7. SPECIAL CONTRIBUTIONS

It is important to recognize the major contributions made by some eminent ergonomists in the formation and direction of the ESA. In particular, these are Cummings, Lane, Cameron, Professor David Ferguson and Dr Alan Howie. Each had a profound influence not only on the Society itself, but also on the achievements of ergonomics in Australian society. Through their efforts and that of many others, challenges have been met and human performance has been enhanced.

8. PROFESSOR RON CUMMING

The late Professor Cumming (1920–86) was one of the first graduates in aeronautical engineering in Australia and, as the leader of Human Engineering Group, carried out important research in operational aspects of aviation at the Aeronautical Research Laboratories. He later became the founding Chairman of the Australian Road Research Board and was involved in committees drafting safety design rules for motor vehicles. In a major shift of career, he became a Professor of Psychology at Monash University, successfully combining his two disciplines in major ergonomics research.

Cumming became the first President of the Ergonomics Society of Australia in 1964, he was the first Australian Fellow of the (American) Human Factors Society and was elected a Fellow of the Australian Academy of Technological Sciences and Engineering (FTSE).

9. DR JOHN LANE

The late Dr Lane (1918–99) is recognized as the father of aviation medicine in Australia and as a pioneer in road safety. In the 1950s he was involved in the development of the Aeronautical Research Laboratories and the 'T-vasis' visual safe aircraft landing system which is still in use today. The holder of a Master of Public Health Degree from Harvard University, he undertook extensive epidemiological research over 40 years. In 1960, trained as a space surgeon by NASA, he became Australian aeromedical monitor in the manned space program.

Lane was a founding member of the Aviation Medical Society of Australia and New Zealand, and of the Ergonomics Society of Australia, being its second President. As a foundation member of the Human Factors Committee of the Australian Road Research Board, he was active in promoting road safety research and had considerable influence on the formulation of vehicle safety standards. He was a member of the Traffic Inquiry Committee of the National Health and Medical Research Council.

Lane was an inspiration to many aspiring ergonomists in Australia and contributed to the development of the discipline not only through his own broad interests and activities, but also by his ability to lead and encourage others to undertake research and work in the ergonomics field.

Biosketch: Corwin Bennett

S. Konz

Department of Industrial and Manufacturing Systems Engineering, Kansas State University, Manhattan, KS 66506 USA

Corwin Bennett received a BS in Industrial Psychology from Iowa State in 1950 and an MS and PhD in Experimental Psychology from the University of Nebraska in 1951 and 1954. He worked first for IBM as a research psychologist from 1954 to 1966 (manager of human factors for IBM's space guidance division). He then shifted to academia, first as Associate Professor for Rensselaer Polytechnic in Troy, New York, from 1966 to 1970, then as Professor, Industrial Engineering at Kansas State University in Manhattan, Kansas, from 1970 until his death.

Corwin was a member of the Illuminating Engineering Society, the Human Factors Society, the Ergonomics Society, the American Psychological Association and the Society of Engineering Psychologists. He was a fellow of both the Illuminating Engineering Society and the Human Factors Society.

As a small example of his national professional activity, he was a member of the US National Committee TC 3.4 Discomfort Glare for 14 years, a member for 8 years of the Industrial Lighting Committee of the Illuminating Engineering Society and a member for 9 years of the Education Committee. He also was very active in state level activities of his professional societies as well as the many campus duties of a professor.

As can be seen, Corwin was interested in illumination and lighting. Specific projects ranged from the office (VDT workstation lighting; discomfort glare in offices; esthetics of interior spaces) to the factory (industrial inspection) and highway (illumination for railroad grade crossings, discomfort glare for roadway lighting).

Corwin had over 70 professional publications; his work on the esthetics of interior design is summarized in his *Spaces for People: Human Factors of Design* (Prentice-Hall, 1977).

Biosketch: EtienneGrandjean

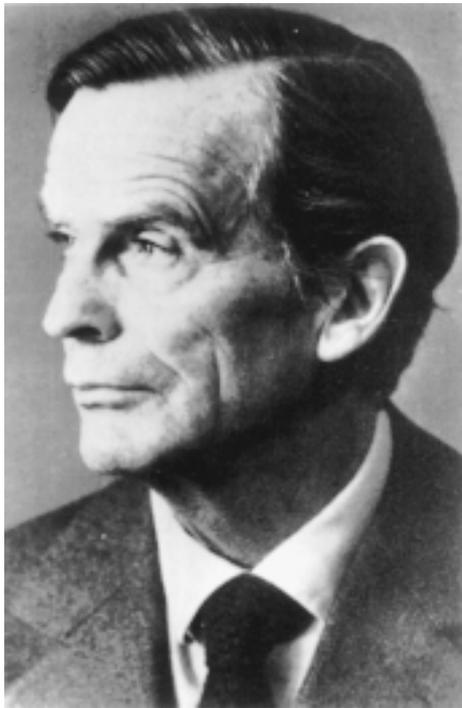
M. Graf, J. Nemecek and H. Krueger
Swiss Society for Ergonomics


Figure 1. Etienne Grandjean.

The name Etienne Grandjean is known by students of ergonomics throughout the world as the author of *Fitting the Task to the Man*. He was a leading pioneer of the science of ergonomics, always emphasizing and ensuring its practical application. In Switzerland, his home country, his name was synonymous with ergonomics for several decades.

Grandjean was born in 1914 in Bern. After completing a medical degree he spent several years at the University Hospital in Lausanne gaining further experience in internal medicine, pathology and physiology. After completing a PhD in human physiology he took up the post of Laboratory Director for the firm Wander, Inc. In 1950, at 36 years of age, he was offered the position of Professor of Industrial Hygiene and Applied Physiology at the Swiss Federal Institute of Technology in Zurich. Before commencing in the new post he spent 6 months at Harvard University in the USA under a Rockerfeller Award.

The curriculum of his predecessor did not include ergonomics, so Grandjean chose to redefine his subject area, set up the new discipline and adjust the curriculum, firstly to suit the needs of his engineering students. He was exceptionally skilled at making the complex interactions between workplace conditions and the human organism comprehensible to the technically oriented student. Analogies and multiple examples were his favored tools; however, he was always careful not to oversimplify the underlying medical processes.

For 33 years Grandjean imparted the principles of humanization of the workplace to young mechanical and electrical engineers, architects, civil engineers and later to information technology students. But the total number of his students was much higher, as he was often invited to give special lectures and courses to a variety professional groups and associations. In this way he spread ergonomic concepts to personal managers, senior managers of industrial concerns, banks and insurance companies, public utilities, trade unions, and many other groups.

Although the interaction between the health and well-being of the working person and his or her work performance are clearly related, Grandjean never allowed performance improvements to be the primary focus of the ergonomist. He always kept preventive healthcare in the foreground of all his work.

His initial scientific work concentrated on physiological research into the effects of physical loading at work. Early studies were with forestry workers, agricultural workers, telephone exchange employees and orchestra players. The production process in the workplaces of Europe and the USA in the 1950s was characterized by heavy manual work with high energy consumption. The demands on the circulatory system often lay at the borders of human endurance. By way of example, lumberjacks at that time were required to cut through forests with handsaws, work that often stressed the cardiovascular system to its limits. With the introduction of the chainsaw their physical workload was substantially decreased.

In the later post-war decades the production process underwent a rapid change that resulted in an overall reduction in the number of worker exposed to heavy muscular work. Workers now used machines. They controlled and supervised complicated equipment, eventually fully preprogrammed production units. As a result of these changes the demands on the worker changed. Jobs increasingly required skilled manual activity, perception and interpretation of information, rapid and correct decision-making and increased vigilance. Grandjean noted that the new working methods and tools carried new types of stresses and strains for the worker, such as noise, vibration, exhaust fumes, increased accident risk, unnatural body postures and increased performance demands. Grandjean changed his area of scientific interest to reflect these new conditions.

He was sensitive to the effects on the workers of the new production and management technology and almost always responded rapidly to developments with his scientific investigations, often to preempt them. A well-cited example is his sensitivity to the advent of the VDU workplace. Although close to retirement, he projected, ahead of the physicists and engineers, the effects of developments in computer hardware on operators. Keeping the human in mind, he appealed to several manufacturers to change their still-conceptual plans better to suit the users. His main topics of interest were the prevention of musculoskeletal disorders and visual complaints.

The subject of seating interested him for many years. Even today many students and workers sit on chairs whose design is based on his specifications. He was one of the first ergonomists to recognize that no seat design could ensure health, and to emphasize the importance of adequate physical movement at the workplace.

The results of his investigations on the effects of modern technology on the human were included in his first book, published in German in 1963 as *Physiologische Arbeitsgestaltung, Leitfaden der Ergonomie* (translated roughly as Physiological Workplace Design, Guidelines from Ergonomics). The book was

written not only with students in mind, but also other practitioners such as engineers, planners, managers and administrators. The text was translated into English and published in 1980 as *Fitting the Task to the Man – An Ergonomic Approach*. It rapidly achieved worldwide popularity and has been translated into over ten languages. It has become a standard introductory text for ergonomics students in many countries. Technological advances were reflected in later editions. The fourth, completely revised edition was published in 1991.

The second area of Grandjean's research and teaching covered the wider living space of humans. Work at home, behavior in the home, the space available for people to move, the dimensions and design of rooms and living spaces, as well as the special situation and needs of handicapped and invalid persons all contained important issues and problems of interest to him. The home is also exposed to disturbances and annoyances that originate outside its borders, environmental factors which impinge on the home, particularly noise from roads, railways and aviation, and environmental chemical pollutants. As in ergonomics, Grandjean identified the important problems for the home environment, systematically investigated them and defined guidelines. Here too explained the problems clearly to architects and civic planners and he influenced their future decisions to make people's home-life more comfortable. The multiple themes of his living area research were laid down in his second book, *Wohnphysiologie — Grundlagen gesunden Wohnens* (The Physiology of Living — Principles of Healthy Homes). It was aimed at sensitizing architects and interior designers to ergonomic considerations.

To reflect the broader scientific interest the Institute was renamed in 1973 as the Institute for Hygiene and Applied Physiology. During Grandjean's directorship of the Institute, over 900 articles were published, covering not only ergonomics themes, but also such diverse subjects as environmental hygiene, industrial hygiene, experimental toxicology, psychophysiology, psychotoxicology, misuse of drugs and stimulants at the workplace, etc. The content of his work ranged from purely experimental natural science research, through epidemiological studies, the implementation of scientific findings, legislation on workplace hygiene, health politics and product design. His advice was sought by numerous national and international journals.

Apart from his well-known scientific publications, Grandjean also published widely in more popular media, being well aware that ergonomics is an applied discipline and its success also depends on the application of its principles to real work places and situations.

Aside from his teaching of undergraduate students of the Swiss Federal Institute for Technology, Grandjean did not neglect the further education of his own collaborators. Under his supervision dozens of young scientists were prepared for academic carriers or completed postgraduate studies. He imparted a systematic scientific approach to his co-workers in a tolerant professional manner, encouraging critical evaluation of work without injuring personal feelings. For most of his colleagues he was not only the boss and supervisor, but also a model of collegiality. His charm was appreciated by all that met him.

The effects of his work were soon recognized far outside the borders of Switzerland. He initiated and collaborated in countless international congresses and edited several books from these meetings. He was granted multiple honors, distinctions and prizes by domestic as well as foreign organizations and universities, including three honorary doctorates from the Universities of Surrey (1970), Stuttgart (1976) and Geneva (1984). He was awarded the "Prix René Barth" from the University of Paris (1953), the American Industrial Hygiene Association's "Yant Memorial Award" (1970), the International Prize for Occupational Medicine "Buccheri la Ferla" (1976) and was the first recipient of the Award of the International Ergonomics Association (1982). He became a Fellow of the Human Factors Society in 1978.

In 1956 Grandjean was a foundation member of the Swiss Society for Social and Preventive Medicine. He was its President for 10 years and was later an honorary member. He regarded the introduction of subspecialties within ergonomics with some concern and felt that ergonomics had to be an interdisciplinary science, not just a topic for specialists solely in psychology, medicine, engineering or design. It was important for him to get practitioners from various disciplines to contribute their knowledge and approach to solving problems. He loved discussion with his peers as much as with younger scientists and sought through constructive questioning and praise always to learn from others.

Although an all-rounder in the best sense of the word, Grandjean never forgot his roots as a doctor of medicine and the importance of the individual. He was continually interested in special cases and was wary of norms and standards, which he felt too often formed psychological cupboards for active thought and lead to a stagnation of progress. They did not correspond well to his medically oriented way of thinking or his artistic leaning, both of which placed most emphasis on the individual and the essential variety in humans and their experiences. He continually sought practical solutions to the problems he found, and he thought about what practitioners needed to be taught to be most effective. Science was not a hypothetical endeavor to Grandjean but an aid to decision-making, with direct effects on the people concerned.

He was a passionate skier and mountaineer as well as an enthusiast of modern art, a humanist, full of the joy of life, with little concern for himself. He spoke French, German, Italian and English fluently. His cultural sensitivity gained him acceptance all over the world.

In the Fall of 1983 Grandjean retired as Director of the Institute for Hygiene and Applied Physiology. He remained a frequent visitor to the Institute for many years, using his retirement to undertake a full revision of his popular textbook. He also continued to work in an advisory capacity to multiple organizations and to regularly attend conferences.

On the 11 November 1991 Grandjean lost his fight against a cancer and passed away. The foundations of ergonomics had been laid during his career and his role in the development of this new scientific discipline was substantial. His impact on it can still be seen in many areas today.

Biosketch: Jean-Marie Faverge

Jean-Marie Faverge was born in 1912 in the French Jura. He was educated in mathematics, before obtaining a degree at the Institut de Psychologie de l'Université de Paris and a state diploma from the Psychotechnicien. In 1945 he was elected Chairman of the "Groupe de psychométrie pédagogique" at the Centre de Recherches et d'Etudes pédagogiques of the French Education Ministry.

He was then invited by Dr André Ombredane in 1947 to join the Centre d'Etudes et de Recherches Psychotechniques in Paris, and soon afterwards he became Professor at the Institut de Psychologie de l'Université de Paris and at the Institut National d'Orientation Professionnelle. His teaching about the adaptation of work to man was based on statistical methods and on job analysis and it led him publish a series of now classic books: *Méthodes statistiques en psychologie appliquée*; *L'analyse du travail* (with A. Ombredane) and *L'adaptation de la machine à l'homme*. These publications contributed significantly to the launch of the ergonomics movement in the French-speaking world.

In Paris, he soon became a member of the "Human Factors — Safety" commission of the European Community for Coal and Steel (ECSC) and civil councilor of the Scientific Action Committee for National Defence. His works on the accident process in coalmines, and in the steel industry started in earnest.

In 1959, he was appointed head of the Psycholocal Laboratory at the Université Libre de Bruxelles, where he developed a teaching in Industrial Psychology and in Ergonomics; at the same time he contributed to the creation of a Institut du Travail modeled on the proposal of the International Labour Organization in Geneva.

Between 1960 and 1975, he carried out a set of researches for the Belgian Productivity Centre (now Institute for Research on Improving Working Conditions), leading him to distinguish four steps or procedures in ergonomics: postural, information, systems and cognitive (or heuristic). During this period, he investigated the concepts of safety and fiability (or reliability) in industrial processes. In 1976–77, Faverge conducted a follow-up study devoted to the difficulties of achieving breakthroughs in ergonomics in industrial settings.

Illness forced his retirement in 1980, leaving one of the richest legacies in the French-speaking world: as a scientist, he was in a position to build up and nurture two different schools of thought: first in Paris, with J. Leplat or M. de Montmollin and the building up of ergonomics; afterwards in Brussels, with G. Karnas on the work analysis, and with V. De Keyser (who teaches at Liège University) and the reliability research in the field of psychological ergonomics.

He was member or chairman of several scientific societies such as the French Psychological Society, the International Association of Applied Psychology and the Psychometric Society. He was one of the French and Belgian founders of the Société d'Ergonomie de Langue Française, which is his major achievement for ergonomic development.

Biosketch: Longin Paluszkiewicz, 1925–89

D. Koradecka

Central Institute for Labour Protection, Czerniakowska Street 16, 00712, Warsaw, Poland

Professor Longin Paluszkiewicz, one of the originators of the Polish science of ergonomics, belonged to the most renowned specialists in ergonomics-related psychology.

He was born on 28 December 1925 in Mstów near Czestochowa. In 1952 he graduated from the University of Warsaw with an MA in Philosophy. His speciality was psychology. In 1968 a PhD was conferred on him and in 1980 a professor's title in the field of Organization and Management.

Paluszkiewicz's career was almost entirely connected with the Central Institute for Labour Protection where he was at first a junior researcher, then Head of Engineering Psychology Department and, finally, Head of the Ergonomics Department. However, he began — before entering university — as a manual worker (fitter and electrician) and next as an administrative worker. During his studies he worked in a traditional domain of psychology counseling. He counseled juveniles on adapting to, sometimes difficult, living conditions, as well as to adults in the field of mental hygiene.

In research work he was originally occupied with an influence of various sources of light and eye and face protectors on both eyesight and the quality and efficiency of work. Yet, his main scientific interest was perception of signals. Paluszkiewicz's related research dealt with ergonomic properties of display and actuator devices (scale graduation, the length of the pointer, its distance from a scale, the color of the background, etc.), the influence of the probability of appearing signals on their perception.

The results of the research on working habits and on acquiring proficiency in using display devices were, in addition to the above-mentioned research, a significant contribution by Paluszkiewicz to the knowledge of ergonomics. The results of the research also included factors that lower this proficiency and making the use of such devices difficult for the perception of information.

Further research concerned various systems of display and actuator devices and the structure of actuator units for vehicles and multifunctional building machinery, as well as designing these units according to the rules and requirements of ergonomics.

In his scientific activity Paluszkiewicz was clear when raising and analyzing problems, and inquiring, and he showed a specific ability to consider the examined problems from different angles. This gathered around him representatives of the humanities and the sciences, who created a harmonious group of ergonomists. Paluszkiewicz's role was to inspire, program and supervise the work of the group.

Paluszkiewicz attached importance to research methodology. In this respect he was a perfectionist and he inculcated such an approach in his co-workers. He also showed an understanding for the relationship between theoretical solutions and their implementation. This understanding was, to a great extent, a result of his experience in industry. Additionally, the findings of his research as well of the research in leading countries, which he published, provided designers and constructors with indispensable data for designing products according to the rules and requirements of ergonomics.

Among his first publications, *Engineering Psychology* deserves consideration. Published first in 1963 (2nd ed. 1966), it was prepared together with Jan Okon, a master under whose wing Paluszkiewicz originally developed. *Engineering Psychology* was the first original Polish scientific publication on ergonomics. An extensive chapter, "Engineering Psychology," included in the university textbook *Psychology of Work* edited by Okon in 1971; is also an important publication in the output of Paluszkiewicz.

Paluszkiewicz included the findings of both his own and world research concerning display and actuator devices in his *Ergonomic Properties of Display and Actuator Devices* (1975). Being an author or co-author of Polish and foreign publications, he contributed to the development of psychology of work and ergonomics as well as to the popularization of knowledge about them. These publications included textbooks for university students and training guides used by the Polish Academy of Sciences, the Chief Technical Organization and companies, as well as 80 entries for Polish reference publications, such as *Encyclopaedia of Technology*. He also prepared documentation for the International Labour Office (ILO) in Geneva and the Council for Mutual Aid.

Paluszkiewicz was a member of the Editorial Committee of *Ergonomia* and also co-operated with *Polish Psychological Bulletin*. He was also a respected lecturer of ergonomics and psychology of work at the University of Warsaw and several other universities, and at training for staff currently responsible for working conditions, i.e. directors, designers, technologists and production organizers. Clarity of style, precision of expression and the ability to present clearly a given subject made his lectures and various presentations always interesting and drew the audience's attention. This derived not only from his knowledge, skill and aptitude, but also from the adjustment of the form and content of lectures and presentations to the listeners' specialization and intellectual level. He inculcated the need for such preparation in all his co-workers.

He was a patriot and he worked for the benefit of society. During World War II he took part in the Warsaw resistance movement and was an active participant in the Polish scout organization "Szare Szeregi." In the Warsaw Uprising he fought in Mokotów in the regiment 'Baszta' and was seriously wounded. Professor Paluszkiewicz presented this period in the third volume of his *Harcerze 1939–45: Szare Szeregi*.

In 1977 Paluszkiewicz co-founded the Polish Ergonomics Society, a member of the International Ergonomics Society (IEA). For his contribution to the development of the Polish Ergonomics Society he was awarded the Medal of Wojciech Jastrzebowski and the title of an honorary member.

He also took part in the meetings of many committees and societies, e.g. the Ergonomics Committee of the Polish Academy of Sciences, the Ergonomics and Labour Protection Committee of the Chief Technical Organization and the Polish Psychological Society. For his merits in scientific and research, organizational, educational and social work he was awarded a number of state distinctions, among others, Zloty Krzyz Zaslugi in 1974 and Krzyze Orderu Odrodzenia Polski (Kawalerski in 1978 and Oficerski in 1986).

Professor Longin Paluszkiewicz died on 26 September 1989 in Warsaw.

Biosketch: Paul Branton

D. J. Oborne

Department of Psychology, University of Wales Swansea, Singleton Park, Swansea SA2 8PP, UK

1. INTRODUCTION

Being an eclectic science, ergonomics attracts its practitioners from a range of disciplines. Although Paul Branton (1916–90) was formally trained as a psychologist, his roots before his relatively late university career were in commerce, industry and the Royal Navy (1942–48). Each environment played a significant role in the development of his views of ergonomics, from both philosophical and psychological perspectives. Each enabled him to become the founder of a predominantly person-centered view of ergonomics.

2. PHILOSOPHICAL INPUTS

Branton's emotional roots were firmly founded in philosophy. Before his training at the University of Reading (1959–62) he was particularly concerned with understanding the bases of personal value judgements and studied critically the philosophical foundations of ethical behavior in general, and morals and politics in particular. He was inspired by the teachings of the German philosopher at Göttingen University, Leonard Nelson (1882–1927), whose ideas were part of a German philosophical tradition that extends back to the critical reasoning of Immanual Kant (1724–1804). This interest in the philosophical bases for understanding behavior, particularly in the tradition of Critical Philosophy, remained with him throughout his life, and helped him to develop and maintain his person-centered view of ergonomics.

Kant's main preoccupation was with moral or ethical behavior. Thus, when he spoke of (rational) action he meant moral action, including such aspects as good deeds, resistance to temptation,

and a virtuous disposition. Taking this view further, Branton argued for a set of metaphysical principles of work that are not at all separable from moral considerations. On the contrary, he felt that moral considerations intrinsically belong to ordinary human work. In this way he spent much of his life attempting to "marry" critical philosophy to psychology. With his colleague Fernando Leal he developed a view that he called the "New Science of Inner Life," the ultimate aim of which was to show that there is "a greatness lying inside the human person" that needs to be understood, nurtured and liberated.

3. PSYCHOLOGICAL AND PHYSIOLOGICAL INPUTS

During his undergraduate training at the University of Reading, Branton developed a strong interest in the physiological and anatomical bases of psychological events. Throughout his future careers his view developed that we should understand person-centered variables from a psychophysiological perspective. For example, boredom and monotony can be understood in terms of physiological adaptation and stimulus inhibition. His study of anesthetist's stress suggested that the stress could be considered to result from an accumulation of "mini panics" arising from a realization that the anesthetists, as well as their patients, had drifted off to sleep during long operations. Also seating comfort, which he studied extensively during his period at Furniture Industry Research Association (FIRA) and then at British Rail, was viewed to be the result of physiological adaptations to postural instabilities.

The recurrent psychophysiological theme that runs through much of Branton's work was stimulated by his undergraduate studies. He frequently considered the importance of rhythmical variations in bodily functioning. He was considerably influenced by the fact that bodies exhibit such rhythms in almost all of their functions — consciously and unconsciously. These fluctuations, he argued, can be perceived as being major influencers of our behavior when interacting with working systems.

On leaving university Branton moved to FIRA (1962–65) with a brief to study the comfort of seating and seats as part of an ergonomics service to that industry. During this time he further developed his thoughts about the nature of ergonomics and the centrality of the individual within the system. In particular, he began to develop views about ways of integrating observable behaviors, such as movement and posture with the less observable and more subjective behaviors to understand better, and fully meet, the needs of the user.

It was during his time at FIRA that Branton developed his theory of postural homeostasis to explain individual comfort-seeking behavior. This theory again emphasizes the interface between psychophysiology and behavior, particularly stressing the fluctuating nature of many psychophysiological processes — in this case the forcing system that maintains a posture when sitting or standing.

Branton argued that the upright or sitting body is an inherently unstable system and postural activity is one of dynamic, fluctuating, body states that maintain the desired posture — "a two-way traffic across the borders between body and mind." Thus, the homeostatic theory of seating comfort considers comfort as being the optimal state between two conflicting body states or

requirements: the need for stability on the one hand and the need to reduce pressure points created by stabilization on the other. Using this conceptualization, Branton developed a seating comfort metric that analyzed postural instability and shifts ("fidgets"), rather than relying on the traditional subjective rating scale approach.

Following his career at FIRA, Branton moved to the MRC Industrial Psychology Research Unit (1966–69) where his interests shifted more towards global industrial problems and how psychological interventions and investigations may help to explain them. It was here that his interests in shiftwork and accidents began to take shape, leading particularly to developing his understanding of stress and decision-making within individuals. His later work on anesthetist stress, particularly resulting from fluctuating levels of awareness, is an example work that had its critical formation during this part of his career.

Indeed Branton returned to this area of work in 1987, as an Honorary Research Fellow at Birkbeck College, University of London. At this time he collaborated with his colleague Pat Shipley on studies relating to stressful experiences of working people to problems of individual control, and being in positions of responsibility.

Moving from FIRA to become Chief Ergonomist in British Rail in 1969, Branton became free to develop his ideas in a specifically applied setting. The list of issues in which he became interested is long and includes studies of train drivers (emotional and physiological states), driver cabs, signaling, driver behavior, passenger environments, and physical environmental influences. Such issues were studied from the viewpoints of skilled behavior, stress, comfort and decision making.

To each area Branton brought his person-centered view of ergonomics: that one should consider the whole person within the system, including the individual's psychophysiological and mental models of the system with which s/he is interacting.

4. SUMMARY

Paul Branton's view of ergonomics was formed by almost all facets of his varied life — from his early life as a tailor in Austria before World War II to his work as an Honorary Fellow at Birkbeck College at the time of his death. His view, and his pivotal role in the foundation of a new facet of ergonomics — person-centred ergonomics — was forged within the realms of Kant's Critical Philosophy and Branton's sense of innate goodness of people.

These views were strengthened during the persecution years in Germany and Austria; in 1937 he fled from Vienna and took refuge in Palestine. In 1948 he moved to the UK and became interested in politics. He studied philosophy and social science in the 1950s, before undertaking full-time undergraduate training in psychology. From this point on, philosophy became married to psychology and different facets of person-centred ergonomics emerged with his employment at FIRA, MRC, British Rail, and then in "retirement" working as an independent consultant and as an Honorary Research Fellow at Birkbeck College.

Biosketch: Paul Morris Fitts

R. W. Pew

BBN Technologies, 10 Moulton Street, Cambridge, MA 02138, USA

Paul M. Fitts was a pioneer in the field of Human Factors Engineering, which he preferred to call Engineering Psychology. He was the first Director of the Psychology Branch of the AeroMedical Laboratory at Wright Patterson Air Force Base, which is now called, after several metamorphoses, the Human Effectiveness Division of the Air Force Research Laboratory. He was a Founding Member of the Human Factors Society of America, now the Human Factors and Ergonomics Society. He was also a prominent Experimental Psychologist who saw only the fuzziest of boundaries between theoretical research and applied system development. His chapter "Engineering Psychology" in the prodigious *Handbook of Experimental Psychology* (edited by S.S. Stevens and published in 1951) was a landmark definition of the field and provided exposure of this new discipline to a generation of psychology graduate students. Regrettably, his career was cut short by his untimely death from a heart attack in 1965 at 52 years of age.

Paul Morris Fitts was born in 1912 in Martin, Tennessee. He received his Bachelor of Science degree in Psychology at the University of Tennessee in 1934, his Master of Arts at Brown University in 1936 and his PhD in Psychology at the University of Rochester in 1938, under Dr Leonard Carmichael. His thesis was on motivation in animals. He immediately returned to the University of Tennessee as an Assistant Professor of Psychology. However, World War II interrupted his career and he moved to Washington in April 1941 to work with a team of psychologists in the US Army Air Forces Office of the Air Surgeon on problems of Air Force pilot selection and training. He served the Air Forces for more than 8 years, first as a civilian, then for 4.5 years as an Air Force officer, rising from first Lieutenant to Lieutenant Colonel by the time of his discharge in October 1946, and then for another 3 years as a civil servant. It was during this time that the US military began to see that psychologists could play a role in determining how to design equipment to adapt it to human requirements and Dr Fitts identified strongly with this new role.

On 1 July 1945, a Psychology Branch of the Aero Medical Laboratory was established at Wright Field in Dayton, Ohio. Dr Fitts, then aged 33, was appointed its first Director and it soon became the unit responsible for all aspects of engineering psychology for the Army Air Forces.

At the Psychology Branch Dr Fitts became involved in setting the research agenda for this new field of "Engineering Psychology" in the military aviation world. He also become involved in several research studies himself. He is probably best known for the pioneering analysis of pilot error experiences in reading and interpreting aircraft instruments and in operating aircraft controls (Fitts and Jones 1947a, b). They cataloged those mistakes on the basis of the design features to which they could be attributed. In addition to several design impacts that could be addressed directly, these studies stimulated research in the Air Force for many years to come. The instrument-reading study was the first to document problems with reading the three-pointer altimeter. The Aviation Safety Reporting System (ASRS) is an extensive NASA data base of commercial aircraft human error incidents anonymously reported and widely used for research that may be regarded as a contemporary manifestation of this early work.

In 1949 Dr Fitts returned to Ohio State University and reactivated the Laboratory of Aviation Psychology. It was later renamed the Systems Research Laboratory when it ceased to be dominated by aviation research. He remained at Ohio State, active in research, teaching and administration, and on the national scene until 1958 when he moved to the University of Michigan where he remained until his untimely death. At Michigan he broadened his interest in the theoretical aspects of human information processing and, together with three colleagues from the Psychology Department, founded the Human Performance Center, a unit within the Psychology Department that became a focus for faculty and graduate students interested in human performance and human information processing.

Throughout his career, Fitts championed the application of psychological research to equipment or systems design. He accomplished this initially through his own research, but after he left the Air Force, his work took a more academic turn, emphasizing research questions that had a payoff in applied work. However, his direct impact on engineering design continued to be felt through his consulting and his participation in significant engineering psychology developments nationally. He was instrumental in helping to organize Division 21 of the American Psychological Association, the division concerned with applied experimental and engineering psychology. He was a founding member and later President of the Human Factors Society, now the Human Factors and Ergonomics Society. He was chairman of several psychology and social science panels, boards and committees sponsored by the Air Force, the Department of Defense and the National Research Council that were influential in establishing a role for engineering psychology.

It was at Ohio State where he conducted the early research and published what is now perhaps his most famous paper in *Journal of Experimental Psychology* in 1954 entitled "The information capacity of the human motor system in controlling the amplitude of movement." Here he showed that an index of difficulty of a movement could be defined in information theoretic terms that accurately predicted movement time as a function of the accuracy required of a movement and the distance moved. The greater the accuracy required, the slower the movement, and the longer the distance moved, the slower the movement. Equation (1) is currently used to describe this relationship, which has come to be called Fitts' Law:

$$\text{MT} = a + b\ [\log_2\ (2A/W)], \quad (1)$$

where A = distance from the starting point to the center of the target; W = target width, and a and b are constants reflecting the specific movement circumstances. In the original paper and in subsequent work he showed that only the constants had to be adjusted to describe (1) reciprocal tapping where the size and separation of the target plates was varied; (2) disk transfer where the difference in the diameter of the disk hole and the peg onto which it was placed reflected the accuracy constraint; (3) a peg transfer task in which pegs were transferred to holes of different sizes; (4) the effect of adding a weight to the hand; and (5) for discrete or continuous movements and under various instructions to be rapid or accurate. Numerous investigators have examined

the predictions in great detail, most notably Welford (1960, 1968), and while marginal gains in predictive accuracy have been proposed by adjustments in the equation, the fundamental relationship and the robustness of the predictions have never been challenged. In subsequent work it has been shown to work for foot movements (Drury 1975), movements of the head (Soede *et al.* 1973), and even movements made with tweezers while looking through a binocular microscope (Langolf *et al.* 1976).

At The University of Michigan, Dr Fitts most important work was in human information processing, more specifically, he used a variety of research paradigms in which the dependent variable was human reaction time or response time. An important contribution was the quantification of the relationship between speed and accuracy of performance. He showed in the laboratory that given quantitative payoffs for performance that favored either speed and accuracy, the human operator would adjust behavior appropriately to maximize that payoff, which meant either responding faster and making more errors or slowing down and being more accurate, depending on the relevant monetary payoff at the time. He went on to develop a predictive sequential sampling statistical decision model that accounted for these trade-offs (Fitts 1966).

It seems likely that Dr Fitts introduced the term "Engineering Psychology." If he did not actually introduce it, surely he was the first to popularize it and to influence its adoption to represent psychology's interests in the human's role in system design and development. He used it in his introduction to a series of Psychology Branch research papers in 1947 to refer to the emerging area of psychological research on equipment design (Fitts 1947). Then in 1951 it became the centerpiece of the title of his chapter in Stevens' *Handbook of Experimental Psychology* (Fitts 1951).

The most interesting thing about Fitts's work is that while the scope of his theoretical and applied interests were very broad, his research had a thread of continuity and specificity that gave it focus. His original interests were stimulated by his introduction to issues from the applied perspective at the Psychology Branch of the Aero Medical Laboratory, and he sustained work on them virtually throughout his career, generalizing and broadening their importance and impact at each new opportunity. All these topics fell under the general rubric that he would come to call *human skilled performance*.

For more detail on Dr Fitts' life, see Pew (1994).

Biosketch: Ross A. McFarland

S. H. Snook

Department of Environmental Health, Harvard School of Public Health, Boston, MA, USA

Ross A. McFarland was one of the founding fathers of Human Factors and Ergonomics in the USA. He was also a founder of the Human Factors Society and served as its president from 1969 to 1971.

Dr McFarland was born in Denver, Colorado, in 1901, and was raised in Missouri. He received a bachelor's degree from the University of Michigan in 1923, and a PhD from Harvard University in 1928 in Physiological Psychology. He pursued an academic career of research and teaching. As a Research Fellow at the University of Cambridge in England from 1927 and 1928, Dr McFarland showed how the lack of oxygen during simulated flights could impair the behavior of RAF student pilots, giving rise to lack of insight and loss of judgment.

From 1929 to 1937 Dr McFarland was an Instructor of Psychology in the Department of Psychology at the College of Physicians and Surgeons, Columbia University, New York City. He investigated the central nervous system's complete dependence upon a normal supply of oxygen, glucose and other organic constituents. In studies using visual tests of differential light sensitivity, he demonstrated for the first time that impairments may be present at altitudes as low as 4000 feet in unacclimatized subjects. These and other findings led to regulations for the use of oxygen by pilots in civil aviation and by military pilots during night combat.

In 1935 Dr McFarland was a member of the International High Altitude Expedition to South America where he continued his studies on oxygen deprivation in acclimatized subjects. During the 4-month expedition members of the party were compared with natives living at altitudes up to 20 000 feet in Chile and Peru.

Dr McFarland joined the Harvard Fatigue Laboratory in 1937 as an Assistant Professor of Industrial Research. At that time the laboratory was housed in the basement of the Harvard Business School. Working with the sociologist Elton Mayo, he investigated some of the physiological problems of industrial workers. His studies centered around mental tests made under various environmental stresses (heat, cold, noise, vibration, etc.).

When Pan American Airways opened air routes over the Pacific and Atlantic Oceans in 1937 and 1939, Dr McFarland was asked to study the fatiguing effects of long distance flights on pilots. He was also an advisor to the airline in 1940 when air routes were openend across Africa. During 1939 and 1940 he became interested in pilot selection and the development of better tests in predicting success or failure. Because of the high failure rates in the military services, Dr McFarland and a group of colleagues at Harvard were asked to make a comprehensive analysis of this problem on 1000 naval aviators. Their results were published as *The Pensacola Study of Naval Aviatlors*. Thirty years later, when follow-up studies were made of the same aviators, the results were not only validated, but also they led to a greater understanding of problems related to heart disease and aging.

With the outbreak of World War II, it was apparent that many older persons would be required to work in industry. Through experimental studies of the aging process, Dr McFarland demonstrated that, with proper placement and supervision, men and women could work productively much longer than originally believed. He stressed the importance of functional rather than chronological age in judging an individual's ability to perform. He also pointed out the close relationship between the oxidative processes and certain functions of the central nervous system. He demonstrated these close relationships in tests of light sensitivity, immediate memory and the loss of insight. His theory, relating the sensory and mental changes seen in aging to alterations in the oxygenation of the body's tissues, has gained widespread acceptance.

In 1943 and 1944 he served as an Operations Analyst for the 13th Air Force in the Solomon Islands campaign, studying combat fatigue in air and ground forces. It was here that he became interested in the problems of designing equipment to meet human capabilities and limitations. He wrote one of the first textbooks in human factors, *Human Factors in Air Transport Design* (McGraw-Hill, 1946), intended primarily for engineers.

Dr McFarland became a member of the faculty of the Harvard School of Public Health, when the Harvard Fatigue Laboratory moved there in 1947. It was here that he developed a new approach to some of the difficult problems of health and safety, not only in the air, but also on the ground and in space. He was one of the first to emphasize the multiple causation of accidents, and to apply the methods of biostatistics and epidemiology in the study of highway injuries and fatalities. Many of the lessons learned in aviation and aircraft design were now applied to automotive design and safety. Research programs included the application of anthropometric and biomechanical data to vehicle design and operation, and the effects of alcohol and toxic agents (e.g. carbon monoxide) on driver performance. Many of the resulting principles have been incorporated into federal regulations relating to air and highway safety. Dr McFarland's new approach attracted many young physicians and engineers to the Harvard School of Public Health for advanced study. In 1953 he published his second book entitled *Human Factors in Air Transportation – Occupational Health and Safety* (McGraw-Hill), primarily for physicians and safety engineers.

In 1957 the Guggenheim Foundation sponsored a teaching and research center at Harvard, and in 1962 the center was endowed. Dr McFarland became the first Director, and the first Daniel and Florence Guggenheim Professor of Aerospace Health and Safety. He and his colleagues at the Harvard School of Public Health trained more than 200 young scientists. Many of his students assisted in the medical aspects of the space program, and others achieved leadership positions in the fields of aerospace medicine, occupational health and highway safety. In 1966, he published his third book, *The Human Body in Equipment Design*, with Drs Albert Damon and Howard W. Stoudt (Harvard University Press). It has been widely used by engineers and industrial designers.

In addition to his three books, Dr McFarland contributed over 200 publications to the scientific literature. Among the many

awards recognizing his professional achievements are the Longacre Award of the Aeromedical Association in 1947 for the safe utilization of aircraft, the Flight Safety Foundation Award in 1953, the John Jefferies Award of the Institute of Aeronautical Sciences in 1956 for contributions to aeronautics through medical research, the Walter M. Boothby Award from the Aerospace Medical Association in 1962 for research in aviation medicine, the Exceptional Service Award of the US Air Force in 1969, and the Distinguished Civilian Service Award of the Department of the Army in 1971. In 1963 he was the first American invited to present the Ergonomics Research Society Lecture, "In Search of a Theory of Ageing", in the UK. He was awarded the Honorary Doctor of Science Degree by Park College, Rutgers University, Trinity College and the University of Denver.

Dr McFarland had also been a consultant or technical advisor to many federal agencies, including the Department of Health, Education and Welfare, the Federal Aviation Administration, and the National Aeronautics and Space Administration. He served on numerous task forces and study groups dealing with various aspects of health and safety. He was also active in numerous scientific and technical organizations, including the Human Factors Society, the Ergonomics Research Society, the American Psychological Association, and the Aerospace Medical Association.

Dr McFarland died in 1976 at the age of 75. He left behind a legacy of outstanding scholarship and warm friendship. His contributions to the field of human factors and ergonomics were enormous, and he was valued highly as a teacher and advisor by his students. He was truly a pioneer of human factors and ergonomics in the USA, and a professional giant among his peers.

Biosketch: Wojciech Bogumil Jastrzebowski

D. Koradecka (editor)
A. Golebiowska (translator)

In the treatise entitled "An Outline of Ergonomics, or the Science of Work Based Upon the Truths Drawn from the Science of Nature", published in *Nature and Industry: a weekly devoted to accessible presentation of all branches of natural sciences, their practical application to living, and the latest discoveries and inventions*, Poznan, Poland (1857), W. B. Jastrzebowski created the foundations of ergonomics.

Wojciech Bogumil Jastrzebowski, the inventor, scientist, educator, and naturalist, was born on 19 April 1799, in Gierwat, Poland. His father died before Wojciech was born, and his mother died when he was nine years old. He attended a primary school in Janów. In 1816, he began attending a secondary school, but due to the poverty and ill health his education was often interrupted. In December 1820, Jastrzebowski began studying at the Department of Building Engineering and Surveying of the University of Warsaw. His knowledge, enthusiasm, and ingenuity made his professors assign him several supporting research projects. In September 1822, he also began studying at the Department of Philosophy (Natural History Unit). During his studies he assisted in the research of several biologists, astronomers and zoologists.

At that time he was commissioned to set up the famous sun dial in the Warsaw Lazienki Park (the sun dial is still there today). As setting up a sun dial required individual measurements for each location, he designed a special piece of equipment "for determining compasses in any space and in every location". The Government Commission called it "Jastrzebowski's Compass", and the inventor was accepted into the ranks of the Warsaw Friends of Science Society.

When the (Polish) November Uprising against the Russian invaders broke out in 1830, Jastrzebowski fought at the battle of Olszynka Grochowska. At that time Jastrzebowski also developed a proposal for the creation of a League of Nations, which opened with the words: "Peace in Europe is permanent and everlasting." According to this proposal, a European Congress should publish a proclamation calling upon all the nations to form a brotherly alliance. All disputes between states would be defused by a commonwealth of nations, whose decisions would be objective and just, and when there was no more unhealthy armaments rivalry between friendly nations, all their effort should be directed towards improving the education of the youth, laws, science, agriculture and industry.

After the fall of the (Polish) November Uprising, Jastrzebowski could not go back to his job at the University of Warsaw. In 1836, he became Professor of Botany, Physics, Zoology and Horticulture in the Institute of Agriculture and Forestry in Marymont. Thanks to him, the Marymont gardens became true protected areas of rare shrubs and trees. Jastrzebowski's students were taught to be methodical and consistent, restrained and patient in the laborious task of fact collecting. At the same time, however, he cautioned them not to become simple archivists of facts; they were to try to unravel the mystery of their creation. Jastrzebowski devoted a lot of time to field trips with his students across all regions of Poland. Those expeditions resulted in a study entitled "Forecasting fair weather, sleet, wind and other changes of the air" (1847), which was also translated into Russian. Thanks to the study's reputation, Jastrzebowski was admitted to several Polish scientific societies, including the Krakow Science Society, the Kielce Agriculture Society, and the Agriculture Society in Lvov.

In addition to the historic treatise: "An Outline of Ergonomics, Or the Science of Work based upon the truths Drawn from the Science of Nature" (1857), Jastrzebowski published "Stichology" and "Mineralogy" (1852). Upon leaving the Institute in Marymont, Jastrzebowski was given the post of works inspector, preserving the dunes of Czerwony Bór and planting trees on them. He settled in Feliksówka, where he created model gardens, nature rooms, and a dormitory for trainees. During the next (Polish) uprising of January 1863 the dormitory emptied. His students and his two sons joined the uprising.

The "Florae Polonicae Prodomus" — even today one of the basic textbooks of plant geography in Poland — was published by Józef Rostafinski in Vienna in 1872. In it, he describes 1550 plants, of which 1090 are labelled with Jastrzebowski's name since their names had been taken from his herbarium. In 1874, Jastrzebowski left his study in Czerwony Bór and tried to recreate a garden with his favourite yews and larches on a small plot of land in the Warsaw suburb of Czyste. At the same time he accepted the offer of the Warsaw–Vienna Railway to plant hedges round its stations and stops. The last time he went out into a field for a rendezvous with nature was in 1879. Jastrzebowski died on December 30, 1882, and was buried at the Powazki Cemetery in Warsaw.

First edition in English: Wojciech Jastrzębowski "An outline of Ergonomics, or the Science of Work based upon the truths drawn from the Science of Nature". Editor: Danuta Koradecka, Warszawa, Central Institute for Labour Protection 1997, translation of Wojciech Jastrzębowski's text: Teresa Baluk-Ulewiczowa, translation of the biographical note: Aleksandra Gołębiowska.

Cognitive Engineering

T. Lambie

Ergonomics and HCI Unit, University College, 26 Bedford Way, London, WC1H 0AP, UK

1. INTRODUCTION

The concept of cognitive engineering is not fixed and unequivocal, but in its various expressions are found certain common features. The fluidity of the idea is not surprising since its arrival is relatively recent, and its formation into something more determinate awaits the outcome of its practices as all disciplines do. There is probably a consensus on what constitutes cognition or cognitive behavior — reasoning, remembering, planning, etc. However, agreeing on what we mean by engineering — particularly of cognition or cognitive behavior — is not so straightforward. One of the reasons that this is so is that engineering is not adequately understood in its relationship with science, and this has perhaps implications for how both science and engineering are understood. The question as it affects technology and engineering is addressed, for example, by the aeronautical engineer Vincenti (1990).

Understanding cognitive engineering is therefore understanding what engineering is by itself and in connection with cognition or cognitive behavior, and there are perhaps two sources for the introduction of the idea into the currency: Simon (1969) and Norman (1981).

2. ORIGINS

Although Simon did not originally give the name engineering to his "artificial science" of the mind, much of his argument suggested that, in general terms, there were two distinct disciplines — pure science and systematic design — that traditional engineering was stultified and, by implication, that the practice of design should be reconceived to get rid of this stultification. This reluctance to call his artificial science of the mind engineering was partly because he saw cognitive science — the investigation of how cognition worked — as dependent partly on cognitive design (e.g. the uses of computing models — *designing* them — to elucidate aspects of cognition). In the context of Artificial Intelligence, for example, he later (Simon 1980) writes that we should perhaps make an explicit recognition that there are two disciplines "by speaking of cognitive engineering as well as cognitive science": that the study of artificial intelligence "is interested, in its applied aspect, not only in understanding but [also] in improving it", and that if we make this recognition then he hopes "that the two ventures will keep in the closest relation with each other, as they have done through the past quarter century. The dangers of confusing the normative with the positive are slight compared with the losses that would be suffered from isolating the science from its engineering applications". The wording of the last sentence strongly implies that it is cognitive science that will suffer if they fail to communicate, not cognitive engineering. In Simon's view, in any case, the discipline of systematic cognitive design is a new and distinct kind of knowledge that has at least a troublesome relationship with science.

Norman (1987), more typically a member of the Cognitive Ergonomics (including HCI) community, writes, however, that he invented the term "cognitive engineering" "to *emphasise* the cognitive aspects of human–machine interaction. … Cognitive engineering is meant to combine with the applied disciplines not to replace them". It represents for Norman a "new approach … more than just psychology … more than psychology coupled with engineering. We need all the disciplines of cognitive science, plus engineering." So for Norman the adoption of the term means that we should broaden our vision of what is involved in the work of HCI; more importantly, that it should lead to principled design that takes us beyond the solution of particular design problems as a craft discipline, with each solution a new one unrelated, except tacitly, to any other. Norman, however, appears to have a more pragmatic interest than Simon in the adoption of an engineering view of cognition. Although he wants to institute a novel approach which provides a greater guarantee so that design knowledge acquired in one project may be carried forward with confidence to support the solution of similar design problems, he makes little of the gaps or the connections between scientific and engineering knowledge.

3. IN PRACTICE

Because it is more precise, methodical, etc. engineering is widely regarded as a more responsible and, consequently, a more politically and socially respectable mode of design. It is associated with operationalization and implementation of design and as such is more practical, out-in-the-open and down-to-earth. So, cognitive systems engineering as practiced by Hollnagel, Rasmussen, etc. was at least partly adopted and developed because it was concerned with systems that were safety critical and complex. As the work matured it attracted attention because it offered better means to design. Rasmussen's work is particularly notable in this respect. Representations and models were offered of a general nature, so that a language of representation might allow generalization across design problems (also Woods and Roth 1988); e.g. formal expressions of behavior at different levels (from tasks to physical operations) corresponding with different levels of knowledge description (from symbols to signs), these to be consolidated by empirical work. The question of the origins of these models and representations is not raised, but the detail and care with which they are expressed and employed means that engineering cognitive systems is probably, both ostensibly and actually, more precise, methodical, etc. It is called engineering therefore to distinguish it from design as art or intuition-based, but it is not just cognitive science either. This version of cognitive engineering is forward-looking to precision and the testing of models and representations rather than backward-looking to the its epistemological roots. The expression of this approach is refined and recapitulated with particular relevance to Cognitive Ergonomics and HCI by Woods and Roth (1988).

For the Cognitive Ergonomics and HCI community, engineering cognition (or cognitive engineering) is partly the expression of a desire to design and build as rigorously and carefully, and, arguably, therefore as explicitly and publicly as possible. The motivation for engineering is, thus, to achieve the aims of a design which answers the requirements of the users and satisfies them of, for example, the safety or financial economy of the design, since the design would not persuade us that it would continue doing what it was claimed to do were it not methodical, precise and explicit. Engineering is supposed to bring

more than faith to the business of design. Nevertheless, it is not enough to aim for design which has precision, rigor, and is public and open to criticism. The grounds for, or principles of, this type of knowledge, which is different from other given kinds, must be examined, and its distinct properties established, or we might be being persuaded of the precision, rigor, etc. of scientific truths not design certitudes.

4. IN PRINCIPLE

The determination of the boundary between science and engineering, as well as being one of the *consequences* of the practical advantages of an open and systematic design activity, might also be one of the *motivations* for the inception of the practice of a distinct discipline of cognitive design such as is involved in Human Factors (HF), HCI, Computer Supported Cooperative Work (CSCW), etc. Conventional engineering disciplines, e.g. aeronautical or electrical engineering, have formed into professions distinct from that of their cognate scientific disciplines (Vincenti 1990). They have an independent existence drawn on by the need to solve specific technical problems which are not soluble by reference to the universal models or theories of science but rather by the need for the construction of models contrived for the particular context set by the design requirements.

It has been found increasingly that addressing design problems in HF, HCI, CSCW, etc. also necessitates turning attention away from the psychological, computational or sociological research of a scientific nature (which aims at universality) and focusing on the problem posed by the target artifact, including the constraint that it meet the given requirements (which aim at the eccentricities of the particular). For Dowell and Long (1998) HF is largely a craft, "the heuristics it possesses being either 'rules of thumb' derived from experience or guidelines derived informally from psychological theories and findings", with the latter representing the science applied, i.e. the more or less *simple* laying of the scientific template onto the design problem to generate the design solution.

However, even if applied science were quite different from pure science and not its *simple* application but were endowed with techniques, methods and practices developed with ingenuity and rigor, in other words, a discipline whose practices resulted in general features which became the ground for addressing novel problems, nevertheless, it would still fall short of fully fledged systematic design or engineering. This is so because systematic design or engineering is not only concerned with the solution of particular problems by the development of particular models, contrasted with the general theories of pure science, but also must engage with the idea of the fabrication of artifacts — the making of something new or the changing of the physical world in some way to lead to an improvement in the performance of some system or other. What arises, then, is a triad — of pure science, applied science and engineering — with engineering principally oriented towards normative or prescriptive knowledge, while science (in its distinct forms as pure and applied) is aimed at positive or descriptive knowledge. This contrast between science and engineering is addressed expressly by Simon, as mentioned above, and by others more casually.

5. FROM DEFINITION TO DISCIPLINE

Without such a journey into the epistemology of science and technology, starting with a definition of engineering takes us a good way forward. Whiteside *et al.* (1988) claim, "Engineering almost always involves construction but it differs from merely 'building' something … design for a purpose (as contrasted with tinkering and puttering) is always an essential part of the process," and, "engineering always operates against a background of scarce resources: talent, materials, time, and money."

Whiteside *et al.* have a particular interest in 'usability engineering', but carrying through their reasonable definition takes us quite a way towards a characterization of the discipline of cognitive engineering more generally — from the inside out rather than from the outside in, as offered by the epistemological approaches. The scarceness of the resources — both physical and cognitive (Whiteside *et al.* include the cognitive resource "talent") — mean that the solution of design problems is dominated by the aim of arriving at *effective* solutions. The designer need not chase the vain goal of optimality or greatest economy except in relation to the requirements, but this property of effectiveness must be pursued with as much explicitness and rigor as possible to fulfill the aims of engineering as defined.

In particular, the effectiveness sought, according to the above, bears on, if carried out conscientiously, the parsimonious use of physical as well as cognitive resources, both consistent with the requirements. So, to focus on (1) the best way (with respect to the requirements) of carrying out the tasks (the specification of the work to be done) and (2) the most economical (with respect to the requirements) employment of cognitive resources results in a division of the design problem into two partitions — that of the work to be carried out, and that of the agency (cognitive or joint cognitive systems) to carry it out. Such a description of the general design problem for cognitive engineering is to be found in Dowell and Long (1998): the duality comprising, respectively, the Domain of Work (the domain) and the Interactive Work System (IWS). The procedure of design, in this conception of cognitive engineering, is to determine the domain and design the IWS to reflect this domain, taking into account the constraints on the cognitive system/s. Further, consistent with the definition of cognitive engineering and with its troublesome relationship with scientific knowledge, the domain should be determined in as *unscientific* (while remaining systematic) a manner as possible. The domain's determination should be "ecological" (also Woods and Roth 1988), i.e. the designer should examine the work as done in its normal setting, not some (probably) unrepresentative model of the work: *in vivo*, therefore, not *in vitro*. This does not exclude resorting to scientific knowledge, but *as such* the input must be recognized to be as conjectural as any other inspiration. The knowledge, whatever its source, becomes engineering knowledge through the practices devised and generalized in the course of solving the design problem.

6. CURRENT AND FUTURE VIEW

Whether considered from a practical or principled angle, or from an analysis of its terminological components, there are remarkable similarities between the various versions of cognitive engineering, and, in large part, the important aspects of the emerging discipline are summed up by Woods and Roth (1988). They describe, in round terms, its attributes as exhibited by Rasmussen (1986), Norman (1987), Dowell and Long (1988) and others. However, Woods and Roth's analysis does not dwell on the manner in which

technological knowledge is defined with respect to scientific knowledge, and, for some, this is what needs addressing in particular.

There is undoubtedly a problem with the unclear status of design knowledge for reasons to do with reliability or guarantee. If design knowledge is loosely connected to scientific knowledge it is important to know how loosely in order to monitor and control the connection, but once this is achieved or believed to be achievable we have something like a distinct applied science with its own rules and practices. And if this transition is acknowledged we cannot easily avoid the same reflection on the transition from this distinct discipline of applied science to that of engineering, since plainly we must account for the move from the positive to the normative which poses different requirements and results in a different domain specification — this transition bringing with it new dangers of degraded reliability. Addressing this problematic connection between the applied scientific knowledge and the putative engineering knowledge leads, consequently, to the definition of engineering — in this case, cognitive engineering. Given the many common features of the different strands of cognitive engineering it might be profitable to establish a common denominator in the form of an analytic or epistemological approach to the delineation of the discipline, thereby helping to bring unity to the fragmented area of cognitive ergonomics and HCI.

Cognitive engineering is a natural development in the face of increasing technical complexity and as a result of the need to control that complexity. Together they force a re-examination of the kind of knowledge that supports systematic design. We look

in general to science to provide guarantees of our knowledge of the natural world. However, perhaps our *understanding* of the natural world needs also the knowledge of how we manipulate it — creating the artificial — and that this knowledge must be allowed to establish its own guarantees; Simon's fear that cognitive engineering might become estranged from cognitive science suggests that cognitive engineering can only complement and consolidate cognitive science if it is truly independent. However, contrary perhaps to his untroubled attitude to the confusion of the positive and the normative, this independence requires constant vigilance in the discrimination of the kind of knowledge exploited by cognitive engineers.

Core Competencies in Ergonomics

International Ergonomics Association
Human Factors and Ergonomics Society, PO Box 1369, Santa Monica, CA 90406, USA

1. INTRODUCTION

Any mature discipline and profession requires understanding of its core competencies. Also, the exercise of defining core competencies is itself well worth while, because it prompts a profession to look closely at itself, its goals and its perceived contribution to society. Once complete, it provides a record of standards by which the profession can ensure quality of performance.

2. COMPETENCY STANDARDS

Competency standards do not themselves represent an outline of certification requirements, although they may be a resource for the certification process. Nor do they represent a curriculum document, although they may help direct the development of a curriculum.

3. DEFINITION OF COMPETENCY

A competency is a combination of attributes underlying some aspect of successful professional performance. An outline of core ergonomics competencies should describe what it is that ergonomists can do in practice.

4. TERMS

Ergonomics competency standards have been developed in terms of units, elements and performance criteria, which is the accepted format.

- *Units of competency* reflect the significant major functions of the profession or occupation.
- *Elements of competency* describe the identifiable components of ergonomics performance which contribute to and build a unit of competency.
- *Performance criteria* describe the standards expected of performance in the ergonomist's work. Expressed in terms of outcomes and professional ergonomics performance, they provide the basis on which an expert assessor could judge whether the performance of the ergonomist reached the standard acceptable for professional practice.

5. SCOPE OF ERGONOMICS

The scope of ergonomics is broad, across many domains. Ergonomists can be involved in both proactive and retrospective problem solving. The contexts for ergonomics practice are diverse and ergonomics must relate to the workplace, transport, the home or to leisure activities, or to the use of a variety of products. The IEA Core Competencies must acknowledge this diversity and should be interpreted with this breadth of scope in mind.

6. USES OF CORE COMPETENCIES

Ergonomics core competencies could be used in a variety of ways. These include:

- Development or review of curricula in ergonomics.
- Accreditation of new and existing ergonomics educational programs.
- Development of comprehensive and equitable assessment processes for the evaluation of a person's professional competence.
- Recognition by ergonomics certification authorities of the competency of graduates holding qualifications in ergonomics conferred by recognized institutions.
- Assessment of competence of eligible overseas qualified ergonomists seeking to practice in another country.
- Assessment of eligible ergonomists who have not practiced for a defined period of time and who are seeking to re-enter the profession or to be re-certified.
- Development of continuing education programs offered by the federated societies.
- Determination of need for continuing professional education by employers.
- Preparation of public information defining ergonomics roles and responsibilities.

7. BENEFITS OF NATIONAL (AND INTERNATIONAL) COMPETENCY STANDARDS

Those who have been involved with the application of Competency Standards have found them of benefit in the following ways:

- National consistency.
- Chance to examine the profession and its scope.
- Better definition of the profession.
- Basis for communication at a national (and international) level.
- A resource for education establishments and curricula.
- Provision of a more equitable basis for certification.
- Quality assurance.

8. REVIEW OF COMPETENCY STANDARDS

Any set of competencies has a limited life and this IEA document will be reviewed on a regular basis.

9. PRESENTATION

The core competencies have been presented in two formats "summary" and "full".

The *summary* version presents the units and elements of ergonomics competency as a summary, for those who require a concise overview. It is expected that any assessment of an individual or program would benchmark against this summary.

The *full version* presents a complete set of units, elements and performance criteria to illustrate the standards of performance required. This full version would be used to illustrate and give more detail on examples of, and criteria for, professional performance against which judgement can be made.

10. VERSION 2, MAY 1999, PPE COMMITTEE: SUMMARY OF CORE COMPETENCIES IN ERGONOMICS: UNITS AND ELEMENTS OF COMPETENCY

Unit 1. Investigates and Analyses the Demands for Ergonomics Design to Ensure Appropriate Interaction Between Work, Product or Environment and Human Capacities and Limitations

1.1 Understands the theoretical bases for ergonomics planning and review.

1.2 Applies a systems approach to analysis.

1.3 Understands the requirements for safety, the concepts of risk, risk assessment and risk management.

1.4 Understands and can cope with the diversity of factors influencing human performance and quality of life, and their interrelationships.

1.5 Demonstrates an understanding of methods of measurement and interpretation relevant to ergonomics appraisal and design.

1.6 Recognizes the extent and limitations to own professional competence

Unit 2. Analyses and Interprets Findings of Ergonomics Investigations

2.1 Evaluates products or work situations in relation to expectations for safe and effective performance.

2.2 Appreciates the effect of factors influencing health and human performance.

2.3 Analyses and interprets research data accurately and without bias, consulting appropriately where required.

2.4 Understand relevant current guidelines, standards and legislation.

2.5 Makes and can justify decisions regarding relevant criteria which would influence a new design or a solution to a specified problem.

Unit 3. Documents Ergonomics Findings Appropriately

3.1 Provides a succinct report in terms understandable by the client and appropriate to the project or problem.

3.2 Communicates clearly to the relevant workforce or general public, and if feasible to the scientific community.

Unit 4. Determines the Compatibility of Human Capacity with Planned or Existing Demands

4.1 Appreciates the extent of human variability influencing design.

4.2 Determines the quality of match and the interaction between a person's characteristics, abilities, capacities and motivation, and the organization, the planned or existing environment, the products used, equipment, work systems, machines and tasks.

4.3 Identifies potential or existing high-risk areas and high-risk tasks, where risk is to health and safety of the individual completing the task or any others affected.

4.4 Determines whether the source of a problem is amenable to ergonomics intervention.

4.5 Justifies decisions on ergonomics interventions or implementations.

Unit 5. Develops a Plan for Ergonomic Design or Intervention

5.1 Adopts a holistic view of ergonomics.

5.2 Incorporates approaches that would improve quality of life as well as performance.

5.3 Develops strategies to introduce a new design

5.4 Considers alternatives for improvement of the match between the person and the product, the task or the environment.

5.5 Develops a balanced plan for risk control, with understanding of prioritization and costs and benefits involved.

5.6 Communicates effectively with the client, any stakeholders, the public and professional colleagues.

Unit 6. Makes Appropriate Recommendations for Ergonomics Changes

6.1 Makes and justifies appropriate recommendations for design-based changes

6.2 Makes and justifies appropriate recommendations for organizational planning-based changes

6.3 Makes and justifies appropriate recommendations for personnel selection, education and training

Unit 7. Implements Recommendations to Improve Human Performance

7.1 Relates effectively to clients and all stakeholders, at all levels of personnel.

7.2 Supervises the application of the ergonomics plan.

7.3 Manages change effectively and sympathetically

Unit 8. Evaluates Outcome of Implementing Ergonomics Recommendations

8.1 Monitors effectively the results of ergonomics change implementation

8.2 Carries out evaluative research relevant to ergonomics

8.3 Makes sound judgements on the quality and effectiveness of ergonomics change implementation

8.4 Modifies a design or program in accordance with the results of evaluation, where necessary.

8.5 Understands the principles of cost–benefit analysis for any ergonomics change.

Unit 9. Demonstrates Professional Behavior

9.1 Shows a commitment to ethical practice and high standards of performance and acts in accordance with legal requirements.

9.2 Recognizes personal and professional strengths and limitations and acknowledges the abilities of others.

9.3 Maintains up-to-date knowledge of national strategies and scientific state of the art, relevant to ergonomics practice.

9.4 Recognizes the impact of ergonomics on people's lives.

11. CORE COMPETENCIES IN ERGONOMICS: FULL OUTLINE

11.1. Units, Elements and Performance Criteria

11.1.1. Unit 1. Investigates and assesses the demands for ergonomic design to ensure the optimal interaction between work, product or environment and human capacities and limitations

11.1.1.1.   Element 1.1. Understands the theoretical bases for ergonomic planning and review of the workplace

Performance criteria:

1.1a Understands theoretical concepts and principles of physical and biological sciences relevant to ergonomics.

- Demonstrates a working knowledge of physics, chemistry, mathematics, anatomy, functional anatomy, physiology, pathophysiology, exercise physiology and environmental science as they apply to ergonomics practice.
- Can apply knowledge of biomechanics, anthropometry,

motor control, energy, forces applied as they relate to stresses and strains produced in the human body.

- Demonstrates an understanding of the pathology relating to environmentally or occupationally generated disorders or causes of human failure.

1.1b Understands the effects of the environment (acoustic, thermal, visual, vibration) on human health and performance.

1.1c Understands theoretical concepts and principles of social and behavioral sciences relevant to ergonomics.

- Demonstrates a working knowledge of sensory, cognitive and behavioral psychology and sociology, and recognizes psychological characteristics and responses and how these affect health, human performance and attitudes.
- Can apply knowledge of information intake, information handling and decision making; sensory motor skills, human development and motivation principles as they relate to human performance.
- Understands the principles of group functioning and socio-technical systems.

1.1d Understands basic engineering concepts, with a focus on design solutions.

- Demonstrates an understanding of design and operation of technologies in which they work.
- Appreciates hardware design problems.
- Understands and can apply the basics of industrial safety

1.1e Understands and can apply the basics of experimental design and statistics.

1.1f Understands the principles of organizational management.

- Demonstrates an understanding of individual and organizational change techniques, including training, work structuring and motivational strategies.

1.1g Demonstrates an understanding of the principles of ergonomics and human–machine interface technology.

11.1.1.2. Element 1.2. Applies a systems approach to analysis

Performance criteria:

1.2a Demonstrates a knowledge of the principles of systems theory and systems design and their application to ergonomics.

1.2b Demonstrates a knowledge of the principles of ergonomics analysis and planning in a variety of contexts, and the scope of information required to ensure quality of life.

1.2c Understands the determinants and organization of a person's activities in the field and plans the analysis according to the organization's strategy and purposes.

1.2d Can explain the scientific or empirical rationale for appraisals selected and has the expertise required to perform them.

1.2e Identifies the demands of the situation and accesses sources of appropriate information.

1.2f Develops action plans with those involved and identifies the critical factors of the ergonomic analysis.

1.2g Carries out a systematic, efficient and goal orientated review of demands appropriate to ergonomics, addressing the needs of the project.

11.1.1.3. Element 1.3. Understands the requirements for safety, the concepts of risk, risk assessment and risk management

Performance criteria:

1.3a Recognizes the importance of safety principles, guidelines and legislation in risk management

1.3b Understands the goals of risk management.

- Demonstrates ability to manage change.
- Understands how to gain commitment of management and participation of worker in risk management approaches.

11.1.1.4. Element 1.4. Understands and can cope with the diversity of factors influencing human performance and quality of life and their interrelationships

Performance criteria:

1.4a Understands the organizational, physical, psychosocial and environmental factors which could influence human performance, an activity, a task, or use of a product and knows how to cope with adverse conditions.

1.4b Understands the impact of individual factors on other possible factors and the implications for ergonomic assessment.

1.4c Recognizes those aspects of the environment that are flexible and changeable.

11.1.1.5. Element 1.5. Demonstrates an understanding of methods of measurement relevant to ergonomic appraisal and design

1.5a Understands the type of quantitative and qualitative data required to clarify the basis for ergonomic appraisal and design, and validates the measurements selected for data collection and/or application.

1.5b Demonstrates the ability to carry out appropriate surveillance of the nature and magnitude of risks.

1.5c Selects the appropriate form of measurement for the particular context.

1.5d Applies measurement procedures and uses measurement instruments effectively, or refers appropriately to other ergonomics team members, to quantify load on the person and human characteristics.

1.5e Understands the concepts and principles of computer modeling and simulation.

1.5f Understands the use of the computer for data acquisition, analysis and design development.

11.1.1.6. Element 1.6. Recognizes the scope of personal ability for ergonomic analysis

1.6a Appreciates when it is necessary to consult and collaborate with a person with different professional skills to ensure comprehensive measurement taking and analysis.

11.1.2. Unit 2. Analyses and interprets findings of ergonomics investigations

11.1.2.1. Element 2.1. Evaluates products or work situations in relation to expectations for error-free performance

Performance criteria:

2.1a Determines the demands placed on people by tools, machines, jobs and environments.

2.1b Evaluates user needs for safety efficiency, reliability and durability, and ease of use of products and equipment and how these are met.

11.1.2.2. Element 2.2. Appreciates the effect of factors influencing health and human performance

Performance criteria:

2.2a Has a basic understanding of the mechanisms by which work or prolonged exposure to environmental hazards may affect human performance or be manifested in injury, disorder or disease.

2.2b Defines efficiency, safety, health and comfort criteria.

2.2c Specifies the indicators of poor match between people and their tools, machines, jobs and environments.

11.1.2.3. Element 2.3. Consults appropriately regarding analysis and interpretation of research data

11.1.2.4. Element 2.4. Analyses current Guidelines, Standards and legislation, regarding the variables influencing the activity

Performance criteria:

2.4a Refers to and applies relevant scientific literature and national and international recommendations and standards appropriate to the project.

2.4b Matches measurements against identified Standards.

11.1.2.5. Element 2.5. Makes justifiable decisions regarding relevant criteria which would influence a new design or a solution to a specified problem

11.1.3. Unit 3. Documents ergonomic findings appropriately

11.1.3.1. Element 3.1. Provides a succinct report in terms understandable by the client and appropriate to the project or problem

11.1.4. Unit 4. Determines the compatibility of human capacity and planned or existing demands

11.1.4.1. Element 4.1. Appreciates the extent of human variability influencing design

Performance criteria:

4.1a Understands the influence of such factors as a user's body size, skill, cognitive abilities, age, sensory capacity, general health and experience on design features.

11.1.4.2. Element 4.2. Determines the match and the interaction between a person's characteristics, abilities, capacities and motivations, and the organization, the planned or existing environment, the products used, equipment, work systems, machines and tasks

11.1.4.3. Element 4.3. Identifies potential or existing high risk areas and high risk tasks

11.1.4.4. Element 4.4. Determines whether the source of a problem is amenable to ergonomic intervention

11.1.5. Unit 5. Develops a plan for ergonomic design or intervention

11.1.5.1. Element 5.1. Adopts a holistic view of ergonomics in developing solutions

Performance criteria:

5.1a Identifies the relative contribution of organizational, social, cognitive, perceptual, environmental, musculoskeletal or industrial factors to the total problem and develops solutions accordingly.

5.1b Considers the impact of legislation, codes of practice, Government Standards and industry-based standards on defined problems and possible solutions.

11.1.5.2. Element 5.2. Incorporates approaches which would improve quality of life in the working environment

Performance criteria:

5.2a Provides opportunities for self-development.

5.2b Considers factors influencing the person's sense of satisfaction with the workplace.

11.1.5.3. Element 5.3. Develops strategies to introduce a new design to achieve a healthy and safe work place

Performance criteria:

5.2a Understands the iterative nature of design development.

5.2b Recognizes the practicalities and limitations of applying ergonomics, including the introduction of change.

5.2c Prepares a design specification report based on the systematic analysis to meet the objectives of the project, for use by industrial designers, engineers, computer scientists, systems analysts, architects or other professionals.

11.1.5.4. Element 5.4. Considers alternatives for optimization of the match between the person and the product, the task or the environment and to achieve a good performance

Performance criteria:

5.3a Establishes appropriate short and long-term goals relevant to the defined problems, in consultation with the client.

5.3b Considers the options available and the balance of approaches to be applied, relevant to the objectives.

5.3d Considers the potential benefits and costs of each form of ergonomic solution.

11.1.5.5. Element 5.5. Develops a balanced plan for risk control

Performance criteria:

5.4a Appreciates the background information required for effective risk management.

5.4b Understands how to control adverse physical and chemical conditions and major pollutants.

5.4c Establishes priorities in relation to level of risks identified, and to their consequences for health safety.

5.4d Selects appropriate forms of risk control, based on theoretical knowledge and ergonomics practice and develops a

comprehensive, integrated and prioritized approach for realistic risk control.

5.4e Identifies where assistive devices and aids could enhance compatibility between the person and the environment.

5.4f Considers the needs of special groups (e.g. aging or disabled).

11.1.5.6. Element 5.6. Communicates effectively with the client and professional colleagues

Performance criteria:

5.5a Discusses with the client, users and management the design or intervention strategies available, their rationale, realistic expectations of outcome, limitations to achieving outcome, and the costs of the proposed ergonomics plan.

5.5b Establishes effective relationships and collaborates effectively with professional colleagues in other disciplines in the development of ergonomic design solutions.

11.1.6. Unit 6. Makes appropriate recommendations for ergonomic design or intervention

11.1.6.1. Element 6.1. Understands the hierarchies of control systems

6.1a Recognizes the safety hierarchy, application of primary and secondary controls and the order of introducing controls.

11.1.6.2. Element 6.2. Outlines appropriate recommendations for design or intervention

Performance criteria:

6.2a Utilizes the systems approach to human–workplace integrated design for new or modified systems and understands design methodology and its use in systems development.

6.2b Applies correct design principles to design of products, job aids, controls, displays, instrumentation and other aspects of the workplace, work and activities and considers human factors in the design of any utility.

6.2c Drafts systems concepts for a functional interaction of tasks/technological variants, work means/tools, work objects/materials, work places/work stations and the work environment.

6.2d Develops appropriate simulations to optimize and validate recommendations.

6.2e Outlines details of the appropriate concept and develops specific solutions for testing under realistic conditions.

6.2f Provides design specifications and guidelines for technological, organizational and ergonomic design or redesign of the work process, the activity and the environment which match the findings of ergonomic analysis.

6.2g Is able to justify recommendations.

11.1.6.3. Element 6.3. Outlines appropriate recommendations for organizational management

Performance criteria:

6.3a Understands the principles of total quality management.

6.3b Recognizes the need to design organizations for effective and efficient performance and good quality of work place.

6.3c Recommends changes to the organizational design appropriate to the problem identified.

6.3d Considers issues such as participation, role analysis, career development, autonomy, feedback and task redesign as appropriate to the client and defined problem.

11.1.6.4. Element 6.4. Makes recommendations regarding personnel selection

Performance criteria:

6.4a Recommends personnel selection where appropriate as part of a balanced solution to the defined problem.

6.4b Applies appropriate criteria for personnel selection, where relevant, according to the nature of the demands.

11.1.6.5. Element 6.5. Develops appropriate recommendations for education and training in relation to ergonomic principles

Performance criteria:

6.5a Understands current concepts of education and training relevant to application of ergonomic principles, including encouragement of learning.

6.5b Implements effective education programs relevant to understanding the introduction of ergonomic measures or to the control of potential risks in the workplace, home, public or leisure environments, and to achieve safe and comfortable and successful performance and productive output in new and/or changed activities.

11.1.7. Unit 7. Implements recommendations to optimize human performance

11.1.7.1. Element 7.1. Relates effectively to clients at all levels of personnel

Performance criteria:

7.1a Communicates with the users, management and other professional colleagues in relation to method of implementation of the new design or risk control measures.

7.1b Uses appropriate processes to motivate the client to participate in the recommended ergonomics program and to take responsibility for achieving defined goals.

7.1c Where appropriate, provides individual guidelines for personnel in a form understandable to the client.

11.1.7.2. Element 7.2. Supervises the application of the ergonomic plan

Performance criteria:

7.2a Implements appropriate design or modifications.

7.2b Facilitates the adaptation to new approaches to activity.

7.2c Provides appropriate feedback on progress to client.

7.2d Incorporates methods to allow continuous improvement.

11.1.7.3. Element 7.3. Manages change effectively

Performance criteria:

7.3a In a work environment, where necessary, overcomes resistance of workers, managers and labor unions to change, and gains their cooperation for implementing new approaches.

11.1.8. Unit 8. Evaluates outcome of implementing ergonomic recommendations

11.1.8.1.   Element 8.1. Monitors effectively the results of ergonomic design or intervention

Performance criteria:

8.1a Selects appropriate criteria for evaluation.

8.1b Assesses level of acceptance of and satisfaction with implemented ergonomic measures.

8.1c Produces clear, concise, accurate and meaningful records and reports.

11.1.8.2.   Element 8.2. Carries out evaluative research relevant to ergonomics

Performance criteria:

8.2a Demonstrates rational, critical, logical and conceptual thinking.

8.2b Critically evaluates new concepts and findings.

8.2c Demonstrates a knowledge of basic research methodology for ergonomics research in an area relevant to individual ergonomic expertise.

11.1.8.3.   Element 8.3. Makes sound judgements on the quality and effectiveness of ergonomics design or intervention

Performance criteria:

8.3a Considers the cost effectiveness of the program in terms of financial implication, improvement in productivity, product usability and human requirements for the enhancement of comfort and safety.

11.1.8.4.   Element 8.4. Modifies the program in accordance with results of evaluation, where necessary

11.1.9. Unit 9. Demonstrates professional behavior

11.1.9.1.   Element 9.1. Shows a commitment to ethical practice and high standards of performance and acts in accordance with legal requirements

Performance criteria:

9.1a Behaves in a manner consistent with accepted codes and standards of professional behavior.

11.1.9.2.   Element 9.2. Recognizes personal and professional strengths and limitations and acknowledges the abilities of others

Performance criteria:

9.2a Recognizes extent of own knowledge in ergonomics, appreciates areas where knowledge and skill are lacking and knows what to do and whom to contact to access missing expertise.

9.2b Demonstrates a desire for life long learning, regularly reviews and updates knowledge and skills relevant to current practice of ergonomics, to ensure appropriate breadth and depth of understanding.

9.2c Recognizes those areas of ergonomics where knowledge is limited and consults appropriately with professional colleagues to ensure application of relevant expertise to particular problems.

9.2d Recognizes the value of tem work between multidisciplinary experts.

11.1.9.3.   Element 9.3. Maintains up-to-date knowledge of national strategies relevant to ergonomics practice

Performance criteria:

9.3a Demonstrates knowledge of government legislation relating to occupational health, control of environmental hazards and other areas relevant to ergonomics practice.

9.3b Understands the industrial, legal and liability issues that impact upon professional ergonomics practice, and takes appropriate action regarding them.

11.1.9.4.   Element 9.4. Recognizes the impact of ergonomics on peoples' lives

Performance criteria:

9.4a Appreciates the social and psychological impact of ergonomics investigations.

9.4b Appreciates professional responsibilities and requirements.

Cultural Ergonomics

M. Kaplan, B. B. Morgan Jr,* and J. Kring‡

International Center for Cultural Ergonomics, *College of Arts and Sciences, and ‡Department of Psychology, University of Central Florida, Orlando, FL 32816, USA

1. THE CONCEPT OF CULTURAL ERGONOMICS

1.1. History

The term "cultural ergonomics" was first introduced in print by Kaplan (1991) while formally setting forth many of the field's features. Pioneering contributions by Chapanis (1975) and Wisner (1989) appeared earlier. The environment in which the new discipline began to emerge had been expanded by two relevant factors: (1) concerns for industrially developing countries had been introduced especially by Sen (1984), Shahnavaz (1984), and Kogi (1985); (2) Hendrick's groundbreaking work (Hendrick 1987) on macroergonomics had enlarged the scope of ergonomics by encouraging attention to ergonomically relevant human-human concerns. The concentration on cultural considerations fits into this milieu very well.

1.2. Focal Elements Encompassed by the Concept

1.2.1. The cultural milieux of ergonomics

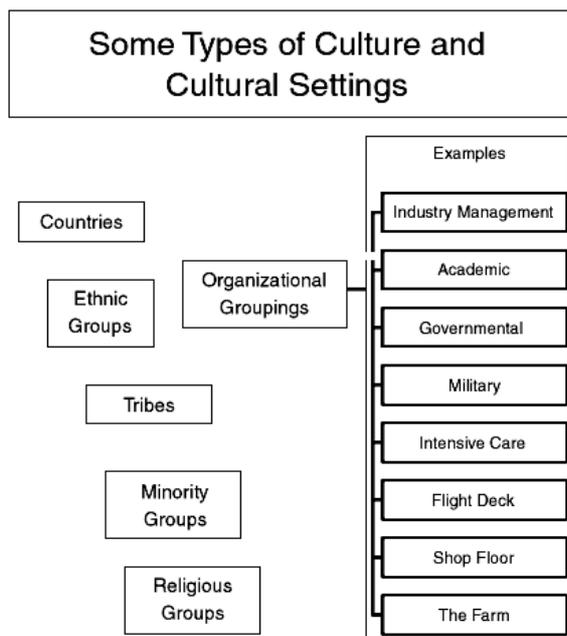
The role of the cultural settings in which work activities occur has been emphasized by Kaplan (1998). Noting the great variety of human groupings, both large and small, in the world's approximately 250 countries (themselves milieus), he argued that "whenever we focus upon a particular example of work, we may speak of the cultural milieu in which it is occurring." Various milieus are shown in Figure 1.


Figure 1. Types of Culture and Cultural Settings
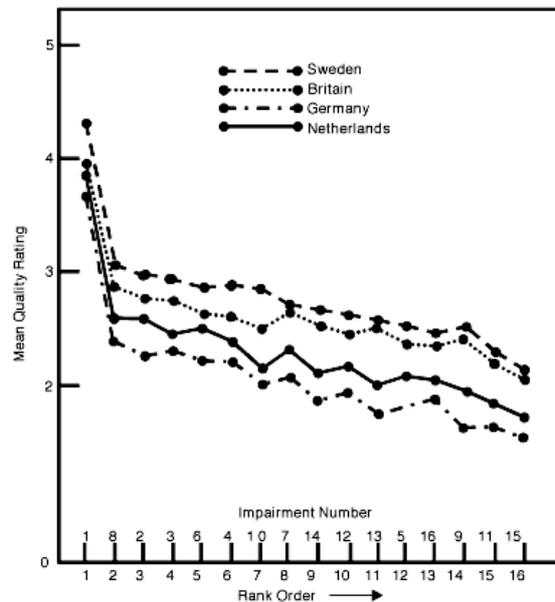

Figure 2. A performance-culture relationship: judgment of picture quality on a monitor as a function of equipment impairment, with country of judges as a parameter (adapted from Gleis and Renhall, 1986; reprinted with permission of Televerket, Farsta, Sweden).

The kinds of human work are many and various. But according to Kaplan, whatever the work, when it is a subject for ergonomic tasking, it calls for recognition of cultural considerations. It was recommended that, when approaching a task, the ergonomist should ask the following questions and, in its execution, take appropriate account of the answers:

- What are the characterisitcs of the cultural milieu in which the work is performed?
- What are the implications for conduct of the work?
- What are accustomed ways of behaving and performing the tasks by the individuals involved?
- What do individuals bring from *their* cultural backgrounds to *this* cultural/work environment?

1.2.2. Human performance and human interfacing

In work environments worldwide, the performance of tasks and, when applicable, the human interfacing that affects the performance are susceptible to cultural influence. This is a central feature of cultural ergonomics, and it applies both to individual performance and to the group performance that is integral to teams and sociotechnical systems. It also gives rise to the notion of culture as an independent variable and as a parameter of functions relating properties of performance to other independent variables that determine them (Figure 2).

More broadly, one may speak of performance-culture relationships, where the performance is occurring in a work environment. Such relationships and pertinent problems requiring solutions and research can be seen throughout topical areas of ergonomics and in relevant aspects of related disciplines such as experimental psychology, industrial psychology, learning psychology, sensory psychology, social psychology, industrial

engineering, business and management, anthropology, and political science.

1.2.3. Cross-national and cross-cultural comparisons

The necessity of developing workable approaches to ergonomic issues with wide-ranging and even global consequences has engendered a need for acquisition and codification of comparative national and cultural information for designing effective and desirable work procedures and programs. Typical areas of concern are (1) international standardization, (2) international variations in occupational health and safety regulations, as in the US National Institute of Occupational Safety and Health (NIOSH) and comparable agencies in other countries, and (3) well-being of workers (International Labour Office 1984).

1.2.4. Ergonomic involvement in critical global-level issues

Extending beyond the confines of discrete cultural settings are problems in which the world itself is the cultural milieu. As enumerated by Moray (1995), they include population pressure, pollution, water shortage, urbanization, food, energy, health and medicine, waste, violence and terrorism, migration, and the clash of cultures. They go beyond usual notions of ergonomics, but Moray sees a role for ergonomics. Arguing that solution of these problems "requires changing human behaviour," he suggests an interdisciplinary approach where "what ergonomics has to contribute to [these] problems ... is essentially a technology for changing behaviours to that which offsets the problems."

1.3. A Summary of Cultural Ergonomics

An integration of the foregoing focal elements, cultural ergonomics is currently regarded as a *coalescence of topical areas* belonging to ergonomics and related disciplines, where each topical area is *susceptible to some form of cultural influence*. It seeks to understand how cultural factors influence and interact with human performance and human interfacing in work environments worldwide. In relation to the cultural settings in which they occur, it explores relevant applied human factors problems and endeavors to design effective solutions for them.

2. TAXONOMY

Given the sizable number and variety of topical areas that are encompassed in the subject matter of cultural ergonomics, there has been a felt requirement for the organization of its content into a workable framework (Kaplan 1998). Here is a proposed taxonomy.

2.1. Categories of Cultural Concern and Culturally Influenced Topical Areas

Comprehensive categories of cultural concern in ergonomics are subdivided into culturally influenced topical areas. Here are the proposed categories followed by some of their topical areas:

- Interaction of cultural variables and standard areas of HFE
  Cultural factors in anthropometry, biodynamics, audition, voice communication, visual perception and displays, controls, human-computer interaction, lighting, temperature, humidity, ventilation, ability assessment, work layout, shift work and hours of work, safety, simulation and training.
- Industrially developing countries and technology transfer
  Analysis of cultural differences with regard to technology

design and utilization (Shahnavaz 1994), ergonomic problems, implementing technology transfer, adapting work procedures to local practices, needed training, adapting training to culture, applying anthropotechnology, using approaches from cognitive anthropology, language and communication problems, shift work.
- Comparative national and cultural approaches to safety issues
  Aviation and aerospace safety; railroad, maritime, and highway safety; local culture influence on the safety culture and power plants; regulation of chemical, gas, biological, and nuclear hazards; safety on the shop floor; industrial safety regulation; international variation in power plant design and safety (Parsons and Taylor 1995); interaction with time of day and performance; attention to age factors; role of abilities and problem-solving facility.
- Organizational design, functioning, and management
  Heterocultural teams and workplace diversity, multinational enterprises, international space station, cultural interactions with macroergonomics and participatory ergonomics, cultural variations in motivators, language and communication in business and industry, modifying products for other countries, modifying work and management procedures for other countries, influence of individualism or collectivism and related dimensions in varied work environments.
- Cultural variation and training needs
  Managing cultural influences affecting students' reactions to cultural or national variations in the teaching of knowledge and skills, adapting teaching to variations in cultural backgrounds, determining and dealing with variations in cultural reactions to simulation training, designing training for harmonious functioning of heterocultural teams, using training techniques from behavior analysis to *rapidly* overcome gaps between deficient skill levels in industrially underdeveloped countries and those required for implementing new technologies, using these techniques to produce the behavioral modifications necessary for resolution of global ergonomic problems (Moray 1995).

3. COMPLEXITY IN CULTURAL INFLUENCE: HETEROCULTURAL TEAMS

When examining performance-culture relationships, it is general to observe discrete cultural factors generating particular performance consequences, as in a foreign language or accent clouding accurate communication between pilot and tower in the English-language environment of air traffic control. Also there are multiple consequences from the heterocultural composition of teams (Morgan *et al.* 1994) and sociotechnical systems. They arise from the involvement of more than one individual and from the interactions generated within these groups.

Attention to cultural and ergonomic concerns in the functioning of teams and sociotechnical systems is of special importance, since they lie at the heart of so many work activities throughout the world, some of them critical for human survival, e.g., air transport, defence operations, and coping with disaster.

3.1. Interactions

Whatever the outcomes of their functioning, whatever the measures of their performance, teams and sociotechnical systems

reflect the contributions of individual members and components. And each individual is exposed to cultural factors. These cultural factors may influence or determine characteristics of the individuals that in turn affect their performance.

Among these characteristics, themselves at least partially *functions of culture*, one can cite aspects of personality; motivation and specifiable incentives to work; knowledge, skills, and abilities; and attitudes toward a variety of concerns, such as authority, other individuals and groups, work requirements, and one's self.

It is a complex undertaking to specify the cultural factors and the ways in which they relate to particular characteristics, and it is equally complex to spell out (a) how these characteristics interact to determine individual performance and (b) how individual performances interact to produce team and system outputs. Systematic research on these matters is indicated.

3.2. Comparative Effectiveness of Heterocultural and Homogeneous Teams

Ultimately, culturally oriented microanalysis may be useful in accounting for the effectiveness of heterocultural team and system outputs. Current examples of these outputs and some cultural aspects of the teams producing them are introduced in the next sections.

3.2.1. Positive consequences of cultural diversity for performance outcome

In some cases of group decision making, heterocultural groups can be more effective than their homogeneous counterparts in identifying problems and generating alternative solutions. Research by Watson *et al.* (1993) showed this effect appearing midway in a 17-week group decision-making task. Each of their heterocultural groups contained a White American, an African-American, a Hispanic-American, and a foreign national from Asia, Latin America, Africa, or the Middle East.

In actual work settings that bring together individuals from different cultures, "groupthink" and its consequences can be avoided in decision-making activities. The quality and diversity of new ideas, as in the management strategy of idea generation and implementation, can be significantly improved by drawing on team members' unique cultural qualities and strengths. A similar positive contribution of diversity is evident in the design of work procedures (e.g., in space walks) and in engineering plans for the international space station, which draw upon specialized experience and resources from 16 nations.

3.2.2. Negative consequences of cultural diversity for performance outcome

Hostility arising from cultural background issues can lead to errors and failures in the execution of team tasks. The international space station provides the setting for potentially serious problems and danger in the interfacing among its crew members. Here are some culturally generated issues that have caused difficulties on short international missions and which have been reported in surveys and interviews: personal hygiene, religious practices, food preferences, misinterpretation or lack of humor, approaches to decision making, refusal to accept alternative points of view (Santy *et al.* 1993, Lozano and Wong,1996).

Cultural variation in the perception of risk is another problem. Research by Vredenburgh and Cohen (1995) showed that com-

pared with Asian subjects, Hispanic, Caucasian, and African-American groups perceived a significantly higher risk in certain situations. Wherever joint participation is required to assure that a dangerous task is accomplished, it could be jeopardized by those team members who, perceiving too high a risk, may be loath to take part. So-called independent and interdependent views of one's self, a function of culture, when jointly represented in a team, may disrupt group performance.

In the independent case, typical of Western cultures, the self is seen as separate from the "social context" and bears little relationship to family, friends, and coworkers. The interdependent case, common to Asian cultures, entails deep involvement with social context (Markus and Kitayama 1991). It has been suggested that where both types are present, independent members might seek to stand out from other team members or promote their own goals over and above the team's goal, thus lessening team cohesiveness and possibly generating conflict.

4. PROGRESS IN CULTURAL ERGONOMICS

4.1. Infrastructure

An International Center of Cultural Ergonomics has been initiated at the University of Central Florida. A central place for channeling information and for communicating among workers and students in the field, it maintains the Cultural Ergonomics Clearinghouse and a website called Culturelink; it also fosters research and educational projects.

4.1.1. Data files

Two sets of files, the *topical area files* and the *regional/cultural area files* have been started within the Cultural Ergonomics Clearinghouse. Their purpose is to organize in a central location both new and hitherto scattered examples of performance-culture relationships associated with the numerous topical and regional/cultural areas. They are intended as a resource for practitioners, researchers, and students.

4.2. Extension of the Taxonomy

Here are some categories of cultural concern that may be added to the taxonomy or given increased attention: (1) human-computer and human-systems interfaces, (2) standardization, (3) ergonomic approaches to aging problems, (4) ergonomic approaches to disability problems, (5) ergonomics and technology of design.

4.3. University Curricula

The first formal course in cultural ergonomics has been introduced at the University of Central Florida along with supervised graduate study in the field. Arguments have been adduced for increasing graduate study and graduate research as part of ergonomics curricula (Kaplan 1998).

Defining Ergonomics/ Human Factors

M. S. Wogalter
Department of Psychology, North Carolina State University, USA
P. G. Dempsey
Liberty Mutual Research Center for Safety and Health, Hopkinton, MA, USA
P. A. Hancock
Human Factors Research Laboratory, University of Minnesota, USA

The focus of this encyclopedia is ergonomics and human factors. The title *International Encyclopedia of Ergonomics and Human Factors* in some respects suggests that ergonomics and human factors are possibly two separate subject areas which are being covered. The conjunctive "and" strongly supports this interpretation. If ergonomics and human factors were synonymous, why not just use one name? Several years ago, the main professional organization of this area in the United States decided to change its name by adding the term ergonomics. They also decided to add the conjunctive "and." It is now called the Human Factors and Ergonomics Society (HFES). If ergonomics and human factors are the same, then why not use a slash instead of the "and" and call it Human Factors/Ergonomics Society? And for that matter why not call this encyclopedia, the *International Encyclopedia of Ergonomics/Human Factors*? It is difficult to pronounce a slash (so it is usually silent), but persons unfamiliar with the field would probably find the slash version even more strange sounding, hearing a string of three words and not knowing if one or two are adjectives. If you are going to keep both ergonomics and human factors in the name — 'and' sounds better. In fact, there is a journal that uses "and", *Human Factors and Ergonomics in Manufacturing.* This journal is edited by the same main editor of this encyclopedia (Professor W. Karwowski).

Many professionals consider the terms ergonomics and human factors synonymous, although others do not necessarily concur. To some, ergonomics has a traditional relationship with the physical aspects of work, while human factors has a greater relationship to cognitive involvement. Ergonomics evolved from studying the interactions between humans and their surrounding work environment (with environment defined broadly to include machines, tools, the ambient environment, tasks, etc.). Use of the term "human factors" tends to be a North American phenomenon with individuals who do work (research, teaching, practicing) that is most concerned with "above the neck" processing (perceptual and cognitive processes, etc.). The rest of the world more frequently use the term ergonomics to include "above the neck" processing as well as "below the neck" processing. In the latter, the areas of biomechanics and physical workplace design are emphasized. The use of the term ergonomics in the United States typically implies "below the neck" activities.

More recently in the United States, ergonomics has been added to names having the label human factors as ergonomics became better known (through mass market public media, such as advertising for cars and chairs). Also the superordinate organization, a level over the national and culture-specific organizations of the field, is called the International Ergonomics Association. Further, all of the worldwide societies use a form of the word ergonomics, not human factors.

Since ergonomics has been more closely allied with the physical aspects of the field, to distinguish it better from the more mental/cognitive part, there has been increasingly greater use of the label "cognitive ergonomics" versus "industrial or occupational ergonomics." Indeed a technical group in HFES has been formed using this name. There is a journal, *International Journal of Cognitive Ergonomics*. One could contrast the name with another journal called the *International Journal of Industrial Ergonomics*, although there is some overlap in subject matter covered in them. We expect to see greater use of the term ergonomics, but we also expect to see people distinguishing between the physical and cognitive sides of the field.

There appears to be a growing consensus that human factors and ergonomics (HF/E) refer essentially to a common body of knowledge. Despite this confluence, we still suffer from a lack of name recognition. The lay public, business, government, and academics generally do not have much of an idea what the field is all about. Most individuals have little problem understanding what established areas like physics, chemistry, mathematics, and astronomy deal with. Like similarly recognized subjects such as history and geography, these areas form the basis of school curricula. The relatively new field of psychology, which is about 100 years old, has become such a well-recognized area that many high schools now offer courses in it. HF/E has this not reached this level of exposure. In fact, exposure to the field is rather scant even for students in colleges and universities. Martin and Wogalter (1987) examined the availability of HF/E courses to college students in the United States. Fifty schools were selected randomly from each of four categories of universities and colleges (research, doctoral, masters, and baccalaureate/liberal arts) from a listing of four-year colleges and universities in the United States. Only 2% (one school) in the sample of liberal arts colleges and only 10% of the master's universities had a course in HF/E. Of the doctoral institutions, 62% had not a single HF/E course, and 44% of the research institutions had no HF/E courses. Other than a brief mention in a back chapter of an introductory psychology text book or of an industrial/organizational psychology text book, most college students have virtually no (or at best, scant) opportunity to learn about the field. This is particularly true if the university does not have an Industrial/Systems Engineering Department.

One obvious and crucial problem lies in the two predominant names that we have talked about above. Human factors is a general, indistinct term; one cannot derive from this name the content of the knowledge domain. A lay person might guess that the field deals with human beings, but they probably would not recognize that it deals with (among other things) people interfacing with technology. Rather, the lay person might expect that a human factors psychologist deals with some special form of therapy, or perhaps, person-to-person interaction (and interestingly, this is one of the few domains that human factors does not address). Also, an engineer who says their area is human factors will also have problems eliciting much understanding by lay persons either.

With the term ergonomics, the problems are different. One is that, unfortunately, the word ergonomics is very close to economics; the two can easily be confused by listeners and

readers. But considering this differently, this resemblance can turned into an advantage as Hendrick (1996a) did in his influential publication entitled "Good Ergonomics is Good Economics."

The "ergo" of ergonomics means work. The breadth of the field could be considered constrained by this prefix. Thus, how "work" is defined is critical. Many people may limit "work" to mean activities associated with employment. This frame of reference would not include leisure pursuits, an area certainly covered by the field's intent. Work can, however, be interpreted broadly, as in its meaning that it involves the general physical expenditure of energy to accomplish a goal. Thus, most of what of humans do (and their bodily processes) could be justifiably considered to be work, and thereby, ergo-related.

But what besides work and the involvement of humans define the field? Whatever the actual name, it should be asked how the area is bound, what is its unique knowledge content, what are its central theses, and how do we provide a concise, succinct statement that characterizes the area? Here, we address the definition question, not simply as another exercise in polemics, but rather as a fundamental evaluation of where our area stands at the start of a new millennium and to distill a way to advance our enterprise to a higher level of societal recognition and value.

One way to examine how an area embraces its domain is to see how it is being represented in various definitions. Definitions reflect how people specify some topic or concept using available language. Terms most frequently used to describe an area's scope

Table 1. Example definitions.

Brown, O., and Hendrick, H.W. (1986)
. . . the relations between man and his occupation, equipment, and the enviroment in the widest sense, including work, play, leisure, home, and travel situations.

Chapanis, A. (1995)
. . . is a body of knowledge about human abilities, human limitations and other human characteristics that are relevant to design

Hancock, P. A. (1997)
. . . is that branch of science which seeks to turn human-machine antagonism into human-machine synergy.

Mark, L.S. and Warm, J.S. (1987)
. . . attempts to optimize the fit between people and their enviroment.

Howell, W. and Dipboye, R. (1986)
Person-machine system design.

Meister, D. (1989)
. . . the application of behavioral principles to the design, development, testing and operation of equipment and systems.

Clark, T.S. and Corlett, E.N. (1984)
. . . study of human abilities and characteristics which affect the design of equipment, systems, and jobs and its aims are to improve efficiency, safety, and well being.

Sanders, M.S. and McCormick, E.G. (1993)
. . . designing for human use.

Wickens, C.D. (1992)
. . . is to apply knowledge in designing systems that work, accommodating the limits of human performance and exploiting the advantages of the human operator in the process.

Table 2. Moderate-length definitions formed from the most frequent terms

(a)	Designing and engineering human–machine systems.
(b)	Applying science to people performing in working enviroments.
(c)	Studying man's limited capabilities relate to safe job operation
(d)	Improving knowledge on the fit between users and tasks.
(e)	The interface between people and machines in systems.

can be a significant source of insight. In the present work, we extracted concise phrases describing HF/E from a previous work (Wogalter et al. 1998) that involved analysis of numerous definitions.

Previously, we took the language from a set of 134 definitions from 78 sources compiled by Licht, Polzella, and Boff (1990), and supplemented them with another 56 definitions from 35 sources of various kinds including HF/E textbooks and brochures, World Wide Web sites, introductory psychology, industrial/ organizational psychology and safety engineering textbooks (Wogalter et al. 1998). Definitions selected were intended to describe the field circumscribed by one or more of the following names: ergonomics, human factors, human factors engineering, and engineering psychology. Some were short, dictionary type definitions (e.g., "the study of work" and "human-machine interface"); other were much longer accounts giving the contents and goals of the field. Example definitions are given in table 1.

In the process of limiting the final list to the most frequently mentioned content words, Wogalter et al. (1998) first stripped the original set of definitions of certain elements, such as connecting words (e.g. the, and, to, which) that were unlikely to reveal meaningful interpretation. Additionally, the basic names designating the field were deleted, e.g. the term "ergonomics" was deleted if it appeared as part of the definition. The terms '"human factors", "human factors engineering", and "engineering psychology" were also deleted when they co-occurred in these specific sequences, but the terms themselves were retained if they occurred in other word contexts and sequences. The remaining terms were then sorted alphabetically. Words with identical prefix roots were combined when the ending/suffix did not change the basic meaning of the word. Words with high frequencies were then used to create definitions of moderate length that express the field of HF/E.

Wogalter et al. (1998) argued that the content words with the highest frequency of mention across the included 134 definitions suggests that they are meaningful components describing the field. By combining these high frequency terms, basic or core definitions of the field can be formed. Moderate frequency terms could be used elaborate the definitions with additional terms that include the methods, goals, and other details. On example is: HF/E involves the application of engineering design to the study and production of safe and efficient human–machine systems. Other examples include Chapanis' (1995) and Wicken's (1992) definitions in table 1. A few additional examples of moderate length appear in table 2.

In Table 3, we have categorized the set of terms in another way. Here there is a small set of categories under the headings who, what, how, when/where, and goal. A quick study of this

Table 3. A short list of terms assigned to a simple category structure describing human factors/ergonomics.

Who	What	How	When/Where	Goal
human	system	engineering	enviroment	safety
people	machine	designing	work	comfort
users	equipment	applying	life	efficiency
person	product	studying		
	technology	optimizing		

categorization undoubtedly inspires a well-suited definition or two. The table also provides a concise set of reference terms for describing our field to others.

Across the entire set of definitions examined in this exercise, the statements reflect a diversity in detail and purpose, varying in how much is given on the field's content, methods, and goals. Sometimes it was difficult to tell whether the wording was actually a definition. Wogalter *et al.* (1998) tended to be liberal in accepting wording as a definition. Under different criteria, some statements would not be considered to be a true definition, but rather a description of methods or goals.

A recent survey and a series of focus groups in the United States (Hendrick 1996b) revealed that one of the primary complaints of HFES members was that untold numbers of people outside the field know little, if anything, about our field. As we discussed at the outset, part of the problem has been our name, but also some of the problem may be that our definitions are not user-friendly. While we formed some of the word groupings and definitions ourselves (which undoubtedly reflect some our own personal biases), they were not produced considering the varied population groups to whom they may be proffered. Using the word lists, a different set of definitions could be formed to target different recipient groups (e.g. lay persons vs. engineering/science experts). In fact, we believe that you can tailor definitions to a specific audience with whom you are speaking to or working.

Technology is a powerful single force that is shaping human behavior. Too often, technology is "mindless" with respect to the individuals who either use it or are affected by it. A small but growing group of professionals seek to mediate between growing technical systems and their human users. As technology become complex, there needs to be even greater efforts in HF/E to enable synergistic relationships. Such an effort will be crucial to the path of true technological progress in the coming years. In order to play its role more effectively, the field needs a clear, concise unequivocal and usable term to describe our efforts. We suspect that the term ergonomics will take that role, along with adjectives of physical and cognitive.

Design

W. W. Gasparski

Institute of Philosophy and Sociology, Polish Academy of Science, Nowy Swiat 72, 00-330 Warsaw, Poland

1. INTRODUCTION

Design (1) is the kind of meta-action (an activity), the supreme purpose of which is a conceptual preparation of change, particularly of other action (actions or systems of them) or any of its elements; (2) the noun "a design" is a description (a pattern) of an artifact thought needed and thus is worthy to be implemented for the purpose of a change; and (3) the verb "to design" is to perform an action (a meta-action) aimed at formulating a design.

In different languages, i.e. in different cultural environments, words of different etymology are used as labels of a concept of design. Let us examine the most characteristic ones.

In English, it is *design* itself based on the Latin *designo* = "to define," "to point out," "to mark," "to form"; and *dissigno* = "to unseal," "to manage." In many languages (whether Anglo-Saxon or not) *design*, taken this time from the English not from the Latin, means "industrial design," i.e. design with an aesthetic flavor, e.g. *disseny* in Catalan, *diseno* in Castilian (Spanish), *estetique industerille* in French. Also, French equivalents for *design* are *dessein*, which means "intention," or *dessin*, which means "pattern" (Polish *deseñ* = decorative design).

Generally, the French ultimate equivalent to design is *conception* from the Latin *conceptio* = "concept," "conception." In Polish and other Slavic languages the label is *projektowanie* based on the Latin *proicio* = "to place something ahead" (like in English "to project a missile"), which is similar to German *projektirung* of the same Latin origin. In both languages "engineering design," especially mechanical one, is labeled *konstuowanie*, *konstruirung* respectively from the Latin *construo* = "to cast," "to arrange." In one group of languages different kinds of design are labeled through using one noun (e.g. *tervezes* in Hungarian) plus different adjectives, while in the other group of tongues different nouns are used. It reflects different beliefs in the unity or disunity of the different kinds of human activity in question.

All languages are unified, however, in one common question, namely whether *design* and *planning* are synonyms (like *suunnitella* in Finnish) or not like (*sheji* = "design" and *jihua* = "planning" in Chinese).

2. PLANNING AND DESIGN

According to Nadler (1981),

> Planning and design are classified together ... because their definitions overlap. The words are often used interchangeably as in "Planning a vacation," or "designing a health care delivery system." No purpose is served by saying that "planning" is open-ended while "design" is specific, or that the former has a longer time horizon, or that the latter is project-rather than program-oriented. Whether it be an architect's blue print, a five-year land-use map, or a family's financial plan, solution specifications are detailed, resource allocations are proposed, innovation is encouraged, and purposes are defined — and this is planning and design.

On the other hand, according to Bunge (1985), design and planning are different, though subsequent, phases of the technological process: "technology may be regarded as the field of knowledge concerned with designing artifacts and planning their realizations, operation, adjustment, maintenance, and monitoring in the light of scientific knowledge."

3. DESIGN AND PRAXIOLOGY

The praxiological point of designing and planning is similar to the Nadler (1981) one, for praxiology recognizes different names for the same kind of human action taken from a methodological point of view. Praxiology, however, accepts traditional names of design/planning-like professions, e.g. architectural design versus urban planning, organizational design versus economical planning, etc. (Gasparski 1993). That position is close to the one expressed by Simon (1981):

> The second state in decision making is to device or discover possible courses of action. This is the activity that in fields like engineering and architecture is called "design"; in military affairs "planning"; in chemistry "synthesis"; in other contexts "invention," "composition"; or that most approving of labels — "creation."

Ecological Approach

J. R. Hajdukiewicz and K. J. Vicente

Cognitive Engineering Laboratory, Department of Mechanical & Industrial Engineering, University of Toronto, Toronto, Canada

1. INTRODUCTION

Over the years many diverse approaches have evolved to study problems in human factors, typically with origins from the field of psychology. This diversification is due to the very large range of problems and multidisciplinary nature of human factors. A number of approaches (e.g. the information processing approach) focus predominantly on the behavior of human operators with less emphasis on the context or environment where work takes place. These approaches may be efficient and useful when work domains are relatively predictable, and tasks are routine and stable. However, many modern work systems are complex, have great flexibility in operation, and have unanticipated situations that require problem solving and appropriate intervention. For these systems, it is important that tasks and actions be considered in the context of the work situation. A relatively new approach based on the ecological perspective accounts for the capabilities and limitations of human operators as well as the context and environment where actions are performed. This approach provides a way of studying human operators, the work environment and their interactions within a single, coherent framework.

The purpose of this chapter is to describe this ecological approach to human factors. The first section presents an overview of the ecological approach, including its foundations and fundamental characteristics. The second section discusses the implications of the ecological approach to human factors in terms of the fundamental characteristics, as well as some examples of how the approach has been applied to human factors problems. The final section discusses the benefits and limitations of the ecological approach to human factors.

2. FOUNDATIONS OF THE ECOLOGICAL APPROACH

The ecological approach is a systems approach for studying the interactions between human organisms and their environment (Meister 1989, Flach 1990, Vicente 1990). The approach has its foundations with the research of Brunswik (1956) and Gibson (1979) in the field of ecological psychology. Each researcher differed in the details of their respective views, but there were a few aspects in common. As a key similarity, both shared the notion that the interaction between the human organism and its environment is at the root of psychology. In contrast, the prevalent view of psychology, referred to as the organismic approach, has been the study of human behavior in relative isolation from its environment (Meister 1989, Flach 1990, Vicente 1990).

Central to the ecological approach are the dual notions that the environment offers the human organism opportunities for action and the human organism adapts to the structure of the environment. These insights are important for studying human behavior, because characteristics of the environment both guide and constrain human behavior. Gibson (1979) referred to these opportunities for action as affordances. It is useful to describe these affordances in relation to system purposes. Thus, affordances are a functional description of the environment relevant to the human operator. As a result, an ecological approach to human factors must start by analyzing the environment and its constraints, relevant to the human operator, before studying human behavior in that environment. This tenet contrasts with the organismic approach, which does not emphasize the importance of the environment, and typically starts by studying human behavior independent of context (Flach 1990, Vicente 1990).

The next section describes the four fundamental characteristics of the ecological approach: reciprocity of person and environment, representative design, primacy of perception, and analyzing the environment first.

2.1. Reciprocity of Person and Environment

Key to the ecological approach is the notion that the human operator and work environment are reciprocally coupled and cannot be studied independently from one another. The coupled interactions between the two form the basis for understanding human behavior. The environment is functionally described with reference to the human operator in terms of affordances or opportunities for action. If the human operator directly or indirectly perceives the affordances, they can guide actions in the environment. In this way, the human operator's behavior is constrained by the environment.

A simple example to illustrate this point, based on a case study by DeSanctis (1984), is the difference between sales graphs and tables as appropriate displays for the human operator. Without knowing the context or task environment in which the information is used and by whom, it is difficult to determine the appropriate display. If the task is to determine a specific sales value on a particular date, tables may be more appropriate than graphs. If the task is to determine the general trend in sales over a range of dates, graphs may be more appropriate than tables. Without considering both the human operator and the work environment simultaneously, design requirements may be erroneous or incomplete. Thus, the reciprocal and coupled relations between the human operator and environment are important, and should form the basis for systems analysis and design.

2.2. Representative Design

The conditions under which one evaluates a design should be representative of the target of generalization in order to have meaningful results. This includes choosing appropriate environments, scenarios, tasks, and human operators. Note that not all aspects of the target environment have to be duplicated, only the ones that are relevant to the problem being studied. Also, careful attention must be paid to the confounding effects of the evaluation that are not representative of the target situation. These effects may produce misleading results that put into question any generalizations of the evaluation. A quote from Toda (1962: 165) gives special emphasis to the importance of representative design. "Man and rat are both incredibly stupid in an experimental room. On the other hand, psychology has paid little attention to the things they do in their normal habitats;

man drives a car, plays complicated games, designs computers, and organizes society, and rat is troublesomely cunning in the kitchen."

In analysis or design, just as much attention should be focussed on representing aspects of the actual environment, as is spent on the people working in that environment.

2.3. Primacy of Perception

Another characteristic of the ecological approach is that information should be presented in a form that allows human operators to exploit the power of their perceptual systems. These systems are more efficient, in terms of energy and time, and less error prone compared with the cognitive processes involved in deduction, analytical reasoning, and problem solving. They are the everyday skills that have been refined through evolution and that are developed in practice. A simple example to illustrate this point is how a person drives a motorcycle. One approach is to let the driver use the sensory information provided by their vestibular senses. This information can be used to directly perceive the dynamics of the motorcycle in the environment and consequently, to act appropriately. Since driving a motorcycle is functionally equivalent to solving a complex set of state equations describing the dynamics of the motorcycle, another approach is to provide the driver with these equations and the tools to solve them indirectly (i.e. via a calculator or other computational tool). Solving the state equations indirectly is a complex and effortful task when compared with perceiving the solutions to these equations directly. Clearly, much is to be gained by taking advantage of actors' perceptual skills.

2.4. Start with Analyzing Environment

The last characteristic of the ecological approach is that the problem should be understood first by starting with an analysis of the environment, before considering actual human behavior in that environment. This characteristic follows from one of the basic tenets of the ecological approach, that the environment has a strong influence on behavior. The parable of an ant's path on a beach by Simon (1981: 64) provides an example of the implications of this characteristic (Figure 1). "Viewed as a geometric figure, the ant's path is irregular, complex and hard to describe. But its complexity is really a complexity in the surface of the beach, not the complexity in the ant."

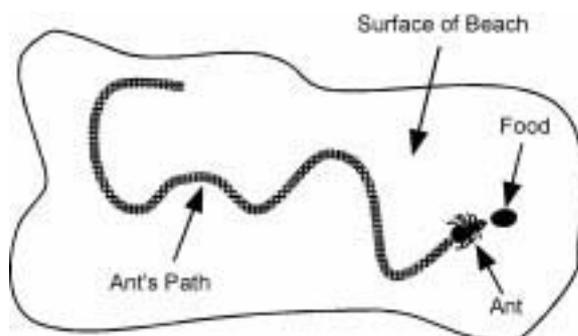
Simon's (1981) parable about an ant on the beach.


Figure 1. Simon's (1981) parable about an ant on the beach.

In the example the beach may be considered as the environment where the ant acts. The ant's cognitive processes may be simple (e.g. move in direction of food and lowest surface gradient). But if the contour of the beach is complex, the ant's behavior (e.g. trajectory) may be viewed as complex. This feature is predominantly the result of the complexity of the environment, not of the cognitive processes of the ant itself.

By studying the environment first, those external influences on behavior may be partitioned from internal influences (e.g. preferences) relevant to the human operator. This characteristic emphasizes the importance of first identifying the work domain landscape and opportunities for action with reference to the human operator, in order to begin to understand human behavior in that environment.

3. IMPLICATIONS OF THE ECOLOGICAL APPROACH FOR HUMAN FACTORS

The increased emphasis that the ecological approach places on the coupling between the human operator and the environment has important implications for the field of human factors. This section discusses some of these implications for analysis, design, and evaluation in human factors, in terms of the foundations and fundamental characteristics previously presented. In addition, the application areas that have benefited from this approach are briefly mentioned.

3.1. Analysis

In terms of analysis, the ecological approach provides a different perspective compared with the organismic approach that has typically been incorporated in human factors. These differences are discussed in terms of human performance modeling and task analysis.

3.1.1. Human performance modeling

With traditional approaches to human performance modeling, behavior is modeled in relative isolation from its context or environment. By not considering the environment and its influence on behavior deeply, analysts may attribute more information processing capabilities (e.g. elaborate mental constructs and processes) to the human operator than actually possessed (Vicente 1990). In Simon's (1981) parable of the ant, the complex trajectory might be explained as the ant having complex psychological mechanisms. In contrast, the ecological approach starts by analyzing the environment relative to the human operator. This tack assists in partitioning accurately those aspects of the environment that influence behavior and the internal mechanisms of the human operator.

Kirlik et al. (1993) provide an example of how an ecological description of the environment can lead to an account of skilled performance in a complex human–machine system. In the study, subjects performed a complex supervisory control task. Kirlik et al. found that it was possible to account for skilled performance in this domain with a model that relied almost exclusively on perception and action. This seems contrary to an organismic perspective that may predict a considerable amount of cognitive processing for the human operator for this task. Therefore, it is important for the analyst first to describe the environment, in order to partition accurately the influences on behavior of the environment and internal mechanisms of the human operator.

3.1.2. Task analysis

With traditional task analysis methods (i.e. organismic approach), analyses typically start with the human operator. The result is typically a description consisting of a single normative sequence of overt behaviors (Vicente 1999). This approach is efficient if the process is routine and predictable. However, there is minimal flexibility to deviate from this path for unanticipated situations. In contrast, the ecological approach starts with an analysis of the environment and narrows the action space by incorporating the capabilities of the human operator. The result is a functional description of the environment consisting of an envelope or field of constrained action possibilities. No single normative sequence of overt behaviors is prescribed. This captures the great flexibility in operation of the system, allowing the human operator to develop efficient strategies for operations, and cope with varying and unanticipated situations. However, this approach requires relatively more autonomy because normative task sequences are not prescribed beforehand.

The difference between the ecological and organismic approaches to task analysis may be illustrated by considering the set of action possibilities for a hypothetical system (Figure 2). With the ecological approach, the boundaries that constrain behavior are identified explicitly. Human operators adapt to these constraint boundaries so trajectories to reach the goal can be determined dynamically and implicitly from any starting position in the action space. In contrast, with the organismic approach, a predefined trajectory to reach the goal is generally identified and made explicit beforehand, incorporating past experience and expert behavior in the work environment. There may be significant limitations in diverting from this prescribed path because the constraint boundaries and other action possibilities may not be apparent to the human operator.

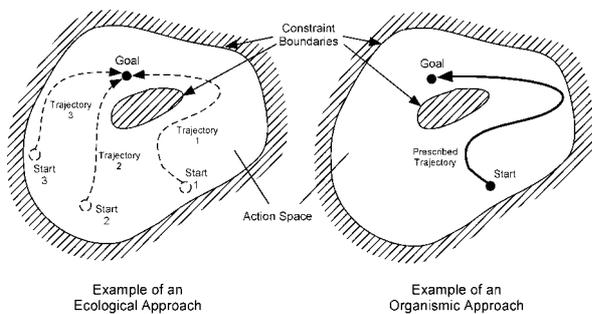
If these constraint boundaries are relatively dynamic, uncertain, or situation-dependent, then the ecological approach may be more appropriate because the human operator may be able to adapt to changing conditions. However, if the constraint boundaries are predictable and stable, the organismic approach may be more appropriate because there may be no need for the human operator to implicitly generate trajectories dynamically. Therefore, it is important to consider the characteristics of system that is analyzed to determine whether the ecological or organismic approaches are most appropriate.


Figure 2. Example of the difference between ecological and organismic approaches to task analysis.

3.2. Design

The ecological approach also provides direction for human factors activities for designing computer-based systems. The goal of design is to develop representations that directly map actual situations in the environment with the human operator's understanding of these situations. The environment relevant to the human operator may be functionally described in terms of interface content and structure. The interface form, a direct or indirect representation of the content and structure, may then be specified to be compatible with the capabilities and limitations of the human operator (e.g. perceptual skills). The emphasis of starting with the environment is critical for design. Before one designs the displays of a system used by a human operator to control the environment, one must know the content and structure of the environment first. Otherwise, the representations developed may not specify the actual environment, potentially resulting in a mismatch between actual situations and the human operator's understanding of these situations. For a detailed account of an ecological approach to interface design for complex systems, refer to Torenvliet and Vicente (1999) on ecological interface design.

3.3. Evaluation

In terms of evaluation, the ecological approach emphasizes the requirement of representativeness to properly evaluate a design. The conditions under which one evaluates the design must be representative of the selected target situation. If not, the differences in the contexts in which behavior takes place (between the evaluation and target conditions) must be addressed. Otherwise, there is a potential for conflicting and confounding results.

3.4. Application Areas

The ecological approach has been applied to a number of very diverse research areas in human factors. One area of human factors has benefited from the ecological approach is the design of interfaces for complex human–machine systems. This area is characterized, in part, as having large problem spaces, dynamic events, a high degree and nested levels of coupling, uncertainty, and disturbances within the environment. The ecological approach is appropriate for this area because it accommodates flexibility in operation, essential for coping with complexity and unanticipated events. Other areas of human factors that have benefited from the ecological approach include human–computer interaction and physical ergonomics design. In addition, wide ranges of application domains have benefited from the ecological approach. These include aviation, command and control, computer programming, engineering design, information retrieval, medicine, process control, and workplace design. For a detailed discussion of a few of these application domains, refer to Chery and Vicente (1999).

4. BENEFITS AND LIMITATIONS OF THE ECOLOGICAL APPROACH

From the discussions above, a number of benefits of the ecological approach to human factors become evident. First, by considering the environment to be as important as the human operator, compatibility and interactions between the two may be realized. Aspects of the environment that influence behavior may be partitioned from the internal mechanisms of the human operator. Second, by analyzing the environment in terms of action

opportunities relative to the human operator, the ecological approach potentially accommodates flexibility to adapt to unforeseen contingencies and recover from errors. These action opportunities allow the human operator to solve problems and generate action paths dynamically and implicitly in the environment based on the actual situation. Third, the display of information is designed to specify the action opportunities in the environment and take advantage of the perceptual systems of the human operator. This potentially provides greater coupling between the human operator and the environment. Fourth, the ecological approach to human factors appears to have a broad scope of applicability across various application domains.

There are a number of limitations of the ecological approach to human factors that are also worth mentioning. First, much effort is required to analyze a system using the ecological approach, because the constraint boundaries and associated action opportunities relative to the human operator need to be determined before design. Second, since no particular sequence of actions is prescribed from the analysis, the human operator may have greater responsibility and autonomy in how the tasks are performed. While this aspect can be beneficial in managing dynamic and uncertain situations, human operators may require relatively more effort to perform routine tasks compared with invoking a prescribed sequence of actions. Third, ecological approaches have not been thoroughly tested compared with organismic approaches (e.g. information processing). Additional efforts are required to evaluate the approach, especially for larger scale systems.

5. CONCLUSIONS

The ecological approach provides a useful perspective for a broad range of human factors problems, especially in domains that have increased complexity, flexibility in operation, and the possibility for unanticipated situations. This chapter has outlined the fundamental characteristics of the ecological approach: reciprocity of person and environment, representative design, primacy of perception, and start with analyzing the environment. These characteristics provide a productive foundation for analyzing, designing and evaluating systems from a human factors point of view.

Epistemological Issues about Ergonomics and Human Factors

F. Daniellou

Laboratoire d'Ergonomie des Systèmes Complexes, Université Victor Segalen Bordeaux, France

1. INTRODUCTION

The reader who browses on the web through the sites of the IEA Federated Societies will find a number of alternative definitions either of ergonomics or of the aims of ergonomics and human factors. These definitions have in common:

- a reference to science
- a reference to "knowledge about the characteristics of human beings"
- a reference to application of that knowledge to the design of "systems and devices of all kinds".

Claims for such a cross-bred identity is not common among scientific disciplines. It may be taken as an invitation to an epistemological examination of the nature of ergonomics.

2. WHAT IS EPISTEMOLOGY ?

Epistemology is the philosophical activity that deals with knowledge and its truth. More practically, as far as science is concerned, the question is to determine the rules and tests that have to be utilized to allow for the use of the word "scientific" to qualify models or theories. There is a unanimous agreement among scientists that not all theories may be called "scientific", but almost none about the nature of the trials they have to undergo to gain this label.

2.1. Major Debates

Major debates are developing in this respect. Let us consider three of them that might be of some importance for ergonomics.

- Some scientists consider that the rules which govern sciences are steady, universal, and complete. They can be used to check the scientific validity of any theory in any discipline. Others dwell on the diversity of disciplines, some of which study "artificially reduced" phenomena in the laboratory (e.g. hydraulics), while others are confronted with irreducible complexity in the field (e.g. hydrology). They argue that epistemological rules have to be reworked within the disciplines, and that this epistemological reflection is one of the tasks of any disciplinary group.
- Some authors consider science as a globally cumulative process, each research adding new knowledge to an age-old construction. Others (Kuhn 1970) describe the history of sciences as a series of crises, turning points, ruptures. New theories do not always encompass former ones, they bring new light on certain topics as well as unexpected shade on others.
- Specific epistemological issues deal with human sciences. Those have to face the fact that human behavior resists prediction. human liberty is not considered as an absence of determinism, but as an ability to rearrange biological, cognitive, psychic, historical, social, cultural contradictory determinisms into new room for action.

2.2. Assessment of Scientific Models

Assessment and validation of scientific models refer to two different processes.

2.2.1 Assessment within the "reduction space"

Scientific models are usually produced in "worlds" the complexity of which has been artificially limited (e.g. the laboratory). In these worlds "perturbations" are avoided. Theories and laws are produced about "pure" phenomena (e.g. friction-free mechanics). The first assessment of theories validates the fact that models relevantly account for phenomena observed under these conditions of reduction. Congresses and journals rally specialists who assume the same "reduction spaces" and have competing theories about them (Latour 1993).

2.2.2 Relevance outside the "reduction space"

No car will ever run according to the laws of friction-free mechanics. This means that there is a need for a second assessment process of scientific theories. This one does not deal with the validity of the model to account for the artificial "world" but with its relevance to describe the real world.

This second assessment process is much less described in the scientific community than the former. One of the reasons for this is that the second assessment may not be carried out only by scientists. Competing scientific models do not only have theoretical differences, they also lead to different industrial or political decisions which have direct effects for the citizens. For instance, alternative models of shift work effects will insist on sleep deprivation or on social life alterations. If labor authorities consider that sleep deprivation models made in the laboratories are more "scientific" than surveys about social life alterations, they may produce laws about shift work that will minimize sleep deprivation, but may lead to severe family or social problems for the workers, who are not just sleepers.

Since competing theories lead to different effects for the citizens, the "second" assessment of theories may not be carried out only by scientists of the same discipline, probably not even by scientists of different disciplines. Processes involving representatives of categories of citizens likely to undergo the effects of theories (e.g. patients, consumers, workers, users) have been described (Latour 1993).

3. UNDERLYING ASSUMPTIONS

Any scientific theory comprises explicit assertions. But it is also based on implicit assumptions on a number of topics, which either the researcher considers as obvious, or the existence of which he/she is not aware. Such underlying assumptions are referred to as "backworld", "paradigm", "underlying assumptions", "beliefs" or "implicit vision". Epistemological approaches endeavor to detect and criticize those tacit assumptions, which are by nature not submitted to assessment.

As far as ergonomics and human factors theories are concerned, such tacit assumptions are numerous. Authors often refer to "work", "health", "improvement" or "technology" without much explicitation of their visions of what lies behind these concepts. Some alternative visions are listed below.

3.1. Models of the Human

Models of the human used by ergonomists implicitly refer to one to four of the following description levels:

- the biological level: the human is considered as an energy processing system (this level includes contributions from anatomy, physiology, biomechanics, biochemistry, toxicology, etc.);
- the cognitive level: the human is considered as an information processing system (this level includes the study of thought processes, representations, optimal decision-making, etc.);
- the psychic level: the human is the subject of a unique history, which has molded his or her personality, leading to a specific subjective processing of the situations he or she experiences;
- the social level: every single individual is a member of several social groups with different cultures, that will partly determine his or her values and habits.

No author would deny the existence of these different levels. In many cases, for the sake of rigor, a research will be framed within one or two of these description levels. In some cases, the authors will discuss what is left aside by not considering the other levels. In most cases they will simply do as if the levels they are using were the only relevant ones.

3.2. Models of Health

Implicit models of "health" can often be found "between the lines" in ergonomic publications.

- Health as the absence of acknowledged pathologies. This common approach does not consider fatigue, discomfort or ill-being as health-related issues, nor does it take into account social dimensions (e.g. poverty).
- Many authors would accept the WHO definition of health, which states that "health is a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity". This vision is much richer than the previous one. Still, it considers health as a "state": you have it or lose it, you are in health or out of health.
- Another model is to consider health as a process: "health is the possibility for every single individual to open up his/her own original way" to the target state described by WHO (Dejours 1995). Health is described here as an ongoing tentative construction (one gets nearer to health or drifts away from it) that can be hindered by situations encountered by the subject. Situations are favorable to health when they give the individuals opportunities to go forward in this construction. Negative situations for health are those which do not allow the individual a way out.

Such different starting points will lead to different descriptions of what should be done to improve occupational health.

3.3. Models of Work

The same diversity will be found about the concept of "work". A first group of differences concerns the levels of description. Most ergonomists would today not describe merely "physical" work — the reference to "cognitive" dimensions (including the so-called "manual" jobs) is now more or less generalized. However, some other dimensions are not commonly considered. For instance, fewer ergonomists will refer to the ethical dimensions of work, to its contribution to the construction of the person's identity, or to its role in the weaving of the social fabric.

A second group of differences is related to the way authors account for, or not, the difference between "what is demanded" of the workers and "what it demands" of them. In many cases, work descriptions are mostly task descriptions: what is considered as "work" is the objectives the worker has to meet (e.g. produce 300 parts a day, stick to quality requirements, adjust the equipment) in given surrounding environmental conditions (heat, noise, etc.). In this sense, work is the same for all workers in a given workplace. Another approach is to focus on work "activity", which is the mobilization of the workers' unique body, intelligence, and personality to fulfill the tasks. This approach will lead to stressing workers' individual and collective strategies to monitor and manage the situation, collect formal and informal information, anticipate incidents and events, cope with malfunctioning and variability, deal with their own variable capacities and limitations. This approach will highlight the fact that operators never only carry out the prescribed tasks, they bring (even apparently tiny) original contributions to the production. There would be no production if the workers stuck to prescribed tasks. Work is not given by formal prescriptions: it is an ongoing personal and collective creation that includes "coping with what is not given".

It appears that work or health may either be considered within one discipline description level, or be described as tentative compromises between resources and constraints falling within the province of different disciplines (see figure 1).

The construction of health and work activity make it necessary for the worker to find resources from different levels to face constraints stemming from different levels or from the outside. Any disciplinary approach makes a section in this transversal process. Work and health are, in a way, "perpendicular" to the fundamental disciplines which study them. One of the challenges for ergonomics is to produce models in which the necessary scientific reduction does not kill the nature of the processes.

3.3.1 Technology

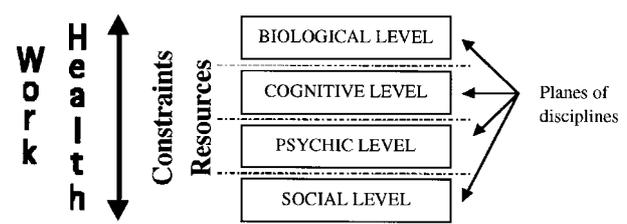
Ergonomists' reference to "technology" may also be based on different backgrounds. In most cases, technology is referred to as the application of scientific knowledge to the design of artifacts. It has to do with physics, electricity, automation, etc. Another approach has been developed by anthropologists (e.g. Mauss, Haudricourt; see Lemonnier 1993) who consider technology in close connection to culture and to choices made by societies. Technology is that gearing through which the human cultural world meshes with the physical world. In this approach the


Figure 1: Health and work as transversal processes

keywords are not "technological progress" but "technological choices".

3.3.2 Organization

Organization is double-faced, but both faces do not have the same weight in ergonomic models. On one side is the organizational structure — charts, work division, procedures, formal rules (but also building lay-out, software passwords, etc.) — that will determine the frame within which the tasks will be accomplished. The second face is the "live" organization made up of the everyday social activity of all actors. There is a double determination between the organizational structure and the "live" organization: at a given instant, the structure largely determines the bounds of actors' social activity. In the long run, the structure can be regarded as an output of this activity. According to what the authors call "organization", they will have different approaches to organizational changes. Will the organization be changed only be designing a new organizational structure? Which kind of interactions between the actors does organizational change require? (Carballeda and Daniellou 1998).

3.3.3 Change

Models of change that can be found in ergonomic publications have different backgrounds. In many cases, the ergonomic contribution to change is an expert one: ergonomists give the scientific position about what is acceptable or not in the workplace. They will prescribe solutions, just like physicians prescribe a medicine: it is strong advice, the legitimacy of which is based on knowledge. It may be taken into account or not, but it is not supposed to be discussed.

Other authors refrain as much as possible from adopting expert positions in ergonomics. Their idea is that changes in workplaces are the results of social interactions between a number of actors (employers and employees, but also customers, suppliers, technicians, administrations, etc.). These ergonomists perceive that they contribute to changes in the workplaces through fostering the social debates and feeding them with specific information. They bring in facts and suggestions, but the actual change will be the results of negotiations between the actors. The ergonomist's contribution in this case is made of indisputable facts and disputable interpretations.

3.3.4 Describing, explaining and understanding

There may be several ways of describing and explaining what is happening in a workplace. In certain cases, the observer analyzes the situation "from outside", using measurements and his or her expert knowledge. In other researches, the workers' opinion is taken into account, by means of questionnaires or interviews.

Ergonomists have mixed feelings about the workers' word: on the one hand, they are usually aware of the importance of taking into account the operator's knowledge, and his or her subjective feelings about the workplace. On the other hand, they know that a number of factors will make it difficult for operators to express themselves about their work:

- a major part of the operator's knowledge is "tacit knowledge" (Polanyi 1983) that can be expressed through action, but that has never been put into words;
- there may be a linguistic difficulty, a lack of relevant words to express what happens in the workplace. In this case, the

workers often answer the observer's questions with something like "it is hard to say";
- workers themselves are caught in socially dominant representations of their own work. A worker may consider that the work is "purely manual work", even if the ergonomist demonstrates a high cognitive load, because the social description of the job refers to manual work;
- last, but not least, the harder the working conditions, the more the workers may build psychological defenses leading them to underestimate the difficulties and risks.

For all these reasons, a number of authors consider that work analysis has to be a joint production of the observer and the observed worker(s). The analyst produces a description and a first interpretation of the situation. The worker may be astonished ("I did not know that I was doing all that"), but he or she will be in a position to comment the description, suggest explanations of what has been observed, and put it in perspective. The "meaning" of work is neither given by the analyst nor by the worker, it comes out as the result of a joint construction.

Any scientific paper in ergonomics and human factors may therefore be questioned as to its underlying assumptions regarding at least the above listed topics.

4. WHICH KIND OF MODELS DOES ERGONOMIC RESEARCH PRODUCE ?

Coming back to the question "Under which conditions may a model be regarded as scientific?", the first point is to identify models of what ergonomic research produces. Two different kinds of models may be found in the results of ergonomic research.

4.1. Models of Operators' Work and its Results

Most of ergonomic research focuses on producing knowledge about the human at work. It may be limited within the frame of a "fundamental" discipline (e.g. physiology, cognitive psychology), or try to give evidence of "transversal" properties of work — for instance, the way a shift worker will organize his or her time takes into account factors such as job content, sleep, food, transportation, social life, family arrangements, life projects.

Knowledge about the human at work may be produced either in real work situations or in the laboratory, where there is an attempt to simulate some of the features of the workplace. In some cases, the research is an iterative process between field studies and laboratory studies.

Methodologies for producing knowledge about the human at work are thoroughly described in the articles of this encyclopedia.

4.2. Models of Change Processes

Another type of model is also dealt with in ergonomic publications. These relate to "work improvement", "change", "project management", or "action methodologies". They do not aim at producing knowledge about the work the ergonomists are observing, but rather about the ergonomists' own work. The question here is "Through which mechanisms can ergonomists improve workplaces?".

- The majority answer to this question in the international ergonomic community is "by applying scientific knowledge". Ergonomics, like engineering disciplines, is considered as an application of science.

- This approach has been thoroughly discussed by Schön (1983), not specifically concerning the ergonomists and human factor specialists, but about all kinds of "practitioners". He calls the first approach "technical rationality": it is dominant in engineering schools and universities: engineers, architects, physicians are supposed to *solve practical problems by applying scientific knowledge.* Schön states that the major challenge for practitioners is to predict the outcome of moves they are likely to make on reality in order to change it. Since we are in complex systems, any move will have expected effects as well as side effects. The practitioners' decision criterion is not "did I get what I wanted?" but "is the result — including the side effects — acceptable?". The practitioner's thought process is based on the availability of media (e.g. drawings) that make it possible to detect the side effects of moves without making them in the real world. This process is described as a "dialog with the situation".

Schön and Argyris plead for a "Theory of practice". Similarly, Latour studies "theorists' practice". Theories of practice are mostly the results of two methodologies:

- one is based on the observation of practitioners or theorists by a researcher, who studies their work as he or she would do with any other worker;

- the other one is "reflexive practice". Here, the researcher is involved in action, as an ordinary practitioner. He or she keeps records of the initial hypotheses, the events that occur, the decision making processes, the assumptions made throughout the intervention. Some of the final results are similar to the initial expectations, while some differ. An a posteriori reflexive position leads the researcher to question the underlying assumptions that have led to unexpected results, and enrich or modify the initial model. The assessment and validation of the new model, as to its predictability value, will be made in further projects by different researchers.

4.3. The Ergonomist as a Worker

In the model of "applied science" the ergonomist is the representative of knowledge about human work. He or she may have difficulties in the field, but their own activity is not considered an object of interest for scientific description.

In the models of "theories of practice", the ergonomist is regarded as a worker whose skills and difficulties have to be analyzed and modeled (in terms of new knowledge) in order to foster action in workplaces.

Such research programs are well known as regards theory of medical practice (Balint) or of ethnographical practice (Devereux). When analyzing the ergonomists practice, attention may be paid to their decision-making processes, their negotiation skills, their interactions with different actors, the kind of power and responsibilities they take on, the ethical problems they encounter, the human costs they go through, the psychic defenses they interpose to stand hard situations. Such models are extremely helpful to teach and train young ergonomists, not only through delivering them basic scientific knowledge.

5. KNOWLEDGE AND ACTION

The attempts of ergonomics to produce scientific knowledge encounter epistemological difficulties that are not usually found in one single discipline:

- ergonomics deals with technical devices and human beings in systems where the "laws" are of different natures;
- it is oriented towards action in real situations;
- it takes on both health and efficiency issues;
- it deals with social situations which raise all the questions of liberty and power struggle;
- it deals with complex systems characterized by non-linear answers, uncertainty about the initial state, variations in the context and the number of influencing factors;
- as a design discipline, it has to do with "things that do not yet exist", the existence of which is both a matter of technical feasibility and political will;
- it is continuously facing ethical dilemmas (what is an acceptable workload?);
- one of the way it uses to produce knowledge about the phenomena is by changing them (knowledge through action).

These features may be considered as weaknesses, that affect the possibility for ergonomics to be regarded as a scientific discipline. Or they may be taken as an opportunity for ergonomics to take part, with a head start over other disciplines, in epistemological debates that are developing about the relations between science and action in complex systems. Its strengths are the reciprocal of its weaknesses: work situations involve a number of constraints that no researcher would dare to impose in the laboratory. Ergonomists have learnt by and by to find ways out in extreme situations. The knowledge they have developed is continuously put to the test of real situations.

Two conditions are probably at stake in the possibility for ergonomics to be regarded as an "epistemologically leading discipline":

- the need for the ergonomic research community to take epistemological issues in earnest and tackle them in their congresses;
- the quality of the relations between ergonomics research and ergonomics practice, and their ability to act as *reciprocal* suppliers.

Ergonomics in the Nordic Countries

T. Ivergaard

Nordic Ergonomic Society (NES), Arbetslivsinstitutet, PO Box 610 (Frosostrand hus A), S-832 23 Froson-Ostersund, Sweden

Thirty years ago, the Nordic Ergonomic Society (NES) was established to represent Denmark, Finland, Norway and Sweden within the fields of Ergonomics and Human Factors. In recent years, the ranks of the NES have been enlarged through the inclusion of Iceland as a formal representative, as well as with the establishment of closer links with the Baltic countries, i.e. Estonia, Latvia and Lithuania. Over the years, national ergonomic societies have been established in all of the NES's member countries — Danish Society of the Work Environment (SAM), Finnish Ergonomic Society (ERY), Icelandic Ergonomic Society (VINNIS), Norwegian Ergonomic Society (NEF), and Ergonomic Society of Sweden (ESS).

The NES has, to a large extent, traditionally been oriented towards work-physiology and a large number of its members have backgrounds within such areas and work within physiology, physiotherapy and rehabilitation. However, even from its inception, the society has had members who are experienced within such fields as work psychology, design and engineering, and occupational health and safety.

Over the past decade, the NES also has had new members from such areas as work sociology, organisational psychology, leadership and training. Members have mainly been concerned with the application and practice of ergonomics. The number of members involved in research has also increased over the years. The principal areas of application for such research have been within industry and government.

As regards membership figures for each respective society, these are:

- Denmark — 908 members.
- Finland — 230 members.
- Iceland — 82 members.
- Norway — 177 members.
- Sweden — 226 members.

In total, the NES has 1623 members.

In conclusion, it should also be noted that in accordance with European Ergonomic Standards, a professional licensing function is attached to the NES.

The European Union's Policy in the Occupational Safety and Health Sector

P. Batra and A. Hatzopoulou
National Technical University of Athens (NTUA), Department of Humanities, Social Sciences and Law, Zografou–Athens, Greece

1. INTRODUCTION

Nowadays, the European Union plays a dominant role in the formation of Occupational Safety and Health (OSH) law frame and policy worldwide. The Community's policy in this sector has come through several stages that almost coincide with its stages of evolution. The purpose of this article is to record this evolution and investigate its impact on the improvement of health and safety conditions in European work sites.

2. THE TREATIES ESTABLISHING THE EUROPEAN ECONOMIC COMMUNITY

The forerunner of the European Union (EU), the European Economic Community (EEC), was established in the 1950s with three treaties:

- The European Coal and Steel Community (ESCS) Treaty, signed in Paris in 1951
- The European Community Atomic Energy Authority (EURATOM) Treaty, signed in Rome in 1957
- The European Economic Community (EEC) Treaty, also signed in Rome in 1957

The European Union (EU) was established by the Treaty of Maastricht in 1992, and modified by the Treaty of Amsterdam in 1997.

Historically, the European Coal and Steel Community Treaty was the first international economic agreement to include occupational safety and health provisions. The reason for this inclusion was the high number of employees in the coal and steel sector and the accompanying high number of occupational accidents and diseases in these industries. Following an accident in Belgian mines in 1956, which caused the death of 262 coal miners, the European Coal and Steel Community Council established a Permanent Committee for Safety in Mines. The main tasks of this tripartite body (2 governmental, 1 employer, and 1 employee representative from each member state) are the monitoring of safety conditions in mines, making proposals for safety improvement, and the dissemination of related information among the member states. The work of this committee over the years has been very beneficial and resulted in the reduction of the number of accidents in European mines.

The main remit of EURATOM was the development of the European nuclear industry along with safety conditions that would ensure the exclusion of hazards to the lives and health of Europeans and the promotion of works of peace. To achieve this scope, many restrictive processes were foreseen in the text of the treaty. The first Occupational Safety and Health directive adopted in 1959 concerned the protection of the public and workers from radioactive radiation.

3. THE PERIOD 1957–1986

In addition to the coal and steel industries, once established, the EEC turned its attention to OSH matters in other economic sectors. Although the main scope of the Treaty of Rome is the single European market, there are social policy references in Articles 117–128. Articles 100 and 118 were the legal base for the adoption of legislative and non-legislative measures in the OSH sector. These articles formed the most important base of the EEC Treaty for the adoption of legislation relative to this area. This provision has more commercial initiatives than social, since the differences in the laws and regulations among member states are factors that stop the free trade of goods and the mobility of people.

During the first 30 years of its existence, the EU aimed at the approach of the member states' legislation for the withdrawal of these barriers in a sequence of different issues affecting OSH. Article 100 refers to the approach of the clauses that directly affect the operation of the Common Market and provides the issuing of relative directives. Article 118 refers to working conditions and the prevention of occupational accidents. The limited authority in the social sector that was originally given to the bodies of the EU was aimed at limiting any misuse of the rules of competition within the Common Market. It was considered certain that the anticipated economic development would automatically result in social progress.

The EU's roles are very important, especially those of the Directorate General of Employment, Industrial Relations and Social Affairs (DG V), which is relevant to OSH matters. The DG V has initiated many directives, regulations, resolutions, and recommendations covering a wide range of OSH issues, always following the scientific and technological progress as well as the social and economic needs of the European workers and the evolution of the EC itself. The Committee, in performing its aims, is consulted by the Advisory Committee of Safety, Hygiene and Health Protection at Work, the Economic and Social Committee, and the European Foundation for the Improvement of Living and Working Conditions sited in Dublin. All these organizations have achieved a high scientific level of decisions through elaborate positions and social dialogue.

The Advisory Committee for Safety, Hygiene and Health Protection at Work was established in 1974 by a Council decision. The composition of the Advisory Committee consists of two governmental representatives, two employers' representatives, and two employees' representatives from each of the member states, and its responsibilities are:

- The exchange of information and experience in the field of OSH connected with existing legislation;
- The facilitation of cooperation among national management and syndicated organizations of employees and employers;

- The discussion of problems and the proposal of solutions applicable on a community scale;
- The examination of scientific progress and consultation with the European Committee.

Its common finding is that the Consultant became an active player in the issuing of documents of a scientific, technical, and political nature and he/she is vital in outlining policy in the field of OSH.

The European Institute for the Improvement of Living and Working Conditions, sited in Dublin, was established in 1975 as a specialized and autonomous organization of the Community. It is responsible for the applied research in the fields of social policy, the implementation of the new technologies, and the improvement and the protection of the environment. It has carried out programs concerning safety and hygiene, promotion of health, dangerous waste, sequences by the new technologies, participation of the employees, and shift work.

Until 1992, a landmark year for the realization of the internal market, the Community issued three action programs in the field of OSH. The first action program was about the period 1978–1982, during which the framework directive was issued for the protection of the employees from dangers related to their exposure to chemical, natural, and biological factors at work. In the same period, special directives were adopted which limited the exposure of employees to lead and asbestos, and where for the first time the role of the employees' representatives was recognized, and also a directive for taking measures against dangers from major industrial accidents. The second action program was about the period 1984–1988 and the main directives issued at that time included one concerning noise and another which forbids the production and use of four chemical substances particularly dangerous to the health of the workers.

4. THE SINGLE EUROPEAN ACT

The difficulties and delays for the completion of the EC policy in the field of OSH must be attributed to the inadequacy of the legislative base before 1986 — namely, the fact that the social policy clauses required unanimity for taking decisions. This gave minorities the opportunity to hold back the proposals of the Commission. By the Single European Act in 1986, and especially Articles 100 and 118, the Treaty of Rome was modified to what is related to OSH. The important change is the institution of minimum specifications for the working environment and the making of decisions in the Council by relative majority.

These changes directly affected the third action program 1988-1992, which was ruled by the philosophy that OSH cannot be considered in the light of financial terms alone, but must also take into account social terms. During this period, among the important legislative work that was completed, the framework for directive 89/391/EEC has a dominant position. This directive introduces the innovative elements of the "occupational risk self-assessment" and the adoption of social dialogue in OSH matters in enterprises. It also establishes a new legislative strategy, which is based on a general law frame with a wide field of application, completed by special arrangements in aiming at the special workplaces and working conditions be covered. The third action program was completed in 1992 with the celebration of the European year for the safety and health at work.

A field of community activities that is directly connected with OSH, but which is also an indirect way of restraining the free trade of goods, is the different national standards by which these goods are produced. In order to withdraw the barriers to transactions resulting from this, the Council established the procedure of information in the field of technical standards and specifications (Directive 83/189/EEC), which ensures the full information of the Committee for everything that happens in this field in every member state. Moreover, it instituted a procedure for the adaptation of fully compatible European and national standards, which are a result of mutual information and cooperation of the National Organizations of Standardization. This procedure is a new approach in the area of standardization and is based on the directives of technical approach, which led to harmonized European standards. In the context of the European Organizations of Standardization, technical committees are operating to examine groups of standards, many of which are related to OSH. Likewise, a great number of the directives of technical procedures and the standards, which are related to them, are connected with OSH issues (directives for low voltage machines and personal protection equipment).

The role of information is also important, not only to the social partners and to the greater population, but also to the members of the Commission. For the wider communication of the former, the Community has issued many informative editions in all the Communities' languages and also publishes the quarterly journal *Janus*. The information campaign reached its peak during the European year of OSH. There is a special committee composed of specialists in every member state for the dissemination of information to all members of the Commission about the progress of harmonization in the directives of minimum specifications. Additionally, special scientific committees are operating for the collection of national statistics on work accidents and occupational diseases.

5. THE SOCIAL CHARTER AND THE MAASTRICHT TREATY

In the 1980s, the "social space" concept was a sheer change from the "market" concepts that were dominant in 1970s. It was determined that the single market should not only be an area of free trade, but also a unified social area where the economic and social cohesion was to be safeguarded. These ideas were confirmed in the Social Charter, which covers twelve categories of fundamental social rights. Some of them are indirectly related to occupational safety and health issues: improvement of living and working conditions, social protection, informing and participation of employees, protection of children and teenagers, aged employees, disabled persons. There is also a special section referring to the safety and health of the employees, highlighting certain initiatives. In the early 1990s, the notion that employees' health and safety is an important part of the social dimension and an integrated aspect of the internal market's realization began to dominate.

The period from the institution of the European Community until the adoption of the Social Charter of the workers' social rights was characterized by the production of legislative work that aimed at the completion of the Common Market. In the 1980s, the notion was emerging that, if the social component was not developed in parallel, there was a risk of torpedoing economic development as well. The policy in the field of OSH

since the early 1990s is a reflection of the new social concepts that have slowly appeared on the European scene. This period is characterized by the undertaking of non-legislative measures aimed at the wide dissemination of information and the training of employers, employees and citizens in general, which are developing in parallel with the legislative action that is now focused on assuring the minimum acceptable working specifications.

In 1992, the treaty for the institution of the European Union, which changed the Treaty of Rome, was signed in Maastricht in the Netherlands. According to this, the twelve member states instituted a European Union, marking a new stage in the construction of the community. The changes introduced by the Maastricht Treaty in the field of OSH are more indirect than direct. They are expressed mainly in the "Protocol of Social Policy" that was appended to the treaty and is the commitment of the eleven signing countries (with the exception of the United Kingdom) to promote a more progressive policy in the social field. Some of the areas of responsibility that have been added by the main body of the Treaty are:

- Social protection, the raising of living standards, improvements to the quality of life, and protection of the environment;
- Policies in the social and environmental fields;
- Rules of the internal market that are related to the protection of OSH, the environment and consumers, who are dependent on a high level of protection.

In addition, articles that concern the protection of public health, the protection of consumers' health, security and economic interests, and the protection of the environment were embodied in the EEC Treaty. A small number of posterior directives are based on these articles, which are supplementary to the main OSH directives.

In 1993, the Commission produced the "Green Paper on the European Social Policy", which has explicit references to issues about the safety and the health of the employees. The issue of minimum common standards in working conditions is of great importance as they are directly connected to the issues of competition and social dumping. The will of the Commission to continue its action in the field of OSH, based on the existing directives, is ensured. The Community legislation continues to hold a dominant position in the securing of minimum specifications for health and safety to all European workers. However, at the same time, the notion has been realized that legislation is not the only way for the institution of social rules to be expressed, but that attention must be paid attention to the agreements arrived at among the social partners. Apart from the standards, the rules, the collective agreements, the definition of rights and responsibilities, oral and tacit behavioral rules are needed for the reduction of conflicts. The main thing contribution needed towards this direction is the unobstructed cooperation of the member states, the European Parliament, and the social partners. The idea that improvement of working conditions means increasing the production costs is considered played out, and, what is more, untrue. On the other hand, the Community shares the view that the improved safety and health of the workers leads to the reduction of production costs through reduction of accidents and diseases. In addition, statistics show that within the EC 10 000 000 work accidents and/or occupational diseases

occur every year, 8000 of which are fatal. The annual cost of these in compensation is estimated at 26 billion ecus, without including the indirect cost, which is not viable for the economy in general.

In Bilbao in 1994, the Community set up the European Organization for Safety and Health at Work as an additional means for the provision and distribution of technical and scientific information. The organization's aims are:

- The collection and distribution of OSH information among the member states;
- The diffusion of research results;
- The organization of educational seminars;
- The development of close bonds among specialized organizations of member states;
- The provision of technical and scientific help to the community bodies.

Other non-legislative actions that characterize the last decade of the twentieth century are the issuing and continuous updating of the European catalogue of occupational diseases and, among the member states, the exchange of public servants who are in charge of controlling the implementation of Directive 89/391/EC.

6. THE AMSTERDAM TREATY

By the end of the millenium, the Community aimed to complete the "General Framework of Action of the Commission of the European Communities in the Field of Safety, Hygiene and Health Protection at Work (1994–2000)". The legislative and non-legislative measures that the Community is going to take in the field of OSH by the end of the year 2000 are reported in this document. Matters that demanded special attention in this period were: transfer of issued directives to member states, small and medium-sized enterprises, social dialogue, information and training of employees, international cooperation and non-legislative measures. The program of non-legislative measures with a view to implementation is focused on eleven special actions the realization of which requires decisions from the Council and the Committee. Currently, decisions have been issued for the composition of the Superior Work Inspectors Committee, the scientific committee for the limits of exposure to chemical substances during work, the SAFE program, and the OSH European week which has been celebrated in the three successive years 1996–1998.

In June 1997, a revision to the Treaty of the European Union was made by the Treaty of Amsterdam. This revision takes into account the tremendous challenges which the Union has to deal with at the start of the twenty-first century. These can be epitomized in the globalization of the economy and its effects on occupation, emigration pressures, ecological imbalances and threats to public health, especially in the view of the widespread of drugs and AIDS. The Union is called on to deal with these issues by the provision of its proposed enlargement. With the Treaty of Amsterdam, substantial changes occurred, especially in social policy, but also to other policies that are related to OSH. After the signing of the Protocol for social policy by Great Britain in May 1997, this was embodied in the Treaty, thus establishing a coherent and effective legislative framework for the community to undertake action in this field. The more important changes, which are related directly or indirectly to the OSH field, are:

- Measures of harmonization, related to the protection of OSH,

the environment and consumers, which are recommended by the Committee, the Council or the Parliament, have to take into account the new scientific data.

- The Community and the member states must take into account the fundamental social rights and aim for the improvement of living and working conditions, social protection, social dialogue and the development of human resources.

The Community supports and complements the activities of the member states related to the improvement of the working environment. To this end, the Council, unanimously and after consulting with Economic and Social Committee and the Committee of the Regions, institutes through directives the minimum specifications of the working environment. Such directives shall avoid imposing administrative, financial, and legal constraints which would hold back the development of small and medium-sized enterprises. The member states can maintain or institute stricter national clauses, which reconcile with the other clauses of the treaty: namely, they do not impact the clauses of competition. They can, as well, assign the implementation of the relevant directives to the social partners, provided that is a mutual request and until the date of harmonization have taken the necessary measures through agreements.

The Commission shall have the task of promoting consultation among the social partners at a community level and shall take any relevant measure to facilitate their dialogue. To this end, before submitting proposals in the social policy field, the Commission shall consult social partners on the possible direction of Community action.

The social dialogue may lead to the establishment of conventional relations, as long as the social partners want so. The agreements made at a community level are implemented in the OSH field, when it is mutually requested, by the signing of parties and the Council's decision taken with qualified majority, and after the Commission's proposal.

The guarantee of a high level protection for the health of man must exist in all community policies. The reference to drugs is more intense. Indirect reference is made for the prevention of AIDS.

The demands for the protection of the consumers are taken into consideration for the determination and implementation of other community policies and activities.

The last few years have been characterized by the growth of harmonization among the member states of the Community directives, which have been issued according to Article 118 and by its modification of the fundamental directives in the light of scientific and technological progress. The path of the OSH structure will be concluded in a different environment, implied by the Amsterdam Treaty, the beginning of negotiations for the enlargement of the Community, and the changes in working conditions (for example, resulting from an increase in the number of aged and women workers, and new forms of occupation). In this light, efforts must be focused on the effectiveness of legislation, preparation for the EU's enlargement, the strengthening of the occupation and the focusing on new working hazards.

7. CONCLUSIONS

The experience acquired in the field of OSH to date can be utilized as a guide for the future. The basic principles have been founded and consolidated, eliminating regressions. Social dialogue is a practice that is going to be implemented more and more in the OSH field, since this was used in the first stages of the EU with great success. The institution of minimum specifications for the working environment with directives and the elaboration of European Standards compatible to them is another stabilized method. The new living and working conditions which may emerge in the Europe of the twenty-first century may change the traditional system of occupational health and safety that is currently practiced. The only sensible way forward, not only in order to sustain it but also to adopt new data, is by the creation and establishment of unified "social space" as a first priority of the European Union, and not as a supplementary to the Common Market.

1. INTRODUCTION

1.1. Aim

This consensus document, while taking into consideration the most recent and significant contributions in the literature, intends to supply a set of definitions, criteria, and procedures useful to describe and, wherever possible, to assess the work conditions that can represent a physical overload for the different structures and segments of the upper limbs. The consequences of physical overload are represented by work-related musculoskeletal disorders (Hagberg *et al.* 1995).

The document is aimed at all the operators, i.e. occupational doctors but mainly technicians, who are, or will be, involved in the prevention of work-related upper limbs musculoskeletal disorders.

From this point of view, the document intends to provide methods and procedures (for an exposure assessment) easily applicable in the field, not requiring sophisticated instrumentation and, when possible, based on observation procedures.

The proposed methods shall be based as far as possible on knowledge and data from scientific literature: when these are contradictory or deficient, reference will be made to standards or pre-standards issued by national and international agencies and bodies, with the experience of researchers involved and common sense.

From time to time it shall be clarified on which (more or less consolidated) basis the different result analysis and interpretation procedures are proposed.

The "guiding principle" that brought about all the choices reported in the document can be summarized in a few lines of the International Code of Ethics of Occupational Health Professionals prepared by the International Commission on Occupation Health (ICOH 1992) "Special consideration should be given to the rapid application of simple preventive measures which are cost-effective, technically sound and easily implemented. Further investigations must check whether these measures are efficient and a more complete solution must be recommended, where necessary. When doubts exist about the severity of an occupational hazard, prudent precautionary action should be taken immediately."

Potential users increasingly demand an easily applicable method for description and assessment of work with repetitive movements, avoiding the risk of "trying to measure everything", "interpreting little" and "changing nothing".

In Europe this is a result of the new legislation (particularly, European Economic Community (EEC) directive 391/90/CEE) which requires employers to evaluate work hazards in their companies and reduce them if necessary. The European Union's "Machine Directive" also deals with this topic, by introducing the need to provide machine designers and manufacturers with easily applied methods with which to evaluate potential health risk factors connected with using these machines.

The group intends to give a response, even if there are still uncertainties from a strictly scientific standpoint; however, the group commits itself to perform subsequent validations especially of as yet unconsolidated issues. Therefore, what is proposed is not a "rigid pattern" but, once some reference points have been

set, it is intended as a dynamic tool able to seek in time the best point of equilibrium between knowledge from research and application requirements.

This document focuses specifically on identification of risk factors and describes some of the methods that have been developed for evaluating them. There is a rapidly developing body of literature on job analysis and as yet no agreement on a single best way to analyze jobs. It is the committee's belief that the appropriate methods depend on the reason for the analysis, e.g. walk through inspection, evaluation of a specific tool or work method, or analysis of a problem job. The appropriate methods will also vary from one work situation to another, e.g. office where workers are performing keyboard tasks or foundry where workers are using powered grinders. Professional judgement is required to select the appropriate methods. Analysis and design of jobs should be integrated into an ongoing ergonomics program that includes management commitment, employee involvement, hazard identification and control, training, health surveillance, and medical case management.

The aim of this section is not a complete overview of the literature. It simply intends to direct readers towards such studies that represent essential contributions for the operational choices which are then suggested by the authors of this study.

In 1987, C.G. Drury (Drury 1987) discussed a method for the biomechanical assessment of pathologies due to repetitive movements, and focused on three main factors (force, frequency, and posture); he suggested a description and assessment method which counts the daily number of "hazardous movements" for the body, and particularly for the wrist.

In 1988, V. Putz Anderson published an interesting book in which he systematically listed all the practical and theoretical knowledge, which was available at the time, on the control and management of cumulative trauma disorders (CTDs) (Putz Anderson 1988). Amongst other things, the book postulates a "risk model" for CTDs, based on the interaction of four main factors: repetitiveness, force, posture, recovery time.

In 1986—7, Silverstein, Fine and Armstrong (Silverstein *et al.* 1986, 1987) highlighted the connection between repetition and force risk factors and Cumulative Trauma Disorders (particularly Carpal Tunnel Syndrome). They also threw light on the fact that there is a synergistic mechanism between the two factors under consideration.

In 1992, Winkel and Westgard suggested some guidelines for the study of occupational risk factors — and of individual ones — related to alterations of the cervical and scapulohumeral region (Winkel and Westgaard 1992).

In 1993, a large group of authors who were part of an ICOH working group, mainly Scandinavian and American, presented a conceptual model for the interpretation of the development of occupational musculoskeletal disorders of the neck and upper limbs (Armstrong *et al.* 1993).

Again in 1993, Tanaka and McGlothin, two NIOSH researchers, presented a conceptual model for the study and prevention of the occupational carpal tunnel syndrome (CTS) (Tanaka and McGlothin 1993). In their method, the exposure limit required is determined by the repetitiveness of movements, by the force used, and by the postural deviations of the joint involved, the wrist in this case.

In 1993, McAtamney and Corlett proposed the Rapid Upper Limb Assessment (RULA) method (McAtamney and Corlett 1993) in which upper limb risk exposure was evaluated using a simple description of the posture, force, and repetitiveness of the muscular action. They also proposed a procedure to calculate a synthetic index.

Guidelines for "practitioners" were presented and discussed by Kilbom in 1994, for the analysis and assessment of repetitive tasks for the upper limbs (Kilbom 1994).

This is an extremely important review, both theoretically and practically, and supplies useful suggestions both for the definition of repetitive tasks, and for the classification of the different issues to consider during analysis.

Frequency of movement is pointed out as being of particular importance for the characterization of risk. For each body region (hands, wrist, elbow, shoulder), indications are given on the frequency limits of similar movements showing a high risk for upper limb injuries where such frequencies are exceeded.

With respect to action frequency, the existence of other overloading factors (high force, high static load, speed, extreme postures, duration of exposure) is considered as being an amplification of the risk level.

In 1995, the contributions of a qualified panel of authors were summarized in a volume devoted to work-related musculoskeletal disorders (WMSDS) (Hagberg *et al.* 1995). Starting from an analysis of the best designed studies on the subject, the book examines the different elements representing occupational risks which could be a cause of the various pathologies of the upper limbs, and possible measurement and analysis methods are indicated for each of the elements considered.

Moore and Garg suggested a model to analyze jobs for risk of distal upper extremity disorders. It is based on the measurement of six variables: force, action frequency, posture, recovery time within a single cycle, speed of work, daily duration (Moore and Garg 1995).

More recently, NIOSH's Center for Disease Control and Prevention published "Musculoskeletal Disorders and Workplace Factors: A Critical Review of Epidemiological Evidence for WMSDs of the Neck, Upper Extremity and Low Back." One of the things that this volume provides is a critical report of studies used to show the association between certain working risk factors (particularly repetitiveness, force, posture and vibration) and individual upper limb pathologies.

There are also various documents prepared by national bodies, institutes, and by International Standards agencies. These represent useful references for the definition of description and analysis procedures and criteria when dealing with tasks that present biomechanical overload for the upper limbs. Among these, the following deserve mention:

- the "Code of Practice Occupational Overuse Syndrome" issued by the Australian Health and Safety Commission in 1988 (Victorian Occupational HSC 1988);
- the "Ergonomic Program Management Guidelines for Meatpacking Plants", issued by the OSHA, USA, in 1991 (OSHA 1991);
- the standard plan for the control of CTDs which is being drafted by American National Standard Institute (ANSI), a USA standards agency (ANSI z—365 Draft Control of CTD—PONT. 1 upper extremity (ANSI 1995);

- the OSHA draft standard "Ergonomic Protection Standard" (Schneider, S. 1995).
- The draft standards pr-EN 1005/3 (Committee European Normative — CEN 1997) and pr-EN 1005/4 (CEN 1997) concerning, respectively, "Safety of Machinery, Human Physical Performance. Recommended force limits for machinery operation" and "Safety of Machinery, Human Physical Performance. Evaluation of Working Postures in Relation to Machinery."
- The draft standards ISO/DIS 11226 (1998): "Evaluation of working postures".
- Sjogaard G., Fallentin N. *"Exposure assessment in repetitive monotonous jobs: Danish national strategies for preventing work-related musculoskeletal disorders"*. Schriftenreihe der Bundesanstalt für Arbeitsschutz. Tagungsbericht 10. *"Problems and progress in assessing physical load and musculoskeletal disorders"*. Dortmund: Bundesanstalt für Arbeitsschutz: 73–81 1996.
- Circular letter No. 5/1994. "Monotonous repetitive work. A model for mapping and evaluating repetitive monotonous work". Danish Working Environment Service: 1–12 1994 (in Danish).

Beyond the specific objectives, these drafts continuously relate the evaluation of force and posture to the other factors. Thus, the force limits are related to action frequency, speed, and work duration. The acceptability of certain postures and movements of the various upper limb segments is established by the duration for which they are maintained and (in the case of movement) to the action frequency.

In summing up this report, room must be given to the checklists that are so often seen in the medical literature, although this is not the occasion to propose a detailed analytical review. In general terms, however, it can be said that checklists have proved useful, either in particular application contexts (e.g. industrial sectors with assembly lines in which the workers carry out a single task) or, in establishing the presence/absence of a job that is "problematic" for the upper limbs (without evaluating the merit of the individual risk factors and the possibility of reducing them).

This study takes into consideration several proposals derived from the most authoritative checklists. At the same time, it searches for models to describe and evaluate each of the main risk factors considered in those checklists.

2. ASSESSMENT GENERAL MODEL AND DEFINITIONS

The description and assessment general model, concerning all exposed workers in a given situation, is aimed at evaluating four main collective risk factors: repetitiveness, high force, awkward posture and movements, lack of proper recovery periods. Such factors shall be assessed as a function of time (mainly considering respective duration).

In addition to these factors, others, grouped under the term "additional factors", should be considered. These are mechanical factors (e.g. vibrations, localized mechanical compressions), environmental factors (e.g. exposure to cold) and organizational factors (e.g. pre-established and non-adjustable rhythms) for which there is evidence of causal or aggravating relationship with work-related musculoskeletal disorders of the upper limbs: the list of such factors is open.

Each identified risk factor is to be properly described and classified. This allows, on the one hand, the identification of possible requirements and preliminary preventive intervention for each factor and, on the other hand, eventually, to consider all the factors contributing to the overall "exposure" in a general and mutually integrated frame. From this viewpoint "numerical" or "categorical" classifications of results may be useful for an easier management of results, even if it is important to avoid the sense of an overt objectivity of methods whose classification criteria may still be empirical or experimental ones.

To this end, the following definitions are important:
- The work is composed of one or more *tasks*; these are definite activities (such as the stitching of clothing, the loading or unloading of pallets, etc), that can occur one or more times in one work shift;
- within a single task, several *cycles* can be identified. Cycles are sequences of technical actions, which are repeated over and over, always the same way. In general terms, cycles describe the completion of an operation on product or, sometimes, the completion of a product unit.
- within each cycle, several *technical actions* can be identified. These are elementary operations that enable the completion of the cycle operational requirements. They may imply a mechanical activity, such as turning, pushing, cutting, etc, or a control activity, e.g. checking for faults, etc. In this case, the action is not necessarily identified with the single body segment movement, but rather as a group of movements, by one or more body segments, which enable the completion of an elementary operation.

There is a terminological problem in defining a technical action: in fact, it is substantially attributable to the concept of "Therblig" (Barnes 1958, 1968) "work element" in some literature sources, or "micromotions and exertions" in the ANSI 2-365 (1995) draft. To solve this terminological problem, it was decided to keep the term "technical action" which is immediately understandable by worksite technical staff. Related examples (picking, shifting, moving, turning) should eliminate any doubtful interpretation. Table 1 lists the main terms used in this document, together with the definitions that best fit the authors operational choices for exposure assessment.

The suggested procedure for assessing the risk should follow the general phases listed hereunder:
- pinpointing the typical tasks of any job, and — among them — those which take place in repetitive and equal cycles for significant lengths of time;
- finding the sequence of technical actions in the representative cycles of each task;
- describing and classifying the risk factors within each cycle (repetitiveness, force, posture, additional factors);
- reassembling of the data concerning the cycles in each task during the whole work shift, taking into consideration the duration and sequences of the different tasks and of the recovery periods;
- brief and structured assessment of the risk factors for the job as a whole.

3. ORGANIZATIONAL ANALYSIS

Organizational analysis should come before the analysis of the

Table 1. Main definitions of recurring terms used in exposure assessment.

Organized work:
the organized grouping of work activities that are carried out within a single working shift; it may be composed of one or more tasks.

Task:
specific working activity aimed at obtaining a specific operational result
The following tasks are identified:
REPETITIVE TASKS: characterized by repeated cycles with mechanical actions
NON-REPETITIVE TASKS: characterized by the presence of non-cyclical mechanical actions

Cycle:
a sequence of technical, mainly mechanical, actions, that is repeated over and over, always in the same way.

Technical action (mechanical):
an action that implies a mechanical activity; not necessarily to be identified with the single joint movement, but rather with the complex movements of one or more body regions that enable the completion of an elementary operation

Potential risk factors

Repetitiveness:
the presence of events (i.e. cycles, technical actions) that are repeated in time, always in the same way.

Frequency:
number of technical (mechanical) actions per given time units (no. of actions per minute)
High frequency is the related risk factor.

Force:
the exerted force required by the worker for the execution of the technical actions.

Posture:
the whole postures and movements used by each of the main joints of the upper limb to execute the sequence of technical actions that characterise a cycle.
Awkward posture: hazardous postures for the main joints of the upper limbs.

Recovery period:
period of time between or within cycles during which no repetitive mechanical actions are carried out. It consists of relatively long pauses after a period of mechanical actions, during which the metabolic and mechanical recovery of the muscle can take place. Lack of recovery is the related risk factor.

Additional risk factors:
additional risk factors may be present in repetitive tasks but are neither necessary nor always present. Their type, intensity, and duration lead to an increased level of overall exposure.

-- work: 460 minutes -------------------------
-- pause: 20 minutes ------------------------ |480 minutes shift
-- daily pause time : ------ 60 (lunch) + 20 (pause)

Figure 1. Definition of repetitive task.

therefore without mechanical actions, it will be defined as a recovery for the upper limbs.

The tasks with non-repetitive mechanical actions remain and shall be defined as NON-REPETITIVE TASKS (but not ''recovery periods'').

The number of foreseen cycles within a REPETITIVE TASK, and the net duration of each cycle, must be counted at this point.

		MIN. IN SHIFT AND MAIN CHARACTERISTICS	
TASK A	PISTON ASSEMBLY	220	REPETITIVE TASK
TASK B	LINE MAINTENANCE OPERATIONS	60	NON-REPETITIVE TASK
TASK C	LINE VISUAL CONTROL	180	RECOVERY
PAUSE	2 x 10 MIN. EACH 60 MIN. (LUNCH)	80	RECOVERY
			TOTAL 480 MIN. WORK (+ 60 MIN. LUNCH)

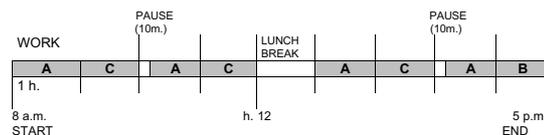
Note: periods of "non-working" in the order of minutes.


Figure 2. Definition of non-repetitive task.

The number of cycles often coincides with the number of pieces to be worked in each shift.

4. RISK FACTORS

	→ 440 pistons must be assembled in 220 min in the 8-hour shift
TASK A described in Example 2	→ the assembly of each piston is to be considered as a single cycle
	→ the cycle duration is 30 sec . (440 pistons in 220 min. net)

Figure 3. Definition of cycle time.

4.1. Repetitiveness: frequency

This is probably the risk factor of greatest importance in many jobs in industry, so much so that the syndromes of specific interest have often been defined through this element (repetitive strain injuries). The characterization of repetitiveness can be used to discriminate the tasks that must be assessed. To this end, the presence of a repetitive task for the upper limbs can be defined as the consecutive activity, lasting at least one hour, in which the subject carries out work cycles similar to each other and of relatively brief duration (a few minutes at maximum). The cycles require the carrying out of mechanical actions.

Once repetitive tasks are submitted to analysis, there is the more important problem of quantifying and assessing repetitiveness. In the literature, a definition of repetitiveness on

four main risk factors and of the additional factors. It is essential to focus on the *real task duration and repetitive tasks*, and on the existence and distribution of *recovery periods*.

The first phase of the analysis is finding the distribution of work times and pauses within the work shift(s).

In this way it is possible to find the duration and distribution of the macro-pauses (RECOVERY PERIODS).

The organized work shift may consist of one or more working tasks.

In turn, each task may be characterized by cycles or by other types of execution.

If the task is characterized by cycles with mechanical actions, it will be defined as a REPETITIVE TASK.

If it is characterized by check operations (examination, inspection) without movements or awkward postures, and

the basis of cycle duration can frequently be found. High repetitiveness, in particular, is postulated with cycles lasting less than 30 seconds (Silverstein *et al.* 1987).

This same proposal is completed by stating that high repetitiveness occurs when over 50% of the cycle time is spent in performing the same type of action. It is to be noticed, however, that it is possible that very short cycles do not require very frequent gestures and movements, and that longer cycles are carried out with a high frequency of actions. Since the development mechanism of tendon pathologies seems to be related to movement frequency, then action frequency is a more accurate estimation factor of this risk element.

Measuring the frequency of the single joint movements would be the best thing for assessment, as some authors suggest. In fact, the highest risk occurs when the same type of movement is frequently repeated by the same joint. Obviously, a direct measurement of joint movement frequency is not always feasible in the field. It would require the measurement of the frequency of each type of movement (flexion, extension, adduction, abduction, etc.) for each of the main joints, and for both upper limbs.

In this proposal repetitiveness is measured, on the one hand, by counting, within the cycle, the number of technical actions performed by the upper limbs and, on the other hand (see, hereafter, analysis of postures and movements), by identifying, for each action, how many times (or for how long) it involves a given posture or movement of each main segment/joint of the upper limbs (hand, wrist, elbow, shoulder).

A description of the technical actions often requires the filming of the job, which must then be reviewed in slow motion. When the cycles are very short (few seconds), a direct observation at the workplace could work as well as filming. If the task is technically complex, it is extremely useful, indeed often essential, to describe the action sequence with the help of company technical personnel experienced in the task itself. Often, the company already has records available in which the task is described and numbered, and the elements constituting successive technical actions are timed (methods—time measurements).

In order to analyze frequency, the following steps have to be implemented:

(a) Description of the technical actions: reviewing the film in slow motion, all technical actions carried out by the right and left upper limbs, must be listed in order of execution. When the same action is repeated more than once, such as drawing a screw, each repetition of a single action must be counted (i.e. turning four times). When a certain action is carried out repetitively, but not on all pieces (i.e. technical actions for quality control, to be carried out once every 4 pieces or every 20 pieces), then the action described is counted with the relevant fraction (one-fourth or one-twentieth). The technical action sometimes coincides with the joint movement. In this case, when the execution of a simple movement is aimed at the execution of a given technical action, it must be counted as a proper technical action (i.e. use finger flexion to push button). Table 2 gives a description of a brief but complex operating cycle recorded at a working post on an engine assembly line. The actions listed are ascribed to the left and/or right upper limbs in numerical terms. Actions not necessarily present in every cycle, are specially calculated.

(b) Calculation of action frequency; from the previously described work organization study, the following are already known: net time of repetitive task, number of cycles in repetitive task, duration of each cycle. From the technical action description it is possible to obtain: the number of actions per cycle, and therefore the action frequency in a given time unit: NO. OF ACTIONS PER MINUTE (Table 2). It is also possible to obtain the overall number of actions in the task/tasks, and consequently for the shift. Additional considerations should be also given to the "cyclicity" (i.e. the changing of frequency during the shift: regular, irregular or cumulated) of a job.

4.2. Force

Force more directly represents the biomechanical effort necessary to carry out a given action, or sequence of actions. Force may be described as being external (applied force) or internal (tension developed in the muscle, tendon, and joint tissues). The need to develop force during work-related actions may be related to the moving or the holding still of tools and objects, or to keeping a part of the body in a given position.

The use of force may be related to static actions (static contractions), or to dynamic actions (dynamic contractions). When the first situation occurs, it is generally described as static load, which some authors describe as a "distinct risk element" (Hagberg *et al.* 1995).

In the literature, the need for using force in a repetitive fashion

Table 2. Example of description and calculation of technical action frequency within a complete cycle.

	NUMBER OF ACTIONS IN A COMPLETE CYCLE	
	RIGHT	LEFT
- Pick up and position gasket in bushing lodging	2	
- Use pincers in right hand and hook 1st spring	2	1
- Use pincers in right hand and hook 2nd spring	2	1
- Shift calibre and push button	2	1
* Spring position correction (once every four pieces)		
- Pick up unscrewing tool and position it	2/4	3/4
- Unscrew or screw spring	1/4	1/4
- Put tool down		1/4
* Substitution of broken spring (once every 20 pieces)		
- Pick up unscrewing tool and position it	2/20	3/20
- Unscrew spring (4 times)	4/20	4/20
- Hold tool		1/20
- Pick out broken spring with pincers (2 times)	2/20	
- Pass tool into right hand	1/20	
- Pick up spring and put it on tool	1/20	2/20
- Position spring and screw it in (4 times)	5/20	5/20
- Put tool down		1/20
Total	9.5	5

No. of pieces per shift	=	2075
Cycle time	=	11.9 sec. per piece
No. of technical actions per cycle: on the right	=	9.5
on the left	=	5.0

Frequency:

Right $\dfrac{9.5 \times 60}{11.9} = 47.9 \cong 48$ (action/minute)

Left $\dfrac{5 \times 60}{11.9} = 25$ (action/minute)

is indicated as being a risk factor for tendons and muscles. Furthermore, a multiplying interaction has been shown to exist between force and action frequency (Silverstein *et al.* 1986), especially for tendon pathologies and nerve entrapment syndromes.

Force quantification in real life contexts is a problem. Some authors use a semi-quantitative estimation of external force via the weight of the objects being handled. In other cases, the use of mechanical or electronic dynamometers has been suggested. The internal force can be quantified by means of surface electromyography techniques.

Finally, other authors suggest using subjective evaluation methods through psychophysical rating scales. On account of in-field applicability problems, two different procedures are advised for the evaluation of the use of force associated with the technical actions present in one cycle.

4.2.1 Use of dynamometers to assess the force required to carry out a given technical action

This procedure is possible and recommendable for actions involving the use of levers, or components of machines and objects. In these cases it is possible to determine the force required to move a lever, or, if the dynamometer is equipped with the proper interface, to simulate the same working action by the workers involved (cross modality – matching). It is to be noticed however that not all technical actions requiring the use of force can be easily determined by means of dynamometers. Besides the observer should be able to establish which technical actions respectively do or do not require the use of force also by asking the operator for the forceful actions.

In order to evaluate the use of force, it is necessary to compare the results obtained on the field with the ability of a reference working population: relevant data are available either in the literature or can be provided by National or International Standards organizations (refer to Appendix C). Additional information on maximal action force may be obtained from the "force atlas" (Rohmert *et al.* 1994).

4.2.2 Use of psychophysical rating scales

In this case, worker's subjective evaluation is used to determine the physical effort associated with the cycle technical actions. Of the different psychophysical scales available in the literature, reference can be made to the "CR10 Borg scale" for perceived exertion (the category ratio scale for ratings of subjective somatic symptoms including perceived force, where 10 defines the relative maximum) (Borg 1982, 1998).

The use of subjective scales is not free from disadvantages likely to affect their reliability (e.g. non-acceptance of the "subjective" method by some employers, conflicting situations influence of motivation, presence of "pathological" subjects, wrong communication of the subjective evaluation goal).

Despite these objections, it is worth mentioning that this technique, if correctly used, allows researchers to evaluate the effort associated with any technical action. In terms of evaluation, reference values are provided by the scale itself. Besides which, according to some authors (Grant *et al.* 1994), the results of the implementation of Borg's Scale, when used for an adequate number of workers, have turned out to be comparable to those obtained with surface electromyography (value of Borg's Scale x

10 @ percentage value with respect to Maximum Voluntary Contraction MVC as obtained by EMG).

The quantification of the effort as perceived by the whole upper limb should theoretically take place for every single action that makes up a cycle. For practical reasons, the actions that require no, or minimal, muscle involvement could be identified respectively as 0 or 0.5 value in Borg's Scale; then the involvement description procedure could only describe those actions, or groups of actions, that require more force than the minimal amount, always using Borg's Scale.

This procedure, when applied to all workers involved, allows researchers to evaluate the average score among subjects for each technical action by asking for the use of force, as well as the weighed average score for all actions and the whole cycle time.

Finally it is to be emphasized that whatever the method used for the description and assessment of force, it is necessary to evaluate:

(1) the average level of force required by the whole cycle — referred to as the maximum force capability, it is defined by reference groups or the group of workers involved;
(2) whether there are in the cycle (and which and how many) technical actions requiring the development of force beyond given levels (peak force)?

It is useful to know also the presence of peaks because the knowledge of average level only can hide their presence.

4.3. Posture and Types of Movements

Upper limb postures and movements during repetitive tasks are of basic importance in contributing towards the risk of various musculoskeletal disorders. A definite agreement is found in literature as to the potential damage coming from extreme postures and movements of each joint, from postures maintained for a long time (even if not extreme) and from specific, highly repetitive movements of the various segments. Moreover, the description of postures and movements of each segment of upper limbs during technical actions of one cycle completes the description of "the repetitiveness" risk factor. The analysis of postures and movements shall be concerned with each single segment of upper limbs (hand, wrist, elbow, shoulder): it is aimed at checking the presence and time pattern in cycle (frequency, duration) of static postures and dynamic movements involving each segment/joint considered.

The description may be more or less analytical but has to be able to appreciate at least the following items:

(a) Technical actions requiring postures or movements of a single segment beyond a critical level of angular excursion (see below).
(b) Technical actions involving postures and/or movements which, even within acceptable angular excursion, are maintained or repeated in the same way.
(c) The duration expressed as a fraction of cycle/task time of each condition reported above.

Joint combination of such description factors (posture/time) will provide the classification of posture effort for each segment considered.

In order to identify the so-called angular excursion critical levels (point (a)), reference is to be made to data and proposals available in the literature.

Table 3 summarizes some of the main description and classification methods of postures and upper limb movements during repetitive work.

It should be particularly noted that the international literature highlights the need both to describe the awkward postures and to study their duration and frequency (Putz-Anderson 1988; Hagberg *et al.* 1995; Moore and Garg 1995). It is, however, to be emphasized that at this stage it is not important to describe all the postures and movements of the different segments of upper limbs, but rather to focus on those that by typology or excursion level (as well as by duration) are the static postures and/or the movements involving greater effort and also requiring improvement.

On the other hand, the literature provides information on the risk of postures and movements maintained or repeated identically for prolonged times (point (b)). This holds true even if the excursion of such postures and movements does not reach the critical levels evidenced above. In this case, however, the "duration" factor (point (c)) becomes even more important in fixing criticalness of "stereotypy" of specific postures or motions.

4.3.1 Static postures

Static postures are considered critical when:
a) they near the extremes of the movement range — independently of the duration
b) they result in the body segment being held in an intermediate position within the joint range for a prolonged period of time. Table 4 shows an original suggestion (Rohmert 1973) of the

use of muscle force in an optimal balance between static load and recovery time.

Static postures may be present both in repetitive and non-repetitive tasks; an investigation is necessary as well. In this case the evaluation criteria are based on the type of 14 postures, continuative maintenance time, adequacy of recovery periods (see Table 4 and section 4.4). Appendix D1 contains the relevant parts of an easily applicable international consensus standard.

4.3.2 Movements

The literature often provides a definition associating movements with duration (or repetitiveness): work cycle less than 30 seconds or the same fundamental work actions performed during more than 50% of the cycle time are to be considered as critical (Silverstein *et al.* 1987). Using the latter criteria it is possible to assert that repetition of the same action in the same joint (stereotypy) is critical when it exceeds 50% of the cycle time, regardless of the size of the movement angle.

Further, the duration seems to be the major factor in view of determining the level of effort associated with movements with critical angular excursion. In this regard, the literature sources are less univocal but for practical purposes reference could be made to a fraction of the cycle equal or above 1/3 (Keyserling *et al.* 1993; Colombini 1998), or to the criteria for which the extreme movements of a single joint should not exceed a frequency of twice a minute; these can be the "rationale" with which to define a significant threshold of effort associated with critical angular excursions.

To obtain an exhaustive description of postural risk it is necessary to cover four operational phases:

Table 4. Rohmert's original suggestion concerning recovery periods (in seconds) for technical actions requiring isometric contractions (equal to or longer than 20 seconds) for applied times and forces.

FORCE (%MVC)	HOLDING DURATION (SEC.)	RECOVERY PERIOD	
	20	2	10%
	30	3	10%
	45	7	15%
up to	120	60	50%
20% MVC	180	180	100%
	240	480	200%
	300	1200	400%
	450	2700	600%
	20	10	50%
	40	40	100%
about	60	120	200%
30% MVC	90	360	400%
	120	720	600%
	150	1200	800%
	20	20	100%
about	30	60	200%
40% MVC	50	200	400%
	70	420	600%
about	20	40	200%
50% MVC	30	120	400%
	40	240	600%
	90	720	800%

(a) a separate description of postures and/or movements by each joint: shoulder, elbow, wrist, hand (type of grip and finger movements) and by type of effort (static, dynamic);

(b) static postures: observation of static postures close to extreme articular range, during the cycle/task time; observation of static postures in the medium of articular range held for a prolonged period of time; observation of grip positions during cycle/task time.

(c) joint movements: presence of articular movements, close to the limit of the range of motion during the cycle/task time; repetitive articular movements, due to presence of the same technical actions (independently of the articular range) for at least 50% of cycle time and subsequently of task time.

To allow the technician to make an easier description and classification of the postural effort (type of posture per time), a form is reported in Appendix A (Table 6) with an example of all the major items for each one of the four segments of the upper limb under consideration in order to obtain a postural score. Appendix D2 contains the relevant parts of an easily applicable international consensus standard.

For practical purposes, a significant cycle should be analyzed for each repetitive task. This is better achieved by videotaping.

The video could be reviewed in slow motion to describe and evaluate the effort of each joint segment, making a distinction between right and left side when the effort is asymmetrical.

4.4. Lack of Recovery Periods

The recovery period is a time during which one or more of the muscle groups that are usually involved in the work tasks are basically inactive (macro-pauses). The recovery period is one of the main factors for overall exposure assessment.

The following may be considered as recovery periods:

(a) work breaks, including the lunch break

(b) those periods during which tasks are carried out, which do not involve the usual muscle groups

(c) those periods within a cycle, with actions implying the total rest of the usually active muscle groups; to be defined as macro-pauses, these periods must be at least 15 consecutive seconds; micro-pauses of very short duration indicated as E.G. EMG gabs of at least 0.2 seconds seems to be of major functional significance but are difficult to detect without technical measurements.

The analysis of the recovery periods is first and foremost a check of their duration and distribution within the cycle, and a macroscopic examination of their presence, duration and frequency within the whole shift. With some exceptions (see later), represented by recovery periods for actions implying protracted static contractions, the description and the assessment of recovery periods should be based on the following:

(a) a description of the actual task sequences involving repetitive movements of the upper limbs, of "light" non-repetitive tasks, and of pauses;

(b) the frequency of the recovery periods with reference to the actual number of working hours per shift;

(c) a ratio between the total recovery time and the total working time, in a shift devoted to tasks involving repetitive movements.

The main problem encountered in analyzing recovery periods is the lack of criteria for an adequate assessment (duration, time scheduling).

In this connection, it is worth making the following considerations.

4.4.1 Static actions

As for static actions, classical muscular physiology studies (Rohmert 1973) provide criteria with which to assess the adequacy of recovery periods as an immediate consequence of a static effort (as a function of its intensity, mostly expressed in percentage of the MVC and duration of involvement).

It should be emphasized, however, that such data refer to effect such as performance or, at best, muscular fatigue but is not fully validated when considering major health effects.

While taking into account such deficiencies, the results of these studies are summarized in Table 4. It shows the various degrees of contraction force, as a percentage of MCV, and the various duration of contraction (in seconds); for each, the minimum necessary muscle recovery periods are indicated, both in seconds and as a percentage of the contraction time. The table is self-explanatory.

After each holding condition, and according to the force developed, an adequate recovery period must immediately follow. If such a period is either absent or inadequate, then there is a condition of risk, all the greater with the greater discrepancy between the actual situation and the optimal one. Table 4 is important as a prevention tool; it offers the optimal division between isometric contraction and recovery periods, to be alternated in strict succession. The corollary of the table, as a prevention tool, is that the force required during isometric contractions that last over 20 seconds (maintenance) must never exceed 50% of MCV.

As to using Table 4, if data about % MCV are not available, it is possible to estimate force using Borg CR10 scale.

Also within non-repetitive tasks characterized by the presence of static postures, it is necessary to use adequate RECOVERY TIMES as suggested in Table 4. Appendix D1 contains the relevant parts of an easily applicable, international consensus standard.

4.4.2   Dynamic actions

As for dynamic actions, no adequate studies are available for evaluating the optimum distribution between repetitive work time (with relative levels of muscular and tendinous effort) and recovery time. A partial exception is the case when so-called intermittent static actions are carried out. For this kind of action, reference should be made to the valuable contribution by Bystrom (1991) that established the maximum acceptable work time before it becomes necessary to have a recovery period, considering a given rate of muscular involvement (expressed in % MVC).

In most repetitive tasks, however, upper limbs actions are typically dynamic and, in the absence of consolidated scientific studies, concerning the optimal distribution of recovery periods, it becomes necessary to refer to "rough" and empirical data reported in the literature or in guide documents and standards (Victorian Occ. HSC Australia 1988; ISO TC 159 Draft 1993; Grandjean 1986).

Logically, if not strictly scientifically speaking, all these documents tend to state that:

(1) work involving repetitive movements of upper limbs cannot be continuously sustained for over one hour without a recovery period;

(2) the recovery period, within one hour of repetitive work, has to be in the region of 10–20% of working time (that is about 5–10 minutes per hour). These rough indications, still to be perfected, may guide description and assessment methods of RECOVERY TIMES with relation to "dynamic" activities of upper limbs.

An example of how to obtain a score for "lack of recovery period" is described in Appendix B.

4.5. Additional Risk Factors

There are other factors, apart from those already discussed, which are considered to be relevant in the development of WMSDs.

They always have their origin in work and must be taken into consideration whenever assessing exposure. They have been described as additional in this work, but not because they are of secondary importance — rather, because each of them can be either present or absent in the various occupational contexts. For a factor to be considered, it has to have an association with WMSDs' effects, as well as having a collective impact (that is, on the whole of exposed subjects or on significant groups of them) and not an individual impact (that is, on single subjects). In other terms, factors such as anthropometric measurements, psychological issues, extra work activities of single subjects are not to be considered at this stage of analysis. The additional risk factors may be mechanical, environmental, organizational ones. The list of factors mentioned here (Table 5) is only an indicative one and is not exhaustive: from time to time each operator will decide on the single factors of interest in view of assessing overall exposure.

Table 5. List of possible additional risk factors (not complete).

MECHANICAL
- Hand-arm vibrations
- Extreme precision in positioning objects
- Localized compression on upper limb structures
- Use of gloves
- Rapid or sudden wrenching movements of upper limbs
- Blows and shocks (such as hammering hard surfaces)

ENVIRONMENTAL
- Exposure to cold
- Exposure to heat

ORGANIZATIONAL
- Machine-paced task
- Incentive payment
- Routine overtime
- Working with tight deadlines
- Sudden peaks of high workload
- Lack of training

Mechanical and environmental factors can be described and assessed according to the corresponding time pattern (frequency, duration). This allows the definition of the amount of time (both with reference to cycle time and task time) spent with that factor. For assessment purposes, it will be considered that the optimal condition is represented by the absence, or a very limited presence, of each additional factor. Organizational factors can be described according to category classifications (at least as present/absent).

5. OVERALL EXPOSURE ASSESSMENT

An overall exposure assessment of upper limb WMSDs must account for different risk factors, described one by one and classified.

If, in fact, it is true that the simplest and most elementary prevention actions can be already undertaken after a good analysis of each risk factor, it is all the more true that more comprehensive prevention strategies (e.g. priority choices) must be based on the assessment of overall exposure, as determined by the different combination of the risk factors considered. In this regard, the literature even now provides data and convincing hypotheses on the interrelation between some of the considered factors.

The force–repetitiveness ratio was examined in relation to effects (Silverstein 1987) and muscular capability and physiology while taking activity times (duration) into consideration (CEN 1997).

On the other hand, the relationship between possible force development and some postures (or movements) of the hand—forearm segment (Eastman Kodak 1983) are known. In a recent CEN document (CEN – PrEN1005/4 1996) upper limb postures and movements are classified according to action frequency and overall task duration.

In another recent CEN document (CEN – PrEN1005/3 1997), the recommended force values to be developed in different kinds of manual action by upper limbs are provided in relation to variables such as action frequency, action speed, and overall task duration.

In spite of this, it should be stated that at the present state of knowledge there still is a lack of sufficient data to outline an accurate and parametric general model, combining all the risk factors considered, particularly when the issue is to fix the "specific

weight" of each factor in determining the overall exposure level. Accounting for this, we have to emphasize the necessity of having even partially empirical models for a synthetic assessment of overall exposure to the risk factors considered.

Methods and procedures for determining synthetic exposure scores are already available in the literature. Even when using simple checklists (Keyserling *et al.* 1993; Schneider 1995) the analytical process closes with a synthetic score classifying exposure.

When slightly more sophisticated exposure description and assessment methods are used (McAtamney and Corlett 1993; Moore and Garg 1995), models and procedures are, however, provided for calculating synthetic indices to account for risk factors.

A synthetic index has been recently proposed (Colombini 1998) providing a classification of the risk factors considered here (repetitiveness, force, posture, lack of recovery periods, and additional risk factors). This synthetic index model has been the object of positive preliminary tests, through epidemiological studies. It allows a classification of the results in a three-zone model, useful for implementing preventive actions following from the exposure assessment process.

Being well aware that the data supporting the above overall exposure assessment models are still deficient and often empirical, it is recommended that, if used, they should be adopted "critically" when studies are carried out for preventive action and/or for the active health surveillance of workers. In this respect, and with these goals, the following aspects should be considered:

(a) The exposure indices proposed at present have a methodological value, showing the concept of the integrated evaluation of risk factors.

(b) Such indices also have a practical value: even if they do not provide an absolute statement of the exposure (and thus of WMSD risk), at least they allow the ranking of exposure levels derived mainly from the combination of the different factors in the different work situations. This allows priority choices of action and intervention. Currently, an index may only be used in combination with health status monitoring (complaints, disorders) of the workers involved, in order to see whether the right action and intervention were chosen.

(c) The exposure indices proposed here should not be intended as standards or reference values to distinguish safe or hazardous conditions; this should be clearly emphasized to the potential users.

(d) The exposure indices proposed here, or in the future, need to be validated by laboratory studies, as well as by epidemiological studies (exposure/effect).

(e) The issue of exposure integrated assessment of upper limb repetitive movements is a crucial problem for future scientific and application developments of ergonomics.

(f) Finally, it should be emphasized that the exhaustive description and classification of the risk factors associated with a given repetitive task, the quantification of consequent exposure in a concise, albeit approximate, index, and the need to perform parallel studies on the clinical effects on exposed workers, all represent both an opportunity and a commitment to carry out further research and intervention in the field in the near future.

APPENDICES

In appendices A and B, some risk assessment examples are shown in order to obtain exposure scores. They represent only a hypothesis of simple methods easily applicable in the field. In appendices C and D, information about the assessment of force, posture, and movement in easily applicable, international consensus standards are presented.

The appendices contain examples of practical methods previously used for measuring exposure and assessing risk. The methods presented in appendices A and B have proved useful in field studies and illustrate possible approaches to the analysis of work place risk factors. In addition, force capacity values included in the preliminary CEN standard (PrEN 1005-3) and the evaluation procedure for postures and movements used in ISO/DIS 11226 and prEN 1005-4 are presented in appendices C and D.

Note: The proposed methods available for work place risk assessment purposes are numerous and the examples presented in this appendix are not especially endorsed or recommended by the authors of the consensus document, nor by the IEA Technical Committee.

Appendix A: An example for calculating postural exposure scores (Colombini 1998)

In order to allow the technician to make an easier description and classification of posture effort (type of posture per time), Table 6 reports a form with an example of all the major items for each one of the four segments of the upper limb under consideration.

There are four operational phases in the form:

(a) A separate description of postures and/or movements by each joint: shoulder, elbow, wrist, hand (type of hold and finger movements), and by type of effort (static, dynamic).

(b) Static postures: observation of static postures close to extreme articular range, during the cycle/task time (A_3, C_3, D_3); observation of static postures in medium leverage angle held for prolonged period (A_4, C_4); observation of grip positions (D_1) during cycle/task time.

(c) Joint movements: presence of articular movements, close to the extreme joint excursions during the cycle/task time (A_1, B_1, C_1); repetitive articular movements, due to presence of same technical actions (independently of the articular range) for at least 50% of cycle time and subsequently of task time (A_2, B_2, C_2, D_2).

(d) Calculation (for each joint) of the postural involvement score within the cycle/task time summing the scores written in the square boxes, checked during the posture analysis.

The posture involvement score is attributed to each joint, taking into account that the presence of a significant effort is given by either of the two minimum scenarios, one for static postures and the other for movements, respectively.

For practical purposes, a significant cycle should be analyzed (preferably by a video) for each repetitive task.

The video could be reviewed in slow motion to describe and evaluate the effort of each joint segment, making a distinction between right and left side when the effort is asymmetrical.

A possible example to obtain a risk score for the lack of recovery periods is shown below.

Example

With the help of Table 6, analyze the work of an operator who picks up a handful of screws with the right hand, and for two-thirds of the cycle fits the screws into their holes, always using the same hand and holding his arms off the table. Cycle time is 15 sec; shift duration is 8 hours.

Begin by observing the shoulders.

The operator first takes the screws from a container (abduction/adduction more than 60°) and then keeps the arm in flexion, in a risk area (>60°) for 2/3 of cycle time.

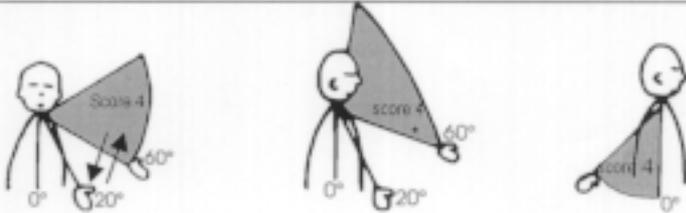
In Table 6, under shoulder sign in A1: 1/3 (score 4), in A3: 2/3 (score 8), in A4 the continuously keeping the arm raised (score 4).

The posture score for the shoulder is 16: in this way critical movements, critical static postures and continuously arm-raised

Table 6: Analysis of upper limb postures as a function of time: a simplified model with an example (example 4)

TASK INVOLVEMENT ....

UPPER LIMB : o RIGHT   o LEFT

SHOULDER POSITIONS AND MOVEMENTS


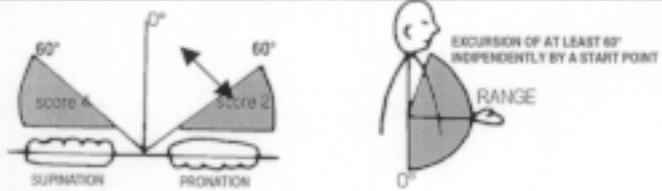
[A1] MOVEMENTS IN EXTREME ARTICULAR RANGE: THEY TAKE : [4] 1/3, [8] 2/3, [12] 3/3 of cycle/task time

[A2] LACK OF VARIATIONS:
performs work gestures of the same type involving the shoulder for at least 50% of the cycle/task time: [4]

[A3] KEEPS THE ARM RAISED (unsupported) by an angle more than 60° or in extension, for :
[4] 1/3, [8] 2/3, [12] 3/3 of cycle/task time.

[A4] KEEPS THE ARM RAISED (unsupported) continuously more than 20° or in extension for at least 50% of cycle task/time: [4]

RISK SCORE IN CYCLE: | 1, 6 |

ELBOW MOVEMENTS


[B1] MOVEMENTS IN EXTREME ARTICULAR RANGE: [4] 1/3, [8] 2/3, [12] 3/3 supination
THEY TAKE : [2] 1/3, [4] 2/3, [6] 3/3 pronation } of cycle/task time
[2] 1/3, [4] 2/3, [6] 3/3 flexion

[B2] LACK OF VARIATION: Performs work actions of the same type involving the elbow for at least 50% of the cycle: [4]

RISK SCORE IN CYCLE: | 0, 8 |

WRIST POSITIONS AND MOVEMENTS

[C1] MOVEMENTS IN EXTREME ARTICULAR RANGE: [2] 1/3, [4] 2/3, [6] 3/3 r/u deviation
THEY TAKE : [4] 1/3, [8] 2/3, [12] 3/3 extension } of cycle/task time
[2] 1/3, [4] 2/3, [6] 3/3 flexion

[C2] LACK OF VARIATION: Performs work actions of the same type involving the wrist for at least 50% of the cycle/task time: [4]

[C3] STATIC POSTURES IN EXTREME ARTICULAR RANGE: THEY TAKE : [2] 1/3, [4] 2/3, [6] 3/3 of cycle/task time.

[C4] KEEPS THE WRIST FLEXED OR EXTENDED OR DEVIATED LATERALLY (ulna or radius)
continuously for at least 50% of cycle/task time: [4]

RISK SCORE IN CYCLE: | 0, 4 |

TYPE OF GRIP AND FINGER MOVEMENTS

[D1] TIME OF THE GRIP AND FINGER POSITION:

		1/3	2/3	3/3
[ ]	TIGH GRIP (1.5 CM)	[2] 1/3,	[4] 2/3,	[6] 3/3
[ ]	PINCH	[3] 1/3,	[6] 2/3,	[9] 3/3
[ ]	PALMAR GRIP	[4] 1/3,	[8] 2/3,	[12] 3/3
[ ]	HOOK GRIP	[4] 1/3,	[8] 2/3,	[12] 3/3
[ ]	KEYING	[4] 1/3,	[8] 2/3,	[12] 3/3
	....	[ ] 1/3,	[ ] 2/3,	[ ] 3/3
	....	[ ] 1/3,	[ ] 2/3,	[ ] 3/3
	....	[ ] 1/3,	[ ] 2/3,	[ ] 3/3

of cycle/task time

LACK OF VARIATIONS:
[D2] performs work actions of the same type involving the same finger(s) for at least 50% of the cycle: [4]
[D3] holds an object in a pinch or palmar (or hook) grip continuously for at least 50% of the cycle: [4]

RISK SCORE IN CYCLE: | 1, 3 |

positions are summed up considering time pattern during the cycle.

As for the elbow, the operator carries out pronation movements (and return from pronation) >60° for two-thirds of cycle time.

Under the elbow B1, enter two-thirds of cycle time for pronation movement (score 4), and in B2 enter "4" for movement stereotypy.

The elbow has an overall score of 8.

The wrist joint does light flexion (and return from the flexion) movements, but for gestures of the same type, and for two-thirds of cycle time. Under C2 fill in 4.

The overall score for the wrist is 4.

The hand is involved in concurrent precision grip (PINCH).

These gestures are always the same, and last for the whole of the cycle. Under D1 sign 3/3 (score 9); under D3 sign the box 4; the overall score the hand is 13.

When the cycle time is extremely short (e.g. shorter than 6 sec.), the stereotypy of the technical actions is always present.

Appendix B: An example for calculating lack of recovery period exposure scores (Colombini 1998)

A still empirical but effective way of performing such analysis is by examining individually the hours that make up the shift; for each hour it is necessary to verify whether repetitive tasks are carried out and whether there are adequate recovery periods (Colombini 1998).

According to the presence/absence of adequate recovery periods within each hour of the repetitive work under examination, each hour is considered as being either "risk-free", or "at risk" if there is a lack of adequate recovery periods.

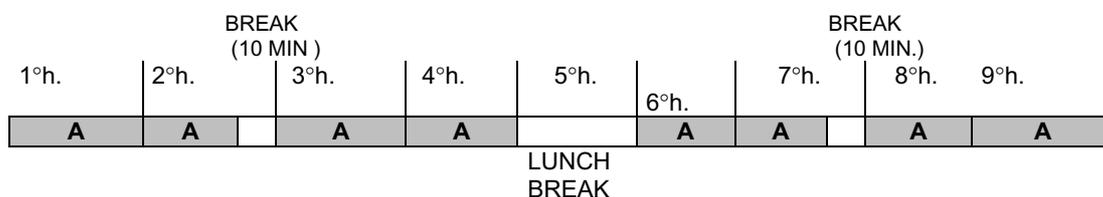
The overall risk related to lack of recovery periods could be determined by the total number of hours of the shift in which recovery is insufficient.

A possible example to obtain a risk score for lack of recovery periods is shown in example 5 (Figure 4).

The risk due to a lack of recovery periods is classified with a score of 4. This expresses the number of hours in the shift in which the recovery is insufficient. In an eight-hour shift, with a lunch break but with no other pauses at all, the score will be 6; in fact, the hour of work followed by the lunch break, just as the last hour before the end of the shift, can be considered as risk-free, because they are followed by adequate recovery periods.

Appendix C: Recommended force limits for machinery operator (PrEN 1005–3 1996)

- Define relevant actions and force directions.
- Obtain distribution parameters (average and standard deviation) of the maximal isometric force for the relevant action in the general adult healthy European population.
- Decide if the machinery is intended for professional or domestic use.

In a working situation where a single repetitive task is carried out (task A), and where pauses are distributed as follows:


the following scheme (protocol) should be adopted:

1st HOUR	= 60 min. TASK (no rec.)	= RISK 1
2nd HOUR	= 50 min. TASK: 10 REC.	= RISK 0
3rd HOUR	= 60 min. TASK (no rec.)	= RISK 1
4th HOUR	= 60 min. TASK	
5th HOUR	= 60 min. REC.	= RISK 0
6th HOUR	= 60 min. TASK (no rec.)	= RISK 1
7th HOUR	= 50 min. TASK: 10 REC.	= RISK 0
8th HOUR	= 50 min. TASK (no rec.)	= RISK 1
9th HOUR	= 60 min. TASK + RECOVERY END OF SHIFT	= RISK 0

Figure 4. Protocol for work/rest schedule on repetitive tasks.

● Determine F_B, i.e. the 15th force percentile for professional use or the 1st percentile for domestic use.

Appendix D 1: Evaluation of working postures (ISO/DIS 11226 1998)

The holding time for upper arm elevation is evaluated using Figure 5.

It is recommended to provide adequate recovery time following the holding time for a certain upper arm elevation.

Appendix D 2: Evaluation of working postures in relation to machinery (CEN prEN 1005–4 1997)

Upper arm elevation

Step 1: refer to figure and table below

Step 2:

(a) Acceptable if there is full arm support; if there in no full arm support, acceptability depends on duration of the posture and period of recovery.

(b) Not acceptable if the machine may be used for long durations.

(c) Not acceptable if frequency ≥10 / minute and/or if the machine may be used for long durations.

The holding time for upper arm elevation is evaluated using the table below.

HOLDING TIME	ACCEPTABLE	NOT RECOMMENDED
> maximum acceptable holding time* ≤ maximum acceptable holding time*	X	X

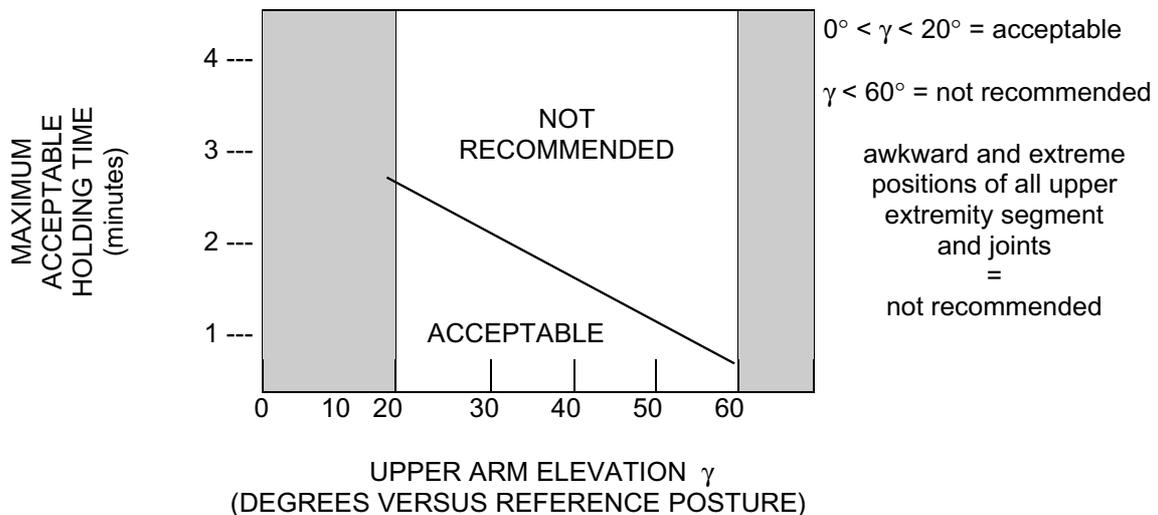
● Taken from the figure below.


Figure 5. Maximum acceptable holding time.
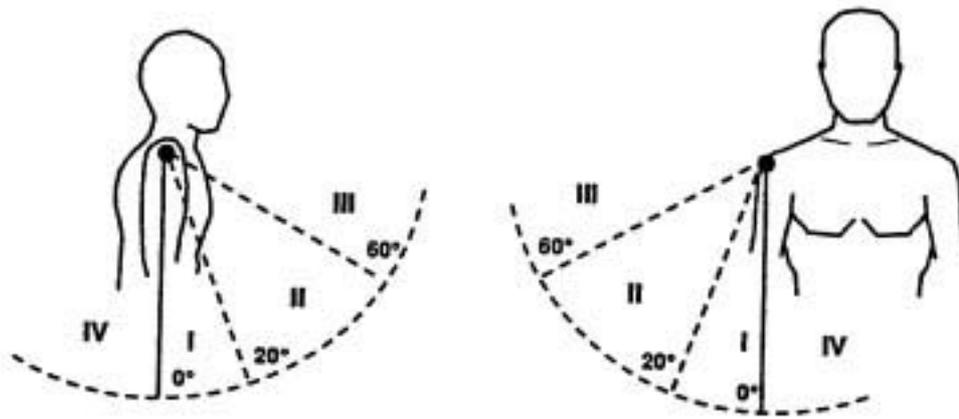

Upper arm elevation

Evaluation of upper arm elevation

	Static posture	Movement	
		low frequency (<2/minute)	high frequency (≥2/minute)
I*	acceptable	ACCEPTABLE	acceptable
II	conditionally acceptable (step 2A)	acceptable	conditionally acceptable (step 2C)
III	not acceptable	conditionally acceptable (step 2B)	not acceptable
IV	not acceptable	conditionally acceptable (step 2B)	not acceptable

Static posture and high frequency movements (≥ 2 / minute), awkward and extreme positions of all upper extremity segments and joints = not acceptable

* It is recommended to strive for working postures with the upper arms hanging down.

Figure 6.

Finnish Ergonomics Society

C.-H. Nygård

Tampere School of Public Health, University of Tampere, PO Box 607, 33101 Tampere, Finland

The Finnish Ergonomics Society (FES) was founded in 1985. Among the founders there were not only active ergonomists, but also institutions including the Finnish Institute of Occupational Health and the Center for Occupational Safety. The current number of members is around 230. The main objective of the FES is to promote the application of current knowledge of ergonomics in the design of safe and convenient, as well as productive and efficient human work systems. This includes improving machines and tools as well as work methods and the work environment. It is the adoption of work to man and of each man to his job. Participatory ergonomics is one of the most powerful processes currently used in Finland for improvements in work and environment — both in research and developments. The possibilities of ergonomics are widely admitted for the aging work force and the promotion of work ability. FES has the following main principals in the activities of the society:

- to place a special emphasis on the application of ergonomics in operation of both occupational health and safety specialists for the improvement of working conditions and environment;
- to advise on netted collaboration in providing information, training and education in the field of Ergonomics;
- to publish a newsletter for members and to hold a World-Wide Web homepage to guarantee the maintenance of the ergonomics information network;
- to support a national CREE committee for certifying European Ergonomists;
- to participate in preparing ergonomic standards;
- to organize an annual national meeting and, every 4 years, a Nordic conference on ergonomics;
- to cooperate in organizing with universities postdoctoral courses and congresses; and
- to work, in cooperation with other organizations, to create a basis for long-term development in education and research in ergonomics in the Baltic states (especially Estonia).

Fundamental Concepts of Human Factors

D. Meister

1111 Willow Avenue, San Diego, California 92109, USA

This article examines the concepts underlying the study of Human Factors Ergonomics (HFE), with particular emphasis on what makes HFE a distinctive discipline.

1. INTRODUCTION

Although the discipline has existed only since the end of World War II, its underlying concepts derive in part from its predecessor, psychology and in part from philosophical principles that go back to the early 19th century and even earlier. These concepts have developed a special meaning because of their application to technology, but it is important for HFE professionals to recognize that they are part of a much older scientific tradition.

2. HFE AS A DISTINCTIVE DISCIPLINE

All scientific disciplines have one critical factor, the need to *know*. The subject-matter of that knowledge determines the nature of the discipline. Physics examines the structure of the atom; biology, the nature of the cell; psychology describes how the human functions. HFE, which developed out of psychology, also seeks to discover the nature of human processes, but in a very special context: the technology the human creates to control the external world.

Many HFE professionals think that because of the close relationship between HFE and psychology, HFE is merely a specialized branch of psychology. Others, including the author of this section, feel that HFE is a distinctive discipline, despite its earlier and continuing ties to psychology. HFE represents humans in interaction with systems in the world around them. One finds little or no concern for such systems in psychology.

Some may feel that it makes little difference what one calls one's work. Labels do, however, make a difference, particularly if a theoretical viewpoint and a methodology are associated with the labels. If one thinks in the idiom of another discipline like psychology, the resultant concepts, and especially the way in which research is performed, will be those of that other discipline (Meister 1999). Although all comparisons are invidious, it is necessary to establish HFE distinctiveness simply to define the scope of its work. As an illustration, HFE is not interested primarily in physiological processes, although this is one of the factors affecting the human's interaction with technology. It is only when these physiological processes affect the way in which the human manipulates technology, that HFE examines those processes. The same is true for all other disciplines with which HFE has relationships.

The ties with psychology, physiology, safety, etc. still persist, just as psychology's ties with physics, chemistry and biology also persist, since the human is also and forever a physical, chemical and biological entity. But if one considers psychology an independent discipline, so is HFE. HFE professionals must always be aware that they are creating new knowledge. If they lack this awareness, they will create a knowledge that, whatever its other qualities, is essentially irrelevant to HFE.

3. HUMAN–TECHNOLOGY RELATIONSHIP

The underlying assumption of HFE is that there is a special relationship between technology and the human. It is impossible to conceive of technology without a human to design and exercise that technology. There is an inherent dynamic within the relationship. If one thinks of that relationship as an equation, behavioral inadequacies will reduce technological efficiency, and technological inadequacies produced by poor design will reduce the effectiveness of human performance. The human dominates the relationship, because technology occurs only when some human molds that technology into a form compatible with human requirements. Technological inadequacies are also produced by behavioral inadequacies. For example, a lack of technician awareness, a conceptual error, caused the Chernobyl nuclear catastrophe.

The proceeding is admittedly an extreme example, but human performance inadequacies occur constantly in situations that fortunately do not lead to catastrophes. Technology can also damage humans severely; a well-known example is muscular trauma which afflicts thousands.

If poor design can cause inadequate human and system performance, then it is logical to assume that more adequate design will produce more effective human and system performance. This is the rationale for HFE; if one did not believe this, it is unlikely that there would be an HFE at all.

4. STIMULUS–ORGANISM RESPONSE (S–O–R) PARADIGM

S-O-R, which was derived from psychology, is a fundamental paradigm. It describes the human as a reactive animal, who perceives stimuli, events and phenomena, assesses these in terms of actions required, and responds appropriately (presumably so, or the human animal would probably have disappeared in earlier ages).

From a more immediate standpoint, however, the significance of S-O-R is that to understand and deal with complex phenomena, it is necessary to *decompose* these into S-O-R elements. Phenomena may be too complex to deal with as they first appear, but decomposition into more molecular elements permits a more meaningful response. The decomposition of X into S-O-R is the first and most important expression of HFE analysis.

This is of course reductionism and one sees it most emphatically in HFE design and in the various behavioral analyses that aid that design. At the same time, this reductionism is balanced by a building-up (composition) process, which in design takes molecular elements like individual software instructions and builds them into a complex computer system. Composition also allows us to understand the relationship between these elements and the whole.

5. SYSTEM CONCEPT

The system concept, which derives from principles developed by Hegel, the 19th-century philosopher, and even more antique philosophers upon which he built (van Gigch 1974) serves as a principle underlying the development and understanding of human–machine systems. The essence of a system is *organization*; a system is created when formerly independent entities are organized in relation to each other. Inherent in the notion of

system is a *purpose* that in technological terms is transformed into the concept of *goal*; it is the goal that organizes the combination and interrelationships of functions and tasks to achieve that goal. The goal is, however, essentially an abstraction; it can exert its influence only by being itself transformed by the behavioral specialist into the *mission* that makes functions and tasks dynamic. It is obvious that we have here a series of conceptual transformations: from purpose to goal to mission to functions and tasks.

Inherent in the system concept is a hierarchy of *complexity*. The development of components into modules like a circuit board and from a combination of circuits to the individual equipment, and from the combination of individual equipments to subsystems and then full scale systems — all of these involve an increase of complexity. All systems, physical, chemical, biological, psychological, manifest varying degrees of complexity. In physical terms the number of components interacting with each other defines complexity. In behavioral terms complexity is conceptualized in information processing dimensions: as the number of changing system states that are displayed to the human as stimuli. Our knowledge of complexity is unfortunately slight, because the topic has not been studied to any extent, but we hypothesize that it is responsible both directly and indirectly for adverse performance effects such as difficulty, workload or stress. Since these conditions are deleterious to the human and to system performance, HFE works to reduce or compensate for complexity.

The system concept has a number of very practical consequences:

1. All behavioral analyses begin with an examination of the goal/mission and decomposition of the functional elements linked by the mission. The same is true of measurement; the performance of system elements and their interrelationships must always be related to the overall system goal.

2. The system concept has also meant the necessity of considering in system design all the elements that may affect goal accomplishment. If a possible system performance-shaping element can even be conceptualized, its possible effect on the goal/mission must be considered, even if, after that consideration, the element or factor is rejected as being unimportant.

3. The concept that human–machine systems are built up progressively from elemental to more complex structures means that different attributes must be considered at different levels of complexity. For example, with greater complexity the designer will be able to consider attributes like transparency (the display of internal system operations to assist in failure diagnosis) and flexibility (the availability of different modes of exercising the system under different conditions).

4. Because, in a Gestalt sense, the system is more than the sum of its parts, it is possible that at some level of complexity a degree of *uncertainty* enters the system, unknown to and uncontrolled by system developers. Because the design process involves transformations (to be discussed below), any transformation involves a certain degree of uncertainty, because the designer must cross domain boundaries. At sufficiently high levels of complexity this uncertainty may create what has been called "emergents," which are system properties that were not anticipated and which in

consequence may have unexpected and potentially negative effects on system functioning.

5. Complex systems and equipments exert control on their human operators because of the way in which the devices have been designed; the operator cannot make a device do what it was not designed to do. Extremely large ergonomic systems like an automobile factory require that its personnel perform in specific designated ways designed to permit accomplishment of the system goal. Human–machine systems are built into *organizations* which control these systems; the study of these organizations and how they affect subordinate system units is a speciality within HFE which is called macro-ergonomics (Hendrick 1997). In a nutshell, larger systems control smaller systems, into which these smaller systems are embedded. System developers may not think that what they are constructing have these organizational effects, but those who have studied this aspect of system functioning report that this control aspect does have significant effects on the performance of individual workers and their equipments.

6. TRANSFORMATIONS

HFE has a continuing problem that might be considered to be the essence of the discipline. This is the necessity to transcend domain boundaries when one attempts to transform principles and data (the behavioral part of the human–technology equation) into human–machine systems (the physical domain). HFE is not alone in being involved with such transformations: an example from biochemistry is the transformation of chemical changes at the synapse into electrical neural impulses. Transformations are a critical function of system design when a behavioral function (for example, to start an engine) is transformed by design into a switch for turning that engine on.

Would that all such transformations were that simple! As system complexity increases, the transformation process becomes more uncertain because the purpose of the transformation may be only partially achieved. Suppose that one has to monitor a complex process control system that is influenced by seven variables, each of which interacts with and may affect every other. The designer, in a more traditional mode, might provide the monitor with 7 discrete gauges; which would require the monitor to estimate the effect of variations in any single variable on each of the other six variables — a daunting cognitive problem. In a more advanced design the designer might provide a single multivariate display in which the computer controlling the process would present the interactive effects of the individual variables in terms of changes in a single display. Even so, the behavioral (cognitive) transformation process is significantly more complex than turning on an engine or monitoring a single display, because it requires the monitor to develop a mental concept based on what the display presents; this may be difficult and the way in which the information contained in the display has been packaged may determine how well the monitor can interpret that information. The display designer must not only conceptualize how to transform the information into a display, but also to imagine how the monitor will interpret that display.

What we see in the example above is the emergence not of a new element, but one which in the earlier days of behavioristic psychology was largely ignored — the mind (the modern term

for mind is something like *cognitive ergonomics*). Initial behavioristic concepts attempted to deal with the mind as a sort of "black box" which was covert and non-observable (observability was *a*, if not *the*, criterion of behaviorism). Objective stimuli and responses could be observed and measured, and since those stimuli and responses could only be received and transmitted through the agency of the black box, the box could be defined by those stimuli and responses.

This behavioristic orientation was perhaps acceptable until modern technology (i.e. the computer) forced HFE to attend to the black box directly, not by deduction. That is because the observable operations of the computer speak primarily to the mind. From the operator's standpoint the computer is little more than a display presenting information and the information displayed requires cognitive functions. Because proceduralized control of step by step operations have been taken over by the computer, only the mind is left as a controlling factor.

7. HFE FUNCTIONS

The primary functions of HFE are (1) to study, explain and predict human performance in the operational environment (OE); and (2) to assist in the development of SEP, which will be compatible with human needs and desires.

The ultimate referent for HFE is the OE, which is where workers perform their technological tasks under routine (i.e. non-laboratory) conditions. Because the OE presents difficulties in controlling phenomena, most HFE studies are conducted in the laboratory (Meister 1989, 1999). The laboratory is the antithesis of the OE, since it abstracts and simplifies that factors influencing the performance being studied (the only exception to this is if the experimenter has a sophisticated simulator that permits the researcher to reproduce OE conditions). Because in most cases laboratory conditions vary widely from those of the OE, it is necessary to validate experimental findings. Unfortunately, very little in HFE is validated in the OE.

Prediction is an inherent function of a science and so it is necessary for HFE to make predictions (preferably in quantitative form) of the kinds of performance one would expect to find in the OE. Such prediction would not only validate laboratory findings, if predictions from those findings were found to be correct, it would extend some degree of control (because of the knowledge gained) over operational system performance. Prediction of laboratory findings to OE situations has almost never been tried in HFE, although there is a speciality called "human reliability" which has been studied, although not under the aegis of HFE. Some HFE experimentalists would say that by developing a hypothesis prior to the research and then conducting the study to determine the accuracy of the hypothesis, this is a form of prediction. However, since the OE is the ultimate referent for HFE findings, prediction must describe OE performance or the prediction is essentially irrelevant.

If the prediction function is almost never performed in HFE, the second HFE function of assisting in the development of human–machine systems is flourishing. This function is the one that distinguishes HFE from all other behavioral disciplines, although, in working within an engineering framework, HFE can also be viewed as a quasi-engineering discipline.

Inadequacies in the study of HFE (the first function) hamper the effectiveness with which the second function can be accomplished. HFE professionals need to take an expanded view of HFE into the 21st century, if the discipline is to achieve its many potentialities. That expanded view must include a greater recognition of the role of concepts and theory in performing HFE functions.

It is of course possible to perform daily HFE tasks without tying them to fundamental concepts, but one cannot go much beyond these quotidian tasks without some awareness of the concepts involved in them.

Germany: Gesellschaft für Arbeitswissenschaft

A. Seeber

Universität Dortmund, Institut für Arbeitsphysiologie, Ardeystr. 67, D-44139 Dortmund, Germany

The Gesellschaft für Arbeitswissenschaft (GfA) is the Human Factors and Ergonomics Society for the German-speaking area. Predominantly it covers members from Germany, Austria and Switzerland, but single members come from other European countries. The GfA was founded in 1953. The roots of ergonomics in Germany can be seen in the Max-Planck-Institute of Occupational Physiology, founded in Berlin in 1912 and transferred later to Dortmund where now is the office of GfA.

The GfA represents a broad range of research and application of ergonomics in occupational health and safety, product design, work and organization design, as well as in organization development and labor policy. The target groups of GfA are all "ergonomically acting or interested people." On the one hand, it can be those taking on ergonomic tasks in practice, such as analysis, evaluation and design of work; on the other hand, it can also be those involved in the design of products and processes. Finally, all those who take responsibility for the realization (e.g. managers) have to be included.

Which principles and activities has the GfA? The specific task of the GfA is in the promotion of scientific and professional interests of Ergonomics/Human Factors. The GfA sees itself especially as an active forum for the dialogue between science and practice and all interested social groups.

The GfA develops and guarantees professional standards not only by participating in standardization or as a German partner for the certification as an Euro-Ergonomist, but also by assessment procedures for journal and congress contributions. As far as possible and as required, it represents the interests of its members in the professional field.

The fundamental principles in achieving this goals are:

- The (working) society is subject to continuous change, which requires an appropriate development of Ergonomics/Human Factors. In that case goal conflicts and tensions will occur and be accepted as normal.
- Ergonomic research and design is always aware of the uniqueness of a human being.
- Ergonomic-acting aims at a prevented design of work, technique and organization, which is oriented towards human and economic criteria.
- Ergonomic solutions are subject to a concept, which is useful to all stakeholders (e.g. employees, management, shareholders, society).
- The persons concerned by analysis, evaluation and design will be — wherever possible — involved in these processes.
- Ergonomics/Human Factors also deals with analysis, evaluation and design of non-gainful employments (f. e. housework, voluntary work, community work, etc.)

The GfA is responsible to its members and it feels obliged to the social goal and it makes contributions — wherever possible — to the maintenance, creation and (where appropriate) distribution of human, economically and environmentally compatible work.

The GfA wants to contribute to the dissemination of these contents not only among its members, but also for as many people as possible. The GfA supports the transfer of ergonomic knowledge by the organization of congresses, workshops and publications.

Twice a year, in the Spring (March) and Fall (September), the GfA organizes conferences for members and other participants. For example, the topic of the 44th Spring Conference 1998 was "Communication and Cooperation;" that for the 45th Spring Conference was "Systems to manage Work Protection — Chance or Risk?" Usually, ~300 participants visit the conferences where they can follow ~100 presentations. Additionally, workshops and tutorials are offered. The Fall conferences are more closed in their issues. The presentations characterize only one area of interests. For example, the Fall Conferences of the mentioned years dealt with "Man–Machine Interfaces" and "Future of Labour in Europe: Management of Company Changes." The Fall Conferences have differing numbers of visitors from ~100 to 400 participants.

The *Zeitschrift für Arbeitswissenschaft* is the scientific journal of the GfA. It has four issues per year. There is also a GfA Newsletter sent to the members of the GfA twice a year. Additionally, the GfA is represented with a web-site: www.gfa-online.de

1. HOW DOES THE GFA WORK?

Who can become a member of the GfA? As mentioned, those persons who are interested in Ergonomics can get the membership of the GfA. About 50% work at universities and similar educational institutions. About 25% work in enterprise. The rest covers retired members. In 1999 the GfA had 685 members.

Important decisions can be done only by the General Assembly of the members which takes part once a year during the annual Spring Conference. An Executive Board with eight members leads the society. Management of the daily tasks is done by the GfA-Office with a Secretary and the elected Secretary-General. The President, the two Vice-Presidents and the other members of the Executive Board are elected for 2 years. They can stay for 6 years on the Board, but the President has to change every 2 years.

Technical groups work in different fields. At the moment just two exist: "Management of Innovative Working Time Systems" and "Future of the Working Society." Besides these working groups, there is a substructure that includes the "Lecturers in Ergonomics," which covers the leading staff from the technical institutes and universities that discuss all the topics for training in ergonomics. There are no regional structures among the members of GfA.

Greece: Hellenic Ergonomics Society (HES)

N. Marmaras and T. Koukoulaki

Hellenic Ergonomics Society, Athens, Greece

1. INTRODUCTION

The Hellenic Ergonomics Society (HES) was founded in July 1988 and became a federated member of IEA in August 1994. It is the association of Greek ergonomists and is located in Athens. According to the society's bylaws, its goal is the development, promotion and propagation of the science of ergonomics through the cooperation, exchange of knowledge, methods and experience between ergonomists as well as other scientists whose fields of specialty include the research and understanding of the participation of the human factor to the design, production and use of machines, displays and production systems.

The membership policy of HES is strict regarding the qualifications of its members so that it maintains a scientific society with members that are both highly qualified and active in the field of ergonomics. According to the society's bylaws, full membership can be attained by any person of Greek nationality who holds a university degree in a field related to ergonomics or has at least 3 years experience in ergonomics.

The HES has 33 active full members. The majority (60%) is engineers; the rest are work physiologists, occupational physicians and other scientists. Among them three are academicians, four hold a PhD in Ergonomics, two hold a PhD in Work Physiology and the rest either hold a Masters degree or have taken a postgraduate course in Ergonomics. Four members are qualified European Ergonomists. The main domains of interest and work activities of the HES members are Human–Computer Interaction, Cognitive Ergonomics, Occupational Health and Safety, Ergonomics for the Disabled, Products and Workplaces Design, and Work Organization.

2. MILESTONES

Some important activities of HES throughout its 10-year existence are:

- A 2-year postgraduate training course in Ergonomics funded by the European Commission (1989–91). The course was jointly organized with the Greek Productivity Center. Two European Ergonomics Institutes collaborated in the course: the HUSAT Institute of Loughborough University, UK, and the IAO institute of Germany. Fifteen trainees holding a university degree in disciplines related to ergonomics (engineers, physicians, psychologists, etc.) graduated from this course.
- The society's participation in the European Year for Occupational Health and Safety (1992). A brochure explaining the role of ergonomics in the prevention of occupational accidents and diseases, as well as in the enhancement of productivity, has been published.
- Organization of two seminars on human–computer interaction and environmental factors (1993).
- Participation in the TE 59 "Health & Safety" Technical Committee of the Greek Standardization Organization providing consultation in ergonomics issues.
- Organization of the 1st National Ergonomics Conference entitled "Applications of Ergonomics in Greece" (Athens, November 1997). The conference was organized jointly with the Technical Chamber in Greece, the main body of engineers in the country (> 70 000 members). Twenty ergonomic studies and interventions carried out in Greece were presented, which covered four generic topics: ergonomic evaluation and prescriptions of workplaces, software ergonomics, ergonomic design, and ergonomics in occupational health and safety. The conference was attended by > 130 participants, which is a very satisfactory number for Greece, and enjoyed wide publicity.
- Participation in the national dialogue on the arrangement of working time and work schedules by publishing and distributing a related article (1998).

The HES publishes a tri-monthly newsletter, "Ergonomic Issues." It is distributed to > 300 professionals interested in Ergonomics.

History of Human Factors in United States

D. Meister
1111 Willow Avenue, San Diego, California 92109, USA

Historical writings can be chronological and/or cultural and/or intellectual. The history of a discipline has elements of all of these (Meister 1999), but this discussion of Human Factors (HF) and what has ultimately been termed Human Factors Ergonomics (HFE) will, because of space limitations, be confined largely to the chronological.

1. ANTECEDENTS TO HF

Technology, some of it quite sophisticated, goes back to ancient times (James and Thorpe 1994), but the antecedents of modern HFE can be traced to the pre-World War I studies in scientific management of Taylor (1919) and the work of the Gilbreths, which eventually led to the time and motion components of industrial engineering (see Meister and O'Brien 1996, Moroney 1995 for a more comprehensive description of the early work).

2. WORLD WAR I

The inception of World War I stimulated, as war always does, the development of much more sophisticated equipment. For example, the primitive flying machines of the Bleriot type were modernized into Spad, Neuport and Fokker fighters. The war also saw the development of the first tanks. Because of the inability of many men to operate these machines, particularly aircraft, much attention was paid to the development of selection tests, and this led in the USA to the recruitment of psychologists to develop and administer these tests. This in turn led to the establishments of aero-medical laboratories, which were continued after World War I and were used as a model for the utilization of experimental psychologists in World War II. Because of the need to expand the number of aviators, the Council of the American Psychological Association established a Committee on Psychological Problems of Aviation, which in November 1918 became a subcommittee of the National Research Council. Twenty-three mental and physiological tests were evaluated by trying them out on Army Aviation cadets.

3. BETWEEN THE WARS

The period between the end of World War I and the start of World War II was largely one of gestation, and with relatively few outstanding accomplishments. Many studies of driver behavior were conducted because of the increasing popularity of the automobile. The research interest in automotive themes has been maintained to the present, with the number of papers published by the Human Factors Society on this topic second only to the number of aviation psychology papers. By the end of World War I two aeronautical laboratories had been established, one at Brooks Air Force Base, Texas, the other at Wright Field outside Dayton, Ohio.

Toward the end of the war and following the armistice in 1918 many tests were given to aviators of the Army Expeditionary Force in Europe to determine the characteristics that differentiated successful from unsuccessful pilots. (A similar effort was made, with the same lack of success, following World War II.) Early aeronautical work explored human and machine performance thresholds at environmental extremes; for example, in 1935 an altitude record of 72 000 feet was set in a balloon. Initial work on anthropometry and its effect on aircraft design and crew performance was begun. Link, a pioneer inventor, developed the first simulator as an amusement device and in 1934 the Army Air Corps purchased its first flight simulator (Dempsey 1985).

During this period also noteworthy research was performed at the Hawthorne plant of the Western Electric Company from 1924 to 1933 to study the effects of illumination on worker productivity. The mere knowledge that they were experimental subjects induced all the workers to exert increased effort, a result now known as the "Hawthorne effect." This suggested that motivational factors could significantly influence human technological performance.

4. WORLD WAR II

In 1939, in anticipation of the coming war and following traditions developed in World War I, the Army established a Personnel Testing Section; the National Research Council created an Emergency Committee on Psychology, whose focus was on personnel testing and selection. This was followed in 1941 by the creation of the Army Air Force Aviation Psychology Program directed by John Flanagan (the creator of the "critical incident" method).

So much was very reminiscent of World War I and, if it had not been accompanied by other activities, would be of little interest to HFE history. The war saw an exponential leap in sonar, radar and high-performance aircraft; the list could go on.

Because this was total war, involving great masses of men and women, it was no longer possible to adopt the Tayloristic principle of selecting a few special individuals to match a pre-existent job. The physical characteristics of the equipment now had to be designed to take advantage of human capabilities and to avoid the negative effects of human limitations.

An outstanding example of the kind of work that was done is the now classic study of Fitts and Jones (1947), who studied the most effective configuration of control knobs for use in developing aircraft cockpits. Two points relative to this example: the system units studied were at the component level; and the researchers who performed the study were experimental psychologists who adapted their laboratory techniques to applied problems.

Early studies of signal discrimination were directed at auditory capabilities of sonar; similar research was performed to determine the visual capabilities needed to detect targets on radar. The aim was to make controls and displays "easier" for operators to perform more efficiently. In cataloging these areas of research it is necessary to point out that they required more than "pure" research; if equipment was developed and/or evaluated as a result of this research, it forced psychologists to work closely with design engineers to make practical use of the HF research. Slowly, but ineluctably, as a result of the enforced intimacy with engineers, applied experimental psychology (the title of the first text on the new discipline, Chapanis *et al.* 1949) was transitioning to HF.

Immediately after the war the military attempted to summarize what had been learned from research performed

during the war. The Army Air Force published 19 volumes that not only emphasized personnel selection and testing, but also contained studies of apparatus tests, psychological research on pilot training, and particularly one on psychology research on equipment design. A second significant publication on what became HF dealt with human factors in undersea warfare.

Why did the efflorescence of what later came to be termed HF and then HFE occur in World War II and not in the earlier war? It was a matter of "critical mass": US participation in World War I lasted only a year and a half; aircraft had been developing since 1903; the tank was put into use only in 1916. The "window of opportunity" for HF lasted only 2 or 3 years, after which the US fell back into its customary somnolence. However, the example of World War I use of psychologists and the research in aero-medical laboratories between the wars provided a pattern for World War II. Moreover, the rise of the "Cold War" between the West and the Soviet Union gave HF an added push. It is also possible that the exponential march of technology — the transistor, the jet engine, the computer, etc. — made a science dealing with human–technology relationships necessary.

5. POST–WORLD WAR II (THE MODERN ERA)

This covers ~20 years from 1945 to 1965. It includes the activities of those who worked in the military in the war and the first generation that followed them.

The beginning of the Cold War fueled a major expansion of Department of Defense (DOD) -supported research laboratories. The immediate post-war environment was particularly hospitable to government-supported research. Laboratories established during the war expanded, e.g. the University of California Division of War Research established a laboratory in San Diego, California. This became the US Navy Electronics Laboratory, which then evolved into the Naval Ocean Systems Center and subsequent incarnations. Each of the services either developed human performance research laboratories during the war or shortly thereafter.

Almost all HF research during and immediately following 1945 was military-sponsored. Universities were granted large sums to conduct basic and applied research (e.g. the Laboratory of Aviation Psychology at Ohio State University). "Think tanks," like the System Development Corporation in Los Angeles and the RAND Corporation that split off from it, were established by the military. Whereas during the war research had concentrated on smaller equipment components like individual controls and displays, the new studies performed by the laboratories embraced larger equipment units, such as an entire workstation or an entire system.

Some of the major psychologists in World War II continued their work. Paul Fitts (considered *the* Founding Father of HF) remained as chief of the Psychology Branch of the Aero Medical Laboratory until 1949. The Air Force Personnel and Training Research Center was built into a corporation-sized organization employing hundreds of specialists in Texas and Colorado.

At the same time opportunities opened up in "civilian" industry (the quotation marks mean that, although industry was in civilian hands, it was supported and dominated by the military). Large companies in aviation like North American, McDonnell-Douglas, Martin Marietta, Boeing and Grumman established HF groups as part of their engineering departments.

The introduction of HF to industry represented a major change in HF. HF was now no longer completely or primarily a research-oriented discipline. The interaction between HF researchers and designers that was fostered in World War II now expanded to HF groups which became integral elements of the system design team. What had formerly been the domain of those who performed "basic" research now had to incorporate the application of their work to the development of physical systems. Even when a formal laboratory was not established, the government, through agencies like the Human Engineering Division at Wright-Patterson AFB or the Army's Behavioral Sciences Research Laboratory, let contracts for human performance research that were awarded to departments of psychology and industrial engineering in universities up and down the country.

To bid on these contracts private companies were formed, like the American Institute for Research under the directorship of John Flanagan who had headed the Army Aviation program; these employed numbers of HF professionals.

All these activities expanded the number of HFE professionals from a very small cadre during the war to at least 5000 professionals (at present), almost all of whom have advanced degrees (MA/MS and PhD). The discipline drew into itself not only psychologists, but also those with training in industrial and other forms of engineering, those with a physiological or safety background, etc. The connection with engineering that had only been vaguely foreseen in the war was now firm and exerted its own pressures on the discipline.

6. POST–MODERNISM (1965 TO PRESENT)

The post-modern period has seen a maturation of the discipline. The Human Factors Society, which was established in Tulsa, Oklahoma, in 1957 with a membership of 60 now has ~5000 members. The number of universities offering graduate programs in what has become HFE has increased significantly. Technology has shunted the discipline in new directions. The development of the computer and the tremendous expansion of computer applications to technology have created a new specialty field for HFE. Empirical HF research in software did not become significant until after 1970, when the personal computer (PC) was developed. Use of the PC by the general public brought with it behavioral problems that stimulated a great deal of research in the development particularly of graphics. Because this was directed at information processing and cognitive capabilities, another new field has recently arisen, cognitive ergonomics, with considerable emphasis on highly sophisticated multivariate displays. The effect of increasing automatization on system performance also received attention, particularly in the field of aviation (the "glass cockpit") with its integrated computerized graphic displays. Organizational psychology has received a new breath of life in the form of macro-ergonomics. Along with this, a traditionally system-oriented HFE has now recognized to some extent the importance of industrialized ergonomics

7. OTHER COUNTRIES

Although much HFE activity developed under American auspices, there were corresponding developments in other countries. HF in the UK proceeded in a manner parallel to that of the USA but

on a much smaller scale. A great deal of cross-fertilization between US and UK ergonomics occurred.

In Western Europe emphasis was very largely on what is called in the US "industrial ergonomics (IE)," which has tended to concentrate more of its attention on worker satisfaction, muscular trauma, biomechanics, etc., topics that have a closer tie with macro-ergonomics that with the more traditional HFE interests in system development. The system development interest is gradually being melded with IE, as exemplified perhaps by the fact that the Human Factors Society (the primary society in US representing HF professionals) changed its name in 1993 to The Human Factors and Ergonomics Society.

The Western orientation to HFE (represented largely by US and UK publications) has influenced HFE activity in Canada and South America, Japan and Australia, as well as Western Europe. HFE in the former Soviet Union took a somewhat idiosyncratic course. The antecedents of modern Russian HFE go back to the late 19th century and to Pavlov, Anokhin and Bernshtein (who are unfortunately not well known outside their native country). The Russian revolution had a devastating effect on Soviet psychologists who were considered by the government to have "bourgeois" and anti-Marxian tendencies. As a result, in the late 1930s laboratories devoted to psychological work were closed and many of their practitioners were exiled or killed. Not until Stalin's death was there a gradual recrudescence, and presently there is a small cadre (perhaps 300?) of HFE professionals functioning. Unfortunately information on what they are doing is not readily available.

American and European publications were allowed to enter Russia, but, to protect Russians against ideological accusations, the Western terminology of the concepts was often changed, although the basic outlines of the concepts remained much the same. There are, however, discernible differences in the Russian orientation, which are described in Meister (1999).

8. SUMMARY

One cannot review the past without anticipating the future. Old problems still remain: precisely what is HFE? What is it supposed to do? Many great challenges face HFE in the 21st century, e.g. the need to develop methods of predicting technological human performance quantitatively; the need to develop acceptable HFE theory and usable human performance models. All of these give HFE professionals much opportunity for further growth.

1. INTRODUCTION

A modern large electrical power plant, powered by nuclear energy, fossil fuels hydro, etc., is a complex human–machine system that controls a thermodynamic process used to produce electrical power. The machine side of the system is a sophisticated arrangement of hardware and software components that are highly reliable, redundant and have a high degree of interconnectedness. The human side of the human–machine system is really a large socio-technological organization with management, engineering, maintenance, operations, and training personnel. Operations personnel interact with the plant through a wide variety of interfaces included in the main control room and various remote monitoring and control stations. Their actions are supported by plant operating procedures and a variety of human–system interfaces (HSI) such as alarm systems, information display systems, controls, diagnostic aids, and communication systems. The safety of such a complex system is supported by extensive analysis of failure modes and mechanisms, engineered features to handle process disturbances, and preplanned human responses to analyzed failures.

While a nuclear power plant (NPP) may be one of the most complex engineered systems, Human Factors/Ergonomics involvement in the design, operation, and maintenance of them was slow to develop and has, at times, been difficult to sustain. In this chapter we will review some of the major events that have shaped the development of human factors in the power industry and some of the individuals that are responsible for its accomplishments. While our main focus is on NPP in the USA, we also address developments in some other countries and in non-nuclear electrical power systems.

2. THE EARLY YEARS, 1950–80

2.1. United States of America

In the USA the field of Human Factors Engineering had become quite well established as a technology and a bridge between behavioral science and engineering by the US Department of Defense (DoD) and its large civilian contractors in the late 1950s and 1960s. However, very little attention was paid to Human Factors (HF) in power systems. There was little or no staff in HF at the US Atomic Energy Commission, predecessor of the US Nuclear Regulatory Commission (NRC), or at the major power plant design firms. Large companies such as General Electric and Westinghouse had human factors staff in many of their military and space divisions but no specialists in their commercial power groups. Nuclear plants that were designed before 1975 were not designed using HF analytical techniques or design standards. Rather, the industry used the same engineering methods that had been developed over the past 50 years in designing hydro and fossil fuel power plants. Interviews with 20 control board designers from a mix of nuclear steam suppliers and architect and engineering firms showed almost no knowledge of human factors/ergonomics and little use of human factors data or methodology in control room design (Parsons *et al.* 1978, Seminara and Parsons 1980).

In 1972 the US Atomic Energy Commission, which later became the US NRC, asserted that insufficient attention was being given to control room design and staffing and operator training and procedures. Alan Swain (1975), at Sandia Labs, identified human factors deficiencies in the design of the engineered safety panels at the Zion nuclear power plant. In 1976, the newly formed Electric Power Research Institute (EPRI) — the research arm of the electric power industry — contracted with Lockheed Missiles and Space Co. to review five typical control rooms. The study performed by Seminara *et al.* (1976) and Parsons *et al.* (1977) discussed the lack of HF principles and showed > 100 photographs of deviations from HF standards and potential areas which could lead to human errors and accidents. When an informal oral presentation of this study was presented to the NRC in Washington, DC, one of the comments was that the NRC considered Human Factors somewhat of a "black art" and was only interested in the back of the control room panels. Another review of 18 control rooms by Finlayson *et al.* (1977) at the Aerospace Corp. was equally negative.

As we have witnessed in numerous situations in various contexts over the years, it often takes a major accident to get the attention of management and the engineering community regarding the lack of good Human Factors Engineering. Such an event occurred on 28 March 1979 at the Three Mile Island Nuclear Plant #2 (TMI-2) in Pennsylvania. Accident investigations disclosed that this catastrophe was due to a variety of factors: inadequate training, a control room poorly designed for people, questionable emergency operating procedures, and inadequate provisions for the monitoring of the basic parameters of plant functioning. The event was a turning point for the nuclear power industry because it emphasized the central importance of human factors to safe plant operation. The President's Commission on the Accident at Three-Mile Island (Kemeny 1979) stated that: "There are many examples in our report that indicate the lack of attention to the human factor in nuclear safety. The control room, through which the operation of the TMI plant is carried out, is lacking in many ways. The control panel is huge, with hundreds of alarms, and there are some key indicators placed in locations where the operators cannot see them. There is little evidence of the impact of modern information technology within the control room … it is seriously deficient under accident conditions."

HF in nuclear safety was suddenly discovered and Joseph Seminara served as a member of the Rogovan Investigating Committee, Stuart Parsons was subpoenaed to testify before the White House Committee on Nuclear Safety, and the NRC contracted with John Snider at the University of Tennessee to assemble a cadre of noted Human Factors specialists (John Hungerford, Stuart Parsons, Earl Wiener, and Chris Wickens), to come to Bethesda, MD, and give all of the NRC managers, engineers and scientists a 1 week crash course in this technology.

In November 1979 the Institute of Electrical and Electronics Engineers (IEEE) devoted an entire issue of their journal, *Spectrum,* to Three Mile Island and provided a large section to human factors and safety using many of the EPRI/Lockheed pictures of control room design problems. The IEEE held their first meeting on Human Factors and Power Plants at Myrtle Beach, SC, in 1979. The industry was finally starting to appreciate that power systems were socio-technical and that technology, people, organizations and regulations interacted with one another in ways that had not previously been understood. Soon after TMI-2, the NRC contracted with the Human Factors Society, to conduct a study of the industry to determine the extent of the problem. The "blue ribbon committee" consisted of Charles Hopkins, Chairman, Richard Hornick, Robert Mackie, Harold (Smoke) Price, Harry Snyder, Robert Smillie and Robert Sugarman. The conclusions of the study were similar to the Lockheed and Aerospace investigations and reaffirmed the lack of human factors in the design of control room controls and displays. Hopkins famous quote was picked up by the press throughout the country, "This disregard for human factors in the control rooms was appalling. In some cases the distribution of displays and controls seemed almost haphazard. It was as if someone had taken a box of dials and switches, turned his back, thrown the whole thing at the board and attached things wherever they landed. For instance, sometimes 10 to 15 feet separated controls from the displays that had to be monitored while the controls were being operated. Also, sometimes no displays were provided to present critical information to the operators. There were many instances where

information was displayed in a manner that was not usable by the operators, or else was misleading to them. A textbook example of what can go wrong in a man–machine system when people have not been taken into account" (Machine Design 1981). Figure 1 is an example of operators adding arrows to the board to indicate the relationship between two related controls after repeated errors had occurred. Figure 2 is a typical control room of that era where no human engineering principles had been applied to the layout.

Some professional human factors specialists did join industrial firms designing nuclear power plants during the late 1970s. Lewis Hanes, later the president of the Human Factors Society, joined Westinghouse's R&D Center in 1973 and soon hired John O'Brien who later headed EPRI's human factors group. Len Pugh was at General Electric in San Jose and helped to lay out Nuclenet, an advanced highly computerized control room. Michael Danchak was at Combustion Engineering in Windsor, Connecticut and was performing human factors research studies on display colors and other variables.

2.2. United Kingdom

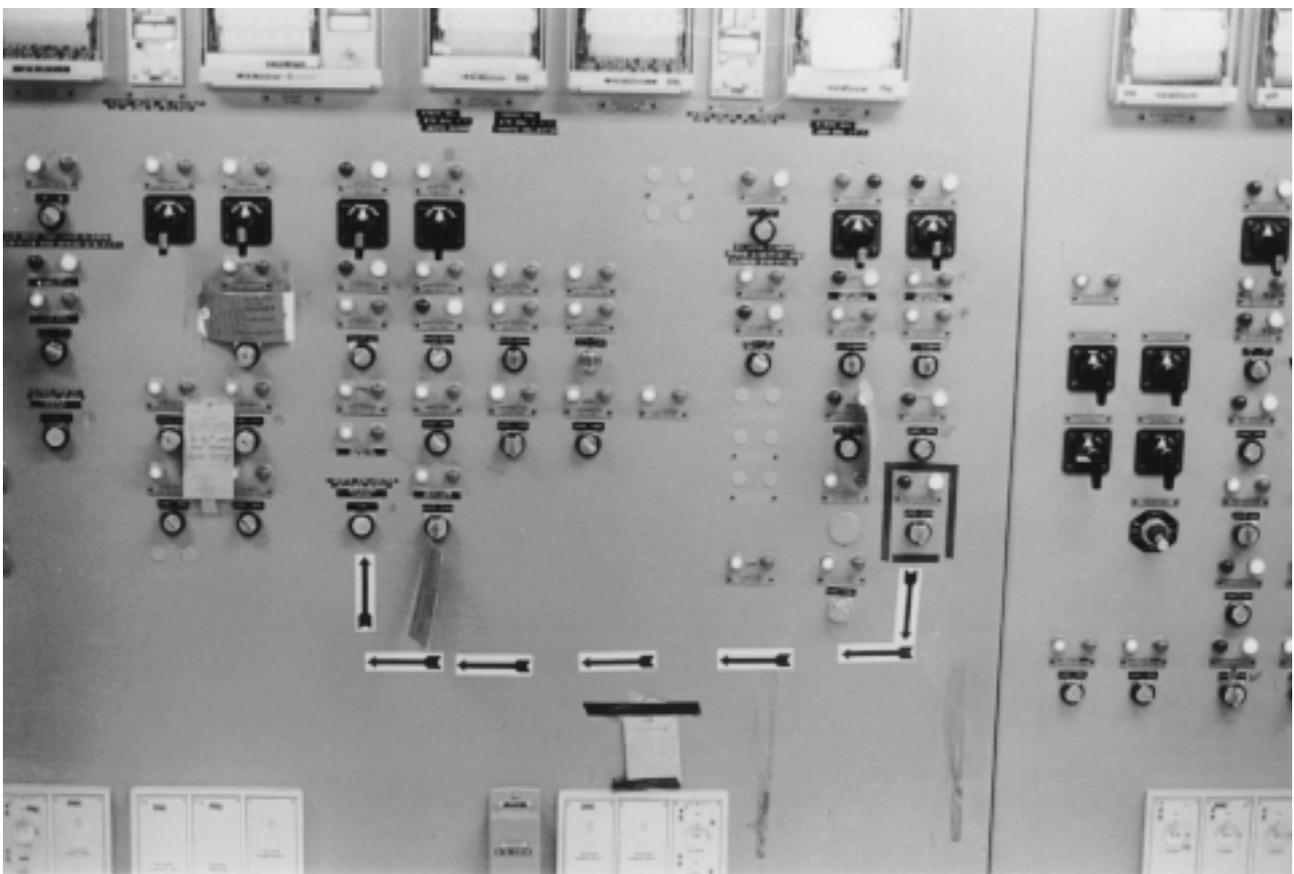
Towards the end of the 1950s the Central Electricity Generating Board (CEGB) became aware of ergonomics and they commissioned Dunlap and Associates in the USA to undertake a pilot survey of human factors aspects of control rooms. The resultant report convinced the CEGB that ergonomics should be taken seriously, and as they were then designing the control room for the Trawsfynydd Nuclear Power Plant, they immediately asked Ron Easterby to act as an ergonomics advisor on the design of


Figure 1.   Operators adding arrows to indicate the relationship of controls
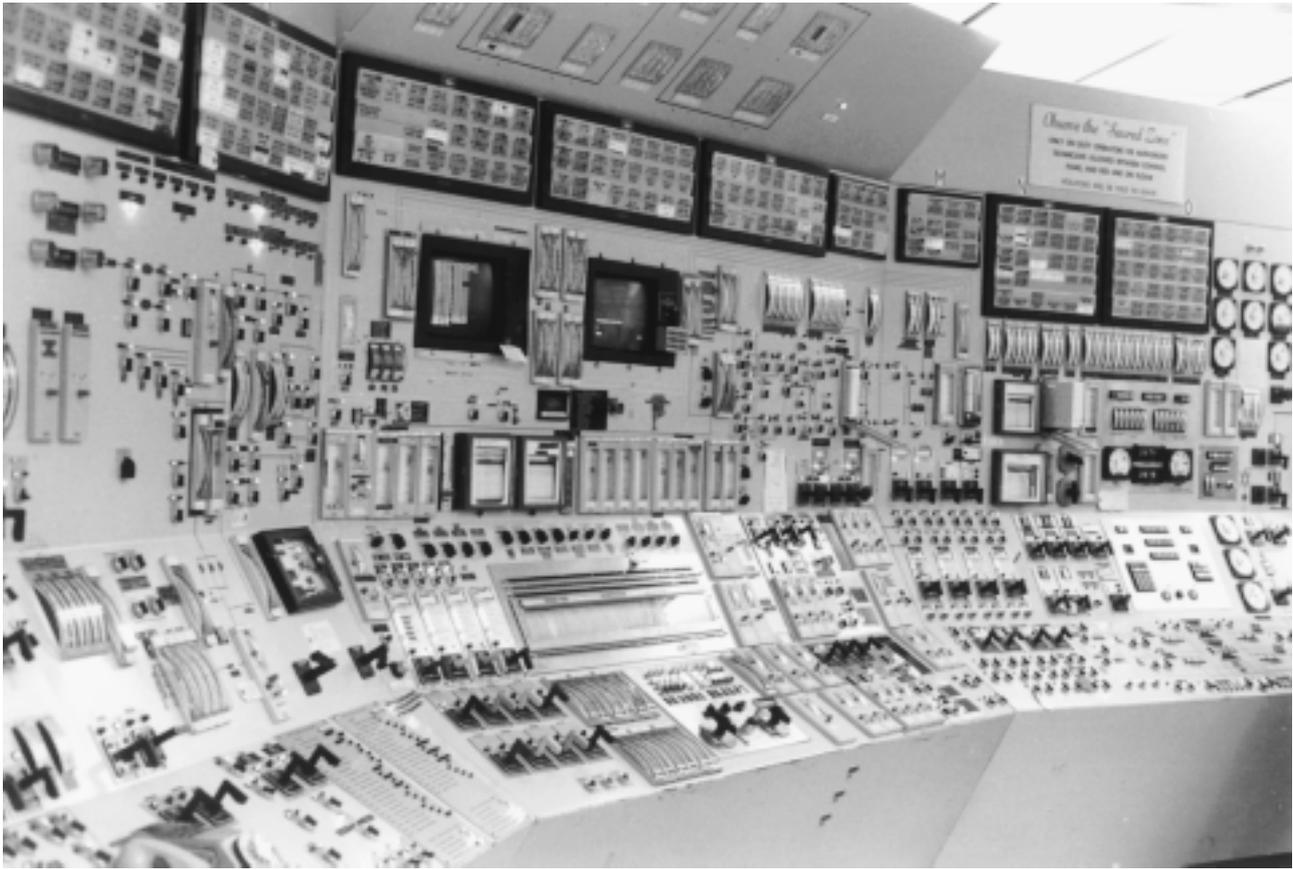

Figure 2.   Typical hardwired nuclear power plant control boards in 1980.

this control room. Easterby ensured that the control room complied with the limited ergonomics guidance that was then available and proposed some modifications to specific interfaces, including a novel mimic display of the control rods.

The resulting control room was acclaimed a success by the CEGB and Reg Sell was appointed as their in-house ergonomist to assist with the design of the control room for the Wylfa Nuclear Power Plant. However, shortly after this appointment, a significant blackout occurred in the south of England, which was attributed to a human error and Sell was diverted to improving the displays for grid control tasks. Thus, much of the design for Wylfa was undertaken by the manufacturer's own ergonomist, Peter Craft.

The design engineers at the CEGB learned much about ergonomics from their experiences on these programs, so that when Sell left the CEGB, it was decided that Reg Pope, an engineer with no formal training in ergonomics or psychology, should head up the ergonomics group. Despite his lack of an ergonomics background, Pope had a good understanding of the operators' requirements and became a powerful advocate of good basic ergonomics throughout the CEGB. This was sufficient while generically similar control rooms were being designed, but by 1979 the CEGB had decided to submit a proposal for a new pressurized water reactor (PWR) to built at Sizewell. This prompted renewed interest in ergonomics by the CEGB and the Nuclear Installations Inspectorate (NII), which was further reinforced as the impact of ergonomics deficiencies on the TMI-2 incident became appreciated. The NII responded to these changed circumstances by asking Lisanne Bainbridge and Neville

Moray to act as their advisors. Meanwhile the Ergonomics Development Unit at Aston University, under the stewardship of David Whitfield, began to build up expertise in this area, with a variety of projects on both nuclear and non-nuclear power plants, for the CEGB and the NII. Perhaps the most notable of these early studies was a comprehensive review of human reliability by David Embrey.

Interest was also being shown in ergonomics on the nuclear fuel reprocessing side. During the early 1980s some limited ergonomics had been undertaken, but by 1987 the tempo was increased significantly as the design work on the massive Thermal Oxide Reprocessing Plant (THORP) began in earnest. Barry Kirwan developed a comprehensive integrated program of task analysis and human reliability analysis to support the design of the computer-based control and display facilities for the plant. This program was to continue for over 5 years, with ergonomists such as Michael Carey, Johanne Penington, Julie Reid and Sue Whalley making major contributions.

2.3. The Soviet Union
The first implementations of human factors principles in the power industry in the Soviet Union were performed by K. M. Gurevich in the 1950s. He investigated Mosenergo's (Moscow Power Co.) operators' behavior during emergencies. The first serious attempts in ergonomic designing of control rooms were done in the Central Institute of Complex Automatics (Moscow) by E. P. Stephany and staff. Later this process was influenced by the Institute of Technical Esthetics (V. M. Munipov and

collaborators), and in the Institute of Psychology, USSR Academy of Sciences (V. F. Lomov and colleagues). Rare attempts to ergonomically influence nuclear power plant designs were made in the Institute of Nuclear Energy. Ergonomics existed mainly as a theoretical science. There were many interesting ideas and sophisticated investigations at the research labs, but they were rarely converted into practical systems. There were no technical standards for control room designs. Engineers applied general construction norms to the design of power plants. Western projects and common sense were the main guidelines. The first simulators were put into operations independently by Mosenergo and the various nuclear plants. There were numerous meetings on psychology and ergonomics on power plant safety. Strong recommendations were made by many outstanding scientists to Soviet Ministry officials, but these were almost always ignored.

3. THE 1980S

3.1. US Nuclear Regulatory Commission

Although the US AEC/NRC had funded research on human factors and human reliability as early as 1972, there was no long-range program and no human factors staff until 1980. In 1981 Dan Jones and other human factors professionals were hired in the Division of Human Factors Safety. In 1983 the NRC published its first long-range human factors research plan (NUREG-0961, 1983) aimed at:

- upgrading personnel qualifications and examinations;
- upgrading operating procedures;
- the utilization of computers;
- the impact on safety of organization and management;
- human contributions to risk and how to reduce them;
- human–machine technology changes that should be considered; and
- HF requirements for severe accident management.

In the 10 years from 1977 to 1987, the NRC funded 125 human factors research projects, studies and related efforts.

As the result of TMI-2, the NRC issued the requirement that operating reactor licensees and applicants for operating licenses perform a detailed human factors design review of their control rooms to identify and correct safety and design deficiencies. Toward this end, NUREG 0700, Guidelines for control Room Design Reviews, was issued in 1981. This 350+ page document was essentially a checklist for reviewing functions, tasks, workspace, communications, annunciator warning systems, controls, visual displays, labels and location aids, process computers, panel layout, and control-display integration. It was used to perform detailed analyses of currently licensed and pending licensed plants. The degree of compliance and amount of retrofitting was frequently dependent upon the utility's attitude toward human factors, and the dedication of various NRC review teams. Other countries, such as Taiwan and Korea, who had purchased nuclear power plants of US design requested that the program be extended to identifying and correcting human engineering deficiencies in their existing plants. Another NRC requirement involved all licensees to install a "safety parameter display system" to aid operators in the rapid determination of plant safety status, something they were unable to do effectively during the accident at TMI. The display system was designed to assist operators in detecting, interpreting and tracking process disturbances by providing a concise display of key parameters

and giving them the ability to observe trends in real time (NRC 1981b).

This Detailed Control Room Design Review (DCDR) program prompted research efforts to determine what might be done cost-effectively to enhance power plant control rooms that were expected to have a nominal 40-year life span. The Lockheed human factors group, under contract to EPRI, paved the way in establishing measures for enhancing existing control room panels with surface changes such as improved labeling, functionally demarcated groupings of related control-display elements, control coding, and marking meter scales to reveal normal and off-normal operating bands (EPRI November 1979). Compare before (Figure 3) and after (Figure 4) enhancement of a Steam Generator Feedwater System Control panel. In this effort to improve an existing panel, none of the control-display elements were moved or replaced. The DCRDR program transformed many deficient control rooms in this fashion.

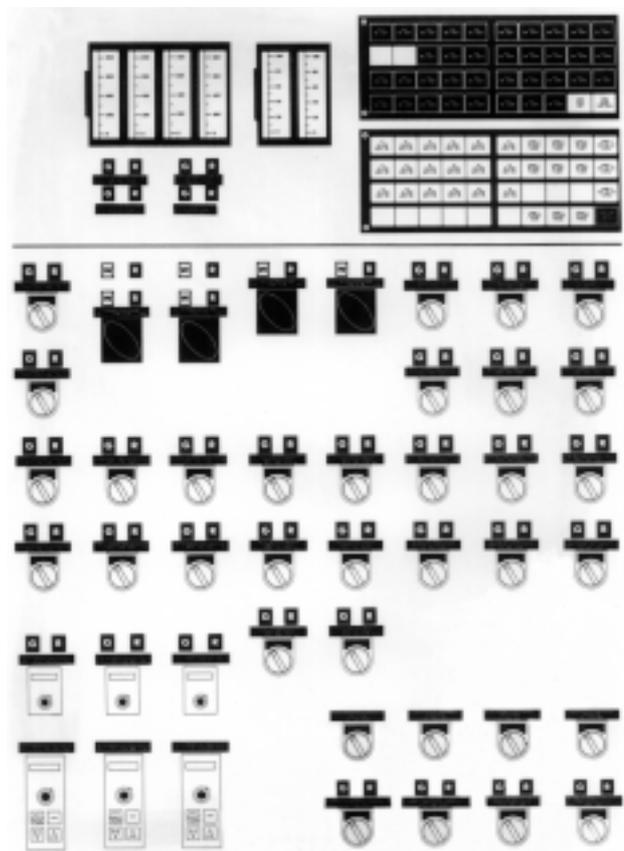
In general, the NRC control room reviews of the 1980s identified a large number of HFE problems and resulted in significant improvements to the Human System Interfaces (HSI) (Eckenrode and West 1997, van Cott 1997). Despite the success of the reviews, there are limitations to the improvements that can reasonably be made to an already designed and operating plant. Many discrepancies are too difficult to correct without completely redoing entire panels. The design review experience


Figure 3.   Feedwater control panel from existing plant (non-human engineered).
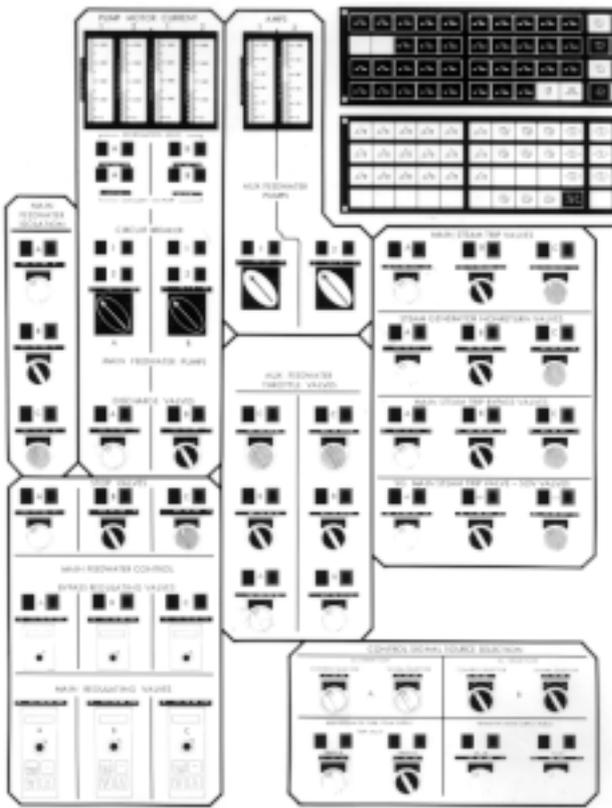

Figure 4.   Same feedwater control panel using labeling and demarcation techniques.

made clear that it is *certainly* preferable to incorporate HFE into the design process from the start.

3.2. Electric Power Research Institute

The long-standing human factors research program of EPRI has produced a series of high quality research reports and research products that are used widely throughout the industry. Because the scope and direction of its HF research program is defined by the industry, the results of the research are usually directly transferable. Other reasons for the success of this program is the overview and direction coming from a task force made up of utility human factors specialists and managers, the stability of EPRI human factors staff, and the fairly constant funding. Over the past 25 years three professional managers have directed the program — Randall Pack, Howard (Jack) Parris, and John O'Brien. The EPRI research program has covered such topics as control room design, alarm systems, computer-generated displays, operator alertness, lighting, qualifications and training, design for maintainability, industrial safety/radiation control, inspection and testing, preventive maintenance, plant enhancement techniques, simulation, labeling and coding, communications, shift length and scheduling, and organization and management. Some of the key technical reports are listed under EPRI in the list of references. It can be seen that these reports include fossil fuel plants and dispatch centers as well as nuclear plants.

3.3. Other Organizations

Soon after TMI-2, the power industry established the Institute of Nuclear Power Operation (INPO) for the transfer of technology from research to industry. INPO recognized that human performance problems were the largest contributors to system accidents and failures in power plants. Accordingly, INPO formulated a Human Performance Enhancement System Program (HPES) to encourage utilities to review significant events in the light of deficiencies in training, procedures, management, self-check techniques or user-unfriendly work environments. The US Department of Energy national laboratories at Brookhaven, Idaho, Livermore, Oak Ridge, Sandia, etc. hired and maintained a large number of human factors professionals with knowledge of power systems. These individuals conducted numerous research studies and provided support to the DOE and the NRC.

During the 1980s some firms including Anacapa Sciences, Essex, General Physics, Honeywell, Lockheed, MPR Associates and Westinghouse conducted numerous studies for the USNRC, EPRI and the utilities. Jens Rasmussen of Denmark created the skill-rule-knowledge paradigm that aided much of the theoretical and analytic work in the field. This work of Rasmussen has had an important impact on the thinking that went into the design of many products now incorporated in plants. Research by David Woods, Erik Hollnagel and Jens Rasmussen on plant safety information systems had a large impact on the development of cognitive engineering. Some of the better known human factors specialists who participated during this time and have not previously been mentioned in this history are: Richard Badalamente, Valerie Barnes, James Easter, Catherine Gaddy, James Geiwitz, Connie Goddard, Douglas Harris, Robert Kinkade, Michael Maddox, Randall Mumaw, Steven Pine, Emilie Roth, Sidney Seidenstein, Alan Spiker, Harold van Cott and Allan Williams,

In 1988, Neville Moray and Beverly Huey edited a report funded by the National Research Council and prepared by an international panel on Human Factors Research and Nuclear Safety. The report presents the panel's recommendations for an agenda of applied research on the human factors issues involved in the safety of nuclear reactors. Two other major publications during the 1980s are: a paper by Woods *et al.* in Salvendy's (1987) edition of the *Handbook of Human Factors*; and a paper by Hanes and O'Brien (1982) in the *IEEE Spectrum*.

3.4. United Kingdom

The 1980s was a time of great expansion for ergonomics in the British power industry, particularly in the nuclear area. The NII soon increased the number of its advisors to form an advisory group known as the Operations and Nuclear Safety Working Group (ONSWG), which consisted of an impressive array of ergonomists with experience of complex systems. By 1981 the UK Atomic Energy Authority (UKAEA) had also become involved in human factors, by appointing David Embrey and Jerry Williams, with a remit to focus upon human reliability issues. The Ergonomics Development Unit also remained at the forefront of practical assessments of UK control rooms, with Les Ainsworth undertaking a comprehensive assessment of different control room evaluation techniques for the NII.

It is interesting to note that by the early 1980s most of the ergonomics had moved from relatively global applications of established ergonomics, to become predominantly task-focused. This demonstrated that ergonomics within the British power industry was fast maturing and becoming accepted at all levels. Another important landmark along this road to increased maturity was passed when the UKAEA commissioned a study of the

ultrasonic inspection of welds, which was probably the first demonstration within the UK that ergonomics could make contributions outside of the control room.

In 1992 Reg Sell spearheaded a campaign for the Ergonomics Society to take part in the Public Enquiry into whether to build a PWR at Sizewell B. This was a momentous decision for British Ergonomics, as it was the first time that the Society had entered such a debate so publicly. The Society did not take a position on the question of whether the station should be built, but argued very forcibly that if it was to be built, ergonomics and human factors must be taken very seriously. The Ergonomics Society's team was chaired by David Whitfield and also included Lisanne Bainbridge, Fred Brigham, Keith Duncan, David Embrey, Andrew Hale, Andrew Shepherd and Ian Umbers. Almost immediately, the CEGB appointed Tom Singleton as their special advisor on ergonomics issues for Sizewell B and from then on, HF/E issues came to the forefront. Indeed the assessor at the Public Enquiry listed some specific ergonomics issues that had to be satisfactorily addressed before an operating license would be granted.

In early 1985 Jerry Williams took charge of the CEGB's ergonomics program for Sizewell B. Subsequently the in-house team was expanded and was later split into two groups. Geoff Pendlebury headed the group that specifically examined operational and procedural issues. This involved undertaking task analyses of critical tasks, then walk-throughs and finally simulator trials with most of the procedures. Pendlebury was supported in this work by Synergy, with Les Ainsworth undertaking most of the task analyses and walk-throughs, whilst Michael Herbert and Ed Marshall ran the simulator trials. Ned Hickling and Denise McCafferty were responsible for the hardware and software interfaces, with support from several different consultants throughout the project. The task analyses that were undertaken for Sizewell have been described in more detail in Ainsworth and Pendlebury (1995).

The Sizewell B project represented a major effort in British ergonomics and most of the input was specific to particular interfaces. However, there were two exceptions to this, which had more widespread practical application. These were a study of operator stress by Tom Cox and a detailed examination of defenses against cognitive or conceptual errors by Ian Umbers and Donald Ridley.

In 1986 and 1987 more ergonomists were appointed elsewhere within the CEGB. At the Central Electricity Research Laboratories in Leatherhead, Michael Herbert and Ed Marshall were involved in several projects, including generic studies of alarm handling and the development of some redesigned interfaces for a coal-fired station. At the Barnwood Offices Jon Berman and Ian Umbers were mainly involved in other Sizewell work, whilst Dave Collier and Jim Jenkinson were finishing the design work for the Heysham Nuclear Power Plant.

The UKAEA initiated an informal working group comprising human factors experts and other representatives from the nuclear industry. This group was started by Ian Watson as the Human Factors in Reliability Group (HFRG) and was soon split into a series of specific working groups. Lisanne Bainbridge presented a series of guidelines for human factors in process control during one of the early meetings, which was subsequently produced as The Short Guide to Reducing Human Error in Process Operations. The first major project of the HFRG was to produce an expanded

form of these guidelines under the chairmanship of Peter Ball, with major inputs from Les Ainsworth, Barry Kirwan, Andrew Shepherd, David Visick and Jerry Williams. Subsequently, the HFRG was extended beyond the nuclear industry, but its working groups are still active.

By 1987 the NII had decided that ergonomics was sufficiently important to justify an inspector specifically to deal with ergonomics issues. Subsequently, David Whitfield was appointed to this post. Soon ergonomics received a further boost from the NII, when it was listed as one of the prime areas for nuclear research. Since then, the NII has defined a series of general ergonomics issues where it feels that further ergonomics research is needed. A group comprising ergonomics representatives from the utilities and the NII then invites research proposals on specific issues that cover these areas and subsequently awards contracts that are funded by a levy of all the nuclear utilities. This has resulted in a wide range of ergonomics studies that are of general, rather than project-specific interest.

3.5. The Soviet Union

On 26 April 1986 the Chernobyl Nuclear Power Plant #4 in the Ukraine exploded and flooded the densely populated heartland of the Ukraine, Belarus and Western Russia with deadly radiation — > 300 times the amount unleashed by the atomic bomb of Hiroshima. There is still strong controversy about human error versus design error and roles of the operators, the designers and the scientists. However, there was no human factors engineering in the design of the control room, and inadequate training and procedures. Chernobyl has brought world attention to what can happen if managers, engineers and scientists disregard the necessity of including ergonomics in the process of designing and operating complex technical facilities (Munipov 1998)

4. THE 1990S

4.1. Nuclear Regulatory Commission

The HSI (Human System Interface) technology being developed for the new generation control rooms was changing rapidly and much of the design was not finalized when submitted to the NRC for design certification. This led to the development of an approach to the HF/E safety evaluation of advanced nuclear plant designs in which the review addresses the design process, as well as final detailed design. There are compelling technical reasons to support this approach. First, it is generally recognized that HFE issues and problems such as those identified above emerge throughout the design process. Second, when HF/E issues are identified before the design is complete, solutions can be considered in a more timely, cost-effective manner, i.e. before design details are locked in. Third, the evaluation of final designs is often based upon the quality of HF/E analyses conducted during the design process, i.e. task analyses to specify control and display requirements. It was further concluded that HF/E reviews should include a variety of assessment techniques.

John O'Hara and colleagues in the human factors group at Brookhaven National Laboratory (BNL) helped the NRC to develop a top-down approach to the conduct of HFE evaluation so that the significance of individual review topics could be seen in relationship to the high-level goal of plant safety. Top-down refers to a review approach starting at the "top" with high-level plant mission goals that are broken down into the functions

necessary to achieve the mission goals. Functions are allocated to human and system resources and are broken down into tasks. Operator tasks are analyzed for the purpose of specifying the alarms, information, and controls that will be required to allow the operator to accomplish assigned functions. Tasks are arranged into meaningful jobs assigned to individual operators and the HSI is designed to best support job task performance. The detailed design (controls and displays, graphical user interface software, maintainability, procedures and training) is the "bottom" of the top-down process. The HF/E safety evaluation should be broad based and include such HF/E aspects of normal and emergency operations, test, and maintenance.

The result of this effort was the HFE Program Review Model which is usually referred to as NUREG 0711 (O'Hara *et al.* 1994). The HFE Program Review Model (PRM) was developed as a basis for performing design certification HFE reviews that include design process evaluations as well as review of the final design. The PRM consists of ten component elements: HFE program planning, operating experience review, functional requirements analysis and allocation, task analysis, staffing analysis, human reliability analysis, HSI design, procedure development, training program development, and verification and validation. Each review element was divided into four sections: Background, Objective, Applicant Submittals, and Review Criteria.

The PRM was used to support several advanced reactor design certification reviews (e.g. GE ABWR, ABB-CE System 80+, and the Westinghouse AP600). The PRM was also used as the basic HFE criteria for the conduct of operational readiness safety reviews for DOE facilities (Higgins and O'Hara 1996).

The NRC research conducted at BNL also led to a significant revision to the guidance contained in NUREG-0700 that was used for the post-TMI control room reviews (NRC 1981a). Following the original control room guidance development in the 1980s, the NRC staff focused on human factors issues for which there were uncertainties in the scientific data needed to support the development of regulation. One such issue was the introduction into control rooms and local control stations of advanced, computer-based HSI technology, a technology that was not used in TMI-era NPP. Advanced HSI designs were emerging because of several factors including: (1) replacement of existing plant HSI with computer-based technologies when existing hardware is no longer supported by equipment vendors, (2) upgrading plants with new, computer-based monitoring and control systems, and (3) development of advanced control room concepts as part of new reactor designs. Each of these developments had the potential for significant implications for plant safety in that they affect the overall role (function) of personnel in the system, the amount of information available, the type of information available, the format of information presentation, the ways in which personnel interact with the system, and the requirements imparted upon personnel to understand and supervise an increasingly complex system. However, the guidance developed in the early 1980s, well before these technological advances, was limited in its applicability to new technology Accordingly, the human factors guidance needed updating.

BNL conducted extensive research into the effects of advanced technology on crew performance. The results were used to develop NUREG-0700 Revision 1 (O'Hara *et al.* 1996). The guidance consists of HFE guidelines, design review procedures,

a computer-based review aid called the "Design Review Guideline" (DRG). Guidance for specific HSI topics such as graphic displays, touch screens, expert systems and local control stations was developed through the application of a general guidance development process (O'Hara *et al.* 1995).

The NRC human factors research at BNL continues to address safety significant HSI technologies such as the alarm systems, advanced information systems, computer-based procedures, soft controls, interface management (e.g. navigation using menus), digital system maintenance, and the design and implementation process associated with control room modernization. The results of these ongoing programs will be used as the basis for the next revision to NUREG-0700, thereby maintaining the document as an up-to-date source of HFE guidance in design and development of electrical power systems.

Currently the NRC's HF Assessment Branch performs inspections of operating plants using professionals such as James Bongerra, David Desaulniers, Richard Eckenrode, Clare Goodman, and Garmon West while the HF Research Branch manages contracted research directed by key personnel such as J. J. Persensky and Jerry Wachtel.

4.2. Industry

Early in the 1990s, the DOE, EPRI, and the NRC provided funding to Combustion Engineering, General Electric and Westinghouse to develop safer and more efficient advanced nuclear power systems. Combustion Engineering, now a division of the Swiss-Swedish giant Asea Brown Baveri (ABB), developed their System 80+, General Electric developed the Advanced Boiling Water Reactor, and Westinghouse Nuclear, now part of British Nuclear Fuels, designed the AP600 System. All of these engineering groups had human factors staffs and utilized current human factors/ergonomics technology during design, development and NRC certification. However, due to the low cost of fossil fuels, gas turbine technology, NRC regulations, and public attitudes in the USA, there have been no orders from US utilities. Combustion Engineering, currently supported in human factors by Robert Fuld, Darryl Harman and Donna Smith, are designing and exporting two System 80+ plants at 1400 MWe each to Korea at the Yanwang and Ulchen plants. General Electric, using the human factors talents of Richard Gutierrez, and the Technatom of Spain in engineering analysis and design, and Stuart Parsons, Joseph Seminara and Linda Taylor as the independent review team, support the Advanced Boiling Water Reactor design project which is building the two Lungmen plants for Taiwan Power Co. The human factors independent review team for Stone and Webster, the Architect and Engineering firm for this project, is contracted to Synergy in the UK with Les Ainsworth, Ned Hickling and Ed Marshall providing technical support.

4.3. Electric Power Research Institute

At EPRI, one major program in the 1990s, managed by Joseph Yasutake, was a joint 5-year program with the Japanese for developing an array of intervention products for improving performance of nuclear power plant maintenance workers. The final summary report by Hanes, Parsons and Taylor describes these interventions (EPRI 1994). Madeleine Gross now manages the human factors long-range strategic program. The tactical program is directed toward better integrating human factors into

the total EPRI engineering effort. The key topics include: identifying key indicators, root causes, and selection of corrective actions; improving procedures, maintenance proficiency and training; and putting the key HF documents on the web for ease of use by utility personnel.

4.4. Professional Organizations

The Institute of Electrical and Electronic Engineers (IEEE) has continued to hold conferences every 3–4 years on Human Factors and Power Plants which have been attended by international experts from utilities, universities, regulation agencies, and researcher organizations. These conferences have played an important role in worldwide information transfer. In 1992, the International Ergonomics Association (IEA) established a Power Systems Technical Group and has been active in information exchange and promoting symposia at the IEA triennial congresses.

4.5. Human Reliability Analysis (HRA)

The topics of risk probabilities, human error, and human reliability analysis (HRA) have been studied in relation to nuclear power plants for the past 25 years by Allan Swain, Neville Moray, John Senders, Jens Rasmussen, Harold Blackman and others. However, this has been a controversial area focusing on: (1) the quantification of human reliability; (2) the lack of hard data for human reliability; and (3) the idea that human reliability debases humans to the level of mechanical system components. Although quantitative HRA data is currently used in plant probabilistic risk analyses, there is no universal agreement on the methods used to develop these data. Blackman and Byers (1998) has recently proposed a six-point program for solving this controversial problem.

4.6. Canada

In Canada the application of a structured methodology for HF/E to the design of CANDU (Canadian Deuterium Uranium) power reactor control rooms, whether for new designs or retrofit projects, has been increasing steadily over the past 10 years. At the present time, new designs and major retrofits have HFE applied in a structured fashion consistent with technical guidance provided in standards such as IEEE 1023 (Guidance for the Application of HFE to Systems, Equipment and Facilities of Nuclear Power Generating Stations). The Canadian planning document, the HFEPP (Human Factors Engineering Program Plan) as described by Beattie and Malcolm (1991) is the main mechanism for incorporating HFE activities in the overall systems design process, and has been used successfully on many projects, e.g. the Darlington Plant near Toronto and the new control room for the CANDU 600 plant under construction in China.

4.7. France

Research and engineering in energy systems including human factors technology has been very active in France. Electricite de France (EdF) is one of the worlds most active designers and marketers of nuclear plants. The French plants have been designed in an evolutionary fashion with one generation of plant design following its predecessor with specific design improvements. The most recent design, the N4, is one of the most advanced designs in operation. The N4 control room underwent extensive testing and evaluation. It is a computer-based control room with seated workstations for operating crewmembers and a large panel display providing high-level status information, important plant parameters, and alarms. With N4's operating in Civaux and Choose, EdF is designing the next generation of reactor.

While EdF has been conducting research and development activities related to plant design and operation, other organizations in the French nuclear industry have been conducting research and investigations into many aspects of nuclear safety and operations. For example, the Nuclear Protection and Safety Institute (NPSI) is a research and consultation organization for the Directorate of Safety and Nuclear Regulation. Their mission is to conduct research and provide evaluations in all aspects related to the control of nuclear risk. These activities include plant safety, protection of people and the environment, management of accidents and nuclear materials transportation. The evaluation activities involve incident investigations as well as reviewing and evaluating information submitted by plant operators for various stages of licensing. These evaluations serve as a technical basis for decisions made by the French regulatory authority.

4.8. Japan

The lessons of TMI and Chernobyl were not lost on the power industry in Japan. A consortium of government and industry initiated a program for human factors research and development. The government side was headed by the Ministry of International Trade and Industries (MITI) and utilized several organizations: the Nuclear Power Engineering Test Center (NUPEC) Institute for Human Factors (focus on basic research), The Japan Power Engineering and Inspection Corporation (focus on reliability improvements), and the Nuclear Power Operation Management Aid System Development Association (focus on man–machine systems). The industry side was made up of several organizations including the Central Research Institute of Electric Power Industry — Human Factors Research Center (focus on applied research), the Federation of Electric Power Companies (focus on human reliability, safety, and control room research), individual electric power companies such as Tokyo Electric Power Company and Japan Atomic Power Company (focus on operation support systems, abnormality diagnostic systems, and reliability), and manufacturers such Mitsubishi. The program is quite comprehensive and includes, for example:

- survey of the current status of HF research;
- human performance and cognitive modeling;
- team performance and performance measurement;
- human reliability research;
- function allocation and automation;
- advanced HSI technology development (including the operation support system — an advanced decision-aiding technology);
- maintenance support system; and
- human factors database development.

Control room development has been influenced by national efforts in Japan to develop advanced HSI technology and operator support systems. These efforts are the result of joint government and industry programs. Unlike control room developments in the USA, the evolution of HSI technology has been gradual.

The conventional (post-TMI) control room (CR) is referred

to as a first generation CR. It is basically a hardwired CR with individual indicators and switches arranged on large-sized panels (typical of many US CR). These control room included a number of post-TMI improvements designed to reduce human error. Control room modifications were assisted by a NUREG-0700-type analyses (many supported by human factors practitioners from US companies such as Essex Corp.). Improvements included color coding of alarm tiles, set point markers, shape coding, system organization of switches and indicators, mimic lines, and the use of CRT for trend monitoring. Work began on the second generation control room in the early 1980s and reflected design objectives to minimize the operators' working area (seated operations), enhance real-time CRT display functions so that plant status can be more easily understood, to reduce operator error during surveillance tests, and to reduce operator workload by utilizing computer controls and computerized operation guides. The "third generation" control rooms featured fully computerized operations, e.g. Toshiba's Advanced Boiling Water Reactor control room called the Advanced Plant Operation by Display Information and Automation (A-PODIA). Current research is being devoted to applying artificial intelligence information processing and operator support for the next generation control room.

4.9. Norway

Although Norway is a non-nuclear country, the premier human factors power systems laboratory in the world is located in Halden. This international joint research effort called the OECD Halden Reactor Project began back in 1958, and was in the beginning focusing on human–machine interaction (HMI). It was decided that all process information should be provided by means of CRT and displayed using process mimics, and where status information used mixed alphanumeric and graphics formats which included mimic diagrams, bar graphs, and trend diagrams. It was also realized that color was a necessary part of the information presentation.

This early work, led to the establishment of the simulator based Halden human–machine laboratory in 1983, which has been the focal point for this area of research and development in Halden. The nucleus in the laboratory has since 1983 been a full-scope pressurized water reactor based upon the Loviisa nuclear power plant in Finland. Today the laboratory is the object for a major upgrading which at the end of 1999 will include four simulators. The existing one, a new pressurized water reactor based on the Fessenheim nuclear power plant in France, a new boiling water reactor based on Forsmark unit 3 in Sweden, and finally a simulator based on the Oseberg petroleum production platform in the North Sea. The experimental facility consists of a cockpit control room for operators and supervisor using CRT, large screens, keyboards and trackballs for interaction. In addition, the laboratory includes an experimenter's gallery from where studies are run and controlled, and where all data collection equipment are supervised. Data collection includes equipment such as computer logging, video cameras, wireless microphones, audio and video mixing, eye movement tracking, etc.

The aim of the human–machine interaction research at the Halden Project is to provide knowledge which can be used by the funding organizations to enhance safety and efficiency in the operation of nuclear power plants by utilizing research about the capabilities and limitations of the human operator in a control room environment. A main premise of this research program element is that as systems evolve and new, more advanced technologies supplant older ones, greater automation of operator functions becomes possible, thereby changing the types of demands which the system will place upon the operator and the potential role which the operator serves in the control room. Understanding the impact of new technology on the role and performance of operating personnel is crucial in decision making for the safety of nuclear power plants.

Today the Halden Project is funded by twenty different countries world wide, and interacts with more than one hundred organizations coming from a variety of areas, including regulatory authorities, vendors, utilities and research organizations. Numerous research projects are being conducted in the area of human factors, for not only the nuclear industry, but also for all kinds of process industry applications. The human factors staff consists of eighteen professionals.

4.10. South Korea

In the late 1990s a small team was set up in South Korea to develop the human–machine interfaces for a new design of Korean reactors. This team under the direction of Yeong-Cheol Shin, developed a comprehensive plan for task analyses to support this design work. At the time of writing, Joongnam Kim and others have started this program.

4.11. UK

During 1992 and 1993 the Sizewell program was wound down (and the THORP project was also coming to a close). There were no immediate plans for further nuclear stations and so the power industry, which had by now been privatized into smaller companies cut down its ergonomics staff, so that only Nuclear Electric and Magnox retained any ergonomists, with small teams headed by Ian Umbers and Ray Hughes respectively. The focus also changed — from design to assessment — and stations that had been built with little or no ergonomics inputs, were subjected to rigorous ergonomics assessments as part of the process of extending the operational life of some of the earlier stations. Another concern lay in assessing the adequacy of new systems to provide a further source of emergency cooling at some of the older stations, and which involved many local-to-plant tasks. All of these assessments were based upon task analyses of selected tasks, and whilst they were mainly control room-based, they also included many manual tasks undertaken on plant. As many of these assessments were being made to support Safety Cases, many of them also involved some form of human reliability assessment. The stations themselves undertook some of these studies, but consultants from Synergy and Vectra also provided much support.

As the millennium drew to its close, Jerry Williams and Craig Reiersen, now both at the NII, started to broaden their interest further from the traditional control issues. Thus, the utilities were forced to provide evidence that human factors had also been adequately considered in a variety of tasks. Typical of these were studies of refueling by Les Ainsworth and of maintenance by Jane Mechan. The NII also sought assurances that personnel downsizing, which up to then had been undertaken with little coordinated planning, could be achieved without jeopardizing safety. To date, one station, Chapelcross has grasped this nettle and with support from Synergy, has attempted to use task analysis

to assess and plan the impact of downsizing proposals upon operational performance.

Away from the nuclear industry, ergonomics in other areas of the power industry was more limited. Les Ainsworth and Michael Herbert undertook two studies of grid control facilities, while Ed Marshall and Michael Herbert developed some guidelines for gas turbine plants and also assessed the proposed computer-based interface for some gas turbine plants.

4.12. International Atomic Energy Agency (IAEA)

The IAEA, with headquarters in Vienna, Austria, has been increasingly examining the role of human factors in plant safety. While human factors has long been identified as a key technology for nuclear safety, the IAEA has more recently focused on programs designed to provide human factors support to countries operating nuclear plants. From a macro-ergonomic perspective, the IAEA has provided support on the role of organizational factors to the safe operation of nuclear plants and the importance of a safety culture. From a micro-ergonomic perspective, the IAEA has been providing information on the human factors aspects of control room modernization. For a variety of reasons, many NPP have been upgrading their plants with digital technology. One reason for this trend is to achieve performance improvements. In other cases, old analog systems become difficult to maintain and are replaced with newer systems. The IAEA has held and is continuing to hold numerous workshops and meetings on digital upgrades initially focusing on software and hardware issues. One factor that frequently emerged as important to the successful implementation of a digital upgrade program is human factors. The human factors issues ranged from understanding the effects of advanced technology (such as computerized operator support systems) on human performance to issues related to operator acceptance and training. Some of the reports resulting from these efforts are IAEA (1991–95).

5. INTO THE NEW MILLENNIUM

As noted above, accidents, events and operating experience has demonstrated the importance of "defense in depth" and the role that human factors plays in it. Defense in depth includes the use of multiple barriers to prevent the release of radioactive materials and uses a variety of programs to ensure the integrity of barriers and related systems (IAEA 1988). These programs include, among others, conservative design, quality assurance, administrative controls, safety reviews, personnel qualification and training, test and maintenance, safety culture, and human factors. IAEA established "Human Factors" as an underlying technical principle that is essential to the successful application of safety technology for NPP. The principle states: "Personnel engaged in activities bearing on nuclear power plant safety are trained and qualified to perform their duties. The possibility of human error in nuclear power plant operation is taken into account by facilitating correct decisions by operators and inhibiting wrong decisions, and by providing means for detecting and correcting or compensating for error" (p. 19). Thus, human factors/ergonomics (HF/E) technology is now internationally recognized as essential to the safe design, operation and maintenance of not only NPP but also other large electrical power plants. Through the 20th century, HF/E has become integral to the design and operation of the control room. As we look toward the turn of the century, we see the extension of HF/E to even broader applications. Some of these applications have already begun, but should receive increased attention in the 21st century:

- Understanding and assessing the influence of organizational factors on safety.
- Focus on individual and crew performance assessment and on the management of unplanned and unanticipated events.
- Further application of advanced technology in the control room:
- staffing reductions;
- performance improvements.
- Extension of successful HSI technologies and programs to HSI out in the plant (outside the control room).
- Improvement of maintenance design and operations.
- Improving data collection and testing methods, including HRA, event reporting, and V&V.
- Understanding and assessing the influence of deregulation on safety.
- Understanding and assessing the influence of license extension on productivity and safety.
- Understanding and assessing the HFE aspects of decommissioning.
- Greater application of HFE to non-nuclear plants operations and maintenance.

While there is every expectation the HF/E considerations will strongly influence the power industry's future; we cannot afford to be complacent. Some serious problems to be faced and overcome are:

- There is a tendency to focus intensely on HF/E when a catastrophe or near-disaster occurs. We should find ways to sustain interest and effort in this discipline between newsworthy accidents.
- Some members of power industry management tend to regard the necessity for HF/E in terms of a temporary "magic bullet" to be applied primarily when a serious problem surfaces rather than developing systematic programs for addressing such concerns in terms of constant preventive measures.
- As regulatory pressures to consider HF/E subside usually due to budget cuts, utilities and government agencies tend to divert resources to other "squeaking wheels."

While many important inroads have been made in the nuclear power industry, there has been only a modest HF/E impact on the design and operation of fossil, hydro, solar, etc. electrical plants. There have been cases where the nuclear division of a given utility was spending enormous resources to enhance operational control rooms from a HF/E standpoint while the fossil division of the same utility was in the process of designing new control rooms with all the usual HF/E deficiencies.

There is a lack of standardization in the methodology and application of HF/E analytical procedures (i.e. functional requirements, function allocations, task analysis, and human reliability analysis) used during the design and development phase. A guidebook with specific examples needs to be developed.

Some people consider nuclear power, particularly in the USA, to be a dying industry making it difficult to recruit and train resources and top talent to be applied in this area of HF/E endeavor.

History of the Gesellschaft für Arbeitswissenschaft (GfA)

H. Schmidtke, A. Seeber, and K. J. Zink

GfA, Ardeystrasse 67, D-44139 Dortmund, Germany

1. HISTORY

The Gesellschaft für Arbeitswissenschaft (GfA), the ergonomics association of the German-speaking area was founded in 1953. It provided a cover organization for several outstanding research personalities and practical experts from Germany, Austria, and the German-speaking regions of Switzerland, who before were scattered over various scientific associations. The time of reconstruction after World War II in Germany and Austria and the structural change in industry in all Western countries focused the attention increasingly upon human capital as a productive factor.

However, more than 50 years earlier, numerous scientists in the fields of medicine, psychology, production engineering, pedagogy, and later sociology had considered the issue of workers and their performance in industry. Fechner deserves mention for providing the first serious experimental evidence of the connection between stimulus and sensation and the threshold term in his main work *Elemente der Psychophysik* in 1860; besides that he published several methodological studies. The first Institute of Experimental Psychology was founded by the physiologist Wundt in Leipzig in 1879. The reorientation from pure basic research towards application-oriented research was achieved by Stern, who coined the term "psychotechnics" in 1903, adopted by Münsterberg in his book *Psychotechnology*, published a decade later.

In addition, a series of associations and organizations such as the Verband für Arbeisstudien (REFA), an association on work studies, and the Rationalisierungskuratorium der Deutschen Wirtschaft (RKW), a curatory for rationalization in German industry, contributed considerably to the development of work science in the German-speaking area. REFA succeeded in distributing ergonomic knowledge over the entire range of industry with its books on time and motion study, industrial engineering, and later the six-volume works on methods of work study. Individual education and research units already existed at the universities before GfA was founded. However, these institutions were integrated into a wide range of different faculties and maintained relatively little contact among each other.

From today's point of view, the Max-Planck-Institute of Industrial Physiology, founded in Berlin in 1912 and transferred to Dortmund later on, has to be considered as the most important unit for ergonomic research in Germany. It undertook a great deal of application-oriented research on the issues of energy transmission in the body during muscular work, blood circulation control, sense physiology, environmental physiology, industrial psychology, much of it under the auspices of Lehmann (from 1927), Müller (from 1930), Graf (from 1929) and Schmidtke (from 1956). In addition, there existed institutions on work science in forestry with Hilf and work science in agriculture with

Preuschen. For practical work in industry REFA proved to be an important conveyor of ergonomic knowledge, since with Bramesfeld it was directed by an outstanding personality who was able to integrate the current knowledge of a large variety of research fields and apply it to the advantage of both workforce and industry.

Perhaps it is no surprise that all these activities in research and industry paved the way towards the foundation of an independent scientific association providing a roof for a variety of different fields. In 1953 the impetus was given by Kellner (Munich), who was then a leading official in the Bavarian Ministry of Labour and Social Affairs. The foundation assembly was held in Nuremberg on 16 October 1953. In contrast to already existing organizations, the foundation assembly put an emphasis on the promotion of research. However, particular strength and institutional power was to be given to the cooperation between industrial physiology, industrial psychology, work pedagogy, technology of work, and industrial sociology. The members agreed on the title Gesellschaft für Arbeitswissenschaftliche Forschung (Association of Ergonomic Research). The choice of the word ergonomic was intended to put special emphasis on the intention of a coordination between the individual research fields.

At the first general assembly in March 1954, some 44 specialists were able to participate. By 1998 the number of regular members had increased to 680. Theoretically there should be a much larger membership. However, several personalities in research and industry working in close connection with ergonomics are members of competing scientific organizations, such as the German Association of Industrial Medicine, the German Association of Psychology, the Professional Association of Psychologists, the German Association of Aerospace Medicine, the Association of German Engineers, and the German Association of Aerospace Engineering. It has to be considered a success that several outstanding personalities from these scientific organizations have been won over to GfA during the last 50 years. This can also be traced back to the fact that, following the tradition of the first scientific congress in 1954, a spring congress had been held every year. In 1958 the name Gesellschaft für arbeitswissenschaftliche Forschung was changed to Gesellschaft für Arbeitswissenschaft (Association of Ergonomics); this was to give a better reflection of its objectives, which cover basic research as well as the transfer of ideas into industry.

Scientific congresses aim at presenting new research results. But they seldom provide a suitable forum to discuss research concepts or methodological questions. In order to create a platform for these issues while giving younger members of research institutes a chance to discuss their unfinished work, an autumn conference has been held every year since 1954. This idea was initiated by Preuschen, who has hosted them in Bad Kreuznach for more than 15 years. As a rule, their scientific concept has been based on the current problems discussed in the fields of economic, labour market, and social policies. Here are some examples:

- higher age at work and office
- women at work
- problems linked to working hours
- young people in the work environment
- reduced performance and preretirement disablement
- definition and evaluation of work performance

- work performance and work environment
- contributions of ergonomics to automation
- application of ergonomic knowledge
- ergonomic aspects in office work
- work organization and motivation
- demand and strain
- systems ergonomics
- communication and cooperation
- management systems for occupational safety

In Germany the congresses have been held almost exclusively in various university cities, in Austria they are held in Vienna, and in Switzerland they are held in Zurich.

During its early years, GfA met with relatively little public interest in the German-speaking area. However, the industry associations and trade unions were interested in the research results in the fields of fatigue and recovery, impact of noise, climate or mechanical fluctuations on performance and health, and methodology of work and time studies. Research results from the wide field of equipment design, design of workplaces, and design of work environments did not attract much attention at that time. Nevertheless, there were ergonomic germ cells in the iron and steel industry, mining, and several producing enterprises. However, their tasks mainly involved work organization, wage definition, and staff selection.

By making it obligatory to follow established ergonomic knowledge in the concept and design of human work, a series of laws and state regulations have led to an increased public awareness of ergonomics from 1972 onwards. GfA profited from this development. On the one hand, the research results presented during the annual congresses have found a much wider audience; and on the other hand, they have stimulated discussion on the ideas and objectives of ergonomics.

In 1946, soon after the end of World War II, several leading personalities released the first ergonomic publication, *Zentralblatt für Arbeitswissenschaft und soziale Betriebspraxis*; their backgrounds were industrial physiology, industrial psychology, work pedagogy, industrial sociology, industrial technology, work organization, and worker protection. The quarterly *Zeitschrift für Arbeitswissenschaft* was founded in 1975 as an organ of GfA. It remains GfA's central publication and is produced alongside REFA's *Arbeitsgestaltung, Betriebsorganisation und Unternehmensentwicklung*. This editorial connection reflects the close relationship between GfA and REFA, the largest technical and scientific association in Germany.

In 1990 GfA created a medal for outstanding scientific achievement, and so far it has been awarded to the members Friedrich Fürstenberg, Walter Rohmert, Heinz Schmidtke, and Eberhard Ulich. Due to their special contributions to ergonomics, the members Hugo Hilf, Herbert Scholz, Gerhardt Preuschen, and Heinz Schmidtke were appointed as honorary members of the association. The Fritz-Giese-Preis donated in memory of Fritz Giese, one of the early pioneers of ergonomics, has so far been awarded to the members Heinrich Dupuis and Klaus Zink. And for several years now, awards have been given to young scientists who produce the best spring congress papers and posters.

The Gesellschaft für Arbeitswissenschaft is a founding member of the International Ergonomics Association.

2. MISSION

In 1998/99 GfA critically and intensively examined its mission and how it reacts to changes in basic conditions. Here is a summary of the discussions among its members. The Gesellschaft für Arbeitswissenschaft eV (registered society) wants to achieve a relevant contribution to the design of living and working conditions by promoting interdisciplinary and holistic research and design concepts. The analysis, evaluation, and design of human work as well as the design of products, services, systems, and environments suitable for human beings, all require a knowledge of different scientific and practice-oriented disciplines. Some of these disciplines are work organization and occupational psychology, occupational medicine, work physiology, industrial sociology, labor policy, vocational education and engineering sciences, economics, and jurisprudence.

GfA integrates this knowledge with a scientific basis. That means the uniqueness of ergonomics and human factors, hence the uniqueness of GfA itself, results from linking individual disciplines (work-related sciences) to achieve a holistic view. In this context holistic not only means the integration of individual disciplines, but also the compatibility of different goals, taking into account human and economic objectives of particular importance.

Work is considered human if it is suitable for people and can be done in a human way and is meant to have neither a negative effect on physical and psychological health nor a lasting and disturbing effect on human well-being. It should correspond to needs and qualifications and enable an individual and/or collective influence on work. Finally, it is necessary to pursue the development of personality by work according to the realization of potential and the promotion of competences. When assessing economic efficiency, one has to consider that solutions might be "efficient" at the level of an individual organization, but might turn out to be inefficient at an economic or social level. All these assessment levels should therefore be taken into account.

The specific task of GfA is the promotion of scientific and professional interests of ergonomics and human factors. For that reason, GfA fosters contact with those who are interested in ergonomics within the German-speaking area as well as at an international level. GfA sees itself especially as an active forum for the dialog between science and practice and all interested social groups. It develops and guarantees professional standards (e.g., by participating in standardization or as the German partner for certification as a Euro-Ergonomist, but also by assessment procedures for journal and congress contributions). As far as possible and as far as required, it represents the interests of its members in the professional field.

Here are its fundamental principles of realization:

- The (working) society is subject to continuous change, which requires an appropriate development of ergonomics and human factors. In that case goal conflicts and tensions will occur and be accepted as normal.
- Ergonomic research and design are always aware of the uniqueness of a human being.
- Ergonomic action aims at a design of work, technique, and organization which is oriented towards human and economic criteria.
- Ergonomic solutions are subject to a concept which is useful

to all stakeholders (e.g., employees, management, shareholders, society).

- Wherever possible, the persons affected by analysis, evaluation, and design will be involved in these processes.
- Ergonomics and human factors also deal with analysis, evaluation, and design of nongainful employment (housework, voluntary work, community work, etc.).
- GfA and its members feel obliged to the social goal and, wherever possible, they make contributions to the maintenance, creation, and (appropriate) distribution of human work that is economically and environmentally compatible.

GfA's target group is all "ergonomically acting or interested people." One group contains those who take on ergonomic tasks in practice, such as analysis, evaluation, and design of work; another group contains those involved in the design of products and processes. Finally, there are those who take responsibility for the realization (e.g., managers). Ergonomic knowledge will be acquired and disseminated by universities, high schools, and application-oriented research institutes; then completed and realized by the ergonomists within the organization.

Even associations, government institutions, and self-help organizations have employees working in the field of ergonomics and human factors. The target group of the GfA is accordingly broad. Here are the central points:

- occupational safety and health protection
- product design
- work and organization design
- organization development and labor policy

Starting from the fact that every person will be confronted with various forms of work in the course of his or her life and will have to deal with the results of work (according to products and services) every day, the broad spectrum of ergonomic topics will then become clear. GfA wants to help spread these ideas among its members and as many other people as possible.

This means GfA must integrate ergonomic knowledge into the education of all those who need these ideas either directly (e.g., production and product design, work organization and organization development, labor protection and work design, personnel development, and in the significant fields of labor policy) or indirectly (e.g., education and training, investment planning, purchase, human resources departments, and management functions). Apart from that, ergonomic knowledge and matters of concern should be imparted by schools of all-round education, but particularly by vocational schools

GfA supports the transfer of ergonomic knowledge by the organization of appropriate platforms (e.g., congresses, workshops, publications, and clearinghouses).

History of Work-related Musculoskeletal Disorders

M.J. Sanders

Department of Occupational Therapy, Quinnipiac College, Hamden, CT, USA

1. INTRODUCTION TO CUMULATIVE TRAUMA DISORDERS

Cumulative trauma disorders (CTD) are injuries that develop in the soft tissues structures of the body such as nerves, muscles, tendons and joints due to prolonged or repeated stresses to a particular part of the body. Such stresses may include awkward or static postures, forceful exertions, vibration and mechanical stresses and may be exacerbated by psychosocial or work organizational issues. While CTD have received notable attention in recent years due to the spiraling incidence in industry and its subsequent impact on industry profits and individuals' lives, CTD are not a new entity. CTD were first described in the 1700s and documented throughout the nineteenth and twentieth centuries as many countries endured an "epidemic" of CTD. These epidemics served as the catalyst to investigate the breadth and causative factors of CTD. Interestingly, the same risk factors proposed to influence the development of CTD in the eighteenth century are the same risk factors that are recognized today.

This chapter will provide an overview of the occurrence of CTD in each country that endured a significant rise of CTD. The discussion will include the focus of investigation in each country, the action taken and speculation as to the cause. This historical overview will illuminate the various theories that help to shape our perspectives of CTD today.

2. EARLY HISTORY OF CUMULATIVE TRAUMA DISORDERS

2.1. Eighteenth-Century Occurrences

Bernardo Ramazzini, known as the father of occupational medicine, was the first physician to chronicle the occurrence of CTD that arose in the workplace. He observed that many of his clients presented with symptoms apparently related to occupational exposures. To investigate these relationships, Ramazzini interviewed his patients about their work tasks, observed their workplaces, and related their physical manifestations to factors within their occupations. In doing so, Ramazzini clearly identified associations between his patients' use of their bodies and physical complaints.

In his *De Morbis Artificum Diatribe* (*The Diseases of Workers*; Wright 1940) Ramazzini (1717: 15) described the respiratory, dermatologic, musculoskeletal and emotional problems of his patients. He opened his treatise with the following observation:

> Various and manifold is the harvest of disease reaped by certain workers from the crafts and trades that they pursue: all the profit that they get is fatal injury to their health. That crop germinates mostly, I think from two causes. The first and most potent is the harmful character of the material that they handle for these emit noxious vapors and very fine particles inimical to human beings and induce particular disease; the second cause I ascribe to certain violent and irregular motions and unnatural postures of the body, by

reason of which the natural structure of the vital machine is so impaired that serious disease gradually develop therefrom.

He continued to describe the posture of scribes and notaries (1717: 421):

> The maladies that afflict the clerks afore said arise from three causes: First, constant sitting, secondly the incessant movement of hand and always in the same direction, and thirdly the strain on the mind from the effort not to disfigure the books by errors or cause loss to their employer when they add, subtract or do sums of arithmetic.

Finally, regarding bakers, he noted (1717: 229), "Now and again, I have noticed bakers with swelled hands, and painful, too; in fact, the hands of all such workers become thickened by the constant pressure of kneading the dough."

Ramazzini poignantly described each task or occupation with careful attention to the potential causes and effects of long-term exposure to toxins, stressful tasks or postures in the workplace. As early as 1717, Ramazzini identified that "constant sitting," "incessant movement of the hand," "strain on the mind" and "violent and irregular motions" were critical factors in predisposing patients to the neuromuscular problems seen today.

Later, in the mid-to-late 1800s, physicians described and designated upper extremity syndromes such as writer's cramp, seamstress' cramp, scrivener's palsy and telegraphists' cramp. These conditions were described as having both physical and psychosocial origins; many were recognized after the advent of technological advances (i.e. telegraphists' cramp coincided with the introduction of Morse code) (Melhorn 1998).

2. CUMULATIVE TRAUMA DISORDERS IN THE TWENTIETH CENTURY

2.1. The Industrial Revolution

The next well-documented occurrences of CTD appeared in the early 1900s during the Industrial Revolution as workers were enticed into higher wages, in exchange for repetitive tasks, assembly-line pacing, and overtime work. When worker's compensation laws upheld coverage for work-related injuries, such as tenosynovitis, insurance companies began to record and further investigate these injuries as related to their clients' occupations. Physicians became the purveyors of decisions regarding worker compensation awards and were compelled to compile data that equated neuromuscular symptoms with work-related activities (Conn 1931).

Evidence of cumulative trauma disorders was most apparent in hand intensive tasks. Early practitioners found that "high speed hand operations," "increased intensity of effort" and "being new to the job" predisposed workers to tenosynovitis (Conn 1931). Attempts to identify the parameters for tolerances of human tendons during repetitive tasks concluded that tenosynovitis would occur in human tendons if repetitions > 30–40 per min or 1500-2000 per h (Hammer 1934).

2.2. The Automated Office

As automation replaced manual labor, work became more efficient and productivity requirements became higher. Workers no longer partook in the "mini-breaks" inherent in operating traditional manual office equipment such as retrieving a typewriter carriage, changing paper or delivering a message. In the automated office, "high speed typewriters" and data-entry machines replaced such

tasks with a keystroke. Workers overloaded the small muscles of the arms and hands instead of using a variety of positions to accomplish the job. In essence, the automated office eliminated any extraneous movements not directly related to the task so that work became streamlined, routine and monotonous. Although each task demanded high levels of concentration, workers became disengaged from the job as a whole.

Hence, the "automated office" of the 1950s emerged as a problematic area for the development of neuromuscular problems. In 1960, at the Fifth Session of the International Labor Organization Advisory Committee on Salaried Employees and Professional Workers office personnel reported physical and "mental fatigue" problems such as eye strain, pain and stiffness in cervical regions, and numbness in the right hand. These complaints prompted an organizational review with ensuing recommendations (ILO Advisory Committee 1960). After the 1960s, many industrialized countries reported an "outbreak" of CTD at different times during their histories.

3. OCCUPATIONAL CERVICOBRACHIAL DISORDERS IN JAPAN

Japan reported a dramatic increase in occupational cervicobrachial disorders between 1960 and 1980. Workers such as typists, telephone operators and assembly-line workers reported pain in the hand and arm that interfered significantly with abilities to perform their jobs. These claims rose to such proportion that in 1964, the Japanese Ministry of Labor issued guidelines for keyboard operators, mandating that workers spend no more than 5 h per day on the keyboard, take a 10-min rest break every hour, and perform < 40 000 keystrokes per day. Companies that implemented these measures reported a decrease in the overall incidence of neuromuscular disorders from 10–20 to 2–5% per industry. However, the overall incidence of CTD continued to rise (Maeda 1977).

Japan subsequently formed the Japanese Committee on Cervico Brachial Syndrome to define the syndrome and fully identify contributing factors. The committee conducted a thorough screening of individuals with neuromuscular complaints (Maeda 1977: 200) and concluded that "how the workers use their muscular and nervous systems at work" and "how the task is organized into the work system as a whole" underlie most conditions. Specifically, researchers identified static loading of postural muscles, dynamic loading of the small arm and hand musculature and muscular fatigue as contributing factors to these disorders. The conditions were found to worsen with insufficient recovery time and excessive workload.

The Japanese committee proposed the name occupational cervicobrachial disorder (OCD) to reflect acknowledgement of problems with both proximal and distal structures. They defined the problem as a functional or organic disorder resulting from mental strain and/or neuromuscular fatigue due to performing tasks in a fixed position or with repetitive movements of the upper extremity (Maeda et al. 1982). Maeda et al. astutely identified a fundamental controversy that exists today; that is, whether OCD is caused solely by factors within the workplace or whether psychological factors such as personal anxiety or workplace stress are the core problems that become magnified by the physical aspect of the workplace.

4. REPETITIVE STRAIN INJURIES IN AUSTRALIA

In Australia the epidemic of repetitive strain injuries (RSI) started in the 1970s and peaked in 1985 with up to 35% of telecommunication workers reporting symptoms of arm pain and muscular fatigue. The "epidemic" spread to include data processors, process workers, bank tellers, musicians and workers in clerical and textile industries. While repetition was initially suggested as the causal factor medical studies could not establish a correlation. Investigators therefore proposed that "psychological rather than physical factors within both the work and social environments ... contributed to the outstanding prevalence" (Ferguson 1971: 284).

The Commonwealth Government of Australia organized a task force on RSI to investigate the factors involved. The task force concluded that both psychological and ergonomic factors contributed to RSI. However, many investigators struggled with whether RSI was a separate disease entity or a grouping of other conditions with similar occupational underpinnings.

The predominant belief holds that the RSI epidemic was based on psychosocial origins. Ireland (1998) chastised the Australian medical community for insinuating that RSI is a medical rather than psychological phenomenon and echoed Ferguson's (1971) and others' beliefs that repetitive strain injury is a sociopolitical phenomena rather than a physical entity. Ireland suggests that RSI is a "collection of inconsistent symptoms" with no objective clinical findings or lab findings to substantiate tissue damage. Ireland attributes the Australian epidemic to a prosperous economy with a waning work ethic, technological changes that increased efficiency but led to job deskilling and job dissatisfaction, and difficulty for older workers to adapt to these changes. Ireland submits that the legal, healthcare, and printed media contributed to the perception that this condition was a physically based injury.

5. OCCUPATIONAL DISORDERS IN SWEDEN, FINLAND AND NORWAY

Scandinavia is considered to be progressive in its laws that protect workers from environmental and ergonomic hazards. Since World War II legislation has encouraged the cooperation of labor and management in issues regarding the work environment (Jensen 1997). The Danish Working Environment Act 1975 emphasized that management held the responsibility for healthy and safe working conditions and that this tenet must be fulfilled in cooperation with employees. Norway and Sweden have corresponding legislation. Although this legislation is in place, these issues are not always fully supported, especially in smaller firms (Jensen 1997).

The Scandinavian countries changed their foci in the 1980s from problems associated with the low back to those associated with upper extremity discomfort in response to increasing complaints of neck and shoulder pain among blue-collar workers (Kvarnstrom 1983). Nordic researchers performed careful studies to identify the contributing factors to neck and arm pain and found significant associations with the type of work being performed (i.e. repetitive, monotonous) and demographic features such as family situation, participation in leisure activities, having a sick spouse, or marital status (Kvarnstrom 1983). The Nordic Council of Ministers recognized the difficulty of comparing studies from country to country and therefore devised the standardized Nordic questionnaire to enhance their ability to compare and compile information among countries.

6. CUMULATIVE TRAUMA DISORDERS IN NORTH AMERICA

Finally, the USA witnessed a gradual rise in CTD from 1980 to 1986 after which point the incidence of reported CTD skyrocketed from 50 000 in 1985 to 332 000 in 1994. This sharp increase was largely attributed to cases in the meatpacking and equipment manufacturing industries. However, a shift to service industry jobs coupled with media awareness has probably contributed to the increase in reporting (Melhourn 1998).

To address the rising incidence of CTD in absence of an ergonomic standard, the Occupational Safety and Health Administration issued Ergonomics Program Guidelines for Meatpacking Plants in 1990 to assist industry in developing CTD prevention programs. The incidence of CTD began a slow descent back to 281 100 in 1996 as businesses began to acknowledge and manage their problems with CTD. The term "cumulative trauma disorder" has been largely used in the USA. However, the National Institute of Occupational Safety and Health (NIOSH) recently proposed the term "work-related musculoskeletal disorders" (WRMSD) to describe these disorders.

Initial investigations in CTD began in the USA with carpal tunnel syndrome in the 1980s and have gradually expanded to examining the incidence of other CTD in high-risk industries such as industrial workers, dental hygienists, electricians and video-display workers.

Research has focussed on delineating the risk factors for CTD, both physical and psychosocial, developing methods to study ergonomics exposures and examining dose-response relationships. In their seminal study, Silverstein et al. (1987) examined the relationship between force and repetition in industrial job tasks. Researchers found that workers in high-force, high-repetition jobs were 15 times more likely to have carpal tunnel syndrome than workers in low-force, low-repetition jobs. This study formed a basis for examining case definitions, methods, and interpreting results relative to CTD exposures. To date, practitioners agree that workers' exposure to a higher number of risk factors will increase the probability of developing a CTD. However, no dose-response relationships have yet been established (NIOSH 1997). Video display work has emerged to be an area widely investigated relative to psychosocial, work design and work organizational factors.

7. CHARACTERISTICS OF CUMULATIVE TRAUMA DISORDERS

Although various names have been attributed to CTD, worldwide investigations of these disorders collectively yield common characteristics. Researchers agree that the following implications that incorporate the work task, the work environment, design of the job and psychosocial characteristics of the individual all contribute to the development of CTD:

- The causes of CTD are multifactorial; they involve physical, psychosocial and work organizational factors. The relative contribution of each factor has yet to be determined.
- CTD are related to the intensity, frequency, and duration of ergonomic exposures; the level of risk for CTD depends on exposure to conditions and the individual capacities.
- Jobs that present multiple risk factors will have a higher probability of causing neuromuscular problems.
- Symptoms of CTD may include distinct features such as objective signs or non-specific symptoms such as pain. CTD present with or without physical manifestations.
- CTD develop insidiously; they may appear after months or years on the job.
- CTD recuperate slowly; they may require extended periods of recovery.
- CTD may reduce worker productivity and cause worker dissatisfaction (Kvarnstrom 1983, Silverstein 1987, NIOSH 1997).

The incidence, causal factors, preventive strategies and legislative acts concerning CTD continue to be explored worldwide. The globally collaborative efforts of researchers are making strides in standardizing assessments and increasing the rigor applied to studies related to CTD. These efforts will increase our understanding and future prevention of CTD in the workplace.

Human Factors, Politics and Power

R. J. Badham

Department of Management and BHP Institute for Steel Processing and Products, University of Wollongong, NSW 2522, Australia

1. WHAT IS HUMAN FACTORS?

Human factors as an engineering discipline that concerns the design of equipment in accordance with the mental and physical characteristics of operators. Since World War II responsibility for seeing that equipment designers take the characteristics of operators and maintenance people into account in their designs has been formalized in the position of human factors engineer, human engineer or ergonomist (Perrow 1983). In more recent years the rise of information or computer-based technologies has led to a rapid increase in human–computer interface or usability engineering. Human factors research may be interpreted more broadly in terms of those disciplines or subdisciplines concerned with the psychological and organizational aspects of the development, implementation and use of technology (Clegg 1993). Narrower concerns with physical or cognitive ergonomics and direct health and safety issues are then broadened to include the impact of technology on the jobs of direct and indirect users, the consequence of technology for changes in organizational structure and processes, and the processes by which technology should be designed and implemented. Despite arguments for adopting a broader view of human factors, survey and case study research carried out for the National Science Foundation's Manufacturing Processes and Equipment Program confirmed that health and safety and ergonomics continue to be the main human factors concerns among US firms (Lund *et al.* 1993).

2. MARGINALIZATION OF HUMAN FACTORS CONSIDERATIONS

Human factors professionals often point to a general failure adequately to consider human factors in technology projects, and commonly attribute this to a lack of awareness or interest in human factors issues by design engineers or the lack of sophisticated quantitative evidence for human factors judgements or easily usable human factors tools and methods. While some explanatory power must be given to such conditions, analysts of organizational power and politics do not regard them as the main reason for the frequent marginalization of human factors considerations. The neglect of human factors is, rather, attributed to organizational factors, in particular the ideas and interests of different affected groups and the distribution of power and resources between them. Perrow (1983) points to the lack of incentives and legitimization for human factors considerations provided by senior management; the culture, training and resources of design engineers; the lack of organizational authority of human factors professionals; and the relative weakness of operators or users of technology who are most immediately disadvantaged by inadequately designed technologies. Clegg (1993) observes that broader organizational, institutional and educational systems have evolved and operate to marginalize human and organizational issues without the deliberate intervention of any particular individual or group. He points in particular to the characteristics of technology development organizations, user firms, education and training cultures, regulatory institutions and public funding bodies. These institutions systematically foster: disempowering attitudes towards end users and a lack of end user skills, knowledge and organization; technology development processes that have goals, design criteria and control mechanisms that foster a narrow technical orientation; technology investment and commissioning practices that systematically undervalue human factors; an education and training system that is biased towards technical skills and creates two antagonistic scientific and humanistic cultures; and a research and development profile that under-resources and narrows the scope of human factors research. The analysis of such influences and how to address them leads the human factors professional into the broader area of organizational power and politics.

3. ORGANIZATIONAL POWER AND POLITICS

Power and politics are not straightforward terms and are highly contested. A key feature of power is, however, the capacity to produce intended effects in line with perceived interests. It is the ability to get things done your way, with the cooperation of others or in the face of their opposition. Political behavior can be seen as the practical domain of power in action, worked out through the use of techniques of persuasion, influence, coercion or manipulation. The roots of such political behavior lie in personal ambition, in organization structures that create roles and departments which compete with each other, and in major decisions which cannot be resolved by reason and logic alone but which rely also on the values and preferences of the key actors involved. Organizational politics is fostered by the existence of vertically and horizontally differentiated groupings, each of which develops its own culture, interests, procedures and practices. Typically, individuals within these subunits, their leaders, and the groups themselves, compete for scarce resources. They interpret organizational events and choices, and attempt to bring about changes, in line with their particular perceptions of their interests and those of the organization.

This view of power and politics directs attention towards the deliberate strivings of individuals and groups in situations of conflict over human factors issues. In line with commonly recognized prescriptions for political "stakeholder" analysis, it has often been noted that it is not in the career interests of highly mobile senior managers to invest heavily in enduring workable systems, that design engineers with different career aspirations control more of the resources and information relevant to human factors considerations than human factors professionals themselves, and that users are often too busy, uninterested or restrictively focused on potential negative consequences for pay and employment to participate effectively throughout the technology development process. Underlying these more obvious political influences are, however, the organizational and structural conditions that create an institutional "mobilization of bias" against the full consideration of human factors issues. Such a bias, consciously or unconsciously promoted within and between organizations, has been referred to as the "second face" or second and third dimensions of power (Buchanan and Badham 1999).

Examples of the mobilization of bias include such issues as

why senior managers are often moved onto other jobs by the time that the technologies they were responsible for acquiring are fully operational. It includes the causes and consequences of factors such as the fact that US managers rotate more frequently than Japanese managers, giving them less of a vested interest in the long term health and performance of their particular areas of responsibility. Perrow (1983) points to broader "error inducing" or "error avoiding" cycles built into the institutional contexts within which senior managers operate. The air transport industry, for example, has an "error avoiding" cycle as performance failures have a relatively immediate effect on profits and reputation, failures receive broad media coverage and are thoroughly and openly investigated by a number of parties, and the causes of failure has significant legal and insurance consequences. Moreover, users of the air transport system can go to other users quite easily, and technological fixes are often not that complex or expensive. In contrast, in the marine transport industry, the international system is made up of conflicting national interests, there are few effective regulations, economic losses are absorbed with little notice and passed onto the final consumer, and human losses are initially restricted to officers and crew, and production pressures are high and competition is a comparatively under-regulated, and the causes of accidents are difficult to determine and impeded by national interests, weak regulatory agencies, weak unions, and the lack of monitoring data.

The perceptions, interests and actions of design engineers are also affected by the broader cultural and institutional settings within which they operate. Engineers are educated in different subdisciplines and within different national contexts, and they work in different departmental and organizational locations with different objectives and constraints. Manufacturing and industrial engineers are often more sympathetic to technology implementation matters than design and development engineers, Scandinavian engineers operate within a training and legislative environment more conducive to considering human factors than their UK counterparts, Japanese manufacturing engineers are often noted for their greater attention to continuous improvement of operating practices than US engineers, influenced by their rotation through operational jobs, more frequent to line management, and less interfirm job mobility.

Human factors professionals may also operate within very different organizational conditions. In those organizations that have more or less strong human resource management representation at senior management level, initiatives such as human resource development or occupational health and safety strategies may alter the criteria against which the work of human factors professionals are judged. Many technology projects, for example, are used as initiatives for cultural change in organizations committed to human resource development, and ergonomic and health and safety considerations then become symbols of management's commitment to people.

Finally, the users or operators themselves differ considerably in character and degree of skill and power. Levels vary considerably in the degree of trust in employer/employee relations, unionism, dependence of employers on employee motivation, skill and expertise etc., all of which strongly affect the will and skill of operators towards participation in technology development. Airplane pilots are, for example, both highly skilled and unionized, and able to devote considerable resources to fighting

allegations of operator error as the source of aircraft malfunctioning and crashes. Representatives of user firms come into conflict with vendors or engineering development companies, line managers conflict with engineering departments, and maintenance people and direct operators each have their own interests and perspectives (Salzman and Rosenthal 1994).

4. POLITICS AND THE ART OF INFLUENCE

Much of the literature on organizational politics has been influenced by a negative view of politics as a black art, something to be reduced or avoided. This interpretation has been dominant among a number of theoretical traditions that have influenced human factors research, such as organizational design and development and socio-technical theory (Buchanan and Badham 1999). The predominance within human factors research of a harder scientific or engineering approach to research and education has tended to encourage such a view of politics as an unfortunate distraction or disruption of the real scientific work of the day. In contrast to such a view, however, has been a more positive view of organizational politics as the techniques and art of getting things done in organizations. Positive political skills are increasingly important when changes are being proposed that cut across organizational boundaries and involve people in changing their traditional patterns of behavior.

As the introduction of technology creates or requires behavioral change, it will inevitably trigger organizational politics. The human factors professional is inevitably part of this process. Badham (1993) argues that human factors professionals need to improve their understanding and skills in this area if they are to be effective actors in technology implementation. Pettigrew (1974) observes that "Specialists do not merely advise, they persuade, negotiate and exercise the power they can mobilize" (p. 27). In so doing they utilize five power sources: expertise; control over information; political access and sensitivity; assessed stature; and the amount and kind of groups support given to the specialist by his colleagues in his own and related specialist groups. The human factors professional, like other specialists, needs to establish credibility if he or she is to be effective. This inevitably involves *anticipating* the varying needs, expectations and reference groups of different groups of executives and specialists involved in or affected by a human factors project. Those specialists who work on their own tasks, become preoccupied with the intricacies of their own expertise, and only see clients when task issues are involved is unlikely to be able to anticipate such needs very well. Successful specialists develop multiplex relationships with other significant partners or clients in a project, and succeed in demonstrating competence in areas salient to the other actors. Buchanan and Badham (1999) argue that such "power skills" should be part of the skills of all professional innovators.

5. THE POLITICS OF TECHNOLOGY

It would be a mistake to restrict the political dimension of human factors research to a question of implementation. It also enters the fundamentals of technological design, what is considered valid knowledge, and criteria against which such goals as system productivity and success are to be measured. What counts as "manufacturing knowledge" is the product of the power relations in which it is constructed (Gillespie 1993) and technologies are shaped by the "technological frames" (Bijker 1995) of the

groups involved in their design and operation. As Perrow (1983: 534, 540) remarks, "The design of systems, and the equipment that is used, is not entirely determined by technical or engineering criteria; designers have significant choices available to them that will foster some types of social structures and operator behaviors rather than others. . . choices that are taken for granted because they are a part of a largely unquestioned social construction of reality — one that should be questioned." Despite such appeals, there have still been few detailed case studies about the actual political processes involved in introducing human factors considerations into technology design and implementation. Human factors professionals need to be aware of the nature of such processes, the political nature of the beliefs and interests of groups that shape technology and affect the role of human factors, as well as the bias inherent in their own assumptions and values.

Human–Machine Systems: Written and Symbolic Communication

S.J.P. McDougall and D.J. Oborne
Department of Psychology, University of Wales Swansea UK

1. INTRODUCTION

The purpose of communication is to convey information. Communication is a process involving two (or more) information-processing individuals or machines. The need for effective communication between individuals and machines is at the heart of human—machine systems. Both words and symbols can form the basis of a visual language through which information is conveyed on interfaces.

The process underlying communication is best understood when one realizes that the linguistic origin of the word is the Latin "communis" meaning common. An essential prerequisite of communication is a common understanding by those involved in the communication process. Oborne (1995) points out that the role of interface designers is to arrange a situation which enhances the chances of the transmitter and the receiver having a maximum common understanding.

Influential psycholinguistic theories have suggested that the communication process is driven by the need to achieve the best possible communication for the least possible communication effort (Sperber and Wilson 1986). This constraint applies equally when communication is between individuals or between human and machine. Interfaces that use written or symbolic communication should therefore be designed in order to make the interpretation of information as easy as possible. Usability considerations therefore need to focus on how meaning can best be represented to allow effective communication via the interface.

2. REPRESENTATION OF MEANING

2.1. Similarities between Symbols and Words

Although icons appear very different from words, they share the same historical roots. Horton (1994) points out that the use of visual symbols is not new and, in fact, is one of the earliest forms of written language. Simple pictorial images have been used to convey information and tell stories in many cultures. The earliest true writing systems were "logographic" (from the Greek "logos" meaning word) and were based on a one-word-one-symbol principle. The alphabetic systems now commonly used came about as visual symbols began to represent sounds rather than words (see figure 1).

2.2. Differences between Symbols and Words

Symbols, by their very nature, are more ambiguous than words. When reading, words and letters act as a code which allows us to arrive at meaning. The code is based on sound and we use our knowledge of letter—sound rules to work out what words refer to (e.g. "cuh-aah-tuh" for cat when we are young). Providing we are skilled readers, the rules governing word "decoding" allow us to access meaning for all but the most difficult and rare words. Reading therefore provides unambiguous access to meaning in a way that is often not possible with symbols.

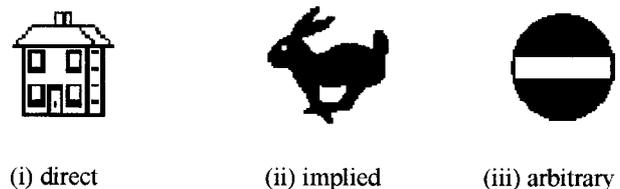
When symbols are used on interfaces there are no definite rules which allow us to decode their meaning. As a result, users often rely on visual associations to understand them. One of the keys to success of graphical user interfaces is the ease with which they enable use of visual associations by capitalizing on the user's existing world-knowledge. Typically collections of symbols or icons are created which represent real world objects. The user can then employ their existing knowledge about the nature of these objects and their interrelationships in order to understand the interface. One of the earliest and most influential systems using this visual metaphor was the Xerox "Star" office workstation (Smith *et al.* 1982). Symbols were designed to resemble papers, folders, filing cabinets, and mail boxes. Relationships between these icons and their meanings were much clearer because their functions related directly to operations performed on physical objects found in an office. This model underpins current interface design and provides a useful way round the problem of ambiguity.

Where the visual metaphor is used, there is usually a direct visual relationship between symbols and their meanings (e.g. when a picture of a house indicates returning to a home page within a series of displays, see figure 2). In other instances the relationship is implied rather than direct and inferences have to be made in order to arrive at meaning (e.g. figure 2(ii) uses our knowledge that rabbits run quickly to indicate that a system is running a process quickly). In other instances, the relationship is arbitrary (e.g. figure 2(iii) indicates no entry) and it is only our familiarity with the symbol that allows us to interpret it.

2.3. Symbols versus Words

Although symbols are inherently more ambiguous than words, the use of symbols on interfaces has mushroomed over the past two decades. This applies, not only to computer interfaces, but to a huge variety of other interfaces (e.g. cars, video players, and washing machines; chemical, oil, and nuclear process control; public information signs). At the very least, symbols are used as an adjunct to written instructions or function labels, but on many occasions completely replace them. Underlying this change is the fact they make communication possible with little effort, or prior knowledge, on the part of the user.

Ancient Egyptian hieroglyph	Sinai script	Moabite stone	Early Phoenician	Greek	Roman
				A	A
				M	M
					O

Figure 1: Evolution of the alphabet


(i) direct (ii) implied (iii) arbitrary

Figure 2. Symbols with direct, implied and arbitrary relationships to their meaning

Graphical user interfaces have increasingly replaced command-driven text-based interfaces. This is because users do not have to rely on remembering and reproducing the correct command but simply need to recognize, or be able to guess, which symbol represents an appropriate function. Recall is much more effortful than recognition and this is reflected in users' performance. Users learning a graphical interface will make fewer errors, require less task-solving time and express more satisfaction than those using a text-based interface. Even where menus reduce the effort involved, novice users show a strong and consistent preference for symbol-based interfaces. Despite the popularity of graphical user interfaces, it is important to remember that written instructions still appear almost everywhere. In practice, text and symbols or graphics are often combined on interfaces. A number of general considerations determine the balance of their use on the interface. These are as follows:

- Symbols offer a universal and international mode of communication and will be used where users may not be skilled readers or share common language (e.g. public information signs).
- Symbols can sometimes convey information in a more spatially condensed way. This can be particularly important where clutter on the interface is likely to be a problem.
- Symbols and graphic displays are better when spatial information needs to be conveyed (e.g. in cockpits).

Written information is important where ambiguity needs to be resolved. Even where there are direct relationships between symbols and their meaning, 20% of users will not understand their meaning when they first encounter them so written labels are important for ambiguity resolution. Often users may initially scan interface symbols to find appropriate information and thereafter will use written labels to determine whether this is in fact the correct part of the interface.

3. DESIGN PRINCIPLES

The manner in which symbols, words, and text are displayed on an interface will either enhance or reduce the chances of effective communication taking place. The design principles employed when using words or symbols will now be considered.

3.1. Words and Text
3.1.1. Legibility
The distance at which the text will typically be read will largely determine type size. The font size should be large enough to be easily legible since type sizes which are too small increase reading times. Hard and fast rules are not appropriate since legibility depends upon context of use. Warnings, for example, need to be legible at a safe distance and placed where they will be noticed. Legibility is increased if simple type faces are used and text consists of a mixture of upper and lower case letters.

3.1.2. Sectioning prose
If text giving instructions uses prose, then dividing the text into meaningful sections allows the material to be structured both perceptually and conceptually since it informs the reader where one set of ideas ends and another begins. Sectioning of prose can be made more prominent by highlighting using increased display luminance, by typographical techniques such as underlining and emboldening, or by coloring different sections. Although the evidence to date suggests that highlighting may have beneficial effects on reading performance and comprehension, caution should taken about the overuse of such techniques since they will only create too many cues for readers and defeat the purpose for which they were originally intended.

3.1.3. Size of display area
While dividing text into distinct areas facilitates the reader's conceptual understanding of the text, the size of the text area relates to lower-level comprehension processes. Width of text should not be too narrow since it will make visual sampling of the text laborious and make comprehension more difficult. By the same token, lines of text which are over long will mean that the reader will take a long time to go back to the beginning of the next line and this will also affect comprehension.

3.1.4. Conciseness and clarity
It is important to be as concise as possible when providing instructions in text since users are less likely to read long sets of instructions. When text is used as a label for icons, long labels should be avoided because they are less likely to be meaningful and will create unnecessary clutter on the screen. Wherever possible use of abstract words should be avoided since their meaning is often "fuzzy" and difficult to define. Concrete words are clearer and more memorable.

Metrics have been used to estimate the "readability" or difficulty of texts. On average, difficult text has a higher percentage of longer words and sentences. This is because longer words tend to be less frequently used and are less familiar and longer sentences place greater processing demands on working memory which has direct consequences for comprehensibility.

3.2. Symbols
3.2.1. Visual complexity
Symbols should be kept as simple as possible since this reduces the overall complexity of the interface and helps make symbols and icons legible and easy to find. If symbol complexity cannot be avoided, increasing their size is important for legibility and this means that fewer can be displayed on the interface. As with text, size requirements to allow symbols to be easily seen will depend on the users' typical viewing distance and the quality of the interface.

3.2.2. Organization and layout
The display should be organized in a way that is compatible with the functionality of the system and allow the user to structure their understanding accordingly. For example, many software packages display clusters of symbols associated with particular functions. Color helps to direction our attention to appropriate parts of the displays and can be used partition displays or to indicate functional relationships between symbols.

As users learn an interface layout, location is likely to become an important cue for symbol search and, if symbols are organized into sensible "conceptual" clusters this will aid both perceptual and conceptual processing. The display should be organized in a way that is compatible with users' likely long-term understanding of the system, i.e. it should be cognitively compatible with the user to allow effective communication to take place.

3.2.3. Shape

Typically, shape is thought to help with visual perception of a display rather than with communicating meaning. When symbols in a set are created so that they differ in shape, this will make them easier to discriminate and reduce search times. Designers can make use of shapes with conventional meanings to represent functions.

3.2.4. Clarity

As we have already noted, the ease with which an interface might be understood is often determined by the pictorialness of the symbols used and the degree to which users might have access to visual metaphors with the real world. The importance of pictorialness decreases as users become more familiar with a system and rely on their familiarity with the system, rather than the visual metaphor, for understanding.

4. CONTEXT AND EXPECTATIONS

The context in which words or symbols are presented may lead to differing interpretations of a system interface. Figure 3 shows a simple example of how meaning can be altered by changing the context. In (i) symbol represents a geometric shape, whereas in (ii) it represents one level of shading. Similar effects can be observed with text as is shown in the sentences below:

> There was a tear in her jacket.
> A tear rolled down his cheek.

Although the words in each sentence are identical, the meaning is changed by the sentence context.

Context is important because it sets up expectations about what is likely to happen next, what procedures we need to follow, and what we can expect of a machine or system. For each contextual situation we have a series of expectations, or "slots", which we use to interpret and communicate in that context. This kind of mental structure is most often referred to as a schema (Schank and Abelson 1977). If users have access to an appropriate schema, it will be an effective tool in reducing the amount of processing effort we need to make in order to interpret information. Dixon (1987) measured how long people spent reading instructions that specified drawing simple geometric shapes which combined to make a picture. When the picture was mentioned at the beginning of the instructions (allowing access to a schema and a set of expectations and procedures), then instructions were read more quickly and drawings were more accurate. These expectancies have been effectively utilized when the visual metaphor is employed on

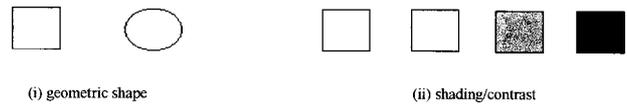
(i) geometric shape   (ii) shading/contrast


Figure 3. The effects of context on symbol meaning

graphical interfaces to reduce the processing required to arrive at an understanding of the interface.

The converse also needs to be considered in design. People will respond more slowly to events or signals which they are not expecting because they require more processing time. For example, system failure usually occurs rarely and users often respond to slowly or inappropriately. This is because users take time to process these events and do not have a set of expected procedures which they might draw upon in order to respond appropriately. Under these circumstances, designers need to ensure that rare events are made salient and obtrusive on the interface in order to allow users to respond effectively. Wherever possible the interface should indicate clearly what that response should be.

5. CONCLUSION

As can be seen from our consideration of the effects of expectancies, effective communication between human and machine is about producing an interface which creates appropriate expectancies in the user. If the interface is successful in accessing appropriate knowledge schemas, then communication will be facilitated and usability increased. Creating systems which are cognitively compatible with the user in this way is a key component of effective user-centered design.

Iceland: Icelandic Ergonomics Society

T. Svensdóttir

The Icelandic Ergonomics Society history is rather less ancient than the history of Iceland, which has been occupied for 1125 years. It was on 8 April 1997 that an ergonomics society was established in Iceland. The formal name of it is Vinnuvistfræðifélag Íslands or VINNÍS in short. The society has its address in Reykjavík. It might be of interest that in 1999 when the society was two years old the population in Iceland was 275 000.

The establishing of an ergonomics society in Iceland was at the initiative of physical therapists working in and interested in the field of ergonomics. A working committee was established in 1996 in cooperation with occupational therapists with the aim of establishing an ergonomics society . The concept of ergonomy was clarified with the assistance of the Nordic and the Swedish Ergonomics Societies statutes. The word "ergonomics" could not be accepted into the Icelandic language. It was therefore necessary to transform "ergonomics" into "vinnuvistfræði" (vinna = work, vistfræði = "ecology", i.e. ecology of work). The word "vinnuvistfræði" has a direct reference to the language and is synonymous with the international concept of ergonomics. We have defined ergonomics in the following manner:

"Vinnuvistfræði" deals with the interaction between human beings and the environment in which they live and work. The environment includes the workplace, equipment, organization of work, communication amongst other things with regard to human needs, well-being and security.

Various professional associations were contacted and encouraged to participate in the establishment of a multiprofessional society like VINNÍS. The result was the establishment of a society with 48 paying members with backgrounds in various professions such as medical, technical, and social science. Institutions, associations, and companies were also founding members. The members of the board are also of different professions.

The goal of VINNÍS is:
- to increase and disseminate knowledge on ergonomics in Iceland
- to facilitate the use of ergonomics in the design of the workplace, work organization, equipment and products.

Through the establishment of the society discourse on ergonomical problems from diverse points of view have been made possible. Members get in touch with other professionals which enables possibilities for direct communication, cooperation, and a flow of information.

The society is open to everyone interested in ergonomics and the working environment. Today there are 85 members from 11 different professional groups, institutions, companies, and associations. Private companies have status as supporting members. Less than 10% of the members have ergonomics as

Table 1. Membership composition by stated profession.

Profession	Total
Architects	4
Interior designers	6
Engineers	4
Ergonomist (MSc)	1
Occupational therapists	21
Industrial designers	2
Physicians	2
Psychologists	4
Physiotherapists	20
Sjuksköterskor	5
Sociologists	2
Other	3
Professional associations	2
Public institutions	4
Private companies	5
Total	85

their major occupation. The following table shows the diversity of members.

The first two years have been characterized by huge interest and enjoyable work. Members have been involved and we have been noticeable in society as a whole. Topic groups have been established with around 25 to 30% of members taking part. The groups themselves have chosen their topic of discussion, method of working and objectives. The following groups were established:
- School environment and school furniture
- VDU work
- Risk assessment in the work environment
- Indoor climate
- Study group on work environment
- PR group

The group on school environment and furniture has contributed considerably to the better ergonomical design of school furniture.

The board publishes two newsletters each year which are distributed to all members. Typical topics are information on VINNÍS activities, on the Nordic Ergonomics Society, latest courses and conferences, newly published books and periodicals on ergonomics. Two discussion meetings are held each year to discuss various issues in ergonomics. The annual meeting is hosted by one of the companies or institutions, to which we also make a site visit.

When VINNÍS celebrated its first year, the board and the PR group arranged an information week on radio and in the newspaper with the greatest circulation. We used the opportunity to draw attention to the society and its objectives. Open theme meetings with a lecturer have been organized twice a year in a café in the center of Reykjavík. Conferences are planned to be a part of the regular activities. In the autumn a half-day conference will be held on the theme "Work environment in a turbulent world".

VINNÍS has been a member of the Nordic Ergonomics Society for one year. It is very stimulating for us to be in contact with other Scandinavian countries with which we hope to work. Ergonomics is, as was stated in the beginning, a new concept for us in Iceland and there are not many who work directly in this field. Though the main emphasis in our Icelandic Ergonomics Society will be on ergonomical questions we will probably also include other work environmental matters. VINNÍS will strive to strengthen its economy in the near future and attract more

organizations and members with technological backgrounds. The future is exciting for us and for the development of ergonomics in Iceland, and we are committed to the future of our society. Those who are interested in further information, or want to make contact, can contact the chairman of the society, Torunn Sveinsdóttir, ph.: +354 567 2500 or e-mail: torunn@ver.is.

IEA Definitions of Ergonomics

1. INTRODUCTION

Ergonomics (or Human Factors) is the scientific discipline concerned with the fundamental understanding of interactions among humans and other elements of a system, and the application of appropriate methods, theory and data to improve human well-being and overall system performance. Derived from the Greek *ergon* (work) and *nomos* (laws) to denote the science of work, its scope extends to all human activity that involves the use of artifacts.

Ergonomists (ergonomics practitioners) contribute to the design of tasks, jobs, products and environments to make them compatible with the needs, abilities and limitations of people.

2. DOMAINS OF SPECIALIZATION

Ergonomics is a systems-oriented discipline and practising ergonomists must have a broad understanding of its full scope. That is, ergonomics espouses a holistic approach in which considerations of physical, cognitive, social, organizational, environmental and other relevant factors are taken into account.

Nonetheless, there exist domains of specialization within the discipline that represent deeper competencies in specific human attributes. These domains of specialization correspond to content knowledge about people rather than system attributes or economic sectors. Ergonomists often work in particular economic sectors or application domains, such as transportation and process control. However, application domains are not mutually exclusive and they change constantly (new ones are created and old ones take new directions), making it nearly impossible to define a useful and comprehensive set of application domains. Moreover, ergonomists can cross application domains and work effectively after an appropriate amount of familiarization. Hence, it is not useful to define application domains. It is far more difficult to cross-domains of specialization without extensive academic training.

The domains of specialization within the discipline of ergonomics include:

- Physical ergonomics is concerned with the compatibility between human anatomical, anthropometric, physiological and biomechanical characteristics, and the static and dynamic parameters of physical work. (Relevant issues include working postures, materials handling, repetitive movements, work-related musculoskeletal disorders, safety and health.)
- Cognitive ergonomics is concerned with mental processes, such as perception, human information processing and motor response, as it relates to human interactions with other elements of a system. (Relevant topics include perception, attention, workload, decision-making, motor response, skill, memory and learning as these may relate to human system design.)
- Social or organizational ergonomics is concerned with the optimization of work systems, including their organizational structures, policies and processes. (Relevant topics include human–system considerations in communication, crew resource management, work design and management, teamwork, participatory design, cooperative work, TQM.)

The International Ergonomics Association (IEA)

Secretary-General, IEA, Poste Restante, Human Factors and Ergonomics Society, PO Box 1369, Santa Monica, CA 90406-1369, USA

1. IEA MISSION STATEMENT

The IEA is the federation of ergonomics and human factors societies around the world. Working closely with its constituent societies and related international organizations, its mission is to elaborate and advance ergonomics science and practice, and to expand its scope of application and contribution to society to improve the quality of life. The following principal goals reflect the IEA mission:

- To develop more effective communication and collaboration with federated societies.
- To advance the science and practice of ergonomics at an international level.
- To enhance the contribution of the ergonomics discipline to global society.

2. ORGANIZATION AND GOVERNANCE

The IEA was organized pursuant to Article 60 *et seq.* of the Swiss Civil Code. The registered headquarters of the IEA is in Zurich with a business office in the USA.

The IEA has the non-governmental organization (NGO) status with the United Nations (UN), World Health Organisation (WHO), International Labor Office (ILO) and International Standards Organization (ISO).

The IEA is governed by a Council comprised of delegates from the member societies and by the Executive Committee of the Council. The IEA Executive Committee comprises of the elected Officers (President, Secretary-General, Treasurer), Chairs of the Standing Committees, Past President (non-voting), Newsletter Editor (non-voting), IEA Historian (non-voting), and the IEA Triennial Congress Chairperson (non-voting). The Standing Committees include: Policy and Development, Science and Technology, Professional Practice and Education, Industrially Developing Countries, Promotion and Publication, and Awards.

3. HISTORY

The origins of the IEA lie in a project initiated by the European Productivity Agency (EPA), a branch of the Organization for European Economics Cooperation. The EPA established a Human Factors Section in 1955, and in 1956 visited the USA to observe human factors research. The next phase of the EPA project was a technical seminar on "Fitting the Job to the Worker" at the University of Leiden in 1957. It was at this seminar that a set of proposals was presented for the formation of an international association of work scientists.

An informal (steering) Committee was appointed to develop the proposals and to organize an international association. The members of that committee were: Professor H. S. Belding, Professor G. C. E. Burger, Professor S. Forssman, Professor E. Grandjean, Professor G. Lehman, Professor B. Metz, Professor K.

U. Smith and Mr R. G. Stansfield. In various phases, members of the Ergonomics Research Society (UK) actively participated in the founding process.

Even though British scientists had founded an Ergonomics Research Society in 1949, "ergonomics" as the name of this new discipline became fully adopted only years later. The Committee decided to adopt the name "International Ergonomics Association" on a preliminary basis until a better name could be found. In 1957, the Council of Ergonomics Research Society (UK) agreed to support the establishment of the IEA.

A preliminary set of bylaws for the proposed international association was prepared and distributed to the informal committee. A special meeting was held in Paris in September 1958, and it was decided to proceed with organizing an association and to hold an international congress in 1961. The committee then designated itself the "Committee for the International Association of Ergonomic Scientists" and elected Professor Burger, President: Professor Smith, Treasurer: and Professor Grandjean, Secretary. Thus, even though the IEA was formally organized in Paris in 1958, the initial organization began with the naming of the informal (steering) Committee at the University of Leiden technical seminar in 1957.

The Committee for the International Association of Ergonomic Scientists met in Zurich during the last phase of the EPA project in March 1959 and decided to retain the name "International Ergonomics Association". The committee also met again in Oxford later in 1959 formally to agree upon the set of bylaws or statutes drawn up by the secretary with the help of committee members and the EPA staff. These statutes were later approved by the association membership at the First Congress of the IEA in Stockholm in 1961.

4. OFFICIAL JOURNALS

Ergonomics, published monthly by Taylor & Francis Ltd, London, is the official journal of the IEA. It published the proceedings of the first IEA Congress in 1961.

Beginning in 2000, the IEA is publishing the IEA *Electronic Journal of Ergonomics*.

5. IEA MEMBERSHIP

The IEA currently has 36 federated societies, two affiliated societies and two sustaining member organizations.

Federated Societies:
- All-Ukrainian Ergonomics Association
- Asociación Española de Ergonomia (Spain)
- Belgian Ergonomics Society
- Brazilian Ergonomics Association (ABERGO)
- Chinese Ergonomics Society
- Croatian Ergonomics Society
- Czech Ergonomics Society
- Ergonomics Society (UK)
- Ergonomics Society of Australia
- Ergonomics Society of the Federal Republic of Yugoslavia
- Ergonomics Society of Korea
- Ergonomics Society of South Africa
- Ergonomics Society of Taiwan
- Gesellschaft für Arbeitswissenschaft (Germany)
- Hellenic Ergonomics Society
- Association of Canadian Ergonomists/ACE

- Human Factors and Ergonomics Society (USA)
- Sociedad de Ergonomia y Factores Humanos de México (Mexico)
- Hungarian Ergonomics Society
- Indian Society of Ergonomics
- Inter-Regional Ergonomics Association (IREA: Russia)
- Irish Ergonomics Society
- Israeli Ergonomics Society
- Japan Ergonomics Society
- Nederlandse Vereniging voor Ergonomie (The Netherlands)
- New Zealand Ergonomics Society
- Nordic Ergonomics Society
- Österreichische Arbeitsgemeinschaft für Ergonomie (Austria)
- Polish Ergonomics Society
- Portuguese Association of Ergonomics (APERGO)
- Slovak Ergonomics Association
- Sociedad Colombiana De Ergonomía (Colombia)
- Società Italiana di Ergonomia (Italy)
- Societe D'Ergonomie de Langue Française (SELF)
- South East Asia Ergonomics Society (SEAES)
- Turkish Ergonomics Society

Affiliated Societies:
- European Society of Dental Ergonomics
- Human Ergology Society (Japan)

Sustaining Members:
- Bureau of the Hungarian Council of Industrial Design and Ergonomics
- Research Institute of Human Engineering for Quality Life (Japan)

6. OFFICERS OF THE IEA

The following individuals has served as elected Officers of the IEA:

1961–64:
- President: S. Forssman
- Secretary-Treasurer: E. Grandjean

1964–67:
- President: G. Lehman
- Secretary-Treasurer: E. Grandjean

1967–70:
- Professor: P. Ruffell-Smith
- Secretary-General: E. Grandjean
- Treasurer: A. Wisner

1970–73:
- Professor: B. Metz
- Secretary-General: F. Bonjer
- Treasurer: A. Wisner

1973–76:
- Professor: F. Bonjer
- Secretary-General: R. Sell
- Treasurer: J. de Jong

1976–79:
- Professor: A. Chapanis

- Secretary-General: R. Sell
- Treasurer: H. Scholz

1979–82:
- Professor: J. Rosner
- Secretary-General: H. Davis
- Treasurer: H. Scholz

1982–85:
- Professor: S. Sugiyama
- Secretary-General: H. Davis
- Treasurer: J. Rutenfranz/B. Shackel

1985–88:
- Professor: H. Davis
- Secretary-General: I. Kuorinka
- Treasurer: B. Shackel

1988–91:
- Professor: I. Kuorinka
- Secretary-General: H. Hendrick
- Treasurer: B. Shackel

1991–94:
- Professor: H. Hendrick
- Secretary-General: P. Rookmaaker
- Treasurer: I. Noy

1994–97:
- Professor: M. Helander
- Secretary-General: P. Rookmaaker
- Treasurer: I. Noy

1997–2000:
- Professor: I. Noy
- Secretary-General: W. Karwowski
- Treasurer: K. Kogi

7. TRIENNIAL CONGRESSES

The IEA has held Triennial Congresses as follows:
- 1961: Stockholm, Sweden
- 1964: Dortmund, Germany
- 1967: Birmingham, UK
- 1970: Strasbourg, France
- 1973: Amsterdam, The Netherlands
- 1976: College Park, USA
- 1979: Warsaw, Poland
- 1982: Tokyo, Japan
- 1985: Bournemouth, UK
- 1988: Sydney, Australia
- 1991: Paris, France
- 1994: Toronto, Canada
- 1997: Tampere, Finland
- 2000: San Diego, USA

The future IEA Congresses are scheduled as follows:
- 2003: Seoul, Republic of Korea
- 2006: Maastricht, The Netherlands

8. AWARDS OF THE IEA

Awards given by the IEA are presented at the Triennial Congress. They are:

- IEA Distinguished Service Award
- IEA Founders Award
- IEA Outstanding Educators Award
- IEA Ergonomics of Technology Transfer Award
- IEA Ergonomics Development Award
- IEA President's Award
- The Liberty Mutual Prize in Ergonomics and Occupational Safety
- IEA/K. U. Smith Student Award

The Awards Committee based upon nominations from the various federated societies selects recipients for the first five awards. Recipients for the IEA President's Award are nominated either by IEA Council or by the IEA Executive Committee: final approval for this award rests with the IEA President. The Student Awards Committee selects recipients for the K. U Smith Student Award

9. RECIPIENTS OF THE IEA AWARDS

IEA Distinguished Service Award:

- 1982: A. Chapanis, E. Grandjean
- 1985: M. Oshima, A. Wisner
- 1988: P. Davis, N. Lundgren, W. Singleton
- 1991: J. Rosner
- 1994: H. Davis
- 1997: H. Hendrick

IEA Founders Award:

- 1991: J. Scherrer
- 1994: K. U. Smith
- 1997: W. Floyd

IEA Outstanding Educators Award:

- 1991: E. N. Corlett
- 1994: W. Rohmert
- 1997: M. M. Ayoub

IEA Ergonomics of Technology Transfer Award:

- 1991: A. Wisner
- 1994: H. Shahnavaz
- 1997: R. Sen

IEA Ergonomics Development Award:

- 1991: K. Kogi
- 1994: J. Leplat
- 1997: D. Meister

IEA President's Award:

- 1997: T. Leamon

IEA/K. U. Smith Student Award:

- 1997: L. Ritmiller

International Ergonomics Standards: ISO/TC 159

W. Schultetus

Institut für angewandte Arbeitswissenschaft e.V., 50968 Köln, Germany

1. INTRODUCTION

Ergonomics is the study of human beings and their work. How can standardization help here? Do we want to standardize man? All ergonomists answer "no" to this question, as machines are supposed to adapt to human beings and not vice versa. However, to provide the means of achieving this objective, the human characteristics and abilities have to be researched and described. Only then can the builder of machines, the organizer of workplaces, and the designer of products for applications in industry, services, and the private sector take proper account of findings in the field of ergonomics. This, in turn, enables them to limit the workload borne by humans to a permissible level and to make a contribution to occupational health and safety.

Human engineering — designing technical products and services to take human characteristics into account — to improve the quality of life and work is becoming a central approach to making products and services more efficient, attractive, and competitive. Applied ergonomics is thus developing into a decisive market factor of the future.

The actual history of standards for ergonomics would have to begin with the first standard that was important for human activities, i.e. that took account of knowledge of human characteristics, abilities, and limits. This was done, for example, by setting the size or strength of the human body in relation to buildings, tools, the work environment, and work systems. Such standards certainly existed long before the concept of "ergonomics" found its way into standardization. It was gradually realized that standardization is an important and efficient way of allowing ergonomic findings to be applied. The International Ergonomics Association (IEA) was behind the establishment of ISO/TC 159, Ergonomics, back in 1975.

2. INSTITUTING STANDARDIZATION IN ERGONOMICS

The scope of ISO/TC 159 is standardization in the field of ergonomics including terminology, methodology, and human factors data. In the context of the scope, the committee, through standardization and coordination of related activities, promotes the adaptation of working and living conditions to the anatomical, physiological, and psychological characteristics of man in relation to the physical, sociological, and technological environment. Among the objectives are safety, health, well-being, and effectiveness.

However, many ISO standards involving aspects of ergonomics have not been developed by ISO/TC 159 for historical and organizational reasons. A survey carried out in Germany in 1996 concluded that more than 10 000 ISO, CEN and DIN standards contain aspects of ergonomics, even though the standard developers were unable to resort to fundamental ergonomic standards for the development of their own standards. This situation is now known and will be modified. The scope of

ISO/TC 159 promotes standardization in the adaptation of working and living conditions to the anatomical, physiological and psychological characteristics of man, with the objective of improving safety, health, effectiveness and well-being.

3. OBJECTIVES

Requirements for ISO/TC 159 to achieve its objectives are:

- to collect and critically review ergonomic data relevant to international standardization, pertinent to the design and manufacturing of machinery, the design and organization of work processes, and the layout of work equipment, as well as the control of the physical environment in the work premises;
- to identify those branches of industry, services, and trade where ergonomic needs will expand or arise with new technologies;
- to recognize the unavoidable time lags in producing as well as their enforcement;
- to set up and to implement comprehensive sub-programs for standardization activities in different fields of ergonomics;
- to make effective use of liaisons with other TCs and SCs through which standards with ergonomic specifications have been or are being produced, sometimes with insufficient consideration of granted ergonomic data and/or principles;
- to create within ISO/TC 159 a strategy planning function in charge of implementing and updating the present strategic policy statement.

Table 1. Organizational structure of ISO/TC 159, Ergonomics

(January 2000)

ISO/TC 159/SC 1, Ergonomic guiding principles

ISO/TC 159/SC 1/WG 1, Principles of the design of work systems

ISO/TC 159/SC 1/WG 2, Ergonomic principles related to mental work

ISO/TC 159/SC 1/WG 3, Terminology

ISO/TC 159/SC 3, Anthropometry and biomechanics

ISO/TC 159/SC 3/WG 1, Anthropometry

ISO/TC 159/SC 3, WG 2, Evaluation of working postures

ISO/TC 159/SC 3/WG 4, Human physical strength: manual handling and force limits

ISO/TC 159/SC 4, Ergonomics of human-system interaction

ISO/TC 159/SC 4/WG 1, Fundamentals of controls and signalling methods

ISO/TC 159/SC 4/WG 2, Visual display requirements

ISO/TC 159/SC 4/WG 3, Control, workplace and environmental requirements

ISO/TC 159/SC 4/WG 5, Software ergonomics and human-computer dialogues

ISO/TC 159/SC 4/WG 6, Human-centred design processes for interactive systems

ISO/TC 159/SC 4/WG 8, Ergonomic design of control centres

ISO/TC 159/SC 5, Ergonomics of the physical environment

ISO/TC 159/SC 5/WG 1, Thermal enviroments

ISO/TC 159/SC 5/WG 2, Lighting environments

ISO/TC 159/SC 5/WG 3, Danger signals and communication in noisy environments

4. WHAT STANDARDS ARE REQUIRED?

The first question asked at ISO was: What standards are required in the field of ergonomics? The scientists answered: "fundamental standards as guidelines for the design of work systems." But the product designers in industry replied: "standards with application-oriented, ergonomic details," — for example, making it possible to design the driver's compartment of a car or the lever on a machine. The organizational structure of ISO/TC 159, Ergonomics, tried to meet these different requirements (table 1).

Standards can be developed at various levels within the following structure:

- basic standards related to fundamental characteristics of man;
- functional standards related to human factors in the operation and use of equipment, processes, products of systems;
- environmental standards related to the effects of physical factors of the environment on human performance, in the range between comfort and health hazards;
- standards for test procedures and for processing ergonomic data, to be applied either in working out standards in the above three categories or in assessing conformity to already accepted standards.

Although these standards serve as aids for product standardizers, a considerable amount of ergonomic data is also required for machine safety. Thus close liaison with ISO/TC 199, Safety of machinery, became necessary.

Moreover, at the end of the 1980s and beginning of the 1990s, the European Single Market produced a demand for standards in the field of ergonomics. To this end, the European Committee for Standardization (CEN) set up Technical Committee 122, Ergonomics, which has liaised closely with ISO/TC 159 in many areas ever since.

5. RELEVANT AREAS OF STANDARDIZATION

The first ISO standard on fundamental ergonomics for the design of work systems, ISO 6385 (1981), Ergonomic principles in the design of work systems, was developed on the basis of the German standard, DIN 33400 (1975), Designing work systems according to ergonomic findings. In this fundamental standard, the committee attached central importance to the work system, to which it then assigned individual components, e.g. work equipment, workspace, work environment, and work organization. This top-down approach assumed that the framework first had to be established into which application-oriented standards could then be incorporated. It was clear from the outset that standards in ergonomics should not be drafted for just any application, but that fundamental standards were needed, providing the means for work instruments and products to be designed. The intention was, for example, to define the fundamental dimensions of the human body, instead of developing standards for anthropometric dimensions specifically applied to office chairs or car seats.

Standards for the design of work systems are therefore not only developed by SC 1, Ergonomic guiding principles, responsible for general principles, they are also included in the work of various subcommittees and working groups that deal with particular work systems, for example, office systems or control centers for process control.

6. INDIVIDUAL HUMAN WORKLOAD

One criterion for evaluating the quality of ergonomic design in each workplace component should be the individual human workload. To take an example, mental workload is becoming increasingly important as a result of mechanization and automation, which is why ISO/TC 159 developed a standard of its own (ISO 10075), dealing with ergonomic principles related to mental workload.

Anthropometry makes a significant contribution to ergonomic standardization. Nowadays, for instance, it is inconceivable that a car should be sold on the world market without appropriate account having been taken of the dimensions of the driver's body.

When designing workplaces, ever greater attention is being paid to the handling of heavy weights because the number of working hours lost due to spinal column disorders has markedly increased. One task of an ergonomics committee should therefore be to assist the workplace designer in this respect and to develop appropriate standards. This was actually done in SC 3, Anthropometry and biomechanics. The proposed standards will establish both maximum permissible and maximum acceptable weights of load to be handled manually (lifting and carrying) by adult males and females at work, occasionally and as a function of frequency of task. It provides recommended limits for manual lifting and carrying while taking into account the intensity, the frequency, and the duration of the manual handling task to enable an evaluation of risk to health in a working population.

Standards for ergonomics play an important role in making systems more usable, particularly through the user interface and the quality of interface components. The large manufacturers of visual display terminals operate internationally and therefore also ask for . Consequently, SC 4, Ergonomics of human-system interaction, has prepared a 17-part series of standards, ISO 9241. In addition, the European Committee for Standardization (CEN) has decided to adopt the ISO standards in this area for the Single Market. The European standards, in turn, replace the national standards in the EC and EFTA states. The importance of corresponding ISO standards has greatly increased as a result. Table 2 shows the results of work within SC 4. Special conditions apply in control centers, which explains why the series of standards was developed; it is shown in Table 3.

For many historical, political, and organizational reasons,

Table 2. ISO 9241, Ergonomic requirements for office work with visual display terminals (VDTs) (January 2000)

Part 1: General introduction
Part 2: Guidance on task requirements
Part 3: Visual display requirements
Part 4: Keyboard requirements
Part 5: Workstation layout and postural requirements
Part 6: Guidance on the work environment
Part 7: Display requirements with reflections
Part 8: Requirements for displayed colours
Part 9: Requirements for non-keyboard devices
Part 10: Dialogue principles
Part 11: Guidance on usability
Part 12: Presentation on information
Part 13: User guidance
Part 14: Menu dialogue
Part 15: Command dialogues
Part 16: Direct manipulation dialogues
Part 17: Form-filling dialogues

Table 3. ISO 11064, The ergonomic design of control centres (January 2000)

Part 1: Principles for the design of control centres
Part 2: Principles of control suite arrangements
Part 3: Control room layout
Part 4: Workstation and layout dimensions
Part 5: Displays and controls
Part 6: Environmental requirements for control rooms
Part 7: Principles for the evaluation of control centres
Part 8: Ergonomic requirements for specific applications

standards concerned with the physical environment of workplaces were drafted under headings other than "Ergonomics". These approaches, often specially oriented to technology and engineering, related more to physical aspects than to the importance of these influences on the human being — for example, standards for lighting, noise, and vibration. As a result, ISO/TC 159/SC 5, Ergonomics of the physical environment, took over standardization in this field and developed standards for the thermal environment, communication in noisy environments, visual and auditory danger signals, and skin contact with hot surfaces.

7. CONCLUSIONS

Standards will not determine workplace design but can provide a useful "starting point" for successful design. Therefore, the object of further ergonomic standardization at ISO — and also at CEN — must be a form of standardization that fosters human-centered, as opposed to technology-centered, development of products and work systems. The basis of this re-orientation is the insight that the gulf between man and technology will widen if products, work systems, and working conditions continue to be designed with nothing but technology in mind. Taking appropriate account of the user in the design process should put new technologies into more effective and more efficient use. ISO/TC 159, Ergonomics, will continue to make an important contribution to this process and ensure that it is not the human who must adapt to the machine, but the machine that is adapted to the human.

ACKNOWLEDGEMENT

Ireland: Irish Ergonomics Society

R. Saunders
Secretary of the Irish Ergonomics Society

An informal group was formed in October 1984 by Dr Tim Gallwey, and in March 1985 it was accepted as a Regional Group of the Ergonomics Society (UK). The Group ran seminars once or twice per year and was involved from 1985 onwards in the development of the ideas and processes for a "European Ergonomist". The aim was to provide the mechanism for establishing and controlling a recognized professional level for ergonomists throughout Europe, in order to provide for mobility between member states and to protect against the practice of those unqualified and/or not competent. The standards were agreed in 1992 and provided the mechanism for the Irish Ergonomics Group to become a fully Irish society.

A constitution was approved at an AGM in March 1993 and the Irish Ergonomics Society was formally launched on the 5 March 1994 when the first Annual Conference was held at the University of Limerick. The Society was admitted to the International Ergonomics Association as an Affiliated Organization at its 12th Triennial Congress in Toronto on 14 August 1994. This makes it the officially recognized society for ergonomics in Ireland. The IES became a Federated Member of the IEA with full voting rights at the IEA Council Meeting in August 1995. The Society also represents Ireland on the Council of the Centre for Registration of European Ergonomists (CREE) which was incorporated legally in the Netherlands on the 1 October 1995 and which administers the registration process for the European Ergonomist (Eur Erg). In June 1998, five applicants from Ireland were accepted as Eur Ergs.

Membership of the Society is available to people with a degree (or equivalent) in the ergonomics field, or with some other cognate or relevant discipline with either the equivalent of two years' full-time work in ergonomics or who have published two scientific papers in the subject. Those who do not meet these requirements but are interested in ergonomics can join as Associates. Appropriate post-graduate courses are on offer at the University of Limerick, National University of Ireland, Galway, and Queens University, Belfast.

THE IES TODAY: 1999

This year sees the Society at something of a landmark stage in its development. Those who have kept the flag flying for so long here (Dr Tim Gallwey, Eleanor McMahon, Steve Chan, Gerry Holmes, Enda Fallon, and others) have been joined over the past five years by new recruits and active members who have graduated from, or are involved in, the post-graduate courses mentioned. Today, the Society's membership stands at 60, almost a 100% increase since 1997.

November 1998 saw the Society organize and host its first ever National Conference, which was an overwhelming success due to the efforts of the conference organizing sub-committee. Over 120 delegates from industry, the public sector, and a number of NGOs attended the one-day event, which focused largely on the topics of immediate concern to the workplace: the law in relation to ergonomics; manual handling; industrial interventions and training schemes; and modern office environments.

The previous year, 1997, saw an international conference on Revisiting the Allocation of Functions: ALLFN '97. Organized by Enda Fallon of NUI Galway, those who attended will testify to its success and the quality of papers and debate.

The Society has organized its own internal annual conference each year since 1994; coinciding with the AGM, it provides a forum for current research to be presented to the membership. The Society also produces a newsletter, *The Irish Ergonomist*. With four editions a year, it keeps members up-to-date on national matters and events, etc., and is supplemented with information from the rest of the world, courtesy of the IEA. The Society also has a National Assessment Board for the processing of applications for European Ergonomist on behalf of CREE.

Finally, an ambitious Programme of Work was presented at this year's AGM, with plans for two industry-aimed workshops this year, the formation of two technical working groups and a Membership Review Committee, a major overhaul of our web site (http://www.ul.ie/~ies/), and the planning of the Second National Conference for early 2000. We have also seen the recent formation of the Occupational Health & Safety Institute of Ireland, a research-oriented institution composed of the universities, the social partners, the Health & Safety Authority, and a number of societies and professional bodies. The IES intends to play a leading role in its formative stage and will be a member of both its Board and Scientific Advisory Committee.

ISO and CEN Standardization Committee for Ergonomics (1999): Organizational Structure

H. J. Sälzer

ISO/TC 159 "ERGONOMICS"

Chairperson: W. Schultetus (interim), Germany
Secretary: H.J. Sälzer; DIN-Berlin
ISO Member responsible: DIN
Scope: Standardization in the field of ergonomics, including terminology, methodology and human factors data.

ISO/TC 159/SC 1 — Ergonomic guiding principles
Chairperson: W. Schultetus, Germany
Secretary: H. J. Sälzer, DIN-Berlin

ISO/TC 159/SC 3 — Anthropometry and biomechanics
Chairperson: Professor Dr T. Itani, Japan
Secretary: K. Suzuki; Japan

ISO/TC 159/SC 4 — Ergonomics of human–system interaction
Chairperson: T. F. M. Stewart, UK Secretary: Mrs C. Bassey, BSI-London

ISO/TC 159/SC 5 — Ergonomics of the physical environment
Chairperson: Professor Dr K. C. Parsons, UK
Secretary: Dr D. S. Fishman, BSI-London

CEN/TC 122 "ERGONOMICS"

Chairperson: Dr K.-P. Scheuermann, Germany
Secretary: H. J. Sälzer, DIN-Berlin
CEN Member responsible: DIN
Scope: Standardization in the field of ergonomics principles and requirements for the design of work systems and work environments, including machinery and personal protective equipment, to promote the health, safety and well-being of the human operator and the effectiveness of the work.

CEN/TC 122/WG 1 — Anthropometry
Convenor: Professor Dr Hans W. Jürgens, Germany
Secretary: N. Butz, DIN-Berlin

CEN/TC 122/WG 2 — Ergonomic design principles
Convenor: Dr K.-P. Scheuermann, Germany
Secretary: N. Butz, DIN-Berlin

CEN/TC 122/WG 3 — Surface temperatures
Convenor: Dr H. Siekmann, Germany
Secretary: R. Schmidt, DIN-Berlin

CEN/TC 122/WG 4 — Biomechanics
Convenor: Mrs Dr J. A. Ringelberg, The Netherlands
Secretary: Drs P. M. de Vlaming, NNI-Delft

CEN/TC 122/WG 5 — Ergonomics of human–computer interaction
Convenor: T. F. M. Stewart, UK
Secretary: Mrs C. Bassey, BSI-London

CEN/TC 122/WG 6 — Signals and controls
Convenor: M. I. Gray, UK
Secretary: Mrs C. Bassey, BSI-London

CEN/TC 122/WG 8 — Danger signals and speech communication in noisy environments
Convenor: Dr H. J. M. Steeneken, Netherlands
Secretary: Drs P.M. de Vlaming, NNI-Delft

CEN/TC 122/JWG 9 — Ergonomics of Personal Protective Equipment (PPE)
Convenor: Mrs Vibeke Andersen, Denmark
Secretary: Søren Nielsen, DS –Charlottenlund

CEN/TC 122/WG 10 — Ergonomic design principles for the operability of mobile machinery
Convenor: Drs K. A. Peereboom, The Netherlands
Secretary: Drs P.M. de Vlaming, NNI-Delft

CEN/TC 122/WG 11 — Ergonomics of the thermal environment'
Convenor: Professor Dr K. C. Parsons, UK
Secretary: Dr David Fishman, BSI-London

CEN/TC 122 ad hoc group — Integrating ergonomic principles for machinery design
Convenor: Dr J. A. Ringelberg, Netherlands
Secretary: S. M. van der Minne, NNI-Delft

STANDARDS DRAFT STANDARDS WORK ITEMS (UNDER PREPARATION)

(State: July 1999)

Ergonomic Guiding Principles

ISO 6385: 1981-06-00
ENV 26385: 1990-06-00
Ergonomic principles of the design of work systems
Abstract: Establishes these principles as basic guidelines. They apply for designing optimal working conditions with regard to human well-being, safety and health, taking into account technological and economic efficiency.

EN 614-1: 1995-02-00
Safety of machinery — Ergonomic design principles — Part 1: Terminology and general principles
Abstract: This document establishes the ergonomics principles to be followed during the process of design of work equipment, especially machinery. Although the principles in this document are orientated towards equipment for occupational use, they are applicable also to equipment for private use. It applies to the

interactions between the operator and the work equipment when installing, operating, adjusting, maintaining, cleaning, repairing or transporting equipment and outlines the principles to be followed in taking the health and safety of the operator fully into account.

prEN 614-2: 1997-12-00
Safety of machinery — Ergonomic design principles — Part 2: Interactions between the design of machinery and work tasks
Abstract: The document deals specifically with task design in the context of machinery design, but the principles and methods may also be applied to job design. It establishes the ergonomic principles and procedures to be followed during the design process of machinery and operator work tasks. It is directed to designers and manufacturers of machinery and other work equipment. It will also be helpful to those who are concerned with the use of machinery.

ISO 10075: 1991-10-00
pr EN ISO 10075-1: 1996-07-00
Ergonomic principles related to mental workload; Part 1: General terms and definitions
Abstract: This Standard represents an extension of ISO 6385, Subclauses 3.7 to 3.9, describing terms and definitions in more detail. Annex A forms an integral part of this standard.

ISO 10075-2: 1996-12-00
pr EN ISO 10075-2: 1998-07-00
Ergonomic principles related to mental workload — Part 2: Design principles
Abstract: Gives guidance on the design of work systems, including task and equipment and design of the workplace, as well as working conditions. Relates to the adequate design of work and use of human capacities.

Under preparation: Ergonomic principles related to mental workload — Part 3: Measurement and assessment of mental workload

Anthropometry

This International Standard is intended for use by ergonomic experts and non-experts, e.g. employers, employees and their representatives, system managers and designers, ergonomics and health experts and public authorities. Experts should be able to choose suitable methods based on the contents of this International Standard and/or to find information to be taken into account or to be followed when constructing methods for mental workload assessment. Non-experts will find useful information for their orientation in the field of assessment and measurement of mental workload, e.g. what kinds of methods are provided, who is able and qualified to use them.

EN 547-1: 1996-12-00
ISO/DIS 15534-1: 1998-04-00
Safety of machinery — Human body measurements — Part 1: Principles for determining the dimensions required for openings for whole body access into machinery
Abstract: The document specifies the dimensions of openings for whole body access as applied to machinery as defined in EN 292-1. It provides the dimensions to which the values given in EN 547-3 are applicable. Values for additional space requirements are given in annex A. This European Standard has been prepared primarily for non-mobile machinery, there may be additional specific requirements for mobile machinery.

EN 547-2: 1996-12-00
ISO/DIS 15534-2: 1998-04-00
Safety of machinery — Human body measurements — Part 2: Principles for determining the dimensions required for access openings
Abstract: The document specifies the dimensions of openings for whole body access as applied to machinery as defined in EN 292-1. It provides the dimensions to which the values given in EN 547-3 are applicable. Values for additional space requirements are given in annex A. This European Standard has been prepared primarily for non-mobile machinery, there may be additional specific requirements for mobile machinery.

EN 547-3: 1996-12-00
ISO/DIS 15534-3: 1998-04-00
Safety of machinery — Human body measurements — Part 3: Anthropometric data
Abstract: The document specifies current requirements for human body measurements (anthropometric data) that are required by EN 547-1 and EN 547-2 for the calculation of access opening dimensions as applied to machinery. The anthropometric data originate from static measurements of nude persons and do not take into account body movements, clothing, equipment, machinery operating conditions or environmental conditions. The data are based on information from anthropometric surveys representative of population groups within Europe comprising at least three million people. Both men and woman are taken into account. Measurements are given, as required by EN 547-1 and EN 547-2, for the 5th, 95th and 99th percentile of the relevant population group within Europe.

ISO 7250: 1996-07-00
EN ISO 7250: 1997-07-00
Basic human body measurements for technological design (ISO 7250: 1996)
Abstract: The document provides a description of anthropometric measurements that can be used as a basis for comparison of population groups. The basic list specified in this document is intended to serve as a guide for ergonomists who are required to define population groups and apply their knowledge to the geometric design of the places where people work and live.

ISO/DIS 14738: 1997-12-00
prEN ISO 14738: 1997-12-00
Safety of machinery — Anthropometric requirements for the design of workstations at machinery
Abstract: The document establishes principles for deriving dimensions from anthropometric measurements and applying them to the design of workstations at non-mobile machinery. It is based on current ergonomic knowledge and anthropometric measurements. It specifies the body's space requirements for equipment during normal operation in sitting and standing

positions. It does not specifically include space demands for maintenance, repairing and cleaning work. It does not give recommendations specifically for visual display terminal workstations at machinery. For these purposes EN ISO-9241-5 can be used in conjunction with this document.

Under preparation: Ergonomics — Computer manikins, body templates
Document scope: This European Standard establishes the general requirements for computer-aided manikins intended for the design and evaluation of workspaces at machinery (or: spaces, furniture and other equipment). These requirements concern the anthropometric and motional (and biomechanical) properties of the manikins, particularly the extent to which they represent the human body and the intended user population. The European Standard also specifies the requirements for the documentation of the manikins in respect to these properties and for the guidance of the user.
The European Standard is intended as a guide for the design and selection of manikins and for evaluation of their usability and accuracy for the specified use.
Under preparation: Selection of persons for testing of anthropometric aspects of industrial products and designs
Document scope: This European Standard determines the procedures to be applied to the composition of groups of persons whose anthropometric characteristics are to be representative of all prospective users of any specific object under test.
These procedures will be applicable to the anthropometric aspects of testing of industrial products and designs having direct or indirect contact with the human body and its functions, e.g. machinery, work equipment, personal protective equipment (PPE), consumer goods, working spaces, architectural details, types of transport.
Under preparation: Safeguarding crushing points by means of a limitation of the active forces
Document scope: Standardization of safe, low forces on crushing points (data concerning forces to which people can be exposed without risk of injury).
Target dates depend on financial support for pre-normative research.
Under preparation: Ergonomics — Reach envelopes
Document scope: This European Standard establishes ergonomic requirements for the metric design of workplaces. It specifies the operation's minimum and maximum reach (reach envelopes for hands and feet).
Under preparation: Anthropometric database
Document scope: The European Standard establishes an anthropometric database for all age groups to be used as the basis for the design of work equipment, workplaces and workstations at machinery.
Under preparation: Notation system of anthropometric measurements used in the European Standards EN 547 Part 1 to Part 3
Document scope: The Technical Report explains the complete notation system of anthropometric measurements used in the European Standards EN 547 Part 1 to Part 3.

Biomechanics

prEN 1005-1: 1998-12-00
Safety of machinery — Human physical performance — Part 1: Terms and Definitions
Abstract: The document provides terms and definitions on concepts and parameters used for EN 1005-2 to 4. Basic concepts and general ergonomic principles for the design of machinery are dealt with in EN 292-1 and 2 and EN 614-1. The study of human physical loading whilst handling/operating machinery relies on methods and techniques developed by different research disciplines (e.g. epidemiology, biomechanics, physiology, psychophysics). It aims to define relevant concepts to further cooperation between research disciplines in this field, and to improve the application of standards when designing machinery.

prEN 1005-2: 1998-12-00
Safety of machinery — Human physical performance — Part 2: Manual handling of machinery and component parts of machinery
Abstract: The document specifies ergonomic recommendations for the design of machinery involving manual handling in professional and domestic applications. It applies to the manual handling of objects of 3 kg or more. The standard provides data for ergonomic design and risk assessment concerning lifting, lowering and carrying in relation to the construction, transport and commissioning (assembly, installation, adjustment), use (operation, cleaning, fault finding, maintenance, setting, teaching or process changeover) and decommissioning, disposal and dismantling of machinery. This standard provides current data on the general population and certain subpopulations.

prEN 1005-3: 1998-12-00
Safety of machinery — Human physical performance — Part 3: Recommended force limits for machinery operation
Abstract: The document specifies force limits for pushing and pulling tasks, gripping, arm work and pedal work under the following conditions: pushing and pulling with whole body exertion and using a two-handed symmetrical grip whilst standing and walking; manual exertion (to/from, up/down, in/out), arm work whilst sitting and standing; leg exertion, one-foot or two-foot forces pushing or pressing of pedal(s) whilst sitting and standing.

prEN 1005-4: 1998-11-00
Safety of machinery — Human physical performance — Part 4: Evaluation of working postures in relation to machinery
Abstract: The document presents guidance to the designer of machinery or its components parts in assessing and controlling health risks due to machine-related postures and movements, i.e. during assembly, installation, operation, adjustment, maintenance, cleaning, repair, transport and dismantlement. The standard specifies recommendations for postures and movements with minimal external force exertion. The recommendations are

Under preparation: Safety of machinery — Human physical performance — Part 5: Risk assessment for repetitive handling at high frequency

Document scope: This European standard presents a risk assessment method for machinery related repetitive movements.
ISO/DIS 11226; 1999-02-00
Ergonomics — Evaluation of working postures
Abstracts: This International Standard establishes ergonomic recommendations for different work tasks. The standard will provide information for all those involved in design, or redesign, of work, jobs and products that are familiar with the basic concepts of ergonomics in general and working postures in particular.

The standard specifies recommended limits for working postures with minimal external force exertion, while taking into account body angles and in time aspects.

This standard is designed to provide guidance on the assessment of several task variables, allowing the health risks for the working population to be evaluated.

This standard applies to the adult working population. The recommendations will give reasonable protection for nearly all health adults. The recommendation concerning health risks and protection are mainly based on experimental studies regarding the musculosekeletal load, discomfort/pain, and endurance/ fatigue related to working postures.

ISO/DIS 11228-1: 1998-08-00
Ergonomics — Manual handling — Part 1: Lifting and carrying
Abstract: The part of this International Standard on manual handling establish ergonomic recommendations for different manual handling tasks. The standard apply to such vocational actions as manual handling. The standard specifies recommended limits for manual lifting and carrying while taking into account respectively the intensity, the frequency and the duration of the task. The standard applies to manual handling of objects with a mass of 3 kg or more.

Under preparation: Ergonomics-Manuel handling — Part 2: Pushing and pulling
Document scope: to be defined

Under preparation: Ergonomics-manual Handling — Part 3: Handling, at high repetition of low loads
Document scope: to be defined

Thermal Environments
ISO 7243: 1989-08-00
EN ISO 7243: 1993-12-00
Hot environments; estimation of the heat stress on working man, based on the WBGT-index (wet bulb globe temperature)
Abstract: Gives a method, which can easily be used in an industrial environment for evaluating the stresses on an individual. It applies to the evaluation of the mean effect of heat on man during a period representative of his activity but it does not apply to very short periods, nor to zones of comfort.

ISO 7726: 1998-11-00
EN ISO 7726: 1993-12-00
Ergonomics of the thermal environment — Instruments for measuring physical Quantities
Abstract: The document specifies the minimum characteristics of appliances for measuring physical quantities characterizing an environment as well as the methods for measuring the physical quantities of this environment.

ISO 7730: 1994-12-00
EN ISO 7730: 1995-07-00
Moderate thermal environments — Determination of the PMV and PPD indices and specification of the conditions for thermal comfort
Abstract: The purpose is to present a method for predicting the thermal sensation and the degree of discomfort (thermal dissatisfaction) of people exposed to moderate thermal environments and to specify acceptable environmental conditions for comfort. Applies to healthy men and women and was originally based on studies of North American and European subjects but agrees also well with recent studies of Japanese subjects and is expected to apply with good approximation in most parts of the world. Applies to people exposed to indoor environments where the aim is to attain thermal comfort, or indoor environments where moderate deviations from comfort occur.

ISO 8996: 1990-12-00
EN 28996: 1993-10-00
Ergonomics; determination of metabolic heat production
Abstract: Specifies methods for determining the metabolic rate, but can also be used for other applications, e.g. for the assessment of working practices, the cost of specific jobs or sport activities, the total cost of activity, etc. Annexes A to G contain: classification of metabolic rate for kinds of activities, classification of metabolic rate by occupation, data for standard person, metabolic rate for body posture, type of work and body motion related to work speed, metabolic rate for typical activities, example of calculation of the average metabolic rate for a work cycle, examples of calculation of the metabolic rate based on measured data.

ISO 7933: 1989-07-00
Hot environments; analytical determination and interpretation of thermal stress using calculation of required sweat rate
Abstract: Describes a method of calculating the heat balances as well as the sweat rate that the human body should produce to maintain this balance in equilibrium. The various terms used show the influence of the different physical parameters. It does not predict the physiological response of individual subjects, but only considers standard subjects in good health and fit for the work they perform.

EN 12515: 1997-06-00
Hot environments — Analytical determination and interpretation of thermal stress using calculation of required sweat rate (ISO 7933: 1989, modified)
Document scope: to be defined

ISO 9886: 1992-11-00
p EN ISO 9886: 1997-06-00
Evaluation of thermal strain by physiological measurements
Abstract: Describes methods for measuring and interpreting body core temperature, skin temperature, heart rate, and body mass loss. Annex A presents a comparison of the different methods concerning their field of application, their technical complexity,

the discomfort and the risks. The measurement techniques are described in annex B, limit values are proposed in annex C.

ISO 10551: 1995-05-00
Pr EN ISO 10551: 1997-06-00
Ergonomics of the thermal environment — Assessment of the influence of the thermal environment using subjective judgement scales
Abstract: Covers the construction and use of judgement scales for use in providing reliable and comparative data on the subjective aspects of thermal comfort or thermal stress.

ISO 11399: 1995-12-00
Pr EN ISO 11399: 1997-06-00
Ergonomics of the thermal environment — Principles and application of relevant international standards
Abstract: Purpose is to specify information which will allow the correct, effective and practical use of International Standards concerned with the ergonomics of the thermal environment. Describes the underlying principles concerning the ergonomics of the thermal environment.

ISO/DIS 12894: 1997-01-00
Pr EN ISO 12894: 1997-01-00
Ergonomics of the thermal environment — Medical supervision of individuals exposed to extreme hot or cold environments
Abstract: This International Standard provides guidance to those concerned with the safety of human exposures to extreme hot or cold thermal environments, about the medical fitness assessment and health monitoring which may be appropriate to and during such exposures. It is intended to assist those with responsibility for such exposures to reach decisions about the appropriate level of medical supervision in different situations. The standard presents guidance that should be read and used in the context of other guidance and legislation applying to each particular situation.

ISO/DIS 13731: 1997-04-00
Pr EN ISO 13731: 1997-04-000
Ergonomics of the thermal environment — Vocabulary and symbols

ISO 9920: 1995-03-00
Ergonomics of the thermal environment — Estimation of the thermal insulation and evaporative resistance of a clothing ensemble
Abstract: Gives methods for estimating the thermal characteristics (resistance to dry heat loss and evaporative heat loss) in steady-state conditions for a clothing ensemble based on values for known garments, ensembles and textiles. Does not deal with other effects of clothing, such as adsorption of water, buffering, tactile comfort. Does not take into account the influence of rain and snow on the thermal characteristics. Does not consider special protective clothing. Does not deal with the separate insulation on different parts of the body and discomfort due to the asymmetry of a clothing ensemble.

ISO/TR 11079: 1993-12-00
ENV ISO 11079: 1998-01-00
Evaluation of cold environments; determination of required clothing insulation (IREQ)
Abstract: Proposes methods and strategies to assess the thermal stress associated with exposure to cold environments. Cold stress is suggested to be evaluated in terms of both general cooling of the body and local cooling of particular parts of the body (e.g. extremities and face). The methods apply to continuous, intermittent and occasional exposure and in both indoor and outdoor work. Specific effects associated with certain meteorological phenomena (e.g. precipitation) are not covered and should be assessed by other methods.

Under preparation: Ergonomics of the thermal environment — Medical supervision of individuals exposed to extreme hot or cold environments

Under preparation: Ergonomics of the thermal environment — Comfortable contact surface temperature

Under preparation: Ergonomics of the thermal environment — Application of International Standards to the disabled; the aged and other handicapped persons

Under preparation: Ergonomics of the thermal environment — Assessment of the long-term thermal comfort performance of indoor environments

Under preparation: Ergonomics of the physical environment — Determination of the combined effect of thermal environment, air pollution, acoustics and illumination on humans

Under preparation: Ergonomics of the thermal environment — Working practices for cold indoor environments

Under preparation: Evaluation of the thermal environment in vehicles

Under preparation: Ergonomics of the thermal environment — Risk assessment of stress or discomfort in thermal working conditions *Under preparation*: Principles of the visual ergonomics — Lighting of indoor work systems

Fundamentals of Controls and Signaling Methods

EN 894-1: 1997-02-00
ISO/DIS 9355-1: 1997-09-00
Safety of machinery — Ergonomics requirements for the design of displays and control actuators — Part 1: General principles for human interactions with displays and control actuators
Abstract: This document applies to the design of displays and control actuators on work equipment, especially machines. It specifies the relationships that have to be maintained between the movements of control actuators, the response of any associated displays, and the human response to information given by the system, to minimize operator errors and to ensure an efficient interaction between the operator and the equipment.

EN 894-2: 1997-02-00
ISO/DIS 9355-2: 1997-09-00
Safety of machinery — Ergonomics requirements for the design of displays and control actuators — Part 2: Displays
Abstract: This document gives recommendations on the selection, design and location of information displays, so that they are adapted to the requirements of the operators, and take account of the circumstances of their use. It includes visual, audible and tactile displays. It applies to displays used in equipment (e.g. machines and installations, control panels, operating and monitoring consoles) for occupational and private use.

prEN 894-3: 1992-10-00
Safety of machinery; ergonomics requirements for the design of displays and control actuators; part 3: Control actuators
Abstract: This document gives recommendations on the selection, design and location of control actuators so that they are adapted to the requirements of the operators, and take account of the circumstances of their use. It applies to manual control actuators used in equipment for occupational and private use.

Under preparation: Safety of machinery — Ergonomics requirements for the design of displays and control actuators — Part 4: Location and arrangement of displays and control actuators
Document scope: This European Standard applies to the design of displays and control actuators on machinery. It establishes general principles for the location and arrangement of displays and control actuators, to minimize operator errors and to ensure an efficient interaction between the operator and the equipment. It is particularly important to observe these principles when an operator error may lead to injury or damage to health.

Ergonomics of Human–System Interaction
ISO 9241-1: 1997-06-00
EN ISO 9241-1: 1997-06-00
Ergonomic requirements for office work with visual display terminals (VDT) — Part 1: General introduction
Abstract: The document introduces multipart standard on ergonomic requirements for the use of visual display terminals for office tasks, provides guidelines for a user-performance approach, gives an overview of all parts of EN ISO 9241 currently published and of the anticipated content of those in preparation and provides some guidance on how to use EN ISO 9241. It describes also how conformance to EN ISO 9241 should be reported.

Under preparation: Amendment 1: Description and application of the software parts (Part 10 to 17)

ISO 9241-2: 1992-06-00
EN ISO 9241-2: 1992-06-00
Ergonomic requirements for office work with visual display terminals (VDT); Part 2: Guidance on task requirements
Abstract: Guidance is relevant to both the organization implementing the system and the people using the equipment and should be applied in accordance with local, regional or national agreements and regulations. The objective is to enhance the efficiency and well-being of the individual user by applying ergonomics knowledge in the light of practical experience, to the design of tasks. The ergonomics principles concerned are set out in ISO 6385.

ISO 9241-3: 1992-07-00
EN ISO 9241-3: 1992-07-00
Ergonomic requirements for office work with visual display terminals (VDT); Part 3: Visual display requirements
Abstract: Establishes image quality requirements (performance specifications) for the design and evaluation of single- and multi-color VDT. At present, the recommendations are based on Latin, Cyrillic, and Greek origin alphabetic characters, and Arabic numerals. Office tasks include such activities as data entry, text processing, and interactive inquiry. Annex A describes analytical techniques for predicting screen flicker, annex B an empirical method for assessing temporal and spatial instability (flicker and jitter) on screen, annex C a comparative user performance test method.

Under preparation: Amendment 1: User performance test
This annex is intended for testing the visual quality of VDUs where the entire set of physical requirements (defined in clause 5) cannot be applied completely. This alternative compliance route shall be used if some clause 5 requirements cannot be applied, for example to flat panel displays.

ISO 9241-4: 1998-08-00
EN ISO 9241-4: : 1998-08-00
Ergonomic requirements for office work with visual display terminals (VDT) — Part 4: Keyboard requirements
Abstract: The document applies to linear detachable keyboard designed for stationary use. It provides guidance on the design of keyboards used of typical office tasks so that the limitations and capabilities of users are considered

ISO 9241-5: 1998-10-00
EN ISO 9241-5: 1999-03-00
Ergonomic requirements for office work with visual display terminals (VDT) — Part 5: Workstation layout and postural requirements
Document scope: This part of ISO 9241 specifies ergonomic guiding principles that apply to the user requirements, design and procurement of workstation equipment for office tasks using VDT. In particular, the general principles and requirements specified in this part of ISO 9241 apply to the standards specifying technical design of furniture and equipment constituting the workplace.
ISO/DIS 9241-6: 1998-04-00
prEN ISO 9241-6: 1996-02-00
Ergonomic requirements for office work with visual display terminals (VDT) — Part 6: Guidance on the work environment
Abstract: The document gives guidance on basic principles for the ergonomic design of the work environment and the workstation, taking into account lighting effects of noise and mechanical vibrations, electrical and magnetic fields and static electricity, thermal environment, space organization and workplace layout. The document is applicable to the work environment and workstation in those work systems where a visual display terminal (VDT) is used for office work.

Under preparation: Ergonomics requirements for office work with visual display terminals (VDT) — Space organization and workplace layout — Consideration supporting the requirements presented in ISO/DIS 9241-6

ISO 9241-7: 1998-04-00
EN ISO 9241-7: 1998-04-00
Ergonomic requirements for office work with visual display terminals(VDT) — Part 7: Requirements for display with reflections
Abstract: This document establishes image quality requirements for VDT's used in luminous environments that may cause reflections from screen. It also applies to monochrome and multicolor displays.

ISO 9241-8: 1997-10-00
EN ISO 9241-8: 1997-10-00
Ergonomic requirements for office work with visual display terminals (VDT) — Part 8: Requirements for displayed colors
Abstract: The document describes minimum ergonomic requirements and recommendations to be applied to colors assigned to text and graphic applications and images in which colors are discretely assigned. The specifications thus exclude photorealistic images and graphics. The document applies to both hardware and software for visual display terminals, because both these sources control the presentation and appearance of color on the display screen

ISO/DIS 9241-9: 1998-05-00
prEN ISO 9241-9: 1998-10-00
Ergonomic requirements for office work with visual display terminals (VDT) — Part 9: Requirements for non-keyboard input devices
Abstract: The document applies to several types of non-keyboard devices designed for stationary use. It gives guidance based on ergonomic factors for the following input devices: mice, pucks, joysticks, trackballs, tablets and overlays, touch sensitive screens, stylist and light pens.

ISO 9241-10: 1996-05-00
EN ISO 9241-10: 1996-05-00
Ergonomic requirements for office work with visual display terminals (VDT) — Part 10: Dialogue principles
Abstract: Gives ergonomic principles formulated in general terms; they are presented without reference to situations of use, application, environment or technology. These principles are intended to be used in specifications, design and evaluation of dialogues for office work with visual display terminals (VDT).

ISO 9241-11: 1998-03-00
EN ISO 9241-11: 1998-03-00
Ergonomic requirements for office work with visual display terminals (VDT) — Part 11: Guidance on usability
Abstract: The document defines usability and explains how to identify the information which is necessary to take into account when specifying or evaluating usability in terms of measures of user performance and satisfaction. Guidance is given on how to describe the context of use of the product (hardware, software or service) and the required measures of usability in an explicit way.

The guidance is given in the form of general principles and techniques, rather than in the form of requirements to use specific methods. The guidance can be used in procurement, design, development, evaluation and communication of information about usability.

ISO 9241-12: 1998-12-00
EN ISO 9241-12: 1998-12-00
Ergonomic requirements for office work with visual display terminals (VDT) — Part 12: Presentation of information
Abstract: The document provides ergonomic recommendations for the presentation of information and specific properties of presented information on text-based and graphical user interfaces used for office tasks. It provides recommendations for the design and evaluation of visual presentation of information including coding techniques. These recommendations can be utilized throughout the design process. The coverage of color is limited to ergonomic recommendations for the use of color for highlighting and categorizing information(see ISO 9241-8 for additional recommendations for the use of color).
The document does not address auditory presentation of information.

ISO 9241-13: 1998-07-00
EN ISO 9241-13: 1998-07-00
Ergonomic requirements for office work with visual display terminals (VDT) — Part 13: User guidance
Abstract: The document provides recommendations for user guidance attributes of software user interfaces and their evaluation. User guidance are covered by this document includes recommendations specific to prompts, feedback and status, error management and online help as well as recommendations common to all these types of user guidance. The recommendations in this document are formulated to be independent of applications, environment, or technology. They correspond to typical situations involving special needs for information and actions.

ISO 9241-14: 1997-06-00
EN ISO 9241-14: 1999-04-00
Ergonomics requirements for office work with visual display terminals (VDT) — Part 14: Menu dialogues
Abstract: This part of ISO 9241 provides conditional recommendations for menus used in user-computer dialogues to accomplish typical office tasks. The recommendations cover menus presented by various techniques including windowing, panels, buttons, fields, etc. These recommendations can be utilized throughout the design process (e.g., as guidance for designers during design, as a basis for heuristic evaluation, as guidance for usability testing).

ISO 9241-15: 1997-12-00
EN ISO 9241-15: 1997-12-00
Ergonomic requirements for office work with visual display terminals (VDT) — Part 15: Command dialogues
Abstract: The document provides recommendations for command dialogues used to accomplish typical office tasks. Command dialogues are sequences of instructions provided by the user to the system which, when processed, result in associated system

actions. Users input (from recall, rather than selecting from a menu) complete or abbreviated command phrases (e.g. mnemonics, letters, function keys, hot keys) in the order required by the command language syntax and the computer performs the activities initiated by the command(s) and their associated parameters.

ISO/FDIS 9241-16: 1999-04-00
prEN ISO 9241-16: 1999-04-00
Ergonomic requirements for office work with visual display terminals (VDT) — Part 16: Direct-manipulation dialogues
Abstract: The document gives guidance on the design of direct manipulation dialogues the user directly acts on objects on the screen; e.g., by pointing at them, moving them and/or changing their physical characteristics (or values) via at the use of an input device.

ISO 9241-17: 1998-08-00
EN ISO 9241-17: 1998-08-00
Ergonomic requirements for office work with visual display terminals (VDT) — Part 17: Form-filling dialogues
Abstract: Ergonomic design of form-filling dialogues, including form structure and output considerations, input considerations and form navigation. Form filling dialogues are dialogues in which the user fills in, select entries for, or modifies labeled fields on a 'form' or a dialogue box presented by the system. This part of ISO 9241 pertains to form filling dialogues generated through both VDT character-based and bit-mapped screen displays and input through keyboards and optional pointing devices.

ISO 13407: 1999-06-00
EN ISO 13407: 1999-06-00
Human-centered design processes for interactive systems
Abstract: The document provides guidance on human-centered design activities throughout the life cycle of computer-based interactive systems. It is aimed at those managing design processes and provides guidance on sources of information and standards relevant to the human-centered approach. It is concerned with both hardware and software components of interactive systems. It addresses the planning and management of human-centered design. It does not address all aspects of project management.

Under preparation: Ergonomics of human system interaction — Guidance on accessibility for human–computer interfaces
Document scope: To be defined
Under preparation: Ergonomics of human–system interaction — Usability methods supporting human-centred design.
Document scope: To be defined
ISO/FDIS 13406-1: 1999-05-00
Ergonomic requirements for work with visual displays based on flat panels — Part 1: Introduction
This part of ISO 13406 establishes the rationale for ergonomic requirements and measurement methods for flat panel displays and defines a flat panel display. It is applicable to flat panel technology applied to displays for office work and other work.

ISO/DIS 13406-2: 1997-07-00
Ergonomic requirements for visual display units based on flat panels — Part 2: Requirements for flat panel displays

This International Standard establishes ergonomic image quality requirements for the design and evaluation of flat panel displays (ISO/CD 13406-1); defines terms needed to address image quality on flat panel displays; specifies methods of determining image quality on flat panel displays; establishes ergonomic principles for guiding these requirements.

This International Standard is applicable to flat panel display screens when used to perform office tasks; flat panel display screens that consist of a regular array of picture elements arranged in evenly spaced rows without built-in gaps; the presentation of alphanumeric characters on flat panel display screens when the characters are based on Latin-origin fonts; the presentation of Asian characters; flat panel display screens that are large enough to display at least 40 Latin-origin characters.

This International Standard is not applicable to: flat panel technology applied to a display that uses optics to form an image that is not the same size as the electro-optical transducer (projection application of flat panel displays); flat panel technology applied to a display limited to fixed-messages or segmented alphanumerics. See 2.13 IEC SC 47C (Central Office) 3: 1992.
Under preparation: Multimedia user interface design — Software ergonomics requirements — Part 1: Introduction and framework
Document scope: This International Standard establishes requirements, recommendations and principles for the design of interactive multimedia user interfaces that integrate and synchronize different media (static media such as text, graphs, images, and dynamic media such as audio, animation and video). This International Standard does not provide detailed design guidance for specific media but addresses issues related to applications integrating different media.
This International Standard applies to presentation and interaction techniques for computer-based multimedia applications in general, including stand-alone and network-delivered applications. It provides recommendations for design and evaluation and addresses issues related to the interaction of different media and to selection and combining media. It applies to the design of the software user interface and does not address hardware issues, such as input or output devices.
This International Standard mainly addresses ergonomic design issues. Due to the intended range of applications and user groups, areas like aesthetic quality of a system also are addressed. The recommendations provided in this International Standard may not apply to systems whose primary purpose is entertainment (such as games).

Under preparation: Multimedia user interface design — Software ergonomics requirements — Part 2: Multimedia control and navigation
Document scope: To be defined.

Under preparation: Multimedia user interface design — Software ergonomics requirements — Part 3: Selection of media and media combination
Document scope: This part of ISO 14915 establishes software ergonomics requirements and recommendations for interactive multimedia user interfaces that integrate and synchronize different

media (static media like text, graphs, images and dynamic media like audio, animation and video). The standard applies to presentation and interaction techniques for computer-based multimedia applications when the prime goal is to support the user's work task or provision of information. The standard applies to training and tutorial multimedia in so far as its recommendations bear on effective delivery of information. It does not deal with pedagogic design issues for tutorial applications and entertainment applications are also not within its *scope*. This standard does provide recommendations for design and evaluation of visual presentation of information but does not make detailed recommendations for dialogue design of multimedia interfaces which is addressed in ISO 14915-2. The focus is on design using appropriate media to convey different types of information, ensuring important parts of the message are comprehended by the user and that messages in multimedia presentations are delivered in a coherent, integrated manner.

Under preparation:
Multimedia user interface design — Software ergonomics requirements — Part 4: Domain specific multimedia interfaces
Document scope: to be defined.

Ergonomic Design of Control Centers

ISO/DIS 11064-1: 1999-02-00
pr EN ISO 11064-1: 1999-02-00
Ergonomic design of control centers — Part 1: Principles for the design of control centers
Document scope: This Part of ISO 11064 specifies requirements and establishes general principles for the ergonomic design of a new control center, as well as for control center expansion, refurbishment, and technology based upgrades. This Part of ISO 11064 covers all types of control centers, for example, those found in process plants, transport/-logistic control systems, and people deployment transportation systems.
Some of the principles regarding design procedures presented in this Part of ISO 11064 can be helpful in the design of mobile control centers, such as those found on trains, locomotives, ships and aircraft, though the standard does not set out to consider control centers of this type.

ISO/DIS 11064-2: 1999-03-00
pr EN ISO 11064-2: 1999-03-00
Ergonomic design of control centers — Part 2: Principles of control suite arrangement
Document scope: This Part of ISO 11064 covers ergonomic design principles of control centers, more specifically the various arrangements of rooms in a control suite. The principles are based on an analysis of tasks that have to be supported by the control room and functionally related rooms. They include identifying functional areas, estimating the space provisions for each functional area, determining operational links between functional areas, and developing preliminary control suite layouts to facilitate the smooth transition between all the activities conducted in the control suite. The control suite includes rooms or areas such as meeting rooms, equipment room, office(s), relaxation room and other rooms that support control room activities, as well as the control room itself. Associated ergonomic considerations include

not only architectural conditions, but social, cultural and environmental factors as well.

ISO/DIS 11064-3: 1997-02-00
prEN ISO 11064-3: 1997-02-00
Ergonomic design of control centers — Part 3: Control room layout
Document scope: ISO 11064-3 established ergonomic principles for the layout of control rooms. It include requirements, recommendations and guidelines on control room layouts, workstation arrangements, the use of off-workstation visual displays and control room maintenance.

ISO 11064-3 covers all types of control center including those for the process industry, transport and dispatching systems in the emergency services. Though this Part of ISO 11064 is primarily intended for non-mobile control centers many of the principles could be relevant/applicable to mobile centers such as those found on ships and aircraft.

Under preparation: Ergonomic design of control centers — Part 4: Workstation layout and dimensions
Document scope: ISO 11064-4 establishes general principles for the ergonomic design of workstations found in control centers. ISO 11064-4 covers all aspects of workstation design with particular emphasis on layout and dimensions, the type of workstations covered include seated and standing control room workstations, seated workstations with visual display terminals, and maintenance workstations. In addition considerations on the type and number of instruments and equipment will be given.

Under preparation: Ergonomic design of control centers — Part 5: Displays and controls
Document scope: ISO 11064-5 deals primarily with the display and input of data to monitor and/or operate processes from control centers. It establishes requirements that shall and recommendations that should be matched by displays and controls. Furthermore it gives permissions and reveals possibilities to support the designer.

It is impossible to cover in depth all relevant aspects of interaction design. Therefore this international Standard is limited to principles and selective in presenting requirements. To promote understanding and to ease access, the design procedure was applied for structuring the text.

The following topics are beyond the standard: The design of equipment like monitors, indicators, meters or input devices neither in hardware nor in software; the design of digital or analogue displays; the design of control actuators; location and arrangement of displays and controls; problems occurring with visual display terminals (VDT) applied to office tasks.

Under preparation: Ergonomic design of control centers — Part 6: Environmental requirements for control rooms
Document scope: ISO 11064-6 establishes environmental requirements for the ergonomic design, upgrading or refurbishment of control rooms, control suite and all other rooms such as offices, technical and auxiliary rooms. The following aspects

are: thermal environment; air distribution principles; lighting environment; acoustical environment; air composition; vibrations.
Under preparation: Ergonomic design of control centers — Part 7: Principles for the evaluation of control centers
Document scope: to be defined

Under preparation: Ergonomic design of control centers — Part 8: Ergonomic requirements for specific applications
Document scope: to be defined

Danger Signals and Communication in Noisy Environments

EN 457: 1998-11-12
Safety of machinery. Auditory danger signals. General requirements, design and testing
Abstract: This standard specifies the safety and ergonomic requirements and the corresponding test methods for auditory danger signals and gives guidelines for the design of the signal to be clearly perceived and differentiated as required in 5.3 of PrPN-EN 292-2. It does not apply to verbal danger warnings (e.g. shouts, loudspeaker announcements). Special regulations such as those for a public disaster and public transport are not effected by this standard.

ISO 7731: 1986-12-00
Danger signals for work places; Auditory danger signals
Abstract: Specifies the safety requirements and the corresponding test methods for work places in the signal reception area and gives guidelines for the design of the signals. May also be applied to other appropriate situations. Does not apply to verbal danger warnings. Special regulations such as those for a public disaster and public transport are not affected.

EN 842: 1996-06-00
Safety of machinery — Visual danger signals — General requirements, design and testing
Document scope: to be defined

ISO 11428: 1996-12-00
Ergonomics — Visual danger signals — General requirements, design and testing
Abstract: Describes criteria for the perception of visual danger signals in the area in which people are intended to perceive and to react to such a signal. Specifies the safety and ergonomic requirements and the corresponding physical measurements.

EN 981: 1996-12-00
Safety of machinery — System of auditory and visual danger and information signals
Document scope: to be defined

ISO 11429: 1996-12-00
Ergonomics — System of auditory and visual danger information signals
Abstract: Specifies a system of danger and information signals taking into account the different degrees of urgency. Applicable to all danger and information signals which have to be clearly

perceived and differentiated as specified in ISO/TR 12100-2. Does not apply to certain fields covered by specific standards.

ISO 9921-1: 1996-11-00
Ergonomic assessment of speech communication — Part 1: Speech interference level and communication distances for persons with normal hearing capacity in direct communication (SIL method)
Abstract: Provides a method for prediction of the effectiveness of speech communication in the presence of noise generated by machinery as well as in noisy environment. Parameters are the ambient noise at the speaker's position, ambient noise at the listener's position, distance between the communication partners and a great number of physical and personal conditions.

Under preparation: Ergonomic assessment of speech communication — Part 0: General description and criteria
Document scope: This part of the standard specifies the requirements for the speech communication quality in case of verbal alert and danger signals, information massages and speech communications in general. Methods to predict and to measure the performance in practical applications are described and examples are given.
Auditory warnings are also omnidirectional and may therefore be universal in many situations. It is required however that, in case of verbal massages, a sufficient intelligibility is offered. If this cannot be achieved synthetic warning signals may be considered.

Under preparation: Ergonomic assessment of speech communication — Part 2: Predictive assessment methods
Document scope: This part of the standard provides more universal methods for prediction of the performance of speech communications. The parameters covered by the prediction methods are: speaker related parameters as vocal effort, distance to listener or microphone; sound pressure level and frequency distribution of the ambient noise at the speaker and listener position: frequency transfer of the (electro acoustic) system; temporal distortion (reverberation, single echoes); hearing aspects of the listener (masking, reception threshold, hearing disorders). All predictive methods are based on the calculation of an effective signal-to-noise ratio in a number of frequency bands in which all types of relevant deterioration are included.

Under preparation: Ergonomic assessment of speech communication — Part 3: Subjective and subjective assessment methods
Document scope: This part of the standard specifies the use of a number of subjectives and objective intelligibility methods which are recommended for the assessment of the type of communications covered by this standard.
Subjective assessments require speakers to produce representative speech signals and listeners to determine the performance, selection of the speech utterances used for the test. For the objective assessment physical measuring methods are used. Depending on the method and application, selected speech or artificial signals replace the speaker. After transmission a physical

analysis is performed on the received signal which results in a performance score.

Touchable Surfaces

EN 563: 1994-06-00
Safety of machinery — Temperatures of touchable surfaces — Ergonomics data to establish temperature limit values for hot surfaces
Abstract: This document applies to hot surfaces of all products and equipment that must or can be touched during their normal use. That includes the area of safety of machinery as well as any other application. It provides data concerning circumstances under which contact with at hot surface may lead burns of the human skin. These data allow the assessment of risk of burning.

EN 563: 1994/A1: 1999-07-00
Safety of machinery — Temperatures of touchable surfaces — Ergonomics data to establish temperatures limit values for hot surfaces
Document scope: This document is an amendment to EN 563; 1994 adding contact periods below 1s.

prEN 13202: 1998-0400
Ergonomics of the thermal environment — Temperatures of touchable hot surfaces — Guidance for establishing surface temperature limit values in production standards with the aid of EN 563

Abstract: The document describes methods for the assessment of the risk of burning when a hot surface is touched by unprotected skin. It describes how surface temperature limit values can be established in product standards with the aid of EN 563. The document is applicable for all kinds of products where hot surfaces cause a risk of burning. It applies as well for electrically powered

Under preparation: Safety of machinery — Surface temperatures of touchable surfaces — Ergonomics data to establish temperature limit values for cold surfaces

Document scope: This standard applies to cold surfaces of all products and equipment that must or can be touched in accordance with their normal use. This standard provides data to assess the risk of injuries caused by contact of the skin with a cold surface. This standard also provides data to be used to establish temperature limit values for cold surfaces to protect against skin or body injuries. These data shall be used in the development of standards for specific equipment where temperature limits are required. (This standard does not provide data for the protection against pain.) This standard applies to solid surfaces. It does not apply to surfaces of liquids.

Ergonomics of Personal Protective Equipment

Under preparation: Ergonomic principles for the design of Personal Protective Equipment — Anthropometric measurements and principles for application to PPE design
Document scope: This European Standard defines basic anthropometric measurements for designing Personal Protective Equipment (PPE) to be worn by an individual against one or more health and safety hazards. This European Standard includes principles for research and application of the relevant anthropometric data to the design of PPE. It also includes principles for checking that a person wearing the PPE can perform the movements required in his activity. This European Standard may be used in conjunction with national or international documents and anthropometric data bases.

Under preparation: Ergonomic principles for the design of personal protective equipment (PPE) — Biomechanics
Document scope: This European Standard describes the biomechanics interaction between Personal Protective Equipment (PPE) on the static and dynamic biomechanics of the human body and its influence on task performance and workload. It describes test principles for acceptance of the PPE. (Care should be taken in applying the principles in work on the surface, under water and in hyperbaric environment.)
This standard includes the principles related to: the static distribution of weight and load on the human body when wearing different PPE and/or combinations of PPE; the dynamic or intertial forces on the human body when using different PPE and/or combinations of PPE; optimization of the influence of biomechanical aspects of PPE on work load and/or task performance.
This standard does not include aspects of biomechanics related to the mechanical deformation of the human skin. This item is included in the prEN xxx (the standard relating to sensory aspects of PPE).

Under preparation: Ergonomic principles for the design of personal protective equipment (PPE) — Thermal characteristics
Document scope: This European Standard is a guide for the evaluation of the thermal effects imposed by PPE/PPE-systems. It defines procedures, criteria and requirements to be applied for the assessment of thermal comfort and physiological strain resulting from the PPE/PPE-system under defined user conditions. The standard also gives guidance on the tests needed to evaluate the thermal characteristics of single PPE to establish the range of thermal conditions in which their use is safe.

Under preparation: Ergonomic principles for the design of Personal Protective Equipment (PPE) — Biological aspects
Document scope: This European Standard gives requirements and test methods for PPE materials to ensure that the materials will not generate substances during the use of the PPE which reversibly or irreversibly affect the user.
This standard provides lists of chemicals and references to chemical lists which are known to generate hazards if coming in contact with the human body and adversely affects health and safety of the user of PPE.
This standard identifies chemicals of which the manufacturers of PPE shall acquire sufficient knowledge in terms of health and safety.

Under preparation: Ergonomic principles for the design of Personal Protective Equipment (PPE) — Sensory aspects
Document scope: This European Standard provides details

regarding the ergonomic principles relating to the interaction between PPE and the human senses: sight, hearing, smell, taste, touch, vestibular orientation and proprioception. It specifies guidelines for evaluating and impairment of sensory perception arising from the use of PPE. It is concerned with the inward flow of sensory signals and the ways in which PPE may adversely affect that flow.

This European Standard does not cover the outward flow of signals (e.g. to give information), although this can also have an impact on the acceptability of any PPE.

Under preparation: Ergonomic principles for the design of Personal Protective Equipment PPE — Introduction to principles and application of European Standards on ergonomic principles for PPE

Document scope: Part 1 of this European Standards sets out the generic principles that shall be considered by those preparing product standards for personal protective equipment (PPE). It also provides background information and guidance on the application of these principles which it is intended should be helpful to those responsible for the drafting of product standards and the design of PPE. It also gives an introduction to subsequent parts of the standard which are a series of application standards that can be used in the preparation of product standards for personal protective equipment.

The aim of this generic standard is to provide: a basic reference for ergonomic requirements and test methods in product standards; a basic reference for ergonomic specifications where no relevant product standards are available; a source of information so that product standards can be drafted to specify PPE that is optimally suited to the people who will use it and the situations in which it is used; a basis for drafting application standards; an introduction to the use of application standards.

Under preparation: Ergonomic Principles for the design of Personal Protective Equipment (PPE) — Headforms and facial features
Document scope: This European Standard defines basic anthropometric measurements for comparing headforms in different population groups.

The standard gives recommendations for additional measurements (facial features) for designing headworn PPE which cover the face.

Ergonomics of Operability of Mobile Machines

Under preparation: Ergonomic design principles for the operability of mobile machinery
Document scope: This European Standard provides ergonomic principles, general design guidelines and basic dimensions for the operability of mobile machinery.

Integrating Ergonomic Principles for Machinery Design

Under preparation: Safety of machinery — Guidance for introducing ergonomic principles and for the drafting of the ergonomics' clauses
Document scope: The approach is based on EN 292-1, EN 292-2 + A1 and EN 414, using an amended version of the step by step method as set out in EN 1050. Each step has been adapted to include ergonomic principles, and practical guidance is given to apply horizontal standards. This European standard may be used for the drafting of C-type standards (product-machinery-standards) and by manufacturers where no relevant C-type standards are available.

Israel: Israel Ergonomics Society

I. Gilad

Faculty of Industrial Engineering and Management, Technion — Israel Institute of Technology, Haifa 32000, Israel

The Israel Ergonomics Society (IES) was founded in 1982 to enhance the state of the Ergonomics discipline in the State of Israel. To do this the founders outlined six goals:

1. To unite all Certified Ergonomists and qualified professionals who practice ergonomics in Israel under one umbrella by creating one national society.
2. To introduce the Ergonomics discipline and its benefits to increase safety and health measures for the working populations and individuals.
3. To spread out the knowledge of Applied Ergonomics in commercial enterprises, industrial and service organizations, for the improvement of productivity and economic status.
4. To aid governmental agencies when ergonomics issues are raised, help the legislator by providing solid ergonomics know how in the decision-making process.
5. To organize conferences, seminars, and professional forums where ergonomics issues are to be discussed, to support R&D activities, where ergonomics problems are to be studied.
6. To establish professional ties with Ergonomics societies around the globe, to build bridges of knowledge with centers of expertise and individual that masters all types of ergonomics.

Over time, the IES has become the representative of the Ergonomics discipline in Israel. The IES is a fairly well recognized organization, and its membership is being kept on a high level of professionalism. Since 1995, the core membership (Full Members of IES) is comprised of about 50 Certified Ergonomists who are practicing all aspects of Ergonomics. The IES is Israel's sole representative to the International Ergonomics Association. The IES's affairs are managed by its Governing Committee headed by a two-year elected Chairperson.

The IES achieves its goals by conducting a variety of activities. IES stands ready to serve the public, where professional activities require research and applied know-how and solving problems related to Ergonomics and Human Factors.

Ergonomics degrees in Israel can be earned on Graduate levels in one of the Universities: Ben-Gurion University and Technion — Israel Institute of Technology. Ergonomics and Human Factors courses are provided in the Industrial Engineering Departments, at MSc and PhD degree level.

1. IES MEMBERSHIP STATUS

The IES is comprised of four kinds of membership groups: Full Member, Associate Member, Representative Member and Student Member.

1.1. Full Member

One who holds a formal academic degree from a recognized university and has 5 years of proven experience in Ergonomics and Human Factors. He has to be recommended to the IES Membership Committee by two Senior IES Members. Alternatively, one who has finished formal Ergonomics studies in a recognized institution and has 10 years of proven experience in Ergonomics and Human Factors. He has to be recommended to IES Membership Committee by three Senior IES Members.

A Senior IES Member is a Professional Ergonomist who has been a Full Member, has been registered in IES for 5 consecutive years, and is serving the profession in a respectful manner.

A Full Member is eligible to vote in IES forums and receive IES publications. He can present himself to IES offices.

1.2. Associate Member

One who is not qualified as a Full Member, but is actively involved in the fields of Ergonomics and Human Factors, for at least 5 years. Alternatively, one who is a Certified Ergonomist and is a member of a foreign Ergonomics Society affiliated to the International Ergonomics Association (IEA). A recommendation from a Senior IES Member is required for this status.

An Associate Member may serve on IES committees and receive IES publications. An Associate Member may not vote in IES forums and may not present as a Full Member of the IES.

1.3. Representative Member

One who is interested in representing an organization, has formal knowledge in Ergonomics and is using as a daily activity.

A Representative Member may receive IES publications; they may not serve as member of IES committees. A Representative Member may not vote in IES forums and may not present as a Full Member of the IES.

1.4. Student Member

One who is a registered student in a university Ergonomics/Human Factors program. A student membership is limited to 3 years. To join the IES as a Student Member a recommendation from a Full IES Member is required.

A Student Member may receive IES publications; but may not serve on IES committees. A Student Member may not vote in IES forums and may not present as a Full Member of the IES.

Italian Society of Ergonomics (Società Italiana di Ergonomia, SIE)

G. Caterina

Università di Napoli Federico II/ Dip., Configurazione e Attuazione dell'Architettura, Via Tarsia 31, I-80135 Naples, Italy

Ergonomics began in Italy at the end of the 1950s, about a decade after K. F. H. Murrel founded the scientific group that gave birth in Oxford to the Ergonomics Research Society (July 1949), and a few months before SELF, a society devoted to the promotion of ergonomics in French-speaking countries. Several studies on the topic had already been developed at the turn of the 20th century, but the term 'ergonomics' was created by Murrel to stress the gathering of different disciplines and with their individual profiles playing a significant role in ergonomics.

In Italy ergonomics was developed in the context cultural background of physiology, hygiene and occupational medicine. Then psychology, sociology, engineering and architecture added their substantial contribution.

In 1961, the Italian Society of Ergonomics was founded in Rome, the same year in which in Stockholm the International Ergonomics Society (IEA) was founded to which the Italian Society of Ergonomics was among the first affiliated members. In 1964, the Italian Ergonomics Association was formed in Milan on the initiative of a multidisciplinary research team. In 1968, this new association merged with the Italian Society of Ergonomics to the present Società Italiana di Ergonomia (SIE). Among the scientists promoting the union of the two associations was an outstanding personage, Professor Caio Plinio Odescalchi, *ad hoc* delegate of the Italian Ergonomics Society.

In the 1960s there were attempts, mainly of an individual nature, at studies, contacts and bibliographic researches, almost entirely in the field of anthropometrics, work physiology, industrial hygiene, occupational medicine or plant design, even though, with special reference to the design context, theoretical intuition already contemplated objectives based on the contributions of a wider range of disciplines.

The first experiments on the workplace, starting from the late 1960s, were dictated by the need to develop analytical methods able to identify conditions of risk, rather than to draw up projects for a real change; this was perhaps due to the difficulty in achieving an organic approach that would take in account the requirements of both the company technicians and the workforce in a period marked by a strong social tension.

The aims of these studies consisted of those aspects that occupational medicine had so far addressed only partially or even neglected, i.e. work postures related to plants and instruments of production, evaluation of energy expenditure for each operation and of parameters for the quantification of heat stress, distribution of information in space and time. Nevertheless, attempts were also made to develop methods to acquire overall knowledge about conditions of production able to cause 'chronic fatigue'.

In this phase, there was a declared awareness of the importance, for ergonomics purposes, of organization analysis but, under the impetus of cultural development and trade union conflicts, participation and subjective aspects were more influential than structural aspects in the assessment of risk conditions.

In the context of workspace experience, the development of ergonomics in the steel industry is of special importance. In 1965, the European Coal and Steel Community (ECSC) initiated research programs and studies on ergonomics within coal and steel industries. In this field the Italian steel industry has developed a significant experience, thus qualifying, with that contribution, as one of the most important reference points for ergonomics in Italy.

In the second half of the 1970s with the beginning of the technological changes, especially in micro-electronics, taking place in a large number of enterprises, a planned and analytical view began to gain ground, taking into more careful consideration the interaction between man and technical systems and thus offering new space to ergonomics. The field of ergonomics activity widened covering all choices concerning the organized work with contributions of knowledge originating mainly from the organization theories.

While in the 1970s the main subject of ergonomics was the man at work, in the 1980s its interest was focused mostly on the consumer with the consequence that the usability context became hard to identify. Therefore, ergonomics is asked especially to design the interface between man and product in which the man is the consumer. There is in this way the passage from the trend man–product to those man–technical system and man–man, the last one mediated by VDT.

In 1996 an important step in the development of ergonomics culture in Italy has been the promulgation of Decree no. 626, in which for the first time ergonomics is officially recommended in a national rule devoted to the prevention of workers risk.

In this new scenario SIE is aiming today to improve education in ergonomics inside Italian universities to define the professional profile and core competences for ergonomists certifying in agreement with the Center for Registration of European Ergonomists (CREE).

Macroergonomics

B. M. Kleiner

1. INTRODUCTION

Many environmental and organizational factors have created the need to develop a macroergonomic perspective, cultivate macroergonomic research, and apply macroergonomic methods and tools. These forces include increased competition, restructuring, changes in technology, changing workforce demographics, increased litigation, shorter product shelf-life, increased global competition, and increased information and communication requirements for products, processes, and people. For example, in industry, increased automation has in many cases inadvertently led to technology dominant designs, creating "leftover" functions for operators to perform. As a result, many jobs are monotonous, boring, fatiguing, unhealthy, unrewarding, and/or unsafe. Other design and redesign efforts have been more subtle in their inattention to the sociotechnical characteristics of work systems, but the results have been equally disappointing. While there have been some who have attempted to improve organizations, systems, and jobs, most often, these components are treated as independent entities — having no relationship to one another. Macroergonomics takes the perspective that these work-system components are interdependent. As interdependent components, work-system components need to be analyzed systematically and jointly in order to maximize performance and wellbeing of workers, groups, and organizations.

2. DEFINITION

As presented by Hendrick and Kleiner (in press), macroergonomics is a sub-discipline of the human factors engineering/ergonomics profession with the stated focus of work system analysis and design. In fact, macroergonomics and work system analysis and design are synonymous. A work system is comprised of personnel (e.g. operators) interacting with hardware and/or software (e.g. computers), an internal physical environment (e.g. illumination, humidity), external sub-environments (e.g. legal, political, technological, cultural) and organizational design, including structures, processes, and management systems. Macroergonomics has also been referred to as the ergonomics sub-discipline concerned with human–organization interface technology. Other sub-disciplines are concerned with other technologies such as human–machine interface technology, human–environment interface technology, human–software interface technology, and human–job interface technology.

3. MACROERGONOMICS AS A SUB–DISCIPLINE

As a formal sub-discipline of ergonomics, there are macroergonomics technical groups in the Human Factors and Ergonomics Society (HFES) and the International Ergonomics Association (IEA), as well as in other national professional ergonomics bodies. For the ergonomics generalist or microergonomics specialist, macroergonomics offers a systems perspective which creates a useful context for microergonomics intervention. In addition, this potentially increases the relevance and potential impact of ergonomics because work system factors often hinder system performance or user acceptance downstream. By considering these factors upstream, success is more likely. For the macroergonomist, the sub-discipline offers more than a perspective. Like other scientific sub-disciplines, macroergonomics has its own research stream of knowledge, research methods, and practical methods and tools.

4. MACROERGONOMICS PERSPECTIVE

For the ergonomics generalist or microergonomics specialist, macroergonomics represents a perspective that provides the ergonomist with an appreciation for the larger system — a perspective that will increase the likelihood that the microergonomic interventions will flourish. Too often, a product, process or interface has been designed without attention to the larger system. In systems terms, the design was optimized, but without attending to the larger system first, the total system can be sub-optimized. That is, ultimately implementation success does not depend only on the merits of a micro-level design but whether and to what extent micro design is aligned with macro-level factors and forces from the environment, including organizational, political, economic, cultural, and legal factors.

5. MACROERGONOMICS RESEARCH

Macroergonomics basic research is concerned with the relationships among technological, personnel, internal and external environmental, and organizational factors and their interactions. These factors and their individual and combined effects on performance have been studied in both the laboratory and in the field that is in actual work systems. The sociotechnical systems research body of knowledge and the ergonomics literature offer a foundation for this research stream. Laboratory research offers the advantage of control, while field studies are often more relevant, but lack the precision afforded by controlled laboratory studies. In both cases, experiments or studies are designed and conducted, typically using humans as research subjects. Various objective performance, usability and subjective data are collected at the individual, group, and organizational levels. These data are statistically analyzed with inferences about causal relationships drawn that contribute to the ongoing development of a research body of knowledge.

6. MACROERGONOMICS METHODS AND TOOLS

Other research methods, often used in combination with experimentation, include survey research, simulation, systems dynamics modeling and ethnography, each with its own set of tradeoffs.

Complementing the empirical research, systematic macroergonomic methodologies for analysis and design of work systems have emerged as well.

The design of a work system's structure and related processes involves consideration of three major sociotechnical system components that interact and affect optimal work system design. These are the technological subsystem, personnel subsystem, and relevant external environment. Each of these components has been studied in relation to its effects on the organizational design dimensions of complexity, formalization, and centralization. Respective empirical models exist to analyze work system structure. Complexity refers to the extent to which the work

system is differentiated or segmented (e.g. vertical, horizontal, spatial) and the extent to which there is integration in order to link the various segments. Formalization refers to the extent to which there is standardization present in the work system (e.g. procedures). Centralization refers to the degree of decision-making performed by relatively few persons, usually at the helm of the organization.

In addition to analyzing and designing the structure of the work system, it is desirable to analyze and design the processes of the work system. One approach is first to scan the external environment of the work system in order to understand the forces that will necessarily affect performance. Next, a technological subsystem analysis will define the type of production system and will detail the work process steps and variances. Then, control of these variances is addressed by identifying the roles needed to control or prevent variances. Following this, joint design of ergonomic solutions is carried out. This involves function allocation and the design of technological and training support for human functions. It is also helpful to evaluate the operators' perceptions of their roles and to redesign the reward sub-system and any other sub-system to support human performance. Finally, a cycle of continuous improvement will periodically review and seek additional changes.

As methods such as these are implemented, a philosophy of "participatory ergonomics" is adopted. Participatory ergonomics implies workers participate in both ergonomic analysis and design, especially as these procedures relate to their jobs. This requires some degree of decentralization or sharing of decision-making. The process of participatory ergonomics can be as simple as involving users in their own usability testing or involving workers in formative or summative evaluation of their workplaces or processes, but may be as complex as training non-professional workers in the concepts and methods of ergonomics for more sophisticated participation. The basic principle is that ownership and quality of results and involvement in the processes of creating results go hand-and-hand.

7. MACROERGONOMICS RESULTS

When a work system has been designed effectively from a macroergonomics perspective, and that effort has been carried through to the microergonomic design of jobs and human–

machine and human–software interfaces, then the work system design is harmonized. As a result, synergistic functioning becomes possible, and system productivity, safety, employee satisfaction, commitment, and perceived quality of work life will be much greater than the simple sum of the parts would suggest or predict.

Macroergonomics has been demonstrated to improve work system performance throughout sub-system areas, including productivity, quality, safety and health, quality of work life, user satisfaction, etc. In terms of the magnitude of improvement, Hendrick (1986) suggested that improvements of 60–90%, or more, are to be expected by macroergonomics approaches, while microergonomic approaches can at best achieve 10–20% improvement.

8. THE FUTURE

As macroergonomics continues to be developed as a sub-discipline, the need increases. Global competition and restructuring continue, creating changes in the demographics of the workforce. As many organizations struggle with their turbulent external environments, they have turned to such approaches as total quality management, reengineering and restructuring. Macroergonomics can be the organizing framework for such approaches to organizational change and process improvement. In this context, the macroergonomist has played the role of change agent.

In addition, systems, products, and processes continue to become more information-dependent, creating heightened needs for the knowledge worker. Optimizing work systems within the context of this unprecedented level of information content is a daunting task for the ergonomist. Macroergonomics offers the perspective, research-based knowledge, methods, and results needed for such a challenge.

Ontology

V. Raskin

Department of English and Interdepartmental Program in Linguistics, 324 Heavilon Hall, Purdue University, West Lafayette, IN 47907-1356, USA

1. INTRODUCTION

"Ontology" is an ambiguous term. It may be used synonymously with the philosophical discipline of metaphysics, an ancient and sometimes maligned theory of most basic categories. It may refer to a much newer discipline of formal ontology, based on mereology and topology, dealing with the formal, mathematical methods of representing elements of reality. And it may refer to engineering artifacts, conceptual structures, used in various applications.

Ergonomics should be particularly and obviously interested in the last, engineering aspect of ontology because of the ergonomic focus on specific applications for specific tasks in specific domains. It is important, however, to lay out the philosophical and formal foundations of ontology because their understanding affects the engineering enterprise directly: a specific ontology can be designed better or worse, more or less costly, more or less effective depending on the developers' understanding of the nature of the phenomena they are dealing with in the process.

Much of ergonomics depends on natural language, especially on the meaning expressed by and in it and on the comprehension of that meaning both by the speakers and hearers. It is in the area of natural language semantics and its application, computational semantics, that the ontological approach has been particularly successful.

2. FACETS OF ONTOLOGY
2.1. Basic Notion and Example

An ontology is understood here as a tangled hierarchy of concepts, such that each concept is a frame with a set of slots and fillers. The specific examples come from one of the largest and richest ontologies in existence, the one developed initially for the MikroKosmos knowledge-based system of machine translation (MT) and available for browsing on the Web at crl.nmsu.edu. Its top level consists of the concept ALL, which has three "children," PROCESS, OBJECT and PROPERTY — the names of the concepts are, however, mere mnemonic labels for human user convenience and can be easily replaced without any changes in the ontology as long as the frames remain constant and consistent. All the other concepts in the ontology are descendants of at least one of those general concepts and inherit their slots and fillers at least monotonously, i.e. vertically down. Thus, the process PERMIT may be represented as:

```
PERMIT
    is-a          directive-act
    agent         human
    beneficiary   human
    theme         event
    agent         permit.beneficiary
    precond       have-authority
    agent         permit.agent
```

theme   OR   permit.beneficiary
permit.theme

The concept is characterized as a DIRECTIVE ACT, which is a descendant of MENTAL ACT, which is, of course, ultimately a descendant of PROCESS (and more closely, a descendant of ACT or ACTION, one of the two children of PROCESS, the other one being STATE). The act has a human agent and a human beneficiary and it concerns an event involving that beneficiary as an agent: provided that the agent of PERMIT, permit.agent has the authority to allow the beneficiary to be the agent of that event (i.e. to perform a certain act) and/or the authority over that kind of act, the beneficiary of PERMIT, permit.beneficiary, is licensed to bring about the event by committing an appropriate act.

Each of the slots and fillers in the concept entry is itself a concept in the ontology (and was not put in the customary small caps for easier reading). In the real ontology, PERMIT will inherit several slots and fillers (certainly and at the very least, the agent/human and beneficiary/human slot/fillers) from its parent, DIRECTIVE-ACT, which, in turn, will inherit (at least some of) them from its parent, COMMUNICATIVE-ACT.

2.2. Foundational Issues in Ontology
2.2.1. Ontology as metaphysics

The term "ontology" is used by some philosophers interchangeably with metaphysics. Metaphysics, the most ancient part of philosophy, dating back at least to Aristotle, deals with the most basic categories of reality: for Aristotle and many others, primarily objects and processes. In the empirical 19th century, metaphysics was perceived as experimentally unverifiable and, therefore, irresponsible, and parts of it may have been so. There has been no going away, however, from the necessity of understanding the basic categories underlying both human thinking and the spectacular successes of empirical sciences. In the 20th century, the concern about foundational issues of physics and other hard sciences has become common and acute. The term "ontology" was used for a while as a "polite" substitute for metaphysics, but towards the end of the century, the later term regained its respectability. Accordingly, "ontology" started being used more correctly as the actual result of metaphysical research, a specific system of basic concepts.

The major issue of metaphysics is the status of properties. The realists recognize the existence of both individuals, such as houses or cars, which are spatio-temporal entities, and of their shared properties, such as costliness or redness, which are not spatio-temporal but rather abstract. Their opponents, the naturalists, recognize only individuals. Both camps, existing in a large number of variations, have a difficult philosophical issue to deal with: for the realists, the different status of properties; for the nominalists, the existence of those properties. For a specific ontology, the matter is only important in one sense, namely, whether the ontology is to contain properties or not, and the nature of any reasonable application usually imposes the realist solution.

2.2.2. Formal ontology

Formal ontology was developed late in the 20th century as a cross of mathematical disciplines of mereology, which studies the relations between parts and wholes, theory of dependence, and topology. But it was originally Edmund Husserl earlier in

the century, who saw a need to establish formal ontology as the "theory of things" parallel to logic, the "theory of truths."

The agenda of formal ontology typically includes explorations into notions of time and space, modality, especially the deontic (imperative, must-do) phenomena, taxonomy of artifacts, and types of inheritance. A specific ontology, in its implementation, has to take a position on each of those and other issues of formal ontology, so the awareness of these issues is essential for the developers.

2.2.3. Ontologies as engineering artifacts

The MikroKosmos ontology, containing over 7000 actual and many more virtual concepts (i.e. concepts derivable from the actual concepts with the help of well-defined rules), was created by a team of computer scientists and linguists over almost a decade at a considerable cost. After the original time- and effort-consuming basic research, which established the top-level concepts and the format of each type of entry, a major effort was devoted to the development of semi-automatic tools of acquisition enabling the participation in the work, at its simplest level, of rank-and-file enterers with a minimal training. This was achieved by an inventive use of easy-to-understand templates for several basic types of concepts. The introduction of the tools made the acquisition of numerous concepts very speedy and inexpensive.

The resulting ontology meets and exceeds the industry's standards of clarity, coherence, and extendibility, and it stands to reason to conclude than any ontology of the future, comparable to this particular one in size and depth, will have to be developed more or less along the same lines: a combination of the tiered approach to acquisition, the use of semi-automatic tools, and the emphasis on cheap labor whenever and wherever practical.

2.3. Ontology and Natural Language

It is in the development of MT and other natural language processing (NLP) systems that the ontological approach proved to be particularly successful. Early MT was of the transfer type: a system was designed on the basis of a minimally required rules of transfer from words of the source language into the words of the target language. While the simplest transfer, word for word, does not work in translation, inventive rules were created to overcome this difficulty in many cases. The resulting translation was, however, pretty rough and not very accurate, making it hard to use without expensive human post-editing.

The alternative to transfer MT was the interlingua approach. Interlingua was a formal representation of text. The input text was analyzed and represented as an interlingua text and the latter was used to generate an equivalent text in the target language. An ontology was introduced as a rich and sophisticated form of interlingua in the late 1980s and won a dominant position in the interlingua approach in the 1990s.

The MikroKosmos ontology is the foundation of the whole knowledge- and meaning-based approach to language processing. As a universal language-independent resource, the ontology is the metalanguage for the lexicon: each lexical entry in a natural language is defined in ontological terms. In the simplest case, the meaning of a word corresponds exactly to an ontological concept; in this case, the entry contains a simple pointer. More often, the match is not exact and an additional constraint, formulated in terms of ontological properties, must be added to

the entry. Yet in other cases, the entry must contain a reference not to a concept but rather to a certain slot and/or filler in its frame.

Even more importantly, the ontology provides a conceptual foundation and world grounding for whole texts. Working with the lexical entries making up a sentence and using the pertinent syntactic information for the natural language being processed, the analyzer produces ontology-based formula, the text meaning representation, for the sentence.

The approach has been successfully tested in non-toy systems of MT, information extraction and summarization, and other sophisticated NLP applications. It is particularly powerful in limited professional domains, which are precisely what ergonomics usually serves in a specific application.

3. STANDARD OBJECTIONS AND REBUTTALS ABOUT ONTOLOGY

While ontology has been gaining ground in natural language and other research, there has been considerable resistance to it from some quarters on a variety of grounds.

3.1. Natural Language Fallacy

Some computational semanticists insist that ontological concepts are simply words of a natural language. For some of them, this is perfectly acceptable and they proceed with their own methodologies, explaining meanings of natural language in terms of the same natural language. Theoretically, this is how the later Wittgenstein's notion of meaning is usually seen. Practically, this is how traditional lexicographers wrote their monolingual dictionary entries. For others, a charge of circularity is raised and it is indicated that the connection between natural language and extra linguistic reality (world grounding mentioned above) is not then addressed.

Whether accepted or rejected as a method, ontological terms cannot be confused with words of natural language. Developed for use by computer, the former are totally devoid of ambiguity, which removes them from natural language. What confuses these critics of ontology is that when a human user reads these terms he or she may know the other, unintended meaning(s) of the word in a natural language that is used as a concept label. The computer does not possess this ability and is, therefore, unaffected by the ambiguity, which renders the ontological labels non-natural.

Besides resulting in disconnecting natural language from extralinguistic reality that it expresses, this natural language fallacy leads to the confusion between object language and metalanguage. All approaches use metalinguistic terms for the categories that they use in language description or representation. Only the ontological approach introduces these categories explicitly and completely, usually in the PROPERTY branch.

3.2. Irreproducibility Charge

Other objections to ontology question the scientific method of the approach. A sound scientific research should be reproducible, they say, but it is clear that two different people, let alone groups, will come up with different ontologies for the same conceptual domain. The confusion here is twofold. First, the creation of ontology is not equal to a scientific experiment, and extending the burden of reproducibility to it requires a considerable

metaphorical extension — of the kind that Chomsky accused B. F. Skinner of in 1959, effectively removing him and eliminating his influence from cognitive psychology. Second, given the same parameters and conditions, as in a scientific experiments, which includes the semi-automatic acquisition tools, different people and groups do indeed come up with identical or compatible results, and this has been tested in practice — unlike the speculative argument of ontology foes.

3.3. Engineering Objections

The objections here are serious because they are cost-related. Ontology acquisition is costly, especially at its initial stage, when methodology and tools have to be developed and deployed prior to and along with the massive acquisition stage. There is, however, a major catch: once done, ontologies can be expanded, borrowed, interchanged, etc. at a nominal cost. A special effort by formal ontologists has led to the development of a standard Knowledge Interchange Format, and both the MikroKosmos ontology and other ready-made ontologies have been successfully borrowed, adjusted, and deployed by other groups in new domains. In other words, the high costs do not need to be incurred more than once, and this was already done.

4. ONTOLOGY AND ERGONOMICS

Ontology is essential for any ergonomic application which deals with conceptual representations. It is especially in limited domains of technology that ergonomics so often operates in that ontology provides a complete theory of the world of the domain, i.e. all the possible objects, processes, properties in minute detail, thus defining formally — mathematically, that is — every possible and impossible state of affairs. Any form of communication, be it in natural language, art, or other visual or audial media, is incomparably improved if underlain by the total clarity guaranteed by the ontology. Ergonomics does not have to expend any resources on developing ontologies. Ready-made ontologies should be used — and have been used — to improve ergonomic methods and results.

An Outline of Ergonomics, or the Science of Work Based upon the Truths Drawn from the Science of Nature

W. B. Jastrzebowski

PART I (NO. 29, PP. 227—31)

A word is as good as a wink to the wise man

***

INTRODUCTION

Hail, Thou great unbounded idea of work! God, Who, as the Bible teaches us, cursed mankind and subjected him to work, cursed him with a father's heart; for the punishment was also a consolation. He who complains against his work knoweth not life; work is an uplifting force by which all things may be moved. Repose is death, and work is life[1])!

If there were as many people preaching the idea of work in other words the idea of the deed as there are those who preach the idea of the word, the thought, the feeling, form, of Mysticism, Idealism, Materialism, Pantheism, Egoism and many other such things, what a great deal of good there would be happening in the world!

What would be the fate of two societies, of which one would be engaged in useful work and praiseworthy deeds, such as the tilling of the soil and the improvement of the people, while the other consisted of persons busy with words, thoughts, feelings, and other things of those just enumerated?

Affecta nihil aliud sunt, nisi accessoria ad facta.

Affections are nothing else, but accessories to deeds.

By their deeds shall ye know them.

Not every one that saith unto Me, Lord, Lord, shall enter into the kingdom of heaven, but he that doeth the will of My Father (Matt. 7:21).

Work enriches or *divitiates* us, making us more like unto the *Divine* . . .

Work is the mother of all good.

He who relies on others shall be forsaken by God.

God cannot save us without us.

Were God to come down from heaven and appoint the Archangels His Ministers and the Angels his servants, there shall still be no happiness in the world until mankind comes to love work and until all people apply all of the forces given them by the Creator to work.

One idle man, in other words one squanderer of the forces and faculties with which Man is endowed by God, may do more evil in the world than a thousand industrious people can do in amends for him.

One bad man can do more damage than ten good men can help.

As the body of a particular man suffers and incurs loss from the ailment, idleness or malfunction of even one of his limbs, so too the body of society suffers and needs must incur detriment if even one part of it is in a similar condition.

What a thousand good men gain in a thousand years of work, one wicked man given to laziness may destroy in one day[2]).

Just as there may be no good wall without good bricks, and no good edifice without good walls, so without good people there may be no good peoples, and without good peoples mankind shall not be good.

Which people, and which of their labors is best — is it not that whereby the most: the most things, the greatest number of people, and they themselves — have been bettered?

The above-cited sentences, whatsoever source they may come from (which is of least import to the truth that through them is revealed, and to the good that may come to us and to all men from the acknowledgement of this truth as indisputable) have been placed at the head of this treatise on work, in other words on the good use of the forces and faculties given Man by his Maker, so that, knowing the need for such work on the strength not merely of our own but of the general conviction, and acknowledging it as an indispensable condition of our happiness and well-being in this world, we many endeavor to bring first our own will unto work, and then the wills of all those of our fellow-brothers whom we have the power to influence by word or example. By this inclining of ourselves and our fellow men unto work we may contribute to the fulfillment of their and our own hopes for the improvement of their and our existence. Which improvement and increase both in the material as in the moral respect haveth its surest warranty only in the said work, *source of all good.*

That this be truly so, that it is only in work that the surest hope lies for the improvement and increase of our own and the general well-being — in work which is useful and commendable, such as the tilling of the soil or the betterment of people and things — no man appears to doubt in the least, since it is only through such work that all things may be improved and rendered fit to serve the common good.

And apart from this our *forces* and abilities, whereby and through the guidance of which we perform our work, develop through our exercise of work, perfecting in the proper respect, and thereby contributing to the advancement and perfection of our entire being, which is the condition for our felicity and without which our existence is meager and ever under the threat of doom. For it is well known that our vital *forces* grow weak and impoverished as much by the *lack* of their exercise as by their *abuse*; and that they are maintained in their proper condition, growing and increasing by their proper and moderated exercise, which we call work, and whereby we improve things, people,

and ourselves, making them and us more conducive to the service of the common good.

But lest that *exercise* of our *forces*, which is the principle and essence of our lives, be too burdensome upon us; that it may bring us to the source of felicity and contentment — we ought ever to arrange it in such a manner that it may not hamper those vital forces in us, but that it may extend to include all those forces we have in us and by which we may serve the said common good.

For it is only through such application of all our forces united that they may be mutual supports one unto another, not only making our work lighter but also bringing us greater profit, as we have seen elsewhere, for instance in the *application* of those forces to the enhancement of the earth's fertility. For if the earth's fertility be improved merely by the least of our vital forces, that is by the physical or *motory* force, the force of movement whereby we subsist only in sleep, in sleepwalking and in the mere unconscious carrying out of our ordinary chores, she shall prove but so little enhanced in her action and capacity to act that for each grain we entrust unto her she shall bring forth but *two* in harvest[3]).

But if we endeavor to raise the earth's fertility by applying both our physical and our aesthetic forces, that is our motory and our *sensory* or *emotional* forces, which will ensue when we cultivate the land industriously and with a sense of taste, the earth's fertility will be doubled by the engagement of our effort so as to bring forth a *fourfold* crop at harvest for every grain sown.

This gives us grounds to suppose that if we were to apply three of our vital forces for the enhancement of the earth's fertility, our physical force, our aesthetic force, and our intellectual force, that is our forces of *motion*, of *feeling*, and of *reason*, then the earth's fertility would become even more efficient, such that for every grain sown the crop would be *eightfold* at harvest-time. This is generally confirmed by all our present-day well-managed farms, that is those that are managed industriously, and according to the precepts of taste and reason, with the use of the three above-mentioned forces. This leads us to the premise that if we could enlist yet a fourth of our forces, adding it to the other three, the earth's fertility could be raised to a still higher power.

And since the relation between the three former forces with respect to the increase of the earth's fertility is, as we believe, a *doubling effect of the previous outcome*, for as we have seen the ration between them is 2: 4: 8, we may thus expect that this fourth force, the moral or *spiritual* force which induces us to work not only for our own and the common good (which entails the glory of God, the welfare of our neighbors, of our fellow creatures and of ourselves) could advance the earth's fertility so much as to yield twice eight, or *sixteen* grains at harvest from every grain sown.

This is not far from the truth, for we have observed through our own experiment, carried out in the strictest conditions, that given our appropriate application of all the four vital forces just mentioned to the earth's fertility, it may be brought to the state where for every grain sown, e.g. of wheat, the harvest from even modestly fertile soil not particularly suited for wheat will be three-hundredfold. But such an occurrence is still not the highest on record, for elsewhere there have been experiments carried out which have shown that with the engagement of but three of man's vital forces, that is his *motory* force, his *emotional* or *sensory* force, and his *intellectual* force, the harvest obtained was over three times the just quoted value of a three-hundredfold crop, that is about one thousand grains of crop from each grain sown — one hundred and twenty-five times eight, which marks the richest ordinary yield to be expected from the application of the three just mentioned forces, and 62 1/2 times 16, that is the crop to be expected from the engagement of all four of our forces, and without their very great exertion.

What has been said here of the earth's fertility, that is of *its increase by the application of our vital forces to it*, holds for all the other forces of living and inanimate Nature. For even those forces, as for example steam power and electrical power, which previously in their natural condition were of so little effect under the exercise of merely our *sensory* forces upon them, have now in our own times progressed so far in their marvelous and beneficial effects to a much higher importance by the application to them of the first three of the human forces. We shall now turn our attention to the forces of living Nature only, of which we say there are only as many as we have observed in our own being, that is four (viz. 1. the physical, kinetic or *motory* force of movement, such as is given to all living creatures, even the lowest of them, the Plants; 2. the aesthetic or *sensory* force which is possessed by all creatures capable of feeling, even the lowest of them, the invertebrates or *Primitive Animals*; 3. the intellectual forces of *reason* of which all comprehending and thinking creatures are endowed, even the lowliest of them such as the fishes, the reptiles, the birds, and the quadrupeds, in other words all *Animals*; and finally 4. the moral or *spiritual* force which has been ascribed only to human beings, that is to *Mankind* proper). If we now turn our attention to these forces of living Nature we shall see that they are even more conducive to give bigger and bigger yields as we exert our vital forces on them than are the forces of inanimate Nature, which make the things on which they act and in which they are lodged produce only inanimate returns, in other words only the utilities, for the common good. But the forces of living Nature can generate, through their development and perfecting brought about by our own forces acting on them, gains which are animate, that is the services, favors or goods, as demonstrated by properly conducted bee-keeping, by well-managed animal husbandry, and by a similarly well-ordered education and management of human resources. As a result of the appropriate education and suitable government of human beings, in other words through the furtherance and management of man's vital forces by himself, those human vital forces turn out to be of incomparably higher value and manifest a greater ability to serve the afore-mentioned common good than the corresponding value and ability in other people who are no so organized.

Such other people, who have not had their vital forces developed and organized by our own forces, are often in the same or even in a worse position than land that is uncultivated as regards their faculty to apply their forces. For uncultivated land, which as is well-known does not yield a harvest of cereals, nevertheless brings forth grasses and herbs, bushes, trees, and other such like beautiful and useful produce; whereas people who are badly educated and not organized, in other words whose vital forces have been neglected or are badly managed, very often not only bring no profit or gain, but are even harmful as regards the common good.

This is clearly the outcome of the failure of our vital forces to

exert an effect on their forces; or it may be the result of an inappropriate application of those forces. For it is well-known that the earth's yield is meager or none at all not only when we have neglected its fertility, but also if we have applied our four vital forces in an inappropriate manner, contrary to the nature of the land and the crops which are to grow on it.

If it is indeed so — and hardly any who considers it well shall have any doubts — as has been shown on the example of the earth, the animals, and mankind, that by the *application of our forces on the external forces of Nature, living and inanimate, these latter forces, and hence also the things and the creatures in which they are lodged and through which they manifest their visible effects, acquire a greater value or ability to serve the common good the more efficiently and the more appropriately we exert our own vital forces upon them*; if it is indeed so, then the exertion of our vital forces for the common good, which is called work, deserves our special and scrupulous attention. All the more so as by such exercise we gain still one further advantage profitable and useful for the common good, for, *like the magnet*, the magnetic force of which, as is well known increases through habitual use, we shall *promote and augment the vital forces within us by their frequent employment, and in consequence we shall achieve an ever greater and more effective increase in the value or virtue of other things and other people, determining their ability to serve the common good*, to which everything is devoted, following the goodness of God, and to which thanks to Man the most perfect creature made in the likeness of God more and more may and should be devoted[4]).

The importance of the proper exercise of our vital *forces* here described, the importance of our work, by which we are to bring and encourage other things, and other creatures like unto us or not, to work, that is to exercise their own vital *forces* for their own, our and the common good, supplies the reason and strong incentive for us to undertake this work of scholarship on work, and even to establish a new discipline regarding a subject which is of no lesser significance than other subjects of scholarly inquiry, not to mention its superiority over other questions of lower standing which merely entertain our curiosity but do not show us what we are to do and how we are to act in this age in which we are now living and which we call the Age of Action; how we should live to make our lives as bountiful as possible at the least expenditure of toil and with the greatest inner contentment, bringing forth fruit for our own and for the common good; ultimately with all due equity to be judged by others and by our own consciences.

Lest this Science of Work, understood as Work in the comprehensive and integral sense, not merely its part that is physical labor or *toil*, but physical, aesthetic, rational, and moral work, that is *Labor*, *Entertainment*, *Reasoning*, and *Dedication*, that is Work to be performed by all the *forces* assigned to us by our Maker and to relate to all the purposes of our existence as intimated by pure religion and an untarnished sense of personal dignity — lest this Science of Work deter us both by its novelty and by its expansiveness, we shall first give its brief outline or structure, and then, if it prove necessary, we shall expound and develop the subject more fully.

The Science of Work, or more accurately works, which we shall venture to call Ergonomics, after the manner of the other sciences, from the Greek *ergon* — work, and *nomos* — principle or law, is similar to the Ananconomics, or the Science of the

Needs which we presented a decade ago, because together they form one Science of Life, that is Bionomics, and are sustained in a quaternal composition because life is determined by the operation of the four already described vital forces to which all that is in nature corresponds, and by which we and our fellow creatures attain to all that is good for ourselves and for the common welfare.

PART II (NO. 30, PP. 236—8)

Work is the mother of all good.
***

(1) By the term Ergonomics, derived from Greek *ergon* (ἔργου) — *work*, and *nomos* (νόμοζ) — *principle* or *law*, we mean the Science of Work, that is the use of Man's forces and faculties with which he has been endowed by his Maker.

(2) The Science of Work, understood in the widest possible sense of the term "work", may be divided into two main disciplines, the science of useful work, which brings improvement or is commendable, by which we mean the good use of Man's forces and faculties with which he has been endowed by his Maker, or their use for the common good; and the science of harmful work, work that brings deterioration, and discreditable work, by which is meant the contrary use and intention to use the said forces and faculties.

(3) Useful work, which is the only kind of work we shall discuss here as the good from which all other goods come, and which rests chiefly in the improvement or perfecting of things, people, and ourselves, is divided, in accordance with the nature of the forces we devote to it and under whose guidance we carry it out, namely into:
Physical, Aesthetic, Rational, and Moral Work;
that is, Work which is
Kinetic, Emotional, Intellectual, and Spiritual,
or *Motory*, or *Sensory*, or *Rational*,
and which may otherwise be known as:
Labor, Entertainment, Thinking, and Devotion
or Toil, or Pastime, or Reasoning, or Dedication

(4) In each of these kinds of work, examples of which are as follow:

the breaking of stones	the playing with stones	the investigation of their natural properties	the removal of stones from the road[5]

there are four chief considerations:
(i) with what creatures do we share this work?
(ii) in which periods of our lives are we particularly suited for this work?
(iii) in what manner may we proceed in this work?
(iv) what are the benefits to be drawn from this work for ourselves and the common good?

Chapter 1: The shared or common nature of human work with the work of other living creatures

(5) The four kinds of work just mentioned above, that is *Labor, Entertainment, Reasoning,* and *Dedication,* are the categories of our own and the general employment; such that the first

category is performed chiefly by our *motory* forces, which we share with all the living creatures, that is plants and vegetables, primitive animals, animals, and humans; the second category is accomplished chiefly by the *sensory* forces, with which we and all the creatures capable of feeling have been endowed, that is humans and the animals and primitive animals; the third is done chiefly by the forces of *reason*, which has been given to all the thinking and reasoning creatures, that is to humans and to the animals; and the fourth is carried out chiefly by the *spiritual* force, which has been apportioned only to the creatures capable of self-dedication to the common good, and such are only human beings. Therefore, as has already been said, these four categories of work are divided as follows:

Labor	Entertainment	Thinking	Dedication

may be and are performed by:

Plants	Primitive Animals	Animals	Humans
	Primitive Animals	Animals	Humans
		Animals	Humans
			Humans

(6) The proof of this obvious truth is to be had in the following creatures:

esparto grass	wrynecks	wise serpents,	humans who devote themselves to work for the common good
earthworms	squirrels	birds, animals	
moles	persons given to entertainment	and similar humans	
common laborers			

The esparto grass which has been mentioned here, like many other plants which send down their roots very deep into the soil, is thus regarded to be performing physical work or Labor. Esparto grass pierces and shakes the soil with its roots just as the earthworm does, thereby facilitating the penetration into it of rainwater and all the substances washed out of the atmosphere, and contributing very significantly to the soil's fertility. Not only esparto grass and other herbal plants, but all vegetal creatures whatsoever perform this kind of work. The most conspicuous proof of this is offered by the trees, which, when they grow in the ground, push aside and move the soil so mightily with their roots, that even were it as dense as can be, even if it contained boulders, it could never withstand the force of pressure exerted by the roots of trees. And when they grow on rocks trees give rise to the breaking up and splitting asunder of those rocks. Even the herbal plants seem to make no meager contribution to this process, as evidenced by the name itself of a species of plant which involves many varieties, the Saxifrage species, the greatest number of specimens of which occurs in the rocky parts of high mountain areas, and which appears to be as good at breaking up the rock surface which is softened by moisture as esparto grass and other plants growing in the soil are at riddling the earth with their roots. And then upon the decay of those roots not only do they enrich the soil with their remains, but they also leave a network of orifices through which rainwater seeps in more easily. The rainwater in turn makes the soil moist and also more fertile

through the draining into it of all the atmospheric gases and emanations in the atmosphere from the burning, fermenting, decomposing, evaporating, and respiring creatures, living or dead.

As we have proved with unquestionable examples, and in accordance with our profoundest conviction, the *Plants*, along with all other living creatures, are engaged on motory work, otherwise called *Labor*. Likewise we could prove that the Lower or *Primitive Animals*, along with all creatures capable of feeling, busy themselves with the work called *Entertainment*; that the *Animals*, along with all the creatures capable of learning, are involved in the intellectual work called *Thinking*; while only *Man*, that is human beings, busies himself with spiritual work otherwise known as *Dedication*. However, since this matter calls for a rather extensive discourse supported by numerous examples to demonstrate its truth, it cannot be entailed in the outline of the Science of Work, but rather in its exposition, which does not concern us here, and the subject of which, relating to the nature of the work carried out by the four kinds of living creatures, may be found by the reader seeking enlightenment on the matter in our *General Natural History* in Jaworski's Yearbook for 1857.

Chapter 2:
On the aptitude of humans to undertake various kinds of work in particular periods of their lives

(7) Since the physical or motory force manifests itself in humans in the active condition in all periods of their lives, that is both in infancy, youth, maturity, and old age, the aesthetic or sensory force manifests itself only in the last three periods; the intellectual or mental force manifests itself chiefly in the last two periods, that is in maturity and old age; and the spiritual force manifests itself chiefly (at the present stage of Mankind's history) only in old age[6]), hence the four above-listed types of work, viz.

Labor	Entertainment	Thinking	Dedication

which are carried out chiefly by the corresponding force, or under its leadership are carried out, or at any rate are most frequently carried out by Man in his

infancy	*youth*	*maturity*	*old age*
	youth	*maturity*	*old age*
		maturity	old age
			old age

A proof for the four circumstances in which Man undertakes work is supplied by the following example:

The taking and eating of useful things[7]	passing one's time on things which are pleasant and beautiful	The examination of unknown and interesting things	The bringing of all things to serve the common good

Chapter 3:
On the methods in which the four kinds of work may be performed

(8) There are four chief methods whereby Humans may undertake, and indeed do undertake work, viz.,

The first method

When they carry out the kinds of work already defined as

Labor   Entertainment   Thinking   Dedication

solely by means of the corresponding main force, that is by the

Motory force   Sensory force   Intellectual force   Spiritual force

In such cases only a minimum effect, or even no effect at all is achieved, for at least the three latter forces, unless assisted by the motory or *executive* force, cannot bear any fruit, they cannot perform any useful deed for the common good[8]). The forces corresponding to these three kinds of work, namely the sensory, intellectual, and spiritual forces, have no power to effect; they are merely such powers the first of which *encourages* or *incites*, the second of which *manages* or *guides*, and the third of which *sanctifies* or *devotes*.

The second method

(9) The second method of undertaking the four different kinds of work is the one undertaken, as in the previous instance, through the corresponding or chief force assisted through the support of the lesser forces, viz. when the four kinds of work, that is

Labor   Entertainment   Thinking   Dedication

may be regarded as manifestations of the following human forces:

| *motory* | *motory* *sensory* | *motory* *sensory* intellectual | *motory* *sensory* intellectual *spiritual* |

or in other words of the following forces:

| *executive* | *executive* *inciting* | *executive* *inciting* guiding | *executive* *inciting* guiding *sanctifying* |

PART III (NO. 31, PP. 244–7)

This will ensue when the different kinds of work are combined; namely, the first kind with toil; the second with toil and pleasure; the third with toil, pleasure, and thought; and the fourth with toil, pleasure, thought, and the love of the common good, that is such good which only man can know and love, and which is unique in that it contains all other goods, chiefly the following four: the glory of the Supreme Perfection, the good of our neighbors, the good of our fellow creatures, and our own good.

In this manner the four mentioned kinds of work are undertaken. All of them are activated by the *executive* force; while the latter three are also supported by the other superior forces; and they shall be bound to render their fruit unto us, all the more bounteously the more forces there are contributing to its achievement.

The third method

(10) The third method of performing work is when we carry out the different kinds of work in the manner described above

but also avail ourselves of the assistance of the forces of other living creatures, that is:

Plants   Primitive Animals   Animals   Humans

endowed, as we know (5), with the following forces:

| *motory* | *motory* *sensory* | *motory* *sensory* intellectual | *motory* *sensory* intellectual *spiritual* |

and hence able to undertake, like ourselves, the kinds of work corresponding to these forces. Other creatures may thus be helpful to us, or at least they can encourage us in our work by their example and induce us to lead a more active life which will yield a richer harvest than when we are relying solely on our own forces in our work and when we receive no external encouragement.

The fourth method

(11) The fourth method of undertaking the four above-mentioned kinds of work ensues when we perform work in the manner described for the two previous instances, but in addition enlist the forces of inanimate Nature, for example the force of steam, wind, water, gravity, or cohesion; or crystalline, organic, electrical, magnetic force, etc. Even if we do not use these forces directly, we endeavor to copy the works produced by these forces, in the production of which the following forces of Nature are particularly manifest:

| *attractive* | *cohesive* | *crystalline* | *organic* |

or in other words,

| the drawing force | the joining force | the ordering force | the vitalizing force |

for it is precisely these four forces or powers of Nature which give rise to and sustain in the true sense of the word such things as, for example,

air	ice	snow crystals	insects trapped in amber
water	chalk	crystalline salt	mammoths
the soil	marble		ammonites
clay	flint		
sand	sandstone		

which things are commonly known as:

| the *Elements* | *Stones* | *Crystals* | *Fossils*, |

or the inanimate entities the forms of which are:

| variable | stable | Regular or ordered | derived from biological forms |

or, in yet another classification, they are:

| originals | rocks | orders | images |

which, even if they were all to consist exactly of the same type of material, e.g. silica, in

sand	sandstone	rock crystal	silica fossils
sandy soil	flint	amethyst	

although they are all composed of silica, yet each conveys an entirely different property. The cause of this is the fact that each of the four arise through the action upon matter of the four different forces just enumerated, not acting in isolation but in their consecutive order. Thus the Elements are the product of the *attractive force*; the second entity, named the Stones, is made as a result of the action of the *attractive and cohesive forces*; the third, the Crystals, come about as a result of the action of the *attractive, cohesive, and ordering forces*; and the fourth entity, the Fossils, is produced when matter is acted upon by all four forces, the *attractive, cohesive, ordering, and vitalizing force*.

(12) These four different things, created in the described manner by the four above-described forces, are characterized chiefly by the circumstance that their natural properties, otherwise known as their lesser or internal properties, consist of an increasing number of qualities proper to inanimate objects and things which have devolved to the inanimate condition, and which may be described as follows:

variable	*variable*	*variable*	*variable*
stable	*stable*	*stable*	
ordered	ordered		
vitalized			

(13) As regards their usefulness or purpose, or their external and superior properties, these four entities are distinct from each other most of all in that if we make active use of them, in order to improve or copy them, or to obtain other objects like unto them as regards the qualities of *variability*; *variability and stability*; *variability, stability and regularity*; and *variability, stability, regularity and vitalization*, as for example:

cultivated land	artificial rocks	ornaments and utensils	mummified and embalmed bodies
fertilizers	man-made caves	tools and instruments	pictures and statues
food and drink	ruins and debris	edifices	machines

We shall of necessity be applying our vital forces: our first force in the *first* case; our *first* and *second* forces in the second case; our *first*, *second*, and *third* forces in the third case; and *all four* of our vital forces in the last case, that is:

motory	*motory*	*motory*	*motory*
	sensory	*sensory*	*sensory*
		intellectual	intellectual
			spiritual

or, in other words, the following forces:

fixative	fixative	fixative	fixative
	pleasure-giving	*pleasure-giving*	*pleasure-giving*
		activating	activating
			virtue-endowing

(14) Thus these four things, or more precisely the four forces to which they owe their creation and properties, may serve us as means to develop our own forces, and hence for their engagement in the carrying out of the four above-described kinds of work (3), and for the yielding of more and more abundant and useful fruit for the common good, the further we will manage to develop that application, and the more we will manage to engage other forces appertaining both to living and inanimate Nature, in the process.

Chapter 4:

On the advantages accruing from the undertaking of the four described kinds of work

(15) There are four chief advantages or benefits which may and indeed do proceed for us from the undertaking of the four described kinds of work, in other words from the good use of our corresponding four vital forces, assisted by the forces of the external world, and these advantages are our Property, Ability, Perfection, and Felicity, which are the same as our *external good*, our *first inner good*, our *second inner good*, and *our third* and *supreme good*.

1. Property

(16) *Property*, otherwise known as the *external good* or *asset*, is acquired by each of the four described kinds of work, viz.

Labor	Entertainment	Thinking	Dedication;

but it is not achieved in equal proportions by each of them. For if we apply them in the second manner of work described above in (9) of the preceding chapter, that is not in isolation but in an increasing combination of the four kinds of our vital forces, then the outcome of such work, even though it be concentrated on one object, shall be all the greater, the greater the participation in it of the four vital forces, according to the relation which has already been shown on the particular examples and unquestioned facts cited in the essay *On Man's vital forces and their significance in his productive or creative livelihood*. These facts and particulars show, for instance, that land which is cultivated by the application of the first of the vital forces, that is *Labor, the work which uses only one vital force*, usually produces (in outcome of its natural fertility being thereby enhanced) two seeds of crop for every seed sown; whereas land cultivated also with the application of Entertainment, Reasoning, and Dedication, in other words work engaging two, three, and four vital forces, for every seed sown yields harvests in a ratio of 4, 8, and 16. This shows that each successive vital force applied to the working of the land to enhance its fertility doubles the preceding outcome. Other forces may be utilized in this manner on all the other things of this world, both animate and inanimate, that is on the one hand, on the

originals	rocks	orders	images,

and on the other hand on the

Plants	Primitive Animals	Animals	Humans

outside of which there are no other categories of things in this

earthly world, and which therefore constitute the full scope of our Property. Therefore we have grounds to believe that each of these eight earthly things and creatures may have its value augmented in the following ratio:

$$2 : \quad 4 : \quad 8 : \quad 16;$$

or in some other similar ratio when we act on it by means of work engaging

| one force | two forces | three forces | four forces |

that is,

| Labor | Entertainment | Thinking | Dedication, |

that is, endeavoring to enhance the value of each of the eight earthly things through the following of our forces:

motory	motory	motory	motory
	sensory	sensory	sensory
		intellectual	intellectual
			spiritual

or, in other words, through the following forces:

performing	performing	performing	performing
	activating	activating	activating
		directing	directing
			virtue-endowing

or, to use foreign loan-words, the forces that are

physical	physical	physical	physical
	aesthetic	aesthetic	aesthetic
		intellectual	intellectual
			moral

2.   Ability

(17) The second chief advantage which we draw from work is that through it we acquire the skill to perform work itself more and more easily and with an ever-growing satisfaction, accuracy, and liking for it. In other words, that we can and are able to undertake work at the expense of a lesser and lesser amount of toil and drudgery, but to the ever-increasing gain of ourselves and the common good. Such an aptitude for the undertaking of work with an ever-increasing facility, satisfaction, accuracy and liking, and with the ever greater saving on effort, time, and material, is called *Ability*, and is our *first inner good* (15), which is acquired, just like *Property* or the *external good*, by each of the four described kinds of work, that is by work which engages

| one force | two forces | three forces | four forces |

that is,

| Labor | Entertainment | Thinking | Dedication. |

But *Ability* will not always be of the same import to us. For if it is the result of the first of our kinds of work, it will be called a *Craft*. If we apply the second, third, and fourth kinds of work respectively, the applicable names for the corresponding abilities will be decorative *Art*, precise *Skill*, and exemplary *Conduct*.

(18) The above shows that just as we have four different kinds of work, so too there are four different aptitudes or abilities for their performance, that is the above-mentioned

useful	decorative	precise	exemplary
Craft	Art	Skill	Conduct

These abilities will be all the more important to us the more we endeavor to devote of our forces for their acquisition, or at least the more we strive to make them the outcome of our undertaking of the four kinds of work; not by the *first manner* for the performance of work (8), which in Chapter 3 we found was the least effective of all, or even totally fruitless; but by the *second*, *third*, and *fourth means* (9, 10, and 11), requiring the application not only of the *physical*, *aesthetic*, *intellectual*, and *moral* forces, but also of other, inner or external forces; or by the combination of the latter with the former if they may profitably be used in combination. This applies particularly to the latter, that is the inner forces, which only then attain their true qualities in the sense of the work referred to as

| Labor | Entertainment | Thinking | Dedication, |

and may serve as means for the acquisition of our first internal good, known as *Ability*, and in particular

useful	decorative	precise	exemplary
Craft	Art	Skill	Conduct

when they are combined in the way described above in Chapter 3, with the use of the second manner of undertaking the four kinds of work just mentioned. For it is only when these forces are combined in this manner that we may perform any of our life's jobs, tasks, professions or offices with the application of

toil	toil	toil	toil
	satisfaction	satisfaction	satisfaction
		cogitation	cogitation
			love

In other words, we shall then be applying a greater and greater number of the forces given us by our Maker, by which these forces will be developing more and more within us, which in turn will become the source of an ever-increasing store of *Ability*. The result of this for us will be not only that the profession or occupation to which we devote our entire lives will be not merely mechanical or in other words motory and pertaining to the *crafts*; but it will also be motory and sensory, in other words *artistic*; or it will be motory, sensory, and intellectual, in other works *skilled*; or finally motory, sensory, intellectual and spiritual, for which no other appropriate name exists at present in this or any other language we know. For this profession, which will only emerge from the state of slumber in which now it persists, at some future time, when the spiritual or moral force attains its rightful place, which is now usurped by the intellectual force of reasoning; and

when the moral force becomes as active as the motory, sensory, and reasoning forces, in other words as the mechanical, aesthetic, and intellectual forces. It is by these three last-mentioned forces that in this the third era of man's history[9] that the useful *Crafts*, the decorative *Arts*, and the precise *Skills* flourish and thrive. But when the fourth era comes[10] it will no doubt come to the blossoming of the exemplary *Sciences*, *Conduct*, and *Deeds*. This may first be expected to come about within our virtuous agrarian Slavonic people and its noble and most innocent occupation of agriculture; an occupation which, since it may be conducted not only industriously as a useful *Craft*, not only industriously and with taste as a decorative *Art*, and not only industriously, tastefully, and skillfully as a precise *Skill*, but also honestly as an exemplary *Science* — will in time acquire that ultimate, and most noble quality, thereby providing an example for other occupations to follow. To this Mankind will be drawn not only by the awakening in those people who practice these abilities of a sense of Man's dignity in his position as the most perfect creature and therefore also the creature expected of the best conduct; but Mankind also will become aware of that important circumstance, especially as regards its material condition, that the outcome of human work in any profession or occupation whatsoever is all the grander the more people come to activate their forces for the acquisition thereof, that is the more they perfect their active, productive, and perfecting forces, the aims and purposes of which are to better things, people, and their own persons and hence also their own and other people's aptitude to serve the common good. Thus they will strive to raise themselves from the state of vegetal or mechanical activity to the state of mechanical, sensory, intellectual, and moral activity, which is the truly human business and the emblem of a truly Christian life founded upon the principle of serving with all of one's forces for the common good, which is the work of God, Guardian of this good, Who has made Man in His own image and likeness, wishing to have him as His helper to care for and attend to this business.

3.   Perfection

(19) The third chief advantage, known as *Perfection* (15), ensuing from the undertaking of work, or in other words from the good exercise of our vital forces, somewhat resembles the second advantage, *Ability*, but differs from it in that while Ability is often regarded as an external as it were property of ours (as the names of its four main kinds[11] indicate), thus separate from us and often finding external expression, either through writing or other means; *Perfection* on the other hand, the advantage now under discussion, is always seen as one of our inner properties, a thing strictly connected with us and a direct consequence of *Ability* in the entire range of its senses as evidenced by the Crafts, Arts, Skills, and Sciences, and an indirect outcome of *Work* or the good exercise of our four vital *forces*, known as the physical, aesthetic, intellectual, and moral forces.

(20) Thus Perfection, which is now under discussion, is the fruit of our *work*, in other words the outcome of the above-mentioned *forces* which always constitutes an integral part of our being, considered in that state which it may and should attain as our forces grow, and therefore known as the potential for growth and development. This potential for development, we observe, is the condition for *Perfection*, which is the chief ornament of our being and the principal condition for our *Felicity*, which we shall discuss in due course.

(21) *Perfection* is acquired like *Ability*, through the exercise of each of the four different kinds of *Work*, viz. by work that is

motory	sensory	intellectual	spiritual

or in other words through:

Labor	Entertainment	Thinking	Dedication (3)

But it will not be of equal import to us, for if it is the fruit of the first kind of work, or the effect of the exercise of the first kind of our *Ability*, that is a Craft, it will be known as health, wholesomeness, perseverance in toil, fitness, firmness, soundness, and most aptly Efficiency. But if we may regard it as the outcome of our second, third, or fourth kind of work, or as the effect of our application to the second, third, or fourth kind of *Ability*, that is to the Arts, Skills, or Sciences, that Perfection will be known in the first case as taste, decorum, courtesy, politeness or Affability; in the second case as wisdom, prudence, proficiency, faculty, or Capability; and in the fourth case [*sic*] goodness, mercy, humanity, equity, honesty, or Virtue.

(22) Hence it may be observed that just as there are four chief kinds of our *Work* and four corresponding *Abilities*, so there are derived from them four kinds of our *Perfecting*, the above-cited

Health	*Taste*	*Wisdom*	*Goodness*

or,

Efficiency	Affability	Capability	Virtue or Worthiness

Apart from their absolute value, by which our being is endowed with a similar value, these Perfections also have a relative value, which concerns the objectives of our active, improving and productive life, the chief purpose of which is to *bring people and things away from the harmful or neutral state, and from the state of little utility, to the state of their being most useful and best suited for the common good, which contains our own good too as a constituent part of its entirety*.

(23) The latter of these values, that is the relative value of the four *perfections*, may be learned from the very names used for them. The first of the *Perfections* is called Efficiency, since it makes us fit to carry out or effect the most difficult tasks without strain, fit to accomplish without fatigue even the most arduous tasks or useful work the aim of which is to make people and things useful, or to make people and things serve the common good. The second perfection is called Affability because if we are endowed of it, it will assure us of acceptance and favor by other people and beings capable of feelings, thereby making them assist us in the performance of the above-mentioned useful work more readily than if they were indifferent to us or did not like us. The third of our four perfections, Capability, is so named because it helps to make us more capable to render service to other people for the common good than merely as simple performers of useful work; so that apart from being endowed of the first and second perfection, that is of Efficiency and Affability, we should also be the capable managers of our own and all other

forces by which that work is carried out. Finally the fourth kind of our universal perfections is called Virtue or Worthiness, goodness or humanity, because if we are endowed of it, it makes us behave in such a manner in the referring of our own and general affairs to the common good that we come to be invested with the supreme virtue or worth, at least in the eyes of other people who also act in this way. Virtue or Worthiness is the only good which deserves the name of ''good'' of all people, since to this alone all peoples have given the appellation of ''goodness''. And since it is also called humanity, which term may not be applied to the other three perfections, Efficiency, Affability, and Capability, as these we share with other living creatures, therefore Virtue or Worthiness is a distinctly human quality, one which marks humanity more distinctly among the other creatures than reason or speech, which hitherto have been recognized as the chief factors distinguishing Man from the animals. But the first three Perfections alone, that is Efficiency, Affability, and Capability, can never give Man the right to call himself a humane, good, or virtuous creature, be these three perfections ever so patently manifested in him.

4.   Felicity

(24) *Felicity*, which is the fourth chief advantage, the fourth chief good which ensues from *work*, and by which we mean the ultimate and supreme contentment we receive from what is external and what is in us as the fruit of our industry that is of our good and active will to use the forces and faculties given us by our Maker; that *Felicity*, like the three preceding goods, that is *Property*, *Ability*, and *Perfection*, may be acquired by each of the four above-described kinds of *work*, that is by work which is

> *motory   sensory   intellectual   spiritual*

or in other words through:

> Labor   Entertainment   Thinking   Dedication

but that *Felicity* will not be of equal value, that is it will not mark the same state of our contentment and beatitude, but will depend on the nature of the kinds of *work* or of the corresponding *forces* which we apply to achieve that Felicity.

(25) If *Felicity* is the fruit of the first kind of work, that is *motory* work or Labor; or in other words, if that Felicity is the direct outcome of the *Perfection* acquired by that work which is called health, wholesomeness, fitness, firmness, soundness, or Efficiency, then that felicity will be of that same import to us as it is to every healthy creature which enjoys its health and the attributes governed by health achieved through the undertaking of motory work. Since this kind of work may be undertaken even by the plants, and also by humans who abide in a somnolent state, merely moving about but neither feeling, thinking, nor loving aught, when they merely apply their physical force only without the three superior forces; since therefore, as I say, such work may be undertaken by the plants and humans abiding in a vegetative condition (the proof of which, in the former case, is the already-mentioned perforation of the soil effected by the roots of plants, or the

motion of the blossoming sunflower as all day its head follows the sun, or the rising up off the ground of any young shoots that might perchance have been pushed down or dropped); hence the *Felicity* which is the resultant of this kind of work and which is called Merriment, is such a form of general felicity in mankind and other beings that it may be manifested by creatures not employing the sensory, intellectual, and spiritual forces, that is the aesthetic, rational, and moral forces, but merely exercising their motory or mechanical force.

(26) Since even the plants are also endowed of this force (the proof of which is supplied, apart from the three above-quoted instances, by 1. the movement of their roots during sprouting downwards into and towards the fertile soil, and of their stems upwards and towards the sunlight; 2. the movement of their young stems, shoots and leaves upwards towards the sunlight and away from the darkness; 3. the opening up of their blossoms in the daytime and during fine weather, and their closing up for the night and during inclement weather; 4. and finally their surfacing in the summer (for the water-growing species) and submerging for the winter after the flowering season is over etc.); since, as I say, even the vegetable creatures are endowed of this force, therefore even they can manifest the felicity which comes of the happy condition of this force, and after the manner of a healthy, sleeping infant, they too may be said to be merry.

(27) This, too, is commonly observed in them when they are in their healthy condition; and furthermore it is attested by the nature of our speech, which allows us to call trees and other plants which enjoy the described *Perfection* or Health merry creatures, thereby granting us the right to acknowledge their potential for the exercise of the first kind of general *Felicity*, which we have called Merriment and which is regarded both in these and in all other creatures and in Man himself as the indirect outcome of the undertaking of the *work* known as Labor, exercised by the *Ability* known as Craft, and therefore the direct consequence of the *Perfection* thereby accruing and named Health or Efficiency.

(28) If our lowest *Felicity*, which has just been described, accordingly may be said to be a felicity bereft of feeling and thus a vegetal kind of felicity, as the ultimate outcome of the application of our lowest force known as the motory force or Power which we share with the plants, and the direct outcome of the physical work known as *Labor*, or of the livelihood pursued through Labor, that is Craft, and of the resulting *Perfection*, which we have called health, wholesomeness, fitness, firmness, soundness, or most aptly *Efficiency*; then presumably it must be no otherwise with our second *Felicity*, the sensory Felicity which we share with the primitive animals, and which by analogy with the name for the first felicity, we may call sensual felicity or Delight.

(29) Indeed, this second felicity may not be assigned any another source but our second vital force, the sensory force or Sensibility, which we share with all the animals capable of feeling, and hence even with the least of them, that is with the Primitive Animals. Since the sensory force is the essence of the *Work* known as Entertainment, which is also performed by the Primitive Animals, as evidenced by the animated movements these creatures carry out reminiscent of our dances, such as the somersaults in the air done by insects

like Hilara and Chironomus, or the leaps over water by the insect Gyrinus; or by the pleasant sounds similar to our music uttered of a summer's evening by the crickets, Cicada orni and Acridium viridissimum; therefore Entertainment should be regarded as the source of the *felicity* described, and known as Delight. And since of this all are thoroughly convinced, it wants no further proof. Furthermore, since Delight is closely connected with the fair Arts, as confirmed by the just quoted dancing and music, which at the appropriate level of perfection are accounted even as belonging to the sublime arts; therefore the similar yet even more perfected or profuse Arts show they are derived from Entertainment as the source of their *Felicity*.

(30) *And since* in addition from Entertainment and the Arts a third good issues, namely the sensory Perfection, or taste, decorum, courtesy, politeness or Affability, which wins for us the acceptance and favor of other people and other creatures capable of feeling, therefore also this third good may and should be acknowledged as the source of the *Felicity* under discussion, that is Delight. Of this all are thoroughly convinced, for whosoever possesses this Perfection, or has ever in any way contributed to the pleasure of other people or creatures endowed with feeling knows how much innocent pleasure or Delight he himself has thereby received. According to what has been said of it here, Delight is a likewise a fruit or outcome of the good exercise of our second vital force which we share with all creatures endowed of feeling; just as Merriment is the fruit or outcome of the exercise of our first vital force, which we share in common with all living creatures. If this is how things stand with the first two kinds of our general *Felicity*, that is Merriment and Delight, then it can be no otherwise with the two superior Felicities, that is intellectual felicity and spiritual felicity, or respectively Consolation and Joy, which we shall now briefly discuss.

(31) The first of these latter felicities, and successively the third felicity, is called intellectual felicity because by analogy with our first and second felicities, Merriment and Delight, which correspond to their respective vital forces and which we share with all living and feeling creatures respectively (that is the plants and the primitive animals) — it is an outcome of our third vital force, the intellectual or rational force, which we share with all the creatures capable of thinking, that is with the Animals. And since this third vital force, otherwise known as capacity or docility, is the essence of the corresponding *work*, that is Thinking, which is practiced by the Animals as well, especially when they lay snares for animals that are more powerful than they; therefore this kind of *work* too may be the source of a *Felicity*, the one now being discussed and called Consolation. For we are made happy or pleased by our rational force when, having developed that force appropriately for the undertaking of the given work, we make plans to benefit or hurt other creatures, and discover the appropriate means to carry out those designs.

(32) This also applies to the Animals, since (as may be observed in trained dogs) they too experience the highest *Felicity*, superior to the ordinary felicity of the senses, that is superior to Delight, when they can do something witty for themselves or for us. And the fact that, along with human beings, animals too achieve such things, is the result of their *ability* or Skill.

This Ability is demonstrated, for instance, by skilled hunters and the dogs and hawks trained by them for the hunt. Therefore this kind of *Ability* may be and indeed is for us humans and for the animals as well a source of the *Felicity* known as Consolation.

(33) As the described *Ability* or Skill denotes the same as the *felicity* of the intellect, generally known as proficiency, wisdom, learning, or most aptly Capability, which makes ourselves and the Animals capable of carrying out more than just the simple, repetitive and mechanical tasks (viz. such that may be carried out by a machine), therefore this *Perfection*, attained by the exercise of the kind of *Ability* corresponding to what we call the exact Skills, should be regarded as the means — more direct than the *Work* known as Thinking which marks this category of *Ability* — to achieve that general Felicity of the intellect known as Consolation.

(34) This Consolation, we observe, is a far higher kind of our general beatitude than Delight, the felicity of the senses; or than Merriment, the felicity of movement, which we may exhibit even when asleep, through a pleasant disposition of the features of our countenance, and which may be considered desirable merely because it is a sign of health and because through it we may stimulate the higher felicities in other people, such as the felicity of the senses, which may be evoked even by the merry plants that enjoy this Merriment thanks to their health, although they presumably do not feel this, yet manifest it to other creatures that are capable of feeling.

(35) Thus if our first three vital *forces*, that is Physical Motion, Sensibility, and Intellectuality, which are the essences of the first three categories of *work*, that is Labor, Entertainment, and Thinking, and also of the first three kinds of *Ability*, that is the useful Crafts, the decorative Arts, and the exact Skills, are the sources of our first three *Perfections*, known as Efficiency, Affability, and Capability, and hence also of the directly resulting first three *Felicities*, that is carefree Merriment, innocent Delight, and lofty Consolation; and if, now, the fourth of these forces which vitalize us, Spirituality or the moral force, is the agent within us of the *work* known as Dedication, thereby evoking that general *Ability* of ours known as the exemplary Sciences, and the fourth kind of our *perfection*, which we have denoted by the terms goodness, humanity, or Virtue; it may not be doubted that this force is correspondingly the fount of a separate Felicity.
(to be continued)

PART IV (NO. 32, PP. 253–5.)

(36) In our own tongue, Polish, apart from the terms Merriment, Delight, and Consolation, we have another homonymous word, that is Joy [Radoos´c´ — Lat. gaudium, translator's note], which nevertheless denotes something superior and occurs especially in our ancient books, such as the translations of the Bible. This is the word most frequently used to mean the moral or spiritual felicity[12] — that felicity which is accessible only to the moral creatures, those able best of all to develop their moral force. Only humans, or the humane, most truly human and humanitarian among the humans, may and indeed do experience this, through the accomplishing of the most perfect and sweetest deeds pertaining to the supreme Perfection.

(37) If now we consider those deeds by which we perfect ourselves, other people and creatures, and the things pertaining to this world which are in an inferior condition due to human error or negligence or through misadventure, as the highest and sweetest deeds of the supreme Perfection — then that *perfecting of people and things*, that is bringing them from a harmful or indifferent condition, or from a condition of little utility, to the state in which they are most useful and best suited to serve the common good; if, thus, we bring them to that condition in which they carry the traits of the supreme Felicity and its most perfect creature, which we consider (and should out of our religious duty consider) to be ourselves — *we will regard this as the loftiest kind of all our deeds*, the supreme mark of our moral *perfection*, known as humanity, goodness or Virtue, which is the condition for the corresponding *Felicity*, which as has already been said, is called Joy.

(38) That Joy — Man's true *Felicity*, which indeed no other being can experience save Man leading a human, humane and humanitarian life, at least at the present stage of Man's development — that Joy is the fruit of its corresponding *Perfection*, the reward of perfect deeds, that is such that are intended to bring man and things to perfection, of this none can be convinced by reasoning, that is through the agency of the third vital force, the force of the intellect or of reason, since the latter force is restricted in its powers of judgement only to matters concerning itself or lesser matters. As regards deeds effected by the force superior to reasoning and by its attendant consequences, such matters may be judged only by that self-same higher force. Hence true judgements in such matters may not be expected of Man the Reasoner but of the Dedicated or Devoted Man, that is of him who accomplishes the said perfect deeds, that is such deeds which are intended to bring men and things to perfection.

(39) If Man the Thinker, that is those who manifest the working of the third of the vital forces as the supreme emblem of their lives, were to claim the right to judge those who work by Dedication or Devotion, they would thereby invest all those inferior to themselves, that is those whose highest activity is feeling, in other words those who are manifest only through the second vital power, the right in turn to judge the thinkers. But the thinkers would not allow this, and indeed could never allow it, as superior things cannot be known by things that are inferior. Likewise, without insult to common sense, by which no doubt they are ruled, the thinkers should not pretend to make themselves, and the generality of Mankind abiding in the third vital force, true and equitable judges of those dwelling within the realm of the fourth vital power and displaying all the vital forces with which Man has been endowed by his Maker.

(40) Now if Man the Thinker, that is those who live by the exercise of the third vital force, were to endeavor truly and equitably to judge the deeds of those who work by Dedication, that is of those whose aim is the perfection of things, other people, and themselves, thereby making them more apt to serve the common good; if, as I say, the former wished to judge the latter, and to enjoy the Felicity enjoyed by the latter, that is Joy; they would only be able to do this if they themselves endeavored to discover and practice this work, or at least instead of leading their hitherto *partial* life, consisting chiefly of thinking, in other words of carrying out intellectual work, if they endeavored to emulate at least for a brief time the *full* life of Man, consisting in movement, feeling, thinking, and dedication, that is in the performance of all four kinds of work which humans may pursue, motory work, sensory work, intellectual work, and spiritual work, in other words Labor, Entertainment, Thinking, and Dedication. They would be qualified to judge in this respect if they themselves enjoyed all the fruits which may be attained through all four kinds of work, that is through the good exercise of all four corresponding forces, assisted by the external forces of nature, and making all four forces their undisputed assets.

(41) Of the fruits obtained from Work and otherwise known as the benefits or goods (15), the first is called Property or the external good (16), which accrues (as we Poles have observed) in geometrical proportion, that is in relation to the square of the value for the previous vital force, viz. a 2 : 4 : 8 : 16 ratio. This good is the least bound to our nature, since it may be easily lost and easily regained. Nevertheless this benefit called Property is an indispensable condition not only for our human happiness, but even of human existence. For no person is able to enjoy a happy life, nor even to live without the external fruits of his own or others' work.

(42) As regards the second fruit of our four kinds of Work, which in (11) [! — cf. 18] we gave the general name of Ability, and the particular appellations of the useful *Crafts*, the decorative *Arts*, the precise *Skills*, and exemplary *Sciences*; as regards this second fruit, which we have called the first inner good, we know it is much more closely connected with our nature that the former good. For those people who have no permanent property at all must have at least a relative mastery of one of the above-described abilities, that is of the useful Crafts, the decorative Arts, the precise Skills, or of the exemplary Sciences. And whatever profession they have chosen, if they practice it diligently, or both diligently and with taste; or diligently, with taste, and rationally; or diligently, with taste, rationally and honestly — they shall in time acquire such proficiency in their profession that they will soon develop such a liking for their occupation as to consider themselves proponents of one of the four categories of general human Ability. We have already explained this for the case of agriculture, which, depending on the four different means of application of our four vital forces, may assume the status of a useful Craft as practiced by all peoples whatsoever, a decorative Art as delineated by Delille in his French Georgics, a precise Skill in the understanding of Thaer and his disciples, or finally as an exemplary Science as presented by Krasicki and Koźmian in their works, Pan Podstoli [The Steward] and Ziemiaństwo Polskie [The Polish Landed Gentlemen] respectively.

(43) As regards the third chief benefit which is the outcome of work, that is Perfection (19), which just like work is of a fourfold nature and consists of *Health*, *Taste*, *Wisdom*, and *Goodness*; or *Efficiency*, *Affability*, *Capability*, and *Virtue* (22); as regards this, the second inner benefit, we have no hesitation whatsoever that it is essentially and integrally connected with us, for not only can it not be removed from us once we have acquired it, but without it we cannot exist at all, or at least

without it we cannot make any significant contribution to human society nor enjoy a position of respect within it.

(44) Since this significant contribution to human society and the related social position are clearly the results of the above-described fourfold Perfection known as *Efficiency*, *Affability*, *Capability*, and *Virtue*, without which we cannot effect any good for the well-being of all or win respect, especially of those people who are also in the service of that universal well-being and who therefore have the right to expect us to help them and work with them to achieve that aim; therefore it is clear that albeit this Perfection, which we have called the second inner good (15), may seem to be our very own and exclusive good, not shared with any other persons, yet in fact it also belongs to other people, and even partially to our fellow-creatures, too. For they all have a certain right to demand this Perfection of us, in return for their own Perfection and the favors granted us thereby.

(45) The fourth benefit which we draw indirectly from the forces given us by our Maker and from the work they accomplish, and hence directly from the Property, Abilities, and Perfections (15) thereby acquired; particularly this fourth and last benefit, known as Felicity (24), the third inner good, is the most closely related with our nature, apparently pertaining to ourselves alone. For only we ourselves, who have acquired this benefit thanks to our work and perfection, appear to be enjoying our own Felicity, while other creatures seem incapable of sharing in our Felicity.

But this is true only of creatures which have no morality, in other words those which have not been endowed with the fourth vital force, or in which this force lies dormant. For as regards all those who partake of this fourth force, manifesting it actively (and this includes above all the humane and humanitarian, truly human people, that is such as, in outcome of an accomplished state of perfection or good education, have activated all their vital forces, including the moral, truly human force, which according to the religious and general conviction they share only with the Heavenly Beings); as regards such moral creatures, who are the most perfect and closest to the Supreme Perfection Itself by virtue of their own perfection, they therefore desire our attaining unto felicity, since without it they can never fully achieve their own perfect felicity, and thus they clearly share in our own state of felicity.

(46) This state of affairs should provide us with the best possible incentive encouraging us, first out of regard for ourselves, secondly out of regard for those creatures, and thirdly out of regard for the Supreme Perfection or Divine Goodness Itself, which desires our Felicity and the Felicity of all of Its creatures according to their faculties for the enjoyment of felicity — to strive to attain to our own felicity, the complete felicity for the achievement of which we have been endowed by our Maker of our four vital forces, and which we may accomplish through the performance of the respective kinds of work and hence also through the exercise of the thus accruing Perfections.

(47) Since we possess four each of the Forces, kinds of Work, and Perfections, which are the means to our achievement of felicity (and would have less if we were not humans, but animals, primitive animals, or plants; or if by keeping dormant our forces proper to the superior creatures we dwelled in the condition of the lesser creatures); hence also our felicity must be fourfold in nature, that is

| *physical felicity* | *aesthetic felicity* | *intellectual felicity* | *moral felicity* |

or in other words,

| *motory felicity* | *sensory felicity* | *rational felicity* | *spiritual felicity* |

The Felicity which we enjoy in common with the four categories of our most perfect fellow-creatures, that is the

| *Plants* | *Primitive Animals* | *Animals* | *Humans* |

may be named, in order of increasing power to bring an increasing degree of happiness, to the point of ultimate beatitude, for ourselves and other living creatures:

| carefree *Merriment* | innocent *Delight* | lofty *Consolation* | heavenly *Joy* |

Above this Felicity none other can be experienced or desired, save perhaps only the assurance that , along with all our neighbors we shall be able to enjoy for all eternity the ultimate of the four felicities, which may be secured by our and their continual dedication to the common and eternal good. For only through dedication, not by fruitless thinking nor ratiocination and investigation, can we and they be convinced that we hold sufficient power to achieve this, and therefore that we are eternal creatures, and that we are capable of enjoying the Eternal Felicity, which we have just defined as Heavenly Joy.

Notes

1 The friends of work will not hold it against the author, he trusts, that he is here repeating some of his main tenets already published elsewhere.

2 As evidenced by the histories of Herostratus and Cleopatra.

3 See our treatise on the *vital forces* and their importance in Man's productive life.

4 To this property of advancement in the human vital forces through their working on the forces of other creatures and things, which resembles the properties of the magnet, we particularly draw the attention not only of the philosophers and the economists, but also of the natural scientists.

5 So that they should not give rise to untidiness or of suffering for people or other creatures of God.

6 A proof of this is supplied in this age by the disposition developed chiefly in aged persons, to undertake even small tasks of dedication for the common good, such as the removal of stones from the road into a stream, that is the elimination of harmful conditions in favor of generally useful conditions.

7 The taking and eating of useful things, and the similar performance of all mechanical activities by means of the motory force alone is manifested not only by all *humans*, but also all the living creatures not excepting the *plants*, as evidenced for example by the flycatcher (Dionaea muscipula) and all the varieties of the sundew (Drosera).

8 Without the exertion of the motory force it is impossible even to speak or write.

9 That is, the Industrial Age, which has followed on the Barbarian Age, which in turn came after the Savage Age.

10 Which shall be the Age of Accomplished Christianity or the Age of Universal Love.

11 That is the Crafts, Arts, Skills, and Sciences.

12 "The angels shall rejoice at the conversion of one sinner".

Person-centered Ergonomics

D.J. Oborne

Department of Psychology, University of Wales Swansea, Singleton Park, Swansea SA2 8PP, UK

1. INTRODUCTION

To emphasize the centrality of the person within the ambit of ergonomics would suggest a tautology. Ergonomics is, and has been since its inception, centered about the person within the system. Stress has always been placed on the need for the environment to be designed to fit the person rather than adopting the Procrustean view of making people fit the environment.

Even a cursory overview of current ergonomic practices, however, demonstrates that much of it is not person-centered in its approach. A systems view, for example, emphasizes the importance of "fitting" environmental outputs to the operator's input capacities, and vice versa. In doing so, it places equal emphasis on the "needs" of people and their environment; people are not central to the approach. Similarly, a cybernetic view perceives people merely as error-inducing and error-correcting mechanisms; not as being central to the effectiveness of the operation as a whole.

Like many of the previous views of ergonomics, the person-centred view argues that the individual and the working system must operate in close harmony for effective operation of the system. It diverges from previous views, however, by arguing that it is the operator who controls the system, who operates it, steers its course and monitors its outcomes. It is individual characteristics such as these that need to be considered in more detail and which determine the system's eventual potential.

Branton (1983) emphasized that human operators within a system inevitably turn it from being a closed loop system in which information flows from one component to the other with (theoretically) maximum efficiency for correcting deviations, to an open-loop system. Instead of a "designed" error correcting system; therefore, the deviation corrections are effected by the operator on the basis of his/her "mental model" of the system and its operation. In this way, rather than emphasizing a mechanistic approach to improving information flow between components within the system, person-centered ergonomics takes as its central point the need to accommodate the human attributes that the person brings to the system.

Thus, the person-centered perception is one in which the operator and his/her abilities define and control the working system. In the course of these interactions, individuals bring to the system a collection of inherent strengths and weaknesses (from such characteristics as experiences, expectations, motivations, etc.) which themselves will work with the system to change it. Such changes are usually to the good, from the viewpoint of such criteria as efficiency and safety. Sometimes, though, the features that the individual brings to the system will include variability, fallibility and maybe even perversity — any of which are more likely to lead to errors and inefficiency. As Wisner (1989) argues, operators will use their "own story" when being asked to control and manipulate events.

2. PERSON-CENTERED COMPONENTS

Arguing that ergonomics needs to take a more central view of the wishes, abilities and needs of the operator begs a major question regarding the nature of the individual's characteristics that need to be considered and which are so important. person-centered ergonomics stresses individual characteristics that help to direct the person's behavior within the system and develop his/her shared identity with the system. Thus, characteristics such as having a sense of purpose, motivation, and awareness are considered, as, too, are more nebulous concepts such as the individual's sense of self and consciousness of his/her actions.

3. PURPOSIVITY

Purpose provides meaning to an action; without a sense of purpose the action will have no meaning as far as the system is concerned. Actions without purpose and meaning become random and lack direction.

The person-centered approach argues that one of the primary features brought to the system by the individual is a sense of purpose, of meaning and action. People are not just "doers"; they are also thinkers. They generate mental models about the world and impose into these structures the potential consequences of their actions. By understanding the individual's reasons for interacting with the system ergonomists will be better placed to design systems that facilitate the actions and are fit for the purpose.

4. ANTICIPATION AND PREDICTION

The existence of purposivity implies some concept of prediction and anticipation. By implication, therefore, the concept of purposivity also suggests that the user will have some notion of the desired outcome and thus some "internal" model of the course of future events. This is an important linkage as far as person-centered ergonomics is concerned. Prediction, and the anticipation that arises from it, concerns the operation of the system within the individual's perceived control and will have major implications for the nature and the quality of the information required for the task. Thus, such features are not merely precursors to efficient operation, they also *determine* the efficiency of the operation.

5. INTEREST, BOREDOM AND ADAPTATION

Allied to a consideration of the purposeful nature of the operator are questions about how far the operator has an interest in the operation under control. Clearly, interest is related to purpose insofar as reduced purposivity can lead to reduced interest; reduced interest can lead to reduced awareness of the environment.

Further analysis of the construct, however, leads to a consideration that it is not so much interest *per se* but the reason for the interest in the job being undertaken that are important. In this respect, interest can be expressed in terms of stimulus-seeking behavior; the nervous system adapts and habituates quite rapidly to any prolonged and unvaried stimulation, leading to cortical inhibition of stimuli and extinction of responses. So boredom, a result of reduced interest, can soon lead to a reduced ability to perceive and respond to important stimuli. Adaptation to the stimuli can have similar effects.

In addition to adaptation, a second effect of reduced interest and stimulation from the external environment is often expressed in terms of a lack of attention to the task and to mind wandering and daydreaming. Such behaviors could be taken to be a means by which people attempt to inject some (internal) stimulation of their own.

6. UNCERTAINTY REDUCTION

A further aspect of the person-centered equation that must be considered, and one that may even be thought of as having an overarching effect, is the reduction of uncertainty. From a psychological viewpoint uncertainty reduction plays a major role in everyday life; we attempt to reduce it if for no other reason than to reduce the stressful effects of unpredictability. Of course, like stimulation and arousal, individual attempts to reduce uncertainty are likely to be tempered by some concept of an optimum level. Indeed, in many respects life would be very boring if all events were perfectly predictable.

The concept of uncertainty is thus important when considering the nature of stressful events at work. Stress is likely to result in a person who is uncertain about what has happened, particularly during a period of "mind wandering." This is particularly the case if one also has a position of responsibility when carrying out the task (a concept considered below).

7. CONTROL AND AUTONOMY

Since increased control over a situation improves the likelihood that the events will occur in the desired and expected manner, it is clear that uncertainty reduction is also related to control. The evidence for "mini-panics" resulting from "mind wanderings" demonstrates that uncertainty occurs when control is relaxed. Or, put in another way: "Only what I do is certain for me."

Discussing the design of computer screens, for example, Branton and Shipley (1986) highlighted the importance of control as an important factor in stress causation and management. They proposed that such display technology has propagated a new "breed" of individuals — "Houston Man" — in which mismatches may occur between the interpretation of events (on the part of the operator) and the intention (on the part of the system). This mismatch creates feelings of uncertainty and mistrust in the system — which is exacerbated by the remoteness of the operator from the action.

The impact of uncertainty on working practices is likely to increase the extent of information-seeking behavior, and also the application of imagination to the job in the absence of information. As a result of a poor quality of external information; therefore, the operator may resort to having to retrieve material "internally."

The ergonomics and organizational psychology literature is full of examples of the need to provide autonomy in working situations. Its absence has been shown to be a major factor in job satisfaction, employee turnover, stress at work, etc. A person-centered view of the situation clarifies the reasons for its importance: increased autonomy and personal control implies increased certainty within the working situation; we are more in charge of the consequences of our actions. This leads both to lower stress levels and to less likelihood of mind wanderings.

8. RESPONSIBILITY

Any discussion of autonomy is incomplete without a consideration of the concept of responsibility. Autonomy and responsibility are clearly interrelated concepts; people who have responsibility ideally have conscious control over their own actions. Thus, an operator who has a sense of responsibility is one who is also self-determined. People at work generally act out their duties in sane and rational ways; in that respect they behave in a reliable way.

Having a sense of responsibility, however, can also have negative effects — particularly in the likelihood of increased stress resulting from it. This becomes particularly important in situations when mind wanderings may occur — the resultant mini panics can be considered to be a direct result of the responsibility (and fear of loss of responsibility) that the operator feels over the situation.

9. THE SELF AT THE CENTER

The six areas of person-centered ergonomics elucidated above illustrate some of the fundamental processes that a person can bring to a situation and which helps to shape behavior when interacting with it. People do not simply interact passively with the environment, merely responding to ergonomically designed displays, using ergonomically designed controls, within an ergonomically designed environment. They are active and creative doers. They develop mental models of the system: how it operates, how it should be operated, how to interact with it, how they should interact with it.

A further feature of person-centered ergonomics is to impress on the six features a meta-view of the roles of various "unconscious" processes in determining and developing these mental models. To disregard such processes is to dismiss crucial features of the operator and the ways in which s/he interacts with the system. As Branton (1987) argues, large sectors of real life will be ignored, while the problems of explaining such basic functions as selective attention of directed awareness still remain with us. 'The largest part of our knowledge is still "tacit knowledge' (Polyani 1958), a concept which has an important role in the general case for the purposive view" (p. 6).

Knowledge could be said to be derived from two sources:
- External knowledge appears from sources that are external to the individual, from others, from the system with which s/he is interacting, from past experience, etc.
- Internal knowledge derives from the "me" part of the self. This includes both conscious and unconscious information about our physiological states, knowledge of our actions, purposes, etc.

As individuals we must be able to differentiate between these two, often competing, sets of information. Unconscious (unselfconscious) behavior helps to shape our conscious behavior through the development of preconceptual thought. It thus helps to mould how we approach an activity and how we eventually carry it through:

To argue for the importance of unconscious and "preconceptual" behavior to eventual conscious activity, however, we must also consider the bridge between this kind of thinking and eventual "doing." This bridge is created by the individual's propositions about the information being assimilated and

manipulated. Such quasi-propositions contain immediate and certain knowledge. One knows the position of one's foot without having to say to oneself "There is my foot," or even without having to think about the foot at all. Indeed, perhaps more importantly, the way in which such material is dealt with forms the structure of the bridge — the individual's own internal model of the system's structure.

By helping to build the bridge between thought and action, therefore, from the ergonomist's perspective such quasi-propositions play an important role in determining how the individual will act within his/her environment.

10. A PERSON-CENTERED APPROACH TO MEASURING BEHAVIOR

The person-centered view of ergonomics extends beyond simply arguing that the operator's individuality is placed centrally within the system. Such an argument also begs the need to study the science of ergonomics and gather ergonomic data within a person-centered framework.

10.1. Empathy

An empathatic approach lies at the center of the person-centered approach to measuring behavior. As Branton (1984) has argued:

> To find ways out of this conceptual maze, one guiding thread may be offered to the researcher. It is to adopt an "epistemic" strategy: to ask himself in the first place at each stage, "How do I know whether this or that statement by the operator is true?" "What is the source of my knowledge?" "How direct or indirect is my perception of the measurement?" "How far is my conjecture based on an analogy and how far does it penetrate to the 'real thing?'" Having thus become conscious of their own inevitable bias, observers (and their readers) are better able to speculate on their subjects' knowledge, values and actual purposes. (p. 505)

Thus, unless the ergonomist can empathize with the individual's situation s/he cannot fully enquire into, or understand, its effects on the individual. It is rather like trying to imagine oneself in the other person's shoes. Empathy thus has important implications for decisions to be made about the ways in which studies are carried out, which variables are to be considered, and how interpretations are to be made of the data. Without such insight ergonomists would simply be attempting to understand the external forces that make the individual act in a particular way — rather than the internal knowledge that the person brings to the situation.

10.2. Multiple Methods

Since the bases on which the behavior is to be analyzed are multifactorial, using both intrinsic and extrinsic knowledge, the person-centered approach argues that data collection is similarly multifaceted. All kinds of approach need to be employed, including cognitive, physiological and psychophysiological, and social, probing into both conscious and unconscious behaviors of the operator. Often, no single measure will provide the insight needed to understand both the user needs and those of the system.

11. SUMMARY

The person-centered view of ergonomics exhibits significant departures from the traditional view of a system. The traditional view sees the system as a closed-loop process in which the two components — "man" and "machine" — operate as equal partners. Rather, it is argued that it is the human actor within the system that plays the crucial and dominant role in the safe and efficient operation of that system. Thus, it is the intrinsic features of "being human" that are the most important.

In this conceptualization people have a sense of purpose in their work; they approach the task with this purpose "in mind." So the system and the task must be designed to accommodate this need. Indeed, the individual's purpose extends beyond just wishing to get the job done. Individuals exhibit activity over and above that required to accomplish the task successfully. This sense of purpose often also involves anticipation and prediction (sometimes even at a quasi-mathematical level) of the consequences, the effects of the action.

It is in the nature of people that they will approach their tasks with a sense of responsibility. This means performing their tasks in the most efficient way and having some kind of control over their actions and that of the system. When these requirements are contravened, when instances occur over which individuals lack control or sense that they have failed, even momentarily, in their responsibility, stress and other negative effects typically occur.

The strength of the person-centered view, therefore, lies in the need to consider not only just the person's actions at work, but also the purposes that underlie the actions. Thus, the person is central to the ergonomic system and brings to the situation needs, wishes and desires, as well as the physical and cognitive abilities that are necessary to carry out the task — along with some limitations that need further understanding.

Poland: Polish Ergonomics Society

L. M. Pacholski and J. S. Marcinkowski

The biggest professional ergonomic organization in Poland is the Polish Ergonomics Society (PES), established in 1977. PES provides educational services in the field of ergonomics, and helps in development of the ergonomic culture in Polish society. PES is a member of the International Ergonomics Association (IEA), and since 1980, the president or representative of PES has been a member of the IEA Council.

The society has 13 local branches in the main cities of Poland, including Warsaw, Poznan, Kraków, Wroclaw, Szczecin, Gdansk, Lodz, Lublin, Zielona Góra, Bydgoszcz-Torun, Katowice, Czestochowa and Kielce. The former Presidents of PES are: Professor Zbigniew Jethon (1977–80), Dr Halina Cwirko (1980–86), Professor Leszek Pacholski (1986–92), Dr Halina Cwirko (1992–98). Since 1999, the President has been Dr Jerzy S. Marcinkowski.

PES has organized the 7th IEA Congress in Warsaw, September 1979, with more than 250 participants from many countries. An important outcome of this meeting was participation in the IEA Congresses for the first time by many people from Eastern and Middle Europe. During the 7th IEA Congress, Professor Jan Rosner was elected the President of IEA and served in that capacity from 1979 until 1982.

The ergonomists associated in PES are actively participating in the IEA Congresses of IEA. During the 13th Congress IEA held in Tampere, Finland, ~40 members of PES presented papers and posters in many of the technical sessions. The society has also coorganized the International Ergonomics Association Conference on Ergonomics of Materials Handling and Information Processing at Work, held in Warsaw, June 1993.

The society cooperates in organizing many ergonomics conferences and international and national seminars for both scientists and practitioners. For the past 50 years, PES has been organizing an annual international seminar of ergonomics teachers concerning the problems of training and education in ergonomics, labor protection and work safety. These seminars are held in beautiful places of the Wielkopolska region of Poland in the last week of June. Professor Leszek Pacholski and Dr Jerzy S. Marcinkowski have headed the Organizational Committee.

The national ergonomic conference of PSE has been held for the past 26 years every October in Kapacz (near Wroclaw). Dr Stefan Frejtak organizes these conferences. Another annual meetings of PES concerning the problems of introducing ergonomic solutions into practice, and accompanied by exhibitions of technical solutions, have been held near Zielona Góra for the past 14 years. Professor Witold Rybarczyk heads the team of organizers for these events. In addition, an annual meeting of PES concerning the problems of ergonomics for people with disabilities has been held in Lodz for the past 5 years. Professor Jerzy Lewandowski heads the team of organizers for these events.

Since 1978, the Polish Ergonomics Society in cooperation with the Committee of Ergonomics of the Polish Academy of Science has published an ergonomics journal (*Ergonomia*; in Polish). In addition, since 1991 the PES in cooperation with the *Centre of Application of Ergonomics* at Zielona Góra has edited a journal on the applications of ergonomics (*Zastosowania Ergonomii*).

Professional Certification in Ergonomics in the USA

Board of Certification in Professional Ergonomics (BCPE)
PO Box 2811, Bellingham, WA 98227-2811, USA

1. INTRODUCTION

As a professional, an ergonomist uses the skills and knowledge from the various human sciences and engineering sciences. The ergonomist matches jobs/actions, systems/products, and environments to the capabilities and limitations of people. According to the Human Factors and Ergonomics Society, '"ergonomics professionals apply human–system interface technology to the design, analysis, test and evaluation, standardization, and control of systems for such purposes as improving human and system performance, health, safety, comfort, and quality of life" (HFES 1998).

Ergonomics is a body of knowledge about human abilities, human limitations and other human characteristics that are relevant to design (Chapanis 1988). *Ergonomic Design or Engineering* is the application of human factors information to the design of tools, machines, systems, tasks, jobs, and environments for productive, safe, comfortable and effective human functioning (Chapanis 1988). Ergonomists apply their skills in business, industry, government, and academia to:

- increase human productivity, comfort, health, and safety; and
- to reduce injury, illness, and the likelihood of errors.

1.1. Operating Philosophy and Code of Conduct

The operating philosophy of ergonomists is to adapt technology to the scientifically established characteristics of people. Applications of technology should not be based on unwarranted assumptions about human capabilities and their adaptability. In support of this philosophy, ergonomists shall:

- hold paramount the safety, health and welfare of the public in the performance of their professional duties;
- perform services only in the areas of their competence;
- shall issue public statements only in an objective and truthful manner;
- shall act in professional matters for each employer or client as faithful agents or trustees, and shall avoid conflicts of interest;
- shall build their professional reputation on the merit of their services and shall not compete unfairly with others;
- shall act in such a manner as to uphold and enhance the honor, integrity, and dignity of the profession;
- shall continue their professional development throughout their careers and shall provide opportunities for the career development of those ergonomists and support staff under their supervision.

1.2. Body of Knowledge

The body of ergonomics knowledge resides in the open literature of textbooks, handbooks, guidelines, standards, journals and electronic databases and from the experience of practitioners. A practitioner acquires ergonomic knowledge through formal course work (lectures, labs, workshops, seminars); self-study; supervised fieldwork and practical experience. Ergonomists integrate knowledge about human function, structure and behavior for practical uses in the design process. Formal courses and degree programs in ergonomics/human factors are available from universities and colleges throughout the industrialized world, and professional societies have existed since 1957 for educational and information exchange purposes. So, while self-study is possible, formal, advanced education specifically in ergonomics/human factors is strongly recommended for people wanting a professional career in ergonomics.

Representative sciences that *contribute* to the body of ergonomics knowledge needed for the design process include:

- Anthropometry and anatomy — human size and shape data for work space design and arrangement, tool/equipment design and job design.
- Biomechanics and kinesiology — kinematic and kinetic methods for the assessment of human physical characteristics and performance relevant to the design of musculoskeletal work.
- Engineering sciences and/or physical sciences — basis for engineering/design opportunity and/or constraints in adapting physical and material nature to human needs and welfare.
- Physiology — energy demands of different activities and responses to heat, cold, vibration, toxins and other environmental and situational conditions that need to be considered in design for safe, healthy and productive human performance.
- Psychology — human sensation, perception, information processing, decision-making, mental workload, learning, memory, adaptation, motivation, stress, individual behavioral differences, maturation, and psychomotor-skill acquisition and performance abilities relevant to the design of systems.
- Management disciplines — planning, organizing, staffing, directing and controlling the activities of multidisciplinary design teams as governed by socio-technical and cultural conventions: standards, codes, regulations, laws, ethics and value to society. This area entails what has become known as *macro-ergonomics*.
- Mathematics and statistics — methodological and numerical basis by which relevant data can be summarized, analyzed, interpreted and synthesized for use in the design process.

The *unique knowledge base of ergonomics* derives from the methods and techniques its researchers and practitioners have developed to distinguish ergonomic design technology from the contributing disciplines enumerated above. This knowledge focuses on the systems approach to human integrated design. Systems design involves the complementary application of natural and human sciences. System design is viewed as an organized approach to decision-making (in any design context) with a proper emphasis on the human factors to achieve system utility without detriment to the humans who manage, control, use or maintain the system. In practice, ergonomic design becomes as much an art as any other engineering design profession. But it is an art based on science, not conjecture on how people do (or should) function.

1.2.1. Ergonomist Formation Model (EFM)

In coordination with the Center for Registration of European Ergonomists (CREE) and in cooperation with the Education and Training Committee of the International Ergonomics Association (IEA), the BCPE, in 1995, adopted the EFM as the fundamental architecture for professional competence in ergonomics.

The subject categories and topics in the EFM (table 1) are taken directly from Rookmaaker *et al.* (1992). The EFM closely matches the curriculum criteria used by the Human Factors and Ergonomics Society (HFES) in the accreditation process for graduate programs in ergonomics/human factors (HFES 1990). Additional information on the education, training, and skills of ergonomists can be found in Bernotat and Hunt (1977), Jahns (1991), van Cott and Huey (1992) and Rentzsch (1994), as well as, in various meeting proceedings of the IEA and its Federated Ergonomics/Human Factors Societies. Table 1 provides the categories and topics of core-ergonomics course work for which documented evidence must be provided. The hours (clock hours for contact and/or studies) shown differentiate between two levels of practice in ergonomics, as well as, the different certification designators awarded by BCPE (Certified Professional Ergonomist — CPE and Certified Ergonomics Associate — CEA).

Table 1. The Ergonomist Formation Model

CATEGORY and TOPICS	CPE (MS/PhD)	CEA (BS)
A. Ergonomic Principles	20 hours	15 hours
1. Ergonomics Approach		Required
2. Systems Theory		Elective
B. Human Characteristics	80 hours	50 hours
1. Anatomy, Demographics and Physiology		Required
2. Human Psychology		Required
3. Social and Organizational Aspects		Elective
4. Physical Environments		Required
C. Work Analysis and Measurement	100 hours	65 hours
1. Statistics and Experimental Design		Elective
2. Computation and Information Technology		Elective
3. Instrumentation		Elective
4. Methods of Measurement and Investigation		Required
5. Work Analysis		Required
D. People and Technology	100 hours	65 hours
1. Technology		Required
2. Human Reliability		Elective
3. Health, Safety and Well-Being		Elective
4. Training and Instruction		Required
5. Occupational Hygiene		Elective
6. Workplace Design***		Elective
7. Information Design***		Elective
8. Work Organization Design***		Elective
E. Applications (projects pursued by the individual during education/training)	6 weeks	Part of on the job Training
F. Professional Issues (ethics, practice standards, marketing, business practice, legal liabilities)	20 hours	5 hours

*** CPE must be competent in at least one design domain

The EFM, however, is incomplete without also consideration of on-the-job experience. For the CPE, at least 4 years are necessary; for the CEA, 2 years are required.

1.2.2. Objectives and points of reference

In addition to the Ergonomist Formation Model, Rookmaaker *et al.* (1992) developed objectives and points of reference for each category topic of the EFM. These are:

(A) Ergonomics Principles — *to understand the guiding principles and theory of ergonomics*
1. Ergonomics approach
   Objective: To recognize the integrated (systems) nature of ergonomics, the centrality of human beings, to use its breadth of coverage and the available knowledge base to adapt the environment to people.
   Points of reference: History of work; current developments; paradigms (designing for individuals versus populations; working in normal versus extreme circumstances); interaction between society and work.
2. Systems theory
   Objective: To recognize the principles of systems theory and how they apply to ergonomics situations.
   Points of reference: Structure and dynamics of systems; human as a system component; system analysis and design (e.g. allocation of functions).

(B) Human characteristics — *to describe and recognize the contributions and effects of the factors contributive to the ergonomics knowledge base on people's physical and psychological well-being, and on their performance*
1. Anatomy, demographics and physiology
   Objective: To recognize and measure the physical characteristics of people and their responses to their activities and their environments with particular reference to health and performance.
   Points of reference: Anatomy; biomechanics and posture; anthropometry; energy and force production; adjustments (stress and strain); individual, gender-related, developmental, racial and cultural variability; chronobiology (e.g. circadian rhythm).
2. Human psychology
   Objective: To recognize behavioral characteristics and responses and to understand how these affect human behavior (including health and performance) and attitudes.
   Points of reference: Psychophysiological and cognitive aspects of information intake, information handling and decision making; individual motivation; human development.
3. Social and organization aspects
   Objective: To recognize the social dimensions of ergonomics and organizations and to specify systems structures suitable to achieve a good quality of working life or performance.
   Points of reference: Motivation and attitudes related to needs of individuals and to working in groups; individual and group functioning; socio-technical systems.
4. Physical environment
   Objective: To understand the human senses and to be able to recognize, measure and specify the appropriate levels of and the characteristics of the physical environment to be suitable for human activities.

Points of reference: Climatic environment; visual environment; acoustic environment; vibration; human senses.

(C) Work analysis and measurement — *to understand, select and use the appropriate methods for investigating ergonomics problems, and for presenting data for evaluating future design solutions to these problems*

1. Statistics and experimental design

Objective: To collect, aggregate, manipulate and evaluate data in a reliable and valid manner.

Points of reference: Descriptive and inferential statistics; probability theory; correlational techniques; estimation and sampling; experimental design; non-parametric statistics.

2. Computation and information technology

Objective: To use (digital) computers, particularly utilize standard packages, for the effective prosecution of ergonomics investigations.

Points of reference: Computation for data collection; computation for calculation; computation for storage, computation for database searches, computer-aided design.

3. Instrumentation

Objective: To use the major measuring instruments, sensors, etc., required by the ergonomist to gather data for investigations, design or evaluation of workplaces, work procedures or work equipment.

Points of reference: Simple and complex equipment; their potential and their limitations.

4. Methods of measurement and investigation

Objective: To understand the major methods and procedures of measurement used in ergonomics investigations, and to know when to use them and how to interpret the results.

Points of reference: Simulations (dynamic and static); methods for observing activity and performance; interviews and questionnaires; epidemiological approach; sampling procedures; checklists.

5. Work analysis

Objective: To describe and understand the determinants and organization of workers' activities in the field or system.

Points of reference: Activity analysis; task analysis; function analysis; task interdependency, communication and cooperation; the importance of strategies in task execution.

(D) People and technology — *to understand an area for application of ergonomics expertise, some models and concepts related to applying ergonomics, and* at least *one special form "ergonomic design" may take on in any area*. *Three "optional" topics must be chosen, at least one being a "design" topic.

1. Technology

Objective: To understand the factors in the chosen area of application that are relevant to the creation of ergonomic situations; in particular to recognize those aspects of the technology that are flexible/changeable. One of the following application areas may be chosen: consumer products; manufacturing; office work; transport; process industry; healthcare; automation; architecture; recreation, arts and leisure activities (see also E, Applications).

Points of reference: Functionality, operation and construction of the technology.

2. Human Reliability (optional)*

Objective: To design and evaluate work situations using 'best practice' in working towards error-free performance.

Points of reference: Accident models; attention, effort and vigilance; error taxonomies.

3. Health, safety and well-being (optional)*

Objective: To design and evaluate work situations to achieve healthy and safe work, as well as contribute to quality of work life.

Points of reference: Safety management; occupational injuries and work-related disorders; safety technology; legislation; characteristics of good quality of work life.

4. Training and instruction (optional)*

Objective: To understand the fundamentals of learning, of training programs and of instruction, and to specify requirements of those programs to achieve successful performance to new or changed work activities.

Points of reference: Learning skills; learning knowledge; assessing job requirements and worker capabilities; designing training programs to bring workers to the level of requirements; designing manuals.

5. Occupational hygiene (optional)*

Objective: To recognize, measure and cope with the presence of adverse physical and chemical conditions and other major pollutants.

Points of reference: National and international recommendations and requirements; their variations and limitations; measurement, protection, control and monitoring.

6. Workplace design (optional)*

Objective: To investigate and design workplaces to match the physical and psychological dimensions of their users and to measure their effect on ergonomically relevant dimensions.

Points of reference: Measurement of activities and performance; workspace layout; use of mockups/simulations to improve designs; evaluation; compatibility between workplace requirements and human capabilities.

7. Information design (optional)*

Objective: To investigate and design the major modes of information transfer to the human for effective and efficient performance of the system.

Points of reference: Signal detection; information processing and attention; display characteristics; information overload; stimulus–response compatibility.

8. Work organization design (optional)*

Objective: To investigate, design and implement work organizations for effective and efficient performance and good quality of work life.

Points of reference: Cooperative analysis and design of new work systems; basics and applications of work–rest schedules; introduction of change.

(E) Application — *to apply ergonomics skills and knowledge to human-oriented systems and products*

Objective: To understand the integrative nature of applying ergonomics, the need for and structure of a specification, and the interactive and iterative nature of work in an applied research or design group, recognizing the practicalities and limitations of applying ergonomics, including the introduction of change.

Points of reference: The applied research/design process is applied in a chosen area such as: consumer products; manufacturing; office work; transport; process industry;

healthcare; automation; architecture; recreation, arts and leisure activities, etc. (see also D1, 'Technology'); intervention techniques.

(F) Professional issues — *to understand how ergonomics affects an individual's way of life and to know how legislative actions and current economic situations affect the application of ergonomics*
Objective: To recognize the impact of ergonomics on people's lives, the costs and benefits accruing from ergonomics activities, the social and psychological impact of ergonomics investigations, and the professional responsibilities and requirements for the ergonomics practitioner.

Points of reference: Legislation; economics; the ergonomist in the organization; ergonomics and society; role of ergonomist in social settings with different interest groups; ethics; development and marketing of the ergonomics profession.

1.2.3. Behavioral objectives for the professional ergonomics practitioner

In addition to the EFM, there are specific behavioral objectives that are applicable to the ergonomics professional. These objectives are the results of Hendrick (1981), who was a member of the US Air Force task force to recommend goals and changes for the human factors/ergonomics profession. The objectives are:

1. Sufficient background in the behavioral sciences to respond to ergonomics questions and issues having psychological or other behavioral implications. Implies the equivalent of a strong undergraduate behavioral science minor.

2. Sufficient background in the physical and biological sciences to appreciate the interface of these disciplines with ergonomics. Implies the equivalent of an undergraduate minor.

3. Sufficient background in hardware engineering to (a) understand design drawings, electrical schematics, test reports and similar design tools; (b) appreciate hardware design problems and the general engineering process; and (c) communicate effectively with hardware design engineers. Implies formal knowledge of basic engineering concepts at the familiarization level.

4. To be able to (a) evaluate and, (b) assist in performing classic man–machine integration, including workspace arrangement, controls, displays, and instrumentation. Implies formal knowledge of ergonomic human–equipment integration technology.

5. To be able to apply knowledge of human performance capabilities and limitations under varying environmental conditions in (a) evaluating design and (b) assisting in the development of design requirements for new or modified systems. Requires formal knowledge at the familiarization level of human performance in the various physical environments (e.g. noise, vibration, thermal, visual).

6. To be able to (a) evaluate and (b) conduct the various kinds of traditional ergonomic analyses (e.g. functional task, time-line, link). Requires formal training in these techniques at the familiarization level.

7. Have sufficient knowledge of computer modeling, simulation, and design methodology to appreciate their utility in systems development, including ergonomic utilization in function allocation, task time-line analysis, workload analysis, crew station layout evaluation, and human performance simulation (this does not include the ability to actually design the models and simulations). Requires math through calculus and introductory computer science, and knowledge at the familiarization level of measurement, modeling, and simulation as these are applied in ergonomics.

8. To be able to apply knowledge of learning and training methodology to the evaluation of training programs and to instructional systems development (ISD). Requires knowledge of that portion of learning theory and research applicable to training and training methodology at the familiarization level. Also requires familiarization with the ISD process.

9. To be able to apply the organizational behavior and motivational principles of work group dynamics, job enrichment and redesign, and related quality of work life considerations in (a) developing ergonomic system design requirements and (b) evaluating the design of complex systems Requires formal knowledge of organizational behavior at the introductory level.

10. To be able to assist in the development and evaluation of job aids and related hardware. Requires knowledge of the state-of-the-art at the familiarization level.

11. To be able to evaluate the adequacy of applied ergonomics research and the generalization of the conclusions to operational settings. Requires formal knowledge of the basic statistical methods and the principles of experimental design at the introductory level.

12. Have at least one area of specialized expertise that goes beyond the introductory graduate level of understanding and application. Requires additional coursework or thesis project in a specialized area as covered in the ergonomics topics descriptions.

1.3. Scope of Practice

Because ergonomics is principally a design discipline, the skills needed for effective practice are similar to those needed for engineering. The focus, however, is on solving human performance problems rather than problems of technology application which engineers emphasize to create hardware and/or software "tools" for enhanced living and working. The stage for ergonomists is set by "tasks" (i.e. "work" or, in Greek, *ergon*) while the stage for engineers is set by "things" (planned-for, created, objects and artifacts) that serve a functional objective. The stage for other career groups such as, healthcare providers, psychologists, sociologists, educators, etc. is the "changing human condition" by providing education, training, therapies, counseling, and practical advice on how to change the human-related factors as affected by the natural and technological worlds.

Differentiating amongst these three "operating stages" becomes important because the scope-of-practice for ergonomists overlaps, to some extent, those of other career fields. This overlap has resulted in two levels of ergonomics practice:

- CPE — a career problem solver who applies and develops methodologies for analyzing, designing, testing, and evaluating systems. A CPE addresses complex problems and advances ergonomics technologies and methods.
- CEA — an interventionist who applies a general breadth of knowledge to analysis and evaluation. A CEA reacts to performance, safety, health and/or quality issues in currently operating work systems.

While the scope of practice for the CPE covers the entire breadth and depth of ergonomics knowledge, the scope of practice for the CEA is limited to the use of commonly accepted tools and techniques for the analysis and enhancement of human performance in existing systems. (Commonly accepted tools and techniques include those which have extensive use, are widely reported in the literature, have established protocols, and which are broadly accepted by practicing CPE. Human performance is defined as including physical, cognitive, psychosocial, organizational, environmental and system factors. Existing systems include current operating systems and their components, but excludes conceptual systems, extensive redesign or design of new systems.) In general, a CEA:

- Analyzes and assesses human interactions in the system.
- Intervenes by making recommendations for improvement of identified mismatches.
- Evaluates effectiveness of implemented recommendations.

Furthermore, the CEA has to recognize those projects which exceed this scope and for which the skills of a CPE must be used. Table 2 compares the fundamental differences in scope of practice of the CPE and CEA. Tables 3–5 provide more detailed comparative examples of the scope of practice of a CEA compared with a CPE.

1.3.1. Analysis and assessment
In table 3, the left column has scope of practice analysis and assessment examples for the CEA while the right column lists the additional functions that a CPE performs.

1.3.2. Intervention
In table 4, the left column has scope of practice intervention examples for the CEA while the right column lists the additional functions that a CPE performs.

1.3.3. Evaluation
In table 5, the left column has scope of practice evaluation examples for the CEA while the right column lists the additional functions that a CPE performs.

1.4. Practitioner Experience
Practitioner knowledge and skills are developed in a large variety of settings and situations leading to specialization in the ergonomist's job functions and systems design applications. Specialization can occur along design criteria lines (e.g. health and safety, marketability) or job function (ergonomics analyst, designer, evaluator or manager). Even so, experience will always involve one or more of the following: analysis, design, testing, evaluation, research, consultation and/or management of human

performance in an operational or developmental engineered-system context. Experience on one system often will be applicable in another system. Specialization among system lines can include:

- Mobility/transportation systems (ground, water, air and space).
- Industrial systems (processing, manufacturing, distribution, etc.).
- Business systems (offices, services, etc.).
- Communication systems.
- Information management systems/computers.
- Educational systems (instructional systems design).
- Regulatory/legal systems.
- Consumer systems.
- Architectural systems.
- Healthcare systems.

Surveys have shown that about 4 years of practical experience are needed before the ergonomist is comfortable with all the principles and practices of his or her profession related to a system design team. For CEA ~2 years of practice are needed to get a thorough familiarity with the methods and protocols used in an intervention strategy. The profession is not static, and continuing education by means of active participation in professional society meetings, workshops, seminars and short courses is strongly recommended to stay abreast of rapid advances in ergonomic technology and information.

1.5. Summary
Three key concepts characterize ergonomics: human performance (work) + ergonomic design (engineering) + systems integration (technology management). Subtract any component concept, and the essence of ergonomics is compromised. The ergonomist strives to balance technological factors with personnel selection and training options to achieve state-of-the-art system performance. The profession's goals are to "humanize technology" by creating jobs and work systems which provide:

- Reasonable human performance.
- Reasonable human workload.
- Reasonable health maintenance.
- Reasonable hazard control and injury-risk management.

2. CERTIFICATION
Certification is a way to assure that something is what it is supposed to be. Applied to professionals, certification ensures that individuals have met a set of standard requirements. The certification process is a structured approach to evaluate individuals in their discipline by assessing compliance to technical standards. Certification is generally a voluntary process by a non-

Table 2. Comparative chart of the scope of practice of a CEA and CPE

CEA	CPE
• Conducts basic workstations analyses	• In addition to conventional problems, addresses more complex and non-conventional problems.
• Applies widely-established techniques to address conventional problems.	• Develops and applies advanced methodologies, mathematical models and/or simulations.
• Works within the "intervention model," i.e., ergonomics-related problems identified at an existing workstation.	• Works within the broader 'system design model' in which intervention may be **one** particular strategy among others.

Table 3. Comparison of the scopes of practice of a CEA and a CPE — Analysis and Assessment

CEA	CPE

SYSTEM

- Conducts basic analysis of a facility to identify problem areas using widely recognized methods such as:
  — reviewing the workers compensation records to identify the three jobs with the highest incidents of musculoskeletal disorders in a plant.
  — conducting a walkthrough survey using a checklist.

- Recognizes musculoskeletal and performance problems from organizational and management factors such as:
  — increased injuries related to downsizing, change of supervision, department restructuring and changes that incorporate policies.

- Conducts basic to complex analyses (multiple facilities, national and international, diverse products, unconventional organizational structures) using existing to novel methods, such as:
  — developing the survey and analysis method to identify multiple factors to prioritize ergonomics-related problems.
  — developing an unique survey which integrates production bottlenecks and turnover, with injuries to prioritize ergonomic projects within a facility.

- Analyzes the organizational and management structure and processes to identify the root causes of injury and performance decrements.

- Analyzes work system structure and processes to determine appropriateness in light of key sociotechnical systems, such as:
  — reviewing organizational structure to develop and implement rule based procedures to lower decision making.
  — altering organizational culture to achieve quality management implementation.

- Uses computer modeling, simulation, and design methodology in systems development, such as:
  — allocating human-machine functions for an advanced manufacturing assembly line.

Task

- Conducts basic task analyses using tools such as checklists, questionnaires, videotaping and force measurement, for example:
  — investigating 50 person office workplace using standard VDT checklist.

- Uses commonly accepted tools and techniques for analysis, for example:
  — assessing manual transfer of chemical bags into a mixing bin using the NIOSH equation.

- Recognizes basic mismatches between the job requirements and human capabilities including physical, cognitive, psychosocial and enviromental, for example:
  — identifying worker injuries that result from workload and deadline pressures rather than from workstation layout.
  — recognizing that a quality problem results from excessive noise levels.

- Identifies obvious sources of error such as viloations of occupational stereotypes, inconsistent displays, controls, control-display arrangements and poor coding design.

- Bases analysis decision on widely recognized design criteria and ergonomics principles.

- Uses simple statistical techniques such as descriptive statistics and performs simple statistical analyses such as t-tests and correlations.

- Recognizes when a sophisticated level of analysis is required.

- Develops and applies advanced analytical methods, mathematical models and simulation, for example:
  — using a simulation model to review stairs in new stadium design
  — using a CAD system to determine adequacy of maintenance accesses.

- Designs and conducts analytical studies, for example:
  — recognizing that multiple workplace changes within a manufacturing cell warrant pilot studies and mock-ups to verify changes.
  — determining a safe workload based on workload analysis by body part, force requirements, pace and work duration.

- Develops and applies theoretical constructs, for example:
  — developing a diagnostic tool for incorporating a knowledge based system for scientists and rule-based system for technicians.

- Conducts error analysis, for example:
  — reviewing five years of operational data to determine human error likelihood for a refinery.

- Interprets study results to determine design requirements, for example:
  — reviewing literature to specify design for a new road grader utilizing either an integrated control stalk or seperate controls.

- Uses advanced statistical techniques such as multi-variate analysis and regression analysis, for example:
  — using multi-variate analysis to predict service call rates based on interaction of overtime requirements and shift assignment.

- Recognizes when the analysis requires a level of expertise in a specialty area at a level that exceeds ones own.

Table 4. Comparison of the scopes of practice of a CEA and a CPE -Intervention

CEA	CPE
• Applies ergonomics principles at the workstation level by: — modifying a packaging station by replacing a lift motion with a slide motion resulting in fewer risk factors and enhanced productivity. — rearranging displays on a control panel based on ergonomics principles of importance and frequency of use.	• Applies ergonomics principles at the work system level by: specifying methods and tools for different types of terrain for tree harvesting to optimize efficiency and safety. specifying resources for enhanced situation awareness in transportation systems.
• Makes basic recommendations for improvement of existing systems, encompassing engineering, administrative and work practice modifications, for example: — rearranging a workplace fixture to eliminate an awkward posture. — rearranging a sequence of work tasks to reduce cycle times. — using anthropometric data to determine the height of an overhead control valve for 5th percentile female worker. — recommending off-the-shelf hardware such as lift tables, hoists, conveyors. — recommending job rotation on an assembly line to control overuse injuries.	• Makes recommendations for the improvement of existing sophisticated systems by applying human-equipment integration technology, for example: — replacing a small motor assembly line with a manufacturing cell to control labor costs, enrich jobs and provide just-in-time output. — restructuring departmental jobs by recombining work modules to better distribute work loads and enhance output. — redesigning a shift schedule to reduce vigilance decrement of radar surveillance operators. — adding test functions to electronic sub-assembly in order to provide knowledge of results, thus enhancing motivation and reducing rework. — designing cognitive aids, such as a procedural storyboard for packing medical instruments.
• Trains employees in ergonomics principles and task techniques, for example: — training office workers on how to adjust workplaces. — training employees to include ergonomics in Job Safety Analyses.	• Develops training programs and materials, for example: — training people in ergonomics analysis, interventions, and evaluation, such as training ergonomics teams or design engineers. — using the training system development process to determine training requirements for computer maintenance personnel. — specifying use of whole versus part task simulators for training pilots.
	• Tailoring conventional intervention methods for new or unique opportunities, for example: — using aviation crew resource management procedures to optimize decision making in a chemical control room.
	• Designing and developing new systems or systems requiring major revision by determining design criteria and applying those specifications to the design, for example: — designing a new software package. — designing a nuclear power plant control room. — revising the manufacturing line to shift from conventional CRT monitors to flat panel displays.
	• Applies knowledge of engineering concepts to communicate with design engineers, for example: — understanding design drawings and appreciating hardware design problems of a new packing line to determine potential design options for reducing the physical job demands.
• Recognizes when the scale or complexity of intervention requires a CPE.	• Recognizes when the intervention requires a level of expertise in a specialty area at a level that exceeds ones own.

governmental agency that recognizes individuals for advanced knowledge and skill (NOCA 1996). According to the Council of Engineering and Scientific Specialty Boards (CESB 1998), "Certification is the recognition of special capability conferred on individuals who meet the education, experience, competency and other requirements for certification in a specified area of practice." Certification is used by many professions to ensure a defined level of competence.

The certification of individuals claiming to be ergonomists was initiated by the BCPE in 1992. The basis for the development of certification criteria, procedures and the content topics of the written examination were several reviews of job/task analyses performed by committees of the Human Factors and Ergonomics Society, the International Ergonomics Association, the Department of Defense, NATO, and the National Academy of Science/National Research Council. These efforts spanned the period between 1970 and 1992. Knowledge, skills and experience domains and topics were then categorized by the *Ergonomics Abstracts* (London: Taylor & Francis, 1993) schema and evaluated for validity and reliability against the most widely used textbooks and handbooks in ergonomics/human factors academic degree programs.

Table 5. Comparison of the scopes of practice of a CEA and a CPE — Evaluation

CEA	CPE
• Uses simple structured evaluation tools and methods to measure effectiveness of ergonomic interventions, for example: ? — administering before and after discomfort surveys to ensure a raised packing station height reduced back discomfort. ? — administering work environment survey to evaluate employee satisfaction with the new work station. ? — conducting a survey to elicit employee preferences for laboratory stools. — using structured interviews to gather feedback on the employee acceptance of a semi-automated ticketing system at an apparel assembly workstation.	• Designs and develops evaluation tools and methods to measure effectiveness of ergonomic interventions, for example: — evaluating effects of introducing robotic packing of television sets, by developing a program which includes determining evaluation requirements and designing or selecting evaluation tools. — specifying human performance measures suitable for meausuring vehicle guidance with cell-phone task sharing.
• Uses simple statistical evaluation such as means and standard deviations, for example: — calculating average area roofed per shift by construction workers and standard deviation for manual nailing versus using nailing guns.	• Conducts sophisticated evaluations including multivariate statistical analysis, for example: – evaluating the interaction effects of increasing lighting and reducing noise on error rate of pill dispensing in pharmacies. — evaluating effectiveness of 12 hour versus 8 hour work shifts in a rotating shift chemical plant.
• Performs cost justification of simple and relatively inexpensive projects, for example: — as part of cost justification, calculating changes in annual lost time accidents and injuries following ergonomic redesign of shoe assembly work stations and determining savings in workers' compensation costs.	• Performs cost benefit analyses, especially of complex and expensive projects, for example: — justifying the cost of modifying a harvesting machine cab to improve visibility in terms of savings from increased harvesting rate and reduced equipment damage from accidents.
• Recognizes when a sophisticated level of evaluation is required.	• Recognizes when the evaluation requires a level of expertise in a speciality area at a level that exceeds ones own.

2.1. Criteria for Certification

Based upon the EFM, the BCPE has defined two career paths for certification. To differentiate between the two levels of practice in ergonomics, different certification designators are awarded by BCPE. The Certified Professional Ergonomist (CPE) is the principal designation for career professionals. Individuals who desire to use the phrase "Human Factors" in lieu of the word "Ergonomics" can chose the Certified Human Factors Professional (CHFP) designation. The designation, Associate Ergonomics Professional (AEP)/Associate Human Factors Professional (AHFP), is granted to individuals who have met the initial CPE criteria but have not taken the complete CPE examination and have not met the 4-year experience requirement. AEP/AHFP is an interim designation. AEP/AHFP individuals have 5 years to complete the requirements for the CPE/CHFP designation. The Certified Ergonomics Associate (CEA) designation are given to individuals who are limited to an interventionist role for system analysis and evaluation.

2.1.1. CPE/CHFP

The BCPE job/task analyses led to the following minimum criteria for certification at the CPE/CHFP level:

- A master's degree in ergonomics or human factors, or an equivalent educational background in the life sciences, engineering sciences *and* behavioral sciences to comprise a professional level of ergonomics education.
- Four years of full-time professional practice as an ergonomist practitioner with emphasis on design involvement (derived from ergonomic analysis and/or ergonomic testing/evaluation).
- Documentation of education, employment history and ergonomic project involvement by means of the BCPE "Application for Certification."

- A passing score on the BCPE written examination.
- Payment of all fees levied by the BCPE for processing and maintenance of certification, in accordance with the following schedule (all fees are non-refundable):
- Application fee: US$10.00.
- Processing and examination fee: US$290.00.
- Annual certification maintenance fee: US$100.00.

2.1.2. AEP/AHFP

On 26 March 1995 the BCPE created an interim or transient Associate category of certification. An individual with the AEP/AHFP designation is considered to be an "ergonomist in training" who has 5 years to transition to the higher designation of CPE/CHFP after completing 4 full-time years of experience. A person can be certified as an AEP or AHFP if he or she:

- Meets the education requirements for BCPE certification (MS in human factors/ergonomics or related field).
- Has passed Part I (on "Basic Knowledge" of human factors/ergonomics) of the BCPE certification examination.
- Currently is working toward fulfilling the BCPE requirement of 4 years practical experience as a human factors and ergonomics professional.
- Note: a person takes the Basic Knowledge portion (Part I) of the BCPE exam immediately after fulfilling the education requirement. Parts II and III of the exam are taken after fulfilling the other BCPE requirements. A person who has graduated from a human factors/ergonomics degree program accredited by an IEA Federated Society (e.g. HFES), will not have to take Part I of the exam. BCPE established the "Associate" level to create a path by which individuals could achieve professional certification in progressive steps. BCPE also wanted to link this path with accredited educational

degree programs by giving some preference (by waiving Part I of the exam) to applicants who have graduated from programs accredited by IEA Federated Societies. BCPE believes this linkage is an important step in strengthening the human factors and ergonomics profession.

- Fees associated with the AEP/AHFP designations are (all fees are non-refundable):
- Application fee: US$10.00.
- Processing and examination: $100.00.
- Annual AEP/AHFP maintenance fee: $60.00.

2.1.3. CEA

On 17 April 1998, the BCPE established a technician level of certification to meet the growing need for certified ergonomists who use commonly accepted tools and techniques for analysis and enhancement of human performance in existing systems, but are not required to solve complex and unique problems, develop advanced analytic and measurement technologies, provide a broad systems perspective, or define design criteria and specifications. The minimum criteria for certification at the CEA level are:

- A bachelor's degree from an accredited university.
- At least 200 contact hours of ergonomics training.
- Two years of full-time practice in ergonomics.
- Documentation of education and employment history by means of the BCPE "Application for CEA Certification."
- A passing score on the BCPE CEA examination.
- Payment of all fees levied by the BCPE for processing and maintenance of certification, in accordance with the following schedule (all fees are non-refundable):
- Application fee: US$10.00.
- Processing and examination fee: US$190.00.
- Annual CEA maintenance fee: US$75.00.

2.2. Procedures for Certification

Certification candidates request application materials by sending a US$10.00 check to: BCPE, PO Box 2811, Bellingham, WA 98227-2811, USA.

The application materials consist of three or four pages of instructions and four or seven pages of forms to be filled out by the applicant. These include:

- Section A — Personal data.
- Section B — Academic qualifications.
- Section C — Employment history (CPE); ergonomics training hours (CEA).
- Section D — Work experience in ergonomic analysis, design, and testing/evaluation (CPE); employment history (CEA).
- Section E — Work product description (CPE).
- Section F — Signature and payment record.

The candidate completes the application and submits it with (1) the appropriate processing and examination fee, (2) an official academic degree transcript and (3) (CPE only) a work product (article/technical report/project description/patent/application, etc.).

The processing and examination fees are non-refundable.

A review panel evaluates all submitted materials and makes recommendations to the Board whether or not the applicant qualifies to take the written examination. The qualifying candidate takes the written examination and is certified after receiving a passing score. This candidate has up to 2 years after the application is received to take the exam. The non-qualifying applicant has *2 years* to correct any deficiencies or missing elements in the application as pointed out by the review panel for completing the application without additional payment.

3. EXAMINATIONS

As the knowledge, skills and experience domains of a maturing career field evolve, it is advisable to develop self-assessment and self-regulatory instruments. These are needed to gauge the status of the profession in relation to societal demands for services and to gauge the preparedness of individuals to meet those demands successfully. For ergonomists, academic standards have been evolving since the 1960s and resulted in the academic accreditation procedures adopted by the Human Factors and Ergonomics Society (HFES) in 1987. Since BCPE established the certification process in 1992, a multi-part examination was defined to assess how well individuals meet the objectives of the EFM.

3.1. Self-screening for Eligibility

People can enter into the practice of ergonomics from other academic disciplines and occupational experiences, not solely ergonomics. Knowledge and skills range from "novice" (those who have attended seminars, short courses, and/or technical/trade meeting presentations) to "expert" (those who have received advanced academic degrees in ergonomics and then practiced ergonomics in work system environments). Certification eligibility criteria reflect the topics of knowledge and skills that together differentiate ergonomics from other career fields and academic disciplines.

As an aide to decide whether an individual should take the CPE or the CEA examination after meeting the academic and experience requirements, a "Self-Screening Score Sheet" (see Appendix C) was developed for guidance.

3.2. Examination Administration

Applicants who have demonstrated eligibility for the examination will be notified regarding the date and location of the next examination ~2 months before the testing date. The examination, requiring a full day for CPE candidates and 4 hours for CEA candidates, will be scheduled generally for the spring and fall, and will probably be offered as an adjunct to the meetings of ergonomics related professional societies and associations. Qualified applicants needing accommodations in compliance with the Americans with Disabilities Act (ADA) are asked to specify their accommodation needs to the BCPE before signing up for taking the examination.

3.3. Scoring Methods

A panel of BCPE certificants with expertise in psychometrics determines the method of establishing passing scores to be used for the examination. Passing scores are established to ensure the applicant's mastery of the knowledge and skills required for the related level of ergonomics practice. The BCPE will periodically review, evaluate, and, as necessary, revise the examinations and scoring to assure that valid and reliable measures of requisite performance capability for ergonomics practice are maintained.

3.4. Retaking the Examination

An applicant who does not pass the examination may retake the examination at the next regularly scheduled examination date and place. A reduced fee will be applied to retakes, and the retake must take place within 2 years of the original application date.

3.5. Examination Development

An examination-development working group is functioning under Board direction to assist in constructing the examination. The examinations were developed from contributions from ergonomics academics, researchers and practitioners (both BCPE certified and non-certified). The Board developed the subject outline and assigned weighting factors to each subject area in accordance with the Ergonomist Formation Model.

3.5.1. CPE/CHFP subject areas

The examination is designed and constructed to examine:

- Fundamental knowledge in ergonomics by means of multiple-choice items. (Part I: 2.0 hours).
- Application skills by means of multiple-choice items and essays to questions spanning the practices and principles appropriately applied in a setting of ergonomists' involvement with systems analysis, ergonomic design, and systems/human performance evaluation. (Part II: 3.0 hours; Part III: 2.0 hours).

The answers to questions in Part II of the test reflect the complexity of problems typically encountered in professional practice. To answer a given question or problem, for example, may require the synthesis and integration of knowledge and techniques from several sources or subject areas. Although questions may involve the application of standard techniques to novel situations, the situations posed will be fundamental to all system designs from an ergonomic perspective as reflected in the cited books.

Part III of the test uses a scenario-based approach to allow the applicant to demonstrate ergonomic knowledge and skills in a particular setting (e.g. industrial, office, transportation, communication, computer systems). The examinee will be expected to select and respond to a subset of presented scenarios requiring ergonomic solutions. The selectivity is designed to enable truly qualified persons to respond adequately to the realistic work situations posed and to allow them to demonstrate professional expertise and practice.

3.5.2. CEA subject areas

The CEA examination is designed and constructed to examine:

- Fundamental knowledge in ergonomics by means of multiple-choice items. (Part I: 2.0 hours).
- Application skills by means of multiple-choice items to questions spanning the practices and principles appropriately applied in a setting of ergonomists' involvement with systems analysis, ergonomic design, and systems/human performance evaluation (Part II: 2.0 hours).

3.5.3. CPE/CHFP and CEA approximate weighting of subject areas

Table 6 summarizes the weighting factors and reflects the Board's best estimate of the relative importance of topics covered based on interpretation of the job/task analyses. By invitation of the

Table 6. CPE/CHFP and CEA Examination Approximate Weighting of Subject Areas

1. Methods and Techniques (M&T)	30%
2. Design of Human-Machine Interface (DHMI)	25%
3. Humans as Systems Components (Capabilities/Limitations) (HSC)	25%
4. Systems Design and Organization (SDO)	15%
5. Professional Practice (PP)	5%

BCPE, ergonomists are invited to draft test questions for the Test Item Data Bank. After evaluation and peer review, the Board selects questions to be included in a scheduled examination. Statistical data are collected and analyzed by the BCPE on the demographics of applicants and their test performance for test-validity and reliability assessment purposes.

3.6. Application Scenarios

Ergonomists work in a variety of settings and situations. Moreover, a variety of professions (engineering, hazard/risk control, project management, labor representatives, system operators/maintainers, health-and-safety specialists, etc.) work with ergonomists to develop technological systems. Different systems may also have different emphases on the type of human factors involved. For example, manual systems may be more concerned with musculoskeletal issues, while automated systems may place a greater emphasis on cognitive factors and/or supervisory-decision-aiding. However, the CEA and CPE should be able to transfer their fundamental knowledge and skills in ergonomics to a comprehensive set of work domains.

The CPE and CEA examinations sample from the following list of "system application scenarios":

1. Mobility/transportation systems (ground, water, air and space).
2. Industrial systems (processing, manufacturing, distribution, etc.).
3. Business systems (offices, services, etc.).
4. Communication systems.
5. Information management systems/computers.
6. Educational systems (instructional systems design).
7. Regulatory/legal systems.
8. Consumer systems.
9. Military systems.
10. Architectural systems.
11. Healthcare systems.

The application of ergonomics will be similar in all these systems to achieve:

1. Reasonable performance (human and system).
2. Reasonable workload.
3. Reasonable health maintenance.
4. Reasonable hazard control and risk management.
5. Reasonable cost/benefit ratios.

3.7. List of Books for Core-Topics Review

The purpose of providing a list of references is to assist applicants in their study preparation for the BCPE examinations. *The suggested references cited herein are not intended as an all-inclusive and complete list; rather, they are provided to enable applicants to direct their study efforts to the subject areas covered in the examination.* The books are general references that address specific system applications at various levels of depth. Consequently, there is

overlap among the topics they cover. Many of the books are available in public, university and/or employer libraries.

The Test Development Working Group of BCPE uses the book list as some authoritative resources for determining appropriate answers to questions and scenarios contained in the BCPE written examinations. That does not mean that test items are directly derived from those books. Test items are a representative sample of core knowledge and skills which ergonomists/human factors personnel working at the various certification levels should be able to demonstrate in writing. The books only provide the current, scientific basis for the needed knowledge and skills. Later editions of a given book generally incorporate advances in the science and/or technology of the subject matter covered.

3.7.1. Preparation for the CEA written examination

The following annotated bibliography is provided to facilitate review of the knowledge-base-of-ergonomics data, methods and techniques germane to the CEA level of practice:

- BAILEY, R.W. 1989, *Human Performance Engineering* (2nd ed.) (Englewood Cliffs: Prentice-Hall; 3rd ed. in press).

This book can be categorized as covering cognitive ergonomics. The system focus is on human–computer–environment performance and the analytical, design and test/evaluation methodology available to create user-centered work systems. In the words of the author: "The primary purpose of this book is to provide designers, particularly those with limited background in psychology, with some knowledge of how people sense, process information, and respond; as well as to introduce data, principles, and methods that are useful in eliciting an acceptable level of human performance in systems."

- CHAPANIS, A. 1996, *Human Factors in Systems Engineering* (New York: Wiley).

As the title implies, this book shows how to integrate human factors into the design of tools, machines, and systems so that they match human abilities and limitations. Unlike virtually all other books on human factors, which leave the implementation of general guidelines to engineers and designers with little or no human factors expertise, this book shows the reader how to prepare project specific system requirements that engineers can use easily and effectively. Additionally, it fully explains the various work products — the standards and specifications — that engineers must produce during development, and shows what human factors inputs are required in each of them.

- EASTMAN KODAK CO. 1983, *Ergonomic Design for People at Work*, vol. 1 (New York: van Nostrand Reinhold).
- EASTMAN KODAK CO. 1986, *Ergonomic Design for People at Work*, vol. 2 (New York: van Nostrand Reinhold).

These are definitive works on industrial human factors/ergonomics. Volume 1 is directed to a practical discussion of workplace, equipment, environmental design and of the transfer of information in the workplace. The second volume includes guidelines for job design, manual materials handling, and shift work.

- KROEMER, K.H.E. and GRANDJEAN, E. 1997, *Fitting the Task to the Man*: *A Textbook of Occupational Ergonomics* (5th ed.) (Philadelphia: Taylor & Francis).

This book is similar to the Kodak books, but has a greater emphasis on work physiology and how to use technology to overcome the stresses and strains of work systems. This popular

book provides a comprehensive introduction to the field of ergonomics. Human physical and mental characteristics, anthropometry, workplace design, heavy physical work, control/display design, work hours and shifts, noise and vibration, and many additional topics are addressed.

- KONZ, S. 1995, *Work Design*: *Industrial Ergonomics* (4th ed.) (Scottsdale: Gorsuch).

This book bridges industrial engineering concepts/methods and ergonomics by providing specific guidelines for human-centered design of jobs. In 34 chapters the analysis, design and evaluation issues for enhancing human performance, workload, safety/health and economic value of production systems are covered with examples drawn from typical manufacturing domains. The 4th edition has extensive coverage on cumulative trauma and manual material handling (including the NIOSH lifting guideline). Chapter 12 gives guidelines for reduction of human error.

- SANDERS, M.S. and MCCORMICK, E.J. 1992, *Human Factors in Engineering and Design* (7th ed.) (New York: McGraw-Hill).

This is the "classic" textbook in the USA for upper-division and graduate level ergonomics/human factors courses. Its previous editions span a period going back to 1957, and it has also become an important resource for practicing professionals in ergonomics/human factors. The book stresses basic concepts, with an empirical research basis, for ergonomic systems development, and provides numerous references to the scientific literature for those who want to delve deeper into a particular topic area.

- WICKENS, C.D, GORDON, S.E. and LIU, Y. 1998, *An Introduction to Human Factors Engineering* (New York: Addison Wesley Longman).

Although it uses the term "human factors," this book comprehensively spans all the topics covered in the BCPE ergonomist formation model. The authors also cite most of the other books listed by BCPE for review by CEA candidates, although those may have somewhat different emphases on various topics covered. In 19 chapters, the general aspects of work systems design methodology and principles are discussed. The writing style is excellent for comprehending the balance needed in using technologies with a human factors focus in different aspects of system and human performance development. From research methods to application domains, performance, safety and health criteria are introduced based on the most current consensus among researchers and practitioners in ergonomics.

In conclusion, these books can serve as a "refresher" to ergonomics for those who have had formal education and training in ergonomics. Trying to study them all two months before the written examination is likely to create high stress with little payoff in knowledge gained.

3.7.2. Preparation for the CPE/CHFP written examination

While the list of references suggested to review for the CEA examination discussed above provides fundamental data, guidelines and methodologies, the following book list spans ergonomics topics to a greater depth and/or more complex relationships among tasks, tools, talents and technology found in modern work science and systems. These books have been,

and continue to be, the most often cited for graduate course work in ergonomics/human factors.

- BOFF, K.R. and LINCOLN, J.E. (eds) 1988, *Engineering Data Compendium — Human Perception and Performance* (Wright Patterson Air Force Base, OH: Harry G. Armstrong Aerospace Medical Research Lab).

In three volumes, the *Engineering Data Compendium* (a) identifies and distills information of value to system design from the existing research literature on human perception and performance, and (b) presents this technical information in a way which is accessible to engineers working in harmony with ergonomists who can interpret the information and judge its applicability in system analysis, design and/or evaluation processes. Topics covered are:

- Visual acquisition of information.
- Auditory acquisition of information.
- Acquisition of information by other senses.
- Information storage and retrieval.
- Spatial awareness.
- Perceptual organization.
- Attention and allocation of resources.
- Human language processing.
- Operator motor control.
- Effects of environmental stressors.
- Display interfaces.
- Control interfaces.

- BOOHER, H.R. (ed.) 1990, *Manprint: An Approach to Systems Integration* (New York: van Nostrand Reinhold).

This book outlines a comprehensive approach to work science and systems development that enables organizations to convert "equipment-dominated" mindsets to those that are more 'people-oriented.' The concepts and theories of economics, ergonomics, engineering and business management are integrated to show a relationship to quality performance and human well-being needed for a rapidly changing global marketplace.

- CHAFFIN, D.B. and ANDERSSON, G.B. 1991, *Occupational Biomechanics* (2nd ed.) (New York: Wiley).

This book reveals how to work and how to design work tools to prevent musculoskeletal disorders and improve manual (physical effort) working conditions for optimal productivity and safety. Based on solidly scientific research findings, the topical structure of this new edition examines:

- Structure and function of the musculoskeletal system.
- Anthropometry in occupational biomechanics.
- Mechanical work-capacity evaluation.
- Bio-instrumentation in occupational biomechanics.
- Occupational biomechanical models.
- Methods of classifying and evaluation manual work.
- Manual materials handling limits.
- Guidelines for seated work.
- Biomechanical considerations in machine control and workplace design.
- Hand tool design guidelines.
- Worker selection and training criteria.

- HAYS, W.L. 1988, *Statistics* (4th ed.) (New York: Holt, Rinehart & Winston).

The behavior of "physical" systems can be described generally by the deterministic mathematics of geometry, trigonometry and calculus.

Because human performance tends to be less predictable and more variable than "machine performance," the mathematical tools of descriptive and inferential statistics play generally a greater role than calculus in ergonomics. This book provides information on elementary probability theory, frequency and probability distributions, measures of central tendency and variability, sampling distributions and point estimation, hypothesis testing (*t*-test, *F*-test, c^2, non-parametric tests, ANOVA, MANOVA, regression analyses, ANCOVA, etc.) which should be part of every professional ergonomist's tool kit. Without knowledge of how and when to use statistics, all ergonomics work becomes only "guess work."

- KARWOWSKI, W. and MARRAS, W.S. (eds) 1999, *The Occupational Ergonomics Handbook* (Boca Raton: CRC Press).

This handbook significantly complements the other books in the list by specifically focusing on the needs of the industrial practitioner faced with issues of physical effort, safety and health, cost/benefit ratio, and regulatory criteria. Nearly 150 international experts in ergonomics have provided their knowledge and skills throughout 111 chapters spanning seven categorical sections:

1. Background.
2. Foundations of Ergonomics Knowledge.
3. Musculoskeletal Disorders — Engineering Factors.
4. Administrative Controls.
5. Organizational Design.
6. Ergonomics and the Working Environment.
7. Applications of Ergonomics in Occupational Settings.

- RASMUSSEN, J. 1986, *Information Processing and Human Machine Interaction — An Approach to Cognitive Engineering* (Amsterdam: Elsevier/North-Holland).

This book provides the concepts and model for an integrated approach to the design of human–machine systems which use advanced information technology for support of human decision making during supervisory control tasks and emergency management. The systems of interest are highly automated and therefore rely more on the cognitive functioning of human operators than on physical functioning and/or effort. The book does not provide specific design methods, but rather a "means-goal" structure which ergonomists can use to create "human-centered" automation.

- SALVENDY, G. (ed.) 1997, *Handbook of Human Factors and Ergonomics* (2nd ed.) (New York: Wiley Interscience).

This "handbook" reads more like a comprehensive textbook with both theoretical and practical knowledge being covered on most aspects of physical, cognitive and socio-technical issues in ergonomics. Sixty chapters, written by more than 100 of the foremost authorities around the world, provide case studies, examples, figures, tables and synopses of the empirical foundations and broad applications of ergonomics/human factors in work systems.

- SIEGEL, S. and CASTELLAN, N.J. Jr 1988, *Nonparametric Statistics* (New York: McGraw-Hill).

The non-parametric techniques of hypothesis testing are uniquely suited to many data of ergonomics/human factors. The tests involved are generally "distribution-free," are usable with simple ranking scales as measures and are suitable for use with

small samples from the total population of interest. The book does a very good job of presenting suitable statistical tests in accordance with various research/evaluation designs involving human performance parameters.

- WICKENS, C.D. 1992, *Engineering Psychology and Human Performance* (2nd ed.) (New York: HarperCollins).

The author states: "I wrote this book because I saw a need to bridge the gap between the problems of system design and much of the excellent theoretical research in cognitive experimental psychology and human performance. … This is not a handbook of human factors or engineering psychology. … The chapters correspond to the flow of information as it is processed by a human being and are not generally organized from the perspective of different system components or engineering concerns." The book is written for: "the student in psychology, … the engineering student, and … the actual practitioner in engineering psychology, human performance, and human factors engineering."

- WOODSON, W.E., TILLMAN, B. and TILLMAN, P.L. 1992, *Human Factors Design Handbook* (2nd ed.) (New York: McGraw-Hill).

Since its publication in 1981, this handbook has become a definitive guide to all aspects of human factors design. This revised and expanded second edition is even more useful for integrating human factors into the design of systems, facilities, equipment, and products to ensure safe and efficient use, and to prevent user error, injury, inconvenience, or dissatisfaction.

The *Handbook* is fully applications-oriented rather than theoretical or tutorial, and recommendations are based on many years of tested usage and effectiveness in the marketplace. It offers guidelines, illustrated with nearly 500 diagrams, checklists, charts, and tables to help the user interpret and apply key concepts and data.

APPENDIX C: SELF–SCREENING FOR BCPE CERTIFICATION ELIGIBILITY

People enter into the practice of ergonomics from a variety of academic backgrounds and occupational experiences. The range of knowledge and skills is from "novice" (people who have attended seminars, short courses and/or technical/trade meeting presentations) to "expert" (people who have received advanced academic degrees in ergonomics and then practiced the career in the real world of work systems). *The Ergonomist Formation Model (EFM)* adopted by the BCPE spans the middle of this broad-range distribution of ergonomics talent. Certification eligibility criteria reflect the topics of knowledge and skills, which together differentiate ergonomics from other career fields and academic disciplines.

As an aide to deciding where any particular individual may fit into the overall ergonomics arena, this "self-screening" score sheet is offered for completion and guidance. More specific information is available in BCPE's *'Candidate Handbook: Certification Policies, Practices and Procedures.'*

A.1.1.Instructions

1. Read over the major categories (lettered) and associate detailed topics (numbered) in the score sheet.
2. Place your score on the line by each topic in accordance with the following "key for point assignments."

Point Assignments:

0 = Never exposed to this topic.
1 = Learned from self-study or "on the job" experience.
2 = Learned from seminars/short-courses/workshops.
3 = Part of my undergraduate program.
4 = Part of my *graduate* program in another field.
5 = Part of my *graduate* program in HF/ergonomics.

3. Compute the subtotal for each category and enter it in the space provided for each category.
4. Compute the grand total and enter it in the space provided.

A.1.2.Interpretation of Scores

The thing to keep in mind for "self-scoring" is that a person qualified in ergonomics will be able to honestly assign some points to each category. The point spread will be balanced across categories and *not* very high in one and very low in another. The latter situation is more indicative of the contributing disciplines to ergonomics than to ergonomics *per se*.

Table 7 provides the score distributions most likely to lead to successful certification for CEA and CPE candidates.

If the grand total falls between 43 and 73 the person should consider the CEA route; if between 79 and 150, the CPE route; those scoring below 43 may be familiar with some aspects of ergonomics, but they should not provide ergonomics services to others. If your score is between the two, 74–78, use your academic background to help you decide — Masters in Ergonomics = CPE; Bachelors = CEA. If more than two categories' scores crossover from CEA to CPE (or vice versa), an indication for lack of depth and/or breadth in ergonomics may be present.

Table 7: Score Distributions CEA and CPE

CATEGORY	CEA	CPE
A	4–6	7–10
B	9–15	16–25
C	9–15	16–30
D	9–15	16–30
E	11–20	21–50
F	1–2	3–5
Grand Total	43–73	79–150

NOTE: 'work' is defined as any purposive human activity requiring effort and skill

Scenario-based Design

J. M. Carroll

VPI & State University, McBryde 660, Blacksburg, VA 24061, USA

Scenario-based design elaborates a traditional theme in human factors and ergonomics: namely, the principle that human characteristics and needs should be pivotal considerations in the design of tools and artifacts. In scenario-based design, descriptions of usage situations become more than orienting examples and background data, they become first-class design objects. Scenario-based design takes literally the adage that a tool *is* what people can do with it, and the consequences for them and for their activities of using it.

1. WHAT SCENARIO-BASED DESIGN IS

In scenario-based design, key situations of use in established work practice are enumerated and described in schematic narratives. Each narrative depicts one or more actors, a defining goal and possibly several ancillary goals, a context of tools and other artifacts, and a sequence of actions and events through which the defining goal is achieved, transformed, obstructed, and/or abandoned. Figure 1 describes the use of a multimedia education system. At an early phase of design, this might be an *envisioned scenario*, vividly conveying a new system concept, or, if this type of system is already in use and being refined, this might be an *observed scenario*, summarizing typical use and current design

Harry is interested in bridge failures; as a child, he saw a small bridge collapse when its footings were undermined after a heavy rainfall. He opens the case study of the Tacoma Narrows Bridge and requests to see the film of its collapse. He is stunned to see the bridge first sway, then ripple, and ultimately lurch apart. He quickly replays the film, and then selects the associated course module on harmonic motion. He browses the material (without doing the exercises), saves the film clip in his workbook with a speech annotation, and then enters a natural language query to find pointers to other physical manifestations of harmonic motion. He moves on to a case study involving flutes and piccolos.

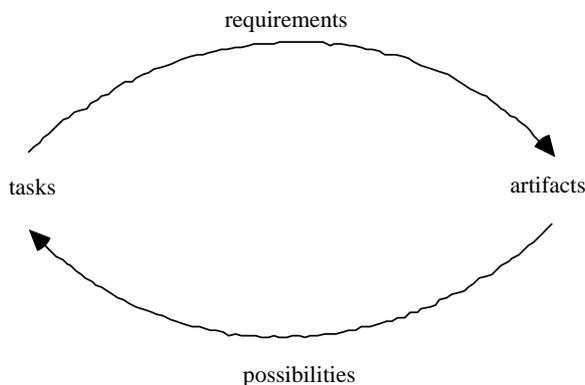
Figure 1. A scenario of use for a multimedia educational system.


Figure 2. The task-artifact cycle. Tasks help articulate requirements for new technology that can support them; designed artifacts create possibilities (and limitations) that redefine tasks.

challenges (for example, how to get users to carry out practice exercises). In either case, the scenario guides the development of requirements and prototypes, and the specification of system functions. Subsequently, it could guide the development of training and documentation, and the design of evaluation tasks.

The ability of scenarios to depict vividly both current and future situations has encouraged their use as working representations in a wide variety of disciplines, from strategic management and operations research to requirements engineering, object-oriented design, and human-computer interaction. In the main, work and technology co-evolve: people engage in tasks and activities. They make discoveries and encounter difficulties; they experience insight and satisfaction, frustration and failure. At length, their tasks and experiences help to define requirements for future technology. Subsequent technological tools, in turn, open up new possibilities for tasks and activities, new ways to do familiar things, and entirely new things to do. They entrain new skills to learn and perform, new opportunities for insight and satisfaction, and new pitfalls of frustration and failure. Ultimately, the new tasks and new technology become a new baseline, helping to evoke requirements for further technology development. Scenarios have been proposed as an integrative representation of work and technology for managing this pattern.

2. WHY SCENARIO-BASED DESIGN IS IMPORTANT

Scenario-based design addresses five key technical challenges in the design of technology: Scenarios evoke reflection in the content of design work, helping developers coordinate design action and reflection. Scenarios are at once concrete and flexible, helping developers manage the fluidity of design situations. Scenarios promote work-oriented communication among stakeholders, helping to make design activities more accessible to the great variety of expertise that contributes to design, and addressing the challenge that external constraints designers and clients often distract attention from the needs and concerns of the people who will use the technology. Scenarios afford multiple views of an interaction, diverse kinds and amounts of detailing, helping developers manage the many consequences entailed by any given design move. Finally, scenarios can be abstracted and categorized, helping designers to recognize, capture, and reuse generalizations, and to address the challenge that technical knowledge often lags the needs of technical design.

2.1. Scenarios evoke reflection in design

Constructing scenarios of use as focal design objects inescapably evokes reflection in the context of doing design. The scenario in figure 1 succinctly and concretely conveys a vision of student-directed, multimedia instruction. It is a coherent and concrete vision, not an abstract goal, not a list of features and functions. Elements of the envisioned system appear in the scenario embedded in the interactions that will make them meaningful to people using the system to achieve real goals — perhaps revelatory, perhaps cryptic, but definitely more than just technological capabilities. For example, the role of natural language query is exemplified as a means of locating further case studies that illustrate the principles of harmonic motion.

The scenario emphasizes and explores goals that a person might adopt and pursue, such as watching the film clips twice,

or skipping the exercises. Some of these goals are opportunistic, such as investigating the Tacoma Narrows collapse because of experience with a totally unrelated bridge collapse, or deciding to branch from bridge failures to flutes. The scenario implicitly articulates the usage situation from multiple perspectives: the student stores and annotates a video clip with speech, raising specific requirements for user interface tools and presentation as well as for particular data structures and memory. The scenario impels the designer to integrate the consideration of such system requirements with consideration of the motivational and cognitive issues in education that underlie the person's actions and experiences.

2.2. Scenarios are at once concrete and flexible

Scenarios reconcile concreteness and flexibility. They are concrete in the sense that they simultaneously fix an interpretation of the design situation and offer a specific solution: the scenario in figure 1 specifies a particular usage experience that could be prototyped and tested. At the same time, scenarios are flexible in the sense that they are deliberately incomplete and easily revised or elaborated: in a few minutes, a piece of the scenario could be re-written (for example, stipulating a system-initiated prompt for the associated course module on harmonic motion) or extended (for example, the objects in the scenario could be described as anchors for a variety of link types).

Scenarios embody concrete design actions and evoke concrete move testing on the part of designers. They allow designers to try things out and get directive feedback. But their flexibility facilitates innovative and open-ended exploration of design requirements and possibilities, helping designers to avoid premature commitment.

The power of scenarios to convey concreteness through tentative and sketchy descriptions derives from the way people create and understand stories. Like the strokes of an expressionist painting, scenarios evoke much more than they literally present. The human mind seems especially adept at overloading meaning in narrative structures, both in generation and interpretation, as illustrated by the remarkable examples of dreams and myths. Indeed, dreams and myths are universal tools for coping with uncertainty. Part of their power stems from being recalled and discussed throughout a community. In a more modest scale, design teams do this too: sharing and developing scenarios helps to control the uncertainties inherent in the work, while strengthening the team itself.

2.3. Scenarios promote work orientation

Scenarios are work-oriented design objects. They describe systems in terms of the work that people will try to do as they make use of those systems. A design process in which scenarios are employed as a focal representation will *ipso facto* remain focused on the needs and concerns of prospective users. Thus, designers and clients are less likely to be captured by inappropriate gadgets and gizmos, or to settle for routine technological solutions, when their discussions and visions are couched in the language of scenarios, that is, less likely than they might be if their design work is couched in the language of functional specifications.

Scenarios help to integrate the variety of skills and experience required in a design project by making it easier for different kinds of experts to communicate and collaborate. They support the direct participation of users and other client stakeholders, helping to anticipate organizational impacts of new technology. Scenarios also ease problems associated with handoffs and coordination in the design process by providing all groups with a guiding vision of the project goal to unify and contextualize the documents and partial results that are passed back and forth.

Scenarios directly support the development of summative evaluation tasks. But perhaps more importantly, maintaining work-oriented scenarios throughout the development process allows formative evaluation walkthroughs to be carried out continuously.

2.4. Scenarios have many views

Scenarios are multifarious design objects; they describe designs at multiple levels of detail and with respect to multiple perspectives. A scenario briefly sketches tasks without committing to details of precisely *how* the tasks will be carried out or *how* the system will enable the functionality for those tasks. The multimedia education scenario in Figure 1 is at an intermediate level, with some detail regarding task flow; it could be elaborated with respect to Harry's moment-to-moment thoughts and experiences in order to provide a more elaborated cognitive view, or with respect to individual interactions to provide a more detailed functional view. Alternatively, the scenario could be presented from the point of view of someone watching Harry, perhaps in order to learn how to operate the system. It could be elaborated in terms of hardware and software components that could implement the envisioned functionality in order to provide a system view. Each of these variations in resolution and perspective is a permutation of a single underlying use scenario.

Scenarios can leave implicit the underlying causal relationships among the entities in a situation of use. For example, in Figure 1 the envisioned speech annotation capability allows adding a personal comment without the overheads of opening an editor and typing text. However, the annotation is noncoded, and thus cannot be edited symbolically. These relationships are important to the scenario, but often it is enough to imply them. This is an aspect of the property of being concrete but rough that we discussed above.

Sometimes it is useful to make these relationships explicit. For example, in another scenario Harry may wish to collect and revisit the set of film clips he viewed and annotated as "reakthroughs in forensic engineering". Unfortunately, his noncoded voice annotations cannot be searched by string. Thus, this new scenario would end in failure. To understand and address the variety of desirable and undesirable consequences of the original annotation design move, the designer might want to make explicit the relevant causal relationships in these two scenarios. Doing so provides yet another view of the envisioned situations, as shown in Figure 3.

Scenarios help designers manage trade-offs. For example, the data structures for the workbook might differentiate between annotated and non-annotated items, allowing annotated items to be retrieved and browsed as a subset. This would not allow Harry to directly retrieve the set of items with a particular annotation, but it would still simplify the search. Alternatively, the search problem might be addressed directly by speech recognition or audio matching, or by including the option of

A video clip of the Tacoma Narrows Bridge collapse

        motion
    evokes curiosity and self-initiated learner exploration
    but may not sufficiently motivate a learners to attempt the course
        module
Speech annotation of a saved video clip
    allows easy attachment of personal metadata
    but does not support indexing or search of metadata

Figure 3. Consequences associated with the orientational video clip and the speech annotation capability in the multimedia education scenario.

text annotation. Each of these alternatives would entrain different elaborations for both the annotation scenario in Figure 1 and the search scenario discussed immediately above. These elaborations could then be explored for further consequences and interdependencies.

2.5. Scenarios can be abstracted and categorized

Scenarios exemplify particular themes and concerns in work and activity situations. Earlier we discussed two scenarios for a multimedia education system. In one (Figure 1), a person is at first opportunistically exploring an information structure, but eventually adopts a particular interest that guides his exploration. In the other, a person wishes to search and organize information that has previously been browsed. Described at this level of generality, these are not scenarios unique to multimedia education systems, or even to computers. They are general patterns for how people work with information. Therefore, it is likely that some of the lessons learned in managing the "opportunistic exploration" pattern or the "searching under a description" pattern in the design of any given situation might be applicable in the subsequent design of other situations. Such a taxonomy of scenarios provides a framework for developing technical design knowledge.

Scenarios can also be classified in terms of the causal relations they comprise. In Figure 1, for example, providing speech annotation simplifies the actions needed to personalize a piece of information. In this causal relation, the consequence is the simplification of organizing and categorizing — a general desideratum in designing interactive systems. Generalizing the relation in this way allows the feature associated with the consequence (in this example, speech annotation) to be understood as a potential means for that consequence, and employed to that end in other design contexts. There is of course no guarantee that the generalization is correct; that can only be settled by trying to use it and succeeding or failing. The point is that such candidate generalizations can be developed from scenario descriptions.

The generalization of the causal relations comprising scenarios can also be carried out across features: speech annotation of data helps people to create a personalized view of their information. But this relation holds independent of whether the data is annotated by speech, by text, or by handwriting. Understanding the relation more generally allows designers to consider any medium for annotation as a potential means of facilitating a personalized data view.

Scenarios can also be taken as exemplars of model scenarios; for example, Figure 1 illustrates a model of opportunistic control.

Harry pursues the link from bridges to piccolos, because that is the aspect of the information that interests him. The system was designed to support this style of use; to that extent it embodies a model of opportunistic control. Other models are possible of course; many instructional systems would require a student to complete the current module before allowing a branch to related material in some other module. Seeing the scenario in Figure 1 as an opportunistic control scenario allows the designer to benefit from prior knowledge pertaining to this model and to contribute further design knowledge of the model based on the current project.

3. WHERE SCENARIO-BASED DESIGN IS GOING

Scenario-based design provides a framework for managing the flow of design activity and information in the task–artifact cycle. Scenarios evoke task-oriented reflection in design work; they make human activity the starting point and the standard for design work. Scenarios help designers identify and develop correct problem requirements by being at once concrete and flexible. They help designers to see their work as artifacts-in-use, and through this focus to manage external constraints in the design process. Scenarios help designers analyze the varied possibilities afforded by their designs through many alternative views of usage situations. And scenarios help designers cumulate their knowledge and experience in a rubric of task-oriented abstractions. This is depicted in Figure 4.

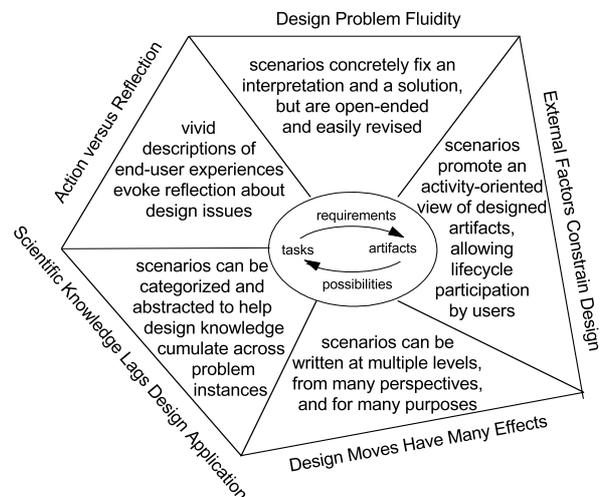
In current practice, scenario-based design techniques are widely used in human–computer interaction. Many new methods for capturing, generating, and classifying scenarios are emerging. For example, scenarios can be directly negotiated with end-users (participatory design), generated by systematically instantiating the signature phenomena of theories of human activity (theory-based design), or by various heuristic brainstorming techniques, like question generation and analogy. Scenarios can be applied in a wide variety of ways in system development. Besides their direct roles as descriptions of current or envisioned system use, they can be employed as bounding contexts for developing design rationales, for theories of human–computer interaction, and for software development (e.g. as use cases).


Figure 4. Challenges and approaches in scenario-based design.

A key challenge is to leverage this wide variety of scenario-based activity more systematically within the development process. The most promising recent developments involve closer integration of practice in human–computer interaction with the development of standard schemata, and support for libraries and reuse frameworks developed in requirements engineering.

South Africa: Ergonomics Society of South Africa (ESSA)

P.A. Scott and J. Charteris
Department of Human Kinentics and Ergonomics, Rhodes University, PO Box 94, Grahamstown 6140, South Africa

The informal beginnings of ergonomics in South Africa, as in many countries, included both academic and professional endeavors of great relevance. The contributions of early luminaries cannot be documented without risking omission of major contributors, many of whom never used, or may not even have known, the term "ergonomics." Among these, Wyndham and Strydom, applied physiologists working in the human performance laboratories of the Chamber of Mines, stand out as international leaders in the field of environmental adaptations whose work was dedicated to ameliorating working conditions in the world's deepest mines.

Not surprisingly, then, it was at the Human Resources Research Laboratory of the Chamber of Mines that preliminary meetings were held in mid-March 1983 to discuss the formalization of Ergonomics in South Africa. A small group of interested individuals took tentative steps towards establishment of an organization for putative ergonomists. In February of the following year a group met at the Design Institute of the South African Bureau of Standards in Pretoria. Thirty participants from academic institutions, governmental bodies and industry offered insights. A study group comprising mainly of academics and businessmen was set up with Brian Hill acting as secretary and Mike Cooke as draftsman of a Constitution.

In February 1985 the Ergonomics Society of Southern Africa was formally inaugurated at the Council for Scientific and Industrial Research Conference Centre in Pretoria on the occasion of the Society's First Conference "Ergonomics '85." The Keynote Speaker, Stuart Kirk from the UK, leant stature to this early attempt to obtain international recognition in troubled socio-political times. Over 100 delegates attended and about 40 papers were presented. The first AGM was held and the society's first Council was instituted with Tony Golding being the first Chairperson of the society.

For the Second Conference, "esa '86" in April 1986, Cape Town was the venue and although the number of attending delegates drop, about 40 papers were presented covering diverse aspects of ergonomics.

From 1987 to 1994 the fluctuating fortunes of the Society mirrored the political turmoil in the country. Without fanfare, however, the society dug-in and survived. In 1987 "Ergonomics SA '87" was staged in Pretoria, again at the CSIR, its theme, "Consumer Ergonomics." No conference was held in 1988 but a small symposium attracted 30 delegates to the theme "Aspects of Work Stress" in Johannesburg, where 10 papers were read. In May 1989 "ergos '89" was the Society Conference, the venue being the University of the Witwatersrand, Johannesburg.

The next year it was decided to establish the society's own journal, and the first of *ergonomics: SA* was published in 1989. Although the articles have been primarily from local contributors, there have been international authors and the Editorial Board includes international referees. The present emphasis of the journal is to encourage articles on applied ergonomics, specifically based on research conducted in industrially developing countries. From 1989 to 1994 membership dropped to a low of 20. In 1994 under revived administration, taking advantage of a revitalized national milieu, the Fifth Conference "esa '94" was held in Grahamstown. Hal Hendrick, distinguished President of the IEA, was keynote speaker at a poorly attended conference where about 20 papers were read. Jack Charteris was elected Chair and a new look, leaner society with a smaller Council was elected. At this meeting it was agreed to focus on establishing a more solid society within the country and to modify the name of the society to the Ergonomics Society of South Africa (ESSA). The Society's flagging fortunes began to turn around, due particularly to the eventual acceptance by the IEA of ESSA as a Federated Member Society. Pat Scott was elected to represent ESSA at the joint IEA/South American Conference in Rio de Janeiro in 1995. The years 1996–98 saw a steady increase in ESSA membership. Houshang Shahnavaz and Pat Scott ran five successful Roving Seminars to introduce the new ILO/IEA "Ergonomics Checkpoints" and in 1996 the Sixth Conference, "esa '96" was staged in conjunction with the National Occupational Safety and Health Association's Convention NOSHCON '96 at the World Trade Centre in Johannesburg. African ILO representative Joshua Nkurlu delivered the Keynote Address.

In 1998 the society's crowning achievement to date, an international conference under the auspices of the IEA, was held in Cape Town. Some 300 delegates from 41 countries attended this conference, the largest and most prestigious gathering of international ergonomists in the history of Africa. The collated papers delivered at this conference, numbering over 100, were published in monograph form in the volume *Global Ergonomics* (Elsevier, 1998). The society has established criteria for, and given effect to, recognition of professional expertise in ergonomics. To date, nine of its members have been accorded the status of "Registered Ergonomist" in recognition of expertise in, service to, and professional consultative contributions in respect of, South African ergonomics.

Although most of the interest in Ergonomics in South Africa has been in the realms of academe with substantial research being conducted and published internationally, over the last decade of the century there has been a significant increase in an awareness of the benefits Ergonomics within the working environment. This has resulted in the establishment of a number of ergonomics consultancies throughout the country. South Africa, as with all industrially developing countries, needs Ergonomic input and the potential for growth in Ergonomic research and application is enormous, making it a challenging and rewarding field to work in.

Spain: Spanish Ergonomics Association

P. R. Mondelo

Dept. Proyectos de Ingeniería, Institut d'Organització i Control de Sistemes Industrials (UPC), Av. Diagonal, 647, Planta 10, E-08028 Barcelona, Spain

The Asociación Española de Ergonomía (AEE)/Spanish Ergonomics Association is a non-profit organization created in 1988 and is a federated member of the International Ergonomics Association (IEA). The aims of the AEE are:

- to link together all Spanish institutions and individuals working, teaching and researching in the fields of ergonomics;
- to promote ergonomics in Spanish companies and various governmental bodies; and
- to assess, according to the IEA standards, existing or projected ergonomics-related activities within Spain.

To reach these goals, the AEE strives:

- to promote and strengthen the role of Spanish ergonomists at a socio-professional level;
- to develop training curricula in ergonomics for university students (undergraduate, graduate, postgraduate levels), and for the working professionals in the fields relevant to ergonomics (i.e. occupational safety and health);
- to publish and disseminate relevant educational materials and research results; and
- to organize ergonomics-related events, gatherings and presenting awards (like the Annual Preemie National de Ergonomía/National Ergonomics Award).

As an example of current activities, the AEE is today working on the organization of a Federation of Spanish-speaking ergonomics societies that will strengthen ties between Latin America and Europe.

Symvatology: The Science of an Artifact–Human Compatibility

W. Karwowski

Center for Industrial Ergonomics, Lutz Hall, University of Louisville, Louisville, KY 40292, USA

> Theories can only be disproved, they can never be proved.
>
> Sir Karl Popper (1902–95)

1. INTRODUCTION

Ergonomics (*ergon* + *nomos*) or the study of work, as originally proposed by W. Jastrzebowski (1857), defines a discipline with very broad scope, i.e. the wide subject of interests and applications, encompassing all aspects of human activity, including labor, entertainment, reasoning, and dedication. Jastrzebowski divides work into two main categories: the useful work, which brings improvement for the common good, and the harmful work that brings deterioration (discreditable work). Useful work, which aims to improve things and people, is classified into physical, aesthetic, rational, and moral work. According to Jastrzebowski, such work requires utilization of the motor forces, sensory forces, forces of reason (thinking and reasoning), and the spiritual force. The four main benefits of the useful work are exemplified through the property, ability, perfection, and felicity.

Contemporary ergonomics, as proposed by Murrell in 1949 (Edholm and Murrell 1973), is considered an applied science, the technology, or both. Furthermore, ergonomics in the recent years has often been politicized and, as a consequence, is trivialized, at least by some, by projecting its solutions onto a common sense, and by pushing towards proving its immediate usefulness in practice. It should be noted here that practicality is a noble goal (Kotarbinski 1965), and is the subject of praxiology, or the "science of efficient actions," developed by Polish philosopher Tadeusz Kotarbinski. However, given the weak methodological basis of ergonomics, its practical applications often cannot be justified due to lack of objective measures of results.

Owing to its broad scope, contemporary ergonomics also lacks identity, and is often perceived by outsiders as a "discipline of everything that is related to the working environment and which in any way affect the human well-being." That is why the physical therapists, occupational physicians, experimental or cognitive psychologists, industrial hygienists, safety professionals or industrial engineers, have as much to say about ergonomics as the "true" ergonomists, i.e. those who have gained their professional status based on relevant education and training. The former category can be called the "ergonomically oriented professionals," while the latter category is the ergonomists.

2. COMPATIBILITY AND ERGONOMICS

According to the Human Factors and Ergonomics Society (HFES 1999), ergonomics advocates systematic use of the knowledge concerning relevant human characteristics in order to achieve compatibility in the design of interactive systems of people, machines, environments, and devices of all kinds to ensure specific goals. Typically such goals are: improved (system) effectiveness, safety, ease of performance, and the contribution to overall human well-being.

Although a key to the above definition of the HFES is the word "compatibility," in the human factors circles the term compatibility is mainly used in a narrow sense only, and is typically related to the problem of information processing. Specifically, the term compatibility is used in relation to design of displays and controls, such as the classical spatial (location) compatibility, or the intention–response–stimulus compatibility related to movement of controls (Wickens and Carswell 1987).

The use of compatibility in a greater context of ergonomics systems has been advocated by Karwowski and co-workers (Karwowski *et al.* 1985, 1988, Karwowski 1991). Recently, Karwowski introduced the term "human-compatible systems" (Karwowski 1997) to focus on the need for comprehensive treatment of compatibility in the human factors discipline.

The *American Heritage Dictionary Of English Language* (1978) defines "compatible" as: (1) capable of living or performing in harmonious, agreeable, or congenial combination with another or others; and (2) capable of orderly, efficient integration and operation with other elements in a system. Probing further, the word "congenial" is defined as "suited to one's needs, agreeable," while the "harmony" (form Greek *harmos*, joint) is defined as: (1) agreement in feeling, approach, action disposition, or the like, sympathy, accord; and (2) the pleasing interaction or appropriate combination of elements in a whole.

From the beginning of contemporary ergonomics, the measurements of the actual or intended compatibility between the system and the human, and the results of ergonomics interventions were based on those measures that best suited different ergonomically oriented professionals. The measures that have typically been used (both negative and positive) include the specific psychophysiological responses of the human body (for example heart rate, EMG, perceived human exertion, satisfaction, comfort or discomfort), as well as a number of indirect measures, such as the incidence of injury, economic losses or gains, system acceptance, or operational effectiveness, quality or productivity. The ergonomists have accepted that status quo for measurements, as they have not developed a unique measure of the system–human compatibility themselves. This lack of the universal way to quantify and measure compatibility is the very essence of ergonomics identity crisis (Karwowski 1998). That is perhaps, or at least in part, the reason why ergonomics is still perceived today by some (Howell 1986) as highly unpredictable area of human scientific endeavor, with great uncertainty about its future as an independent and unique discipline, if such a status is attainable at all.

3. AN ARTIFACT SYSTEM AND THE ARTIFACT–HUMAN COMPATIBILITY

To introduce the concepts of human-compatible systems, instead of traditional use of the name: "human–machine system," it is proposed here to use the term of an "artifact–human system," resulting from combining two of its integral parts, i.e. the artifact system and the human system, as follows:

artifact system + human system = "artifact–human system."

An "artifact system" is defined as a set of all artifacts (meaning objects made by human work), as well as natural elements of the environment, and their interactions occurring in time and space afforded to us by nature (or God). Owing to its interactions, the artifact system is often a dynamic system with high level of complexity, and it exhibits a nonlinear behavior. A human system is defined as the human (or humans) with all the characteristics (physical, perceptual, cognitive, emotional, etc.), which are relevant to an interaction with the artifact system.

Consequently, instead of the: "human–machine compatibility," it is proposed here to use the "artifact system-to-human system compatibility," or, in short, the artifact–human system compatibility. This notation expresses the premise that it is the artifact system that should be compatible with the human system, and that such compatibility should primarily be assured by design of the artifact system.

It should also be noted that an artifact system and human system are subject to mutual adaptation. In order to survive, biological systems must be adaptable, that is capable of functioning in an uncertain environment (Conrad 1983). The same applies to the artifact system. Adaptation means here an alteration or adjustment by which an individual or an artifact improves its condition in relationship to its environment. Adaptation implies such changes that allow for a system to become suitable to a new or special use or situation. This notion admits that optimal compatibility may be achieved by adaptation (primarily design or learning) of both systems.

4. SYMVATOLOGY

It is clear from the above discussion that we need to develop a new science that will aim to discover laws of the artifact–human compatibility, propose theories of the artifact–human compatibility, and develop quantitative matrix for measurement of such compatibility. Only then, when such measure(s) are available and used to objectively demonstrate the value of ergonomics discipline to the outside world, there can be hope for ergonomics to gain its claim for the independence and uniqueness among other sciences. Shortly, ergonomics needs help from another science that is yet to be developed. This new science is called the symvatology.

Symvatology, is coined by using two Greek words: *sumbatotis* = *symvatotis* (compatibility) and *logos* = *logos* (logic, or reasoning about). Specifically, the new word is the result of joining the "symvato-" (from symvatosis) and "logy" (a combining form denoting the science of).

Symvatology is proposed here as the science of the artifact–human (system) compatibility. As such, symvatology will be the corroborative discipline to ergonomics, in that it will help to build solid foundations of the science of ergonomics.

To optimize both the human and system well-being and their performance, the system–human compatibility should be considered at all levels, including the physical, perceptual, cognitive, emotional, social, organizational, environmental, etc. This requires a way to measure the inputs and outputs that characterize the set of system–human interactions (Karwowski 1991). And yet, we do not know today any more than Jastrzebowski knew when he proposed the science of work, how

to measure the system–human compatibility. Without the ability to identify, evaluate and measure the artifact–human compatibility one cannot claim to improve the system–human well-being and performance. Ironically, today we do not have a matrix for measurement of such compatibility, which is critical to credibility of ergonomics as a discipline.

Furthermore, the goal to measure the artifact–human compatibility can only be realized if we understand its nature. We need to discover and understand the laws governing the compatibility relations between the people and the natural and artificial systems that surrounds them. We need to develop a discipline that will aim to observe, identify, describe, perform empirical investigations, and produce theoretical explanations of the natural phenomena of the artifact–human compatibility. In short, as the above are the elements of any science, we need to develop the new science of artifact–human compatibility.

Given below is the discussion of some critical concepts of this new science that must be further developed and used in order to drive a universal measure of compatibility for evaluation of the artifact–human systems. These concepts include system complexity, incompatibility, entropy, and system regulation.

5. SYSTEM COMPLEXITY

The *American Heritage Dictionary of English Language* (1978) defines "complex" as consisting of interconnected or interwoven parts. Based on our earlier work (Karwowski *et al.* 1988, 1995), the artifact–human system (S) can be represented as a construct which contains the human subsystem (H), an artifact subsystem (A), an environmental subsystem (E), and a set of interactions (I) occurring between different elements of these subsystems over time (t). Further discussion on this subject can be found in (Karwowski 1995).

The set I is viewed here as a set of all possible interactions between people, artifacts, and various environments that are present in a given state of the system. These interactions reflect the existence (or non-existence) of the relationships between the subset of all relevant human characteristics (H), such as anatomical, physiological, biomechanical, or psychological, the subset of characteristics of the artifact subsystem A, and the elements of N, representing the subset of environmental conditions (physical environment, social support, organizational structure, etc.). These interactions also impact the system complexity.

6. MEASUREMENT OF THE ARTIFACT–HUMAN SYSTEM COMPATIBILITY

The compatibility is a dynamic, natural phenomenon affected by the artifact–human system structure, its inherent complexity, and its entropy or the irreducible level of incompatibility between the system's elements (Karwowski 1995).

The structure of system interactions (I) determines the complexity and related compatibility relationships in a given system. Therefore, compatibility should always be considered in relation to the system's complexity. The complexity–compatibility paradigm representation for the artifact–human system is shown in Figure 1.

The system space, denoted here as an ordered set [(complexity, compatibility)] are defined by the four pairs as follows [(high, high), (high, low), (low, high), (low, low)]. Under

COMPATIBILITY	LOW, HIGH ——————— LOW, LOW	HIGH, HIGH ——————— HIGH, LOW

COMPLEXITY

Figure 1. The compatibility-complexity paradigm representation for the artifact system.

the best scenario, i.e. under the most optimal state of system design, the artifact–human system exhibits high compatibility and low complexity levels. It should be noted that the transition from high to low level of system complexity does not necessarily lead to improved (higher) level of system compatibility. Also, it is often the case in most of the artifact–human systems, that an improved (higher) system's compatibility can only be achieved at the expense of increasing system's complexity.

7. COMPLEXITY–INCOMPATIBILITY PRINCIPLE

As discussed by Karwowski *et al.* (1985), the lack of compatibility or ergonomic incompatibility (EI), defined as degradation (disintegration) of the artifact–human system, is reflected in the system's measurable inefficiency and associated human losses. In order to express the innate relationship between the system's complexity and compatibility, Karwowski *et al.* (1988, 1994) proposed the Complexity–Incompatibility Principle, which can be stated as follows: "As the (artifact–human) system complexity increases, the incompatibility between the system elements, as expressed through their ergonomic interactions at all system levels, also increases, leading to greater ergonomic (non-reducible) entropy of the system, and decreasing the potential for effective ergonomic intervention." The principle was illustrated by Karwowski (1995), using as an example of design of the chair and the design of a computer display, two common problems in the area of human–computer interaction. In addition, Karwowski (1996) discussed the complexity–compatibility paradigm in the context of organizational design

It should be noted that the above principle reflects the natural phenomena that others in the field have described in terms of difficulties encountered in human interacting with consumer products and technology in general. For example, according to Norman (1989), the paradox of technology is that added functionality to an artifact typically comes with the trade-off of increased complexity. These added complexities often lead to increase human difficulty and frustration when interacting with these artifacts. One of the reasons for the above is that technology which has more features have also less feedback. Moreover, Norman argues that the added complexity cannot be avoided when functions are added, and can only be minimized with good design that follows natural mapping between the system elements (i.e. the control–display compatibility).

8. ENTROPY

Entropy, related to the probability of an order/disorder, is s useful

concept for analysis of the artifact–human systems, as changes in entropy (disorder) can be measured. The entropy of the universe, which is an isolated system, is continually increasing, that is, the disorder of the universe is increasing. Natural processes spontaneously move from the more ordered to the less ordered (more probable) state. However, the low entropy (or well-ordered systems) can be found in an open or closed system.

As discussed by Silver (1998), life maintains low entropy against the universe tendency to higher level entropy. Furthermore, so called dissipative structures are capable of maintaining their own entropy constant, but at the expense of increased entropy of the surrounding environment (or its part), leading to an increase in the total entropy of the whole system.

Of great importance to the artifact–human systems is that the dynamic equilibrium is more ordered and, therefore, less probable than the normal state. This is because the system in the sate of dynamic equilibrium has lower entropy. Depending on how widely open or isolated the system is, the maintenance of the lower entropy level over time may be more or less difficult.

The earth is an open system. It allows for the exchange of energy and matter. The ordered state survives as long as either energy or material is continuously fed to them. To maintain their equilibrium, living organisms (human system) need an input of material and energy.

Isolated systems are closed to the transfer of matter or heat. Such systems move toward states of higher entropy (lower order) and stop changing when they reach an equilibrium state, characterized by the maximum entropy. This does not preclude local islands of decreasing entropy, but the overall entropy of the closed system (like the universe) always increases (Silver 1998).

9. ENTROPY OF THE ARTIFACT–HUMAN SYSTEMS

The artifact–human systems can be an open, isolated or closed, depending on their purpose, structure, and dynamic state of interactions with the outside environment, which is not always intentional, or where the intentions change. As such, these systems will show changing levels of entropy (or order) over time.

It should be noted here that a change (increase) in incompatibility, which we will denote here as (change in) an ergonomic disorder, that is exhibited by many artifact–human systems, is natural. Such a change follows nature by tending to increase the disorder or increase the system entropy as much as possible. Incompatibility is considered an "attractor," that means a state or phenomenon to which the system will gravitate whatever the initial conditions, or a steady state point at which the system starts (if poorly design to begin with) and where it remains.

As discussed by Karwowski (1995), the entropy of the artifact–human system (S) (system entropy: E(S)) will be modeled using the entropies (E) due to the human-related interactions (H-subsystem), artifact-related interactions (A-subsystem), environment-related interactions (N-subsystem), and time (T). In view of the above, the system entropy E(S) can be defined as a function of entropy of the set of ergonomic interactions E(I) and time (T) as:

$$E(S) = f[E(I), T],$$

where E(S) is an expression of the total system incompatibility with the human.

Since the set of ergonomic interactions (I-subsystem) consists of the possible relations between the subsystem elements of {H}, {A}, and {N}, the E(I), can be expressed as:

E(I) = {E(H), E(A), E(N)},

where E(H) is the contributing entropy due to human subsystem, E(A) is the contributing entropy due to artifact subsystem, E(N) is the contributing entropy due to environmental subsystem.

It should be noted that E(H), or the contributing entropy due to human subsystem, is interpreted here as "the entropy due to natural human limitations, which adversely affect the compatibility of an artifact system with the human characteristics defined by a subset (H)."

The entropy of an artifact–human system (S) depends on the variety and complexity of all relevant interactions for the subsystems H, A and N. Any manipulation of elements of the artifact–human system may result in subsequent changes in the number or structure (or both) of other interactions, and, therefore changes in system entropy.

10. COMPATIBILITY REQUIREMENTS AND SYSTEM REGULATION

In design of human-compatible systems, one must consider the structure of system interactions (I) at the given system level, which induces complexity of that system. It is the complexity of the {A} and {N} subsystem interactions that defines the ergonomic compatibility requirements (CR) of the system. In general, the greater the system compatibility requirements (CR), the greater the need for the ergonomic intervention efforts, called here the system regulation. Therefore, it follows that an entropy of the artifact–environment {A, N} system, or the system regulator, E(R), is also defined by the system's structure complexity.

It should be noted that the optimal (ergonomic) system has minimal ergonomic compatibility requirements, i.e. minimal system incompatibility. In other words, the optimally designed artifact–human system satisfies most (if not all) of the compatibility requirements.

The artifact (A) and environmental (N) subsystems can be regulated (at least to some degree), and are jointly called the system regulator (R). Consequently, the sum of their respective entropies defines the entropy of the system regulator E(R):

E(R) = E(A) + E(N), or equivalently

E(R) = E{(A) + (N)}, denoted as E(R) = E(A,N).

It follows from the above discussion that an entropy of the regulator E(R), also defines the system's compatibility requirements (CR). This is because at any given level of human entropy E(H), the E(R) is directly related to the artifact–human system entropy E(S), which is the outcome of such regulation.

The above can be illustrated as the process system regulation, with E(H) as the system input, E(R) as the system regulator, and the artifact–human system entropy E(S) as the output, with the regulation structure as:

$$E(R)$$
$$E(H) \quad E(S)$$

According to Ashby 's (1964) law of requisite variety, for the

system shown above, the outcome, i.e. the entropy E(S) can be defined as:

E(S) >= E(H) + E(H(R)) – E(R),

where E(H(R)) is the entropy of the regulator (R) when the state of human subsystem (H) is known.

When E(H(R)) = 0, i.e. when the regulator subsystem R={A, N} is a determinate function of the human subsystem (H) functioning under R, the above equation transforms as:

E(S) ≥ E(H) – E(R),

showing that system entropy can be defined as a difference between the human entropy and entropy of the regulator.

The above equation also indicates that system entropy E(S), if minimal at a given design stage (and given the specific value of the human entropy E(H)), can only be further reduced by increasing entropy of the regulator (R). In the context of ergonomics design, this means increasing the current system design complexity. On the other hand, this also implies a need for increasing the system's compatibility requirements (CR).

Following the Ashby's (1964) law of requisite variety, Karwowski (1995) proposed the corresponding law, called the "law of requisite complexity," which states that only design complexity can reduce system complexity. The above means that only added complexity of the regulator (R = re/design), expressed by the system compatibility requirements (CR), can be used to reduce the ergonomics system entropy (S), i.e. reduce the overall artifact–human system incompatibility.

It should be noted that the minimum value of the artifact–human system's entropy E(S)MIN is equal to the human entropy E(H), and occurs when the value of E(R) = 0, indicating the system state where no further system regulation is possible. This is called the ergonomic entropy of the system:

E(S)MIN ≥ E(H), when E(R)= 0.

As discussed by Karwowski *et al.* (1995), the ergonomic entropy E(S)MIN is the "non-reducible" level of system entropy with respect to ergonomic intervention (regulation) efforts. It should be noted, however, that this entropy can be modified by the non-ergonomic means, that is through the human, rather than system, adaptation efforts. This can be done by reducing the value of human entropy E(H), through improvements in human performance and reliability by training, education, motivation, etc.

11. CONCLUSIONS

An artifact system was defined as a set all artifacts and natural elements, and their interactions occurring in time and space afforded to us by nature, and subject to adaptation. The focus of the proposed new science: "symvatology" is the investigation of natural phenomena that characterize the artifact–human system compatibility. The purpose of such investigations is to provide the necessary design knowledge for development of the human-compatible systems (Karwowski 1997). The benefits of such systems have been advocated by the ergonomics/human factors discipline for years.

Symvatology should be a useful science in that it should help to advance the progress of ergonomics discipline by providing methodology for design for compatibility, as well as design of

compatibility between the artificial systems (technology) and the humans. In the above perspective, the goal of ergonomics should be to optimize both the human and system well-being and their mutually dependent performance. It is not enough to assure the well-being of the human, as one must also optimize the well-being of a system (i.e. the artifacts-based technology and nature) to make the proper uses of life (Hancock 1999).

Taiwan: Ergonomics Society of Taiwan

T.–Z. Lee

Ergonomics Society of Taiwan, Department of Industrial Management Science, National Cheng Kung University, Tainan 701, Taiwan

The Ergonomics Society of Taiwan (EST) was founded in February 1993 by more than 150 founding members. Compared with the Human Factor/Ergonomics Society of the USA or the Ergonomics Society of the UK, EST is relatively small and young. Yet, EST is eager to be part of the international ergonomic society.

The purposes of EST are:

- To promote the basic research and practical application of ergonomic knowledge and rules.
- To provide qualified ergonomic services.
- To enhance interaction with international ergonomic society.
- To serve its members by necessary means such as publishing a newsletter and a journal, by holding conferences.

For the past few years, EST has worked hard to serve these purposes. An annual meeting was held regularly with a heavy academic touch. Conferences and workshops were given to academia as well as practitioners. For those activities, EST has been working closely with the National Science Council, Institute of Occupational Safety and Health, and Ministry of Transportation of Taiwan, and of course, with various companies.

To serve the domestic ergonomic society better, the 'EST Bulletin' newsletter is published quarterly. The academic journal of EST *Journal of Ergonomic Study* was inaugurated in March 1999.

The interaction between EST and the international ergonomic society began with Swedish professors Shahnavaz and Winkel in 1993, and continued with scholars from China, France, Japan, Korea, Sweden and the USA. This has been especially because of the Sino-France Joint Conference, which has been held every 2 years in alternating countries.

In October 1995, EST was approved to be a Federated Member of International Ergonomic Association (IEA), and it has maintained its active role ever since. In November 1996, EST sponsored the 4th Pan-Pacific Conference on Occupational Ergonomics, which was an IEA-approved conference.

To keep up with the development of the Taiwanese economy and international trends, the EST will keep on growing and booming.

Task Analysis

L. Ainsworth

Synergy Consultants, Royal Oak Barn, Cumbria, LA11 6QB, UK

1. INTRODUCTION

Task analysis is the study of the tasks that have to be undertaken by individuals or groups in order to achieve particular system goals. Thus, it could be argued that task analysis is almost as old as tasks themselves and certainly the systematic investigations of manual tasks by Gilbreth and others in the early 1900s could be considered as task analyses. However, the term "task analysis" was first popularized within the psychological and ergonomics communities by R. B. Miller in the early 1950s (Miller 1953). Miller considered that all task investigations should start by breaking down a complex task into a series of sub-tasks or task elements to produce task descriptions, consisting of an action verb and a noun, that described each of these task elements. To Miller, task analysis referred to the subsequent methodical examination of these task descriptions. In order to ensure that all the important task features were considered during this process, Miller specifically obtained the following data for each task element:

- Cues initiating the action
- Controls used
- Decisions involved
- Typical errors
- Response required
- Criterion of acceptable performance
- Feedback of task completion

Subsequently, other workers in the field have modified Miller's original approach to suit their own particular requirements. This has meant that the split between task description and task analysis has become blurred, with most workers in the field taking the pragmatic view that task analysis encompasses all aspects of the investigation of task-based performance from data collection through to the analysis of those data.

2. THE PURPOSE OF TASK ANALYSIS

In its simplest form, task analysis merely provides a set of task descriptions that can be used to ascertain whether persons have been provided with the basic control and display facilities to enable the tasks to be undertaken, or to check the accuracy of any operating instructions. However, the real value from task analysis comes from more in-depth investigations that probe into the relationship between various aspects of the task and the psychological/physiological requirements of the person undertaking that task. For new systems this should ensure that all aspects of a task will be designed in a manner that assists the person to operate safely and efficiently, whilst for existing systems, task analyses should identify any task features where there is a potential for human errors or other problems.

There are several task analysis methods that can be used to obtain deeper insights into different aspects of task design and by selecting these carefully, it is possible to address a range of issues, which include:

- Functional allocation
- Design/assessment of interfaces or procedures
- Development/assessment of training
- Human resource planning
- Workload measurement
- Human reliability assessment
- Incident investigation

3. THE TASK ANALYSIS PROCESS

It is appropriate to consider task analysis as a three-stage process, which is preceded by careful planning and preparation, as depicted in figure 1. However, it must also be stressed that task analysis is a highly iterative process in which it is often necessary to amend the approach that is being taken, dependent upon the findings that are obtained.

The main task analysis methods that can be used in these three stages are mentioned briefly below and more detailed descriptions to most of them are given in Kirwan and Ainsworth (1992).

4. DATA COLLECTION

There are three ways by which task analysis data can be obtained; namely the exploitation of existing data, the acquisition of verbal reports, or the observation of task performance. The data sources must be selected carefully to ensure that the data are representative and to reduce bias. If possible, any findings should be verified by using alternative data sources.

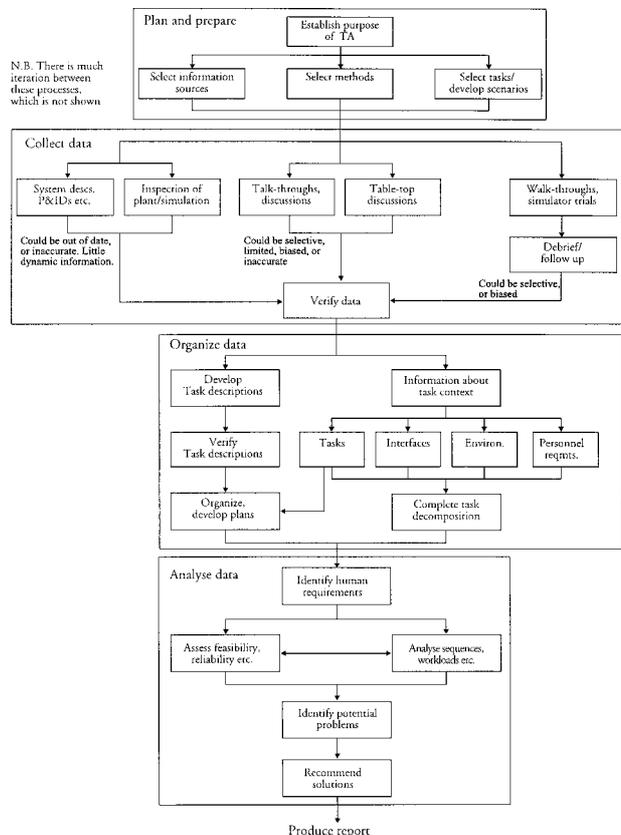
Verbal reports are particularly useful and these range from relatively informal discussions about limited aspects of a task, through to more structured talk-throughs in which a person describes all the steps that would be undertaken in a more


Figure 1.   Task analysis process.

complex scenario or operating procedure, but does not actually undertake any tasks. A slightly higher level of fidelity and realism can be achieved by undertaking a walk-through. This involves asking a person to describe particular tasks whilst walking around a system, or some representation of it, and pointing to the controls and information sources that would be used. The strong visual cues that are available during a walk-through generally mean that the reports can be much more complete and detailed. However, the most comprehensive source of task data will come from direct observations of simulator trials or actual operations.

Another useful source of data for task analyses is a table-top discussion. This is a structured discussion by a selected group of experts, in which an attempt is made to seek out the view of individuals with different technical backgrounds in order to better understanding some of the underlying issues and constraints.

5. DATA ORGANIZATION

During this stage the analyst develops task descriptions and then organizes these and categorizes other task information in ways that are appropriate for systems design or the consideration of human performance. During this process the analyst will apply ergonomics knowledge and past experience from previous analyses to start to develop insights and to identify where additional data may be necessary.

Usually, the main tasks that are being investigated are relatively complex. Therefore, in order to understand them, it is first necessary to break them down into a comprehensive set of smaller tasks that are each more tractable for the analyst to deal with. Thus, data organization begins by developing a set of task descriptions that each describes a specific subtask which is at an appropriate level of complexity for further analysis. These task descriptions can be written by working through the main task and identifying each step in turn, or alternatively hierarchical task analysis can be used.

Hierarchical task analysis (HTA) was originally developed by Annett and Duncan for determining training requirements and a good early account of this approach is given in Annett *et al*. (1971). HTA involves establishing the main goal of a task, then this goal is re-described in greater detail as a small, but all-encompassing set of subordinate goals. This process of re-description continues for these sub-goals until a point is reached beyond which further re-description is deemed by the analyst to be unnecessary. At this point the analyst will have a comprehensive set of task descriptions that have been organized hierarchically. A great advantage of developing the detailed task descriptions in this hierarchical manner is that it assists the analyst to ensure that no important subtasks have been missed, but it does not necessarily mean that the person undertaking the task will develop a mental model of the task that is based upon the same hierarchy. Therefore, if an analyst wishes to show how a set of subtasks might be undertaken, it is necessary to develop an organizing element, or "plan", that specifies the conditions under which each of the sub-goals might be carried out in order to achieve a higher level goal.

When an analyst has broken down a task into a comprehensive set of task descriptions, regardless of how this breakdown was achieved, it is necessary to obtain data for each subtask methodically about specific features that are of particular interest, such as the interfaces that are used, the skills that are required, or the alarms that are given. This process of obtaining specific additional information to supplement each task description is known as task decomposition and the task decomposition categories that are used must be carefully selected to enable an analyst to address the specific issues that are of concern.

Miller's "task analysis" in 1953 was actually a task decomposition in which he proposed that several specific items of information should be collected about each task element by recording particular aspects of task performance or the interfaces that were used. Many other aspects of the tasks can be used as decomposition categories and can be recorded methodically in the same way by directly looking at task performance or various features that are provided. However, decomposition information need not be limited to directly observable features, but can also include inferences about psychological mechanisms that might be made by an analyst, such as estimates of human error or comments about the potential workload.

6. DATA ANALYSIS

When the data associated with each task description have been organized, the analyst can start to identify how well the system supports the person(s) undertaking the tasks and fulfils the human needs that must be met in order to complete the tasks safely and effectively. This will entail first identifying the human requirements, with particular emphasis upon the psychological requirements, such as information processing, decision-making or the likely memory loads. In some cases the analyst will be able to make these judgements directly from the data that are available, but it may also be necessary to transform some of the data in order to identify the salient points.

There are many data analysis methods that can be used during task analysis and most of these have widespread application elsewhere. The approaches to some of the main issues are described briefly below.

6.1 Analysis of the working environment

Where physical factors are of concern, surveys of the environmental conditions or workplace surveys of key dimensions based upon anthropometric requirements, such as desk heights or display positions, can be useful.

6.2 Analysis of information requirements

An analysis of the information requirements can be made to assess the interfaces that are provided, or to identify the knowledge requirements of a task. Such an analysis should consider the information demands placed upon a person and their ability to understand and assimilate the information that they are given. It is also necessary to consider how faults and problems can be detected and diagnosed.

Various charting techniques are useful for examining the information requirements. Where it is necessary to identify the information and control requirements for particular tasks and to establish the interrelationships between tasks, information flow diagrams can be useful. These are also known as decision–action diagrams, because they present complex task sequences graphically in terms of the actions and decisions that are necessary. At the decision elements, these analyses consider all the possible

decisions that may be made, regardless of whether they are correct or appropriate.

Another charting technique that can be useful is a functional flow diagram. These are constructed by identifying the functions and sub-functions that have to be performed and then arranging these as a sequence of blocks that are linked together, using logical gates where appropriate, to indicate the interrelationships between them.

6.3   Analysis of task sequence

Task sequences can be examined in terms of the instruments/ information sources that are used, or communications links, by link analysis. Link analysis was originally used to examine communications or interactions between team members by representing each person on a schematic diagram and then drawing a line between these whenever there is some communication or interaction between particular individuals. This method, which is also known as a frequency link analysis, can be adapted to examine the relationships between different parts of an interface by drawing links between interface items whenever the focus of attention changes. However, this only shows the frequency with which particular interface items are linked, and does not give any information about task sequence.

If information about task sequences is required, it is more useful to undertake a spatial link analysis (which is similar to a spatial operational sequence diagram). In these representations a continuous line is drawn between items as the focus of attention changes. Thus, it is possible to work through the entire task by tracing this line.

Other types of operation sequence diagram can be used to look at other aspects of sequences of task actions. For example, a temporal operational sequence presents different task actions against a timescale, and a partitioned operational sequence diagram shows separate operation sequences for different aspects of a task that might be undertaken together and this can be useful for identifying interactions between them.

6.4   Analysis of temporal requirements and workload

Two important issues that can be investigated by task analysis are how long particular tasks might take and whether a person has the capacity to perform the task reliably. Various timeline techniques can be used to investigate the former, whilst workload assessment is appropriate for the latter. However, in many applications it will be necessary to ensure that a balance is maintained between the time that is taken and the workload that is imposed and so it will be necessary to use the two techniques together.

6.5   Analysis of errors

There are many techniques that can be used to investigate human errors, either by developing quantified estimates of human reliability, or by making entirely qualitative assessments. In either situation, the basic task information will be derived from some form of task analysis.

Task steps where there is a potential for human error are often investigated by using either event trees or fault trees, which show the logical and temporal dependencies between. Another useful technique for identifying potential human errors is a Human HAZOP. This is a table-top method that requires experts to make judgements for each task step about the likelihood of particular types of human errors from a prescribed list.

6.6   Analysis of cognitive processes

It is clear that complex decision-making and other cognitive tasks might be done in different ways on different occasions, even by the same person. Therefore, as well as directly investigating the overt task actions themselves, it is sometimes necessary to examine the underlying cognitive processes that are involved in order to understand the underlying strategies that might be developed to undertake particular tasks.

Several cognitive task analysis methods have been proposed to specifically examine cognitive aspects of tasks. Typical of these are the Generic Error Modeling System (GEMS) of Reason (1987), and Applied Cognitive Task Analysis (ACTA) by Hutton and Militello (1996). Each of these proposes a model of the processes of information handling and the structure of that information in human memory. This is then used as a framework for data organization and interpretation. However, it is also possible to make inferences about the cognitive structure of tasks without using a specific cognitive model. For instance, decision–action diagrams can be supplemented by asking additional questions in order to define the underlying conditions and reasons behind particular decisions.

There is also another central issue concerned with cognitive task analysis, namely how to elicit information about the different approaches that may be taken to a task and the reasoning behind these. These depend upon various knowledge elicitation techniques, such as verbal protocol analysis, which requires operators to verbalize without interruption whilst they undertake a task, or the withheld information technique, which probes into the way that information is used, by forcing persons to make decisions with incomplete information.

Training and Acquisition of Complex Tasks

B. P. Goettl

Air Force Research Laboratory, Lackland AFB, TX 78236-5507, USA

1. INTRODUCTION

Today's systems are more complex than ever before posing monumental challenges for training. Computers can be used to improve training of complex tasks and simulate complex scenarios for the purpose of task rehearsal. They have an inherent appeal and can produce immersion into the training environment. Because of these characteristics, computer-based training systems can give the illusion of training, but without sound learning principles they can be ineffective. Training systems, whether computer based or not, must be founded on empirically derived principles of learning. Here a review of metrics for evaluating training systems will be followed by a short review of training principles and a summary of guidelines and recommendations.

2. TRAINING SYSTEM METRICS

Two metrics of training systems are important in the evaluation of training systems. These metrics include training effectiveness and training efficiency.

2.1. Training Effectiveness

Training effectiveness is defined as training that leads to improved performance. It is usually the metric of interest in training research. This is because the primary goal of training research is often to show that one method of training is more effective than another method. In prototypical studies, the experimental group practices on the training system under development while the control group practices on the criterion task. Both groups are then tested on the criterion task and training effectiveness is measured in terms of performance transfer between the two groups.

The simplest measure of transfer, which Gagne *et al.* (1948) called the *raw score* formula, is simply the difference between the experimental group and the control group on the criterion task. For measures on which poor performance results in large numbers (e.g. response time), the performance of the experimental group is subtracted from the performance of the control group. For measures where poor performance results in small numbers (e.g. percent correct), the control group is subtracted from the experimental group. In this way positive values always reflect positive transfer while negative values reflect negative transfer. The major drawback of this formula is that comparisons between different tasks are difficult and often impossible. A popular method used to compensate for this comparison problem is to divide the savings by the performance of the control group. This *percent improvement* formula is given by the equation:

$$T_{\% \text{ improvement}} = (C_b - E_b)/C_b \text{ x } 100. \tag{1}$$

While this formula normalizes for the performance level of the control group, it does not compensate for different amounts of improvement that are possible for different tasks. For tasks in which the range of performance is small, a small difference between the experimental and control group may be quite meaningful even though the percent improvement is not large. Tasks showing large variance in performance may produce large percent transfer scores even though the changes do not represent meaningful learning effects. To avoid these problems, Singley and Anderson (1989) recommend the *percent learning* formula for transfer. In this formula, transfer is the amount of savings divided by the amount of performance gain by the control group. This measure of transfer is given by the formula:

$$T_{\% \text{ learning}} = (C_{b1} - E_{b1})/(C_{b1} - C_{b2}) \text{ x } 100. \tag{2}$$

Here C_{b1} is the initial performance of the control group on the criterion task, C_{b2} is the performance of the control group following practice on the criterion task and E_{b1} is the initial performance of the experimental group on the criterion task following training. With this formula, negative scores represent negative transfer, positive scores represent positive transfer, and scores > 100 represent a sort of "super transfer" in which the experimental group shows greater improvement than does the control group. A training protocol showing positive transfer that is < 100% may be considered successful if it is cheaper or safer than training on the criterion task, or if it produces additional benefits related to other dimensions of the task.

2.2. Training Efficiency

Training efficiency is measured in terms of training costs. An increase in efficiency is realized when the same level of training effectiveness can be achieved with a training system that is less costly than the system against which it is compared. Cost is measured not only in terms of hardware, software, time and instructor support, but also in terms of safety for the trainees and instructors. While training effectiveness is usually the primary focus of basic research on training, from a practical standpoint, efficiency is often just as important as, if not more important than, training effectiveness. This is because operational training facilities must balance both the cost and the effectiveness of a training system. For example, while time-in-aircraft may be more effective than simulators for training piloting skills, simulator-based training is much less expensive in terms of hardware costs and potential loss of life. Training efficiency can also be realized when trainees share instructional resources without a meaningful loss of training effectiveness, such as when partners alternate practice periods on a training simulator.

2.3. Trade-off Between Effectiveness and Efficiency

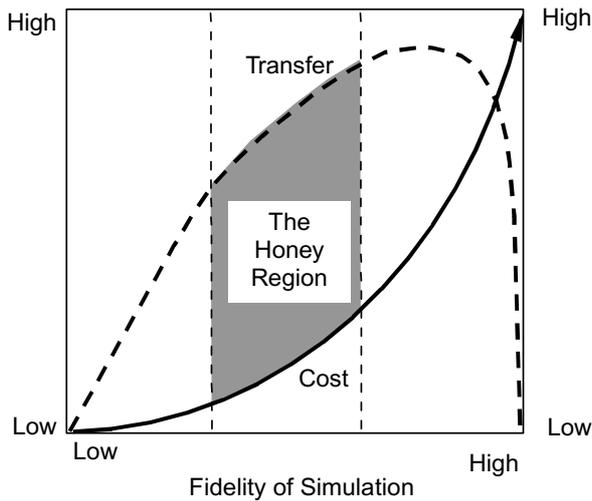
The practitioner needs to find an appropriate balance between the effectiveness of prospective training systems and their associated costs. In the case of pilot training, for example, one must choose between the effectiveness of flight time and the cost efficiency of simulators. Practitioners are often faced with the task of comparing several training systems that differ in effectiveness and efficiency. Training system fidelity often plays a major role in the trade-off between effectiveness and efficient. High fidelity simulators have the ability to allow workers to train in environments that are nearly identical to the operational environment. These simulators are founded on the assumption that the training environment should match the work environment as closely as possible to maximize the transfer. While similarity between the


Figure 1. Training effectiveness and training cost as functions of training system fidelity (adapted from Roscose 1980, exhibit 17.3)

training and work environment can improve transfer, there are many situations in which the operational environment is not an optimal learning environment. In these situations high fidelity training can be ineffective as well as inefficient. For example, Schneider *et al*. (1982) showed that use of operational radar screens for training air traffic controllers to perceive aircraft turn radii is ineffective and costly. Typical aircraft require ~4 min to complete a full turn. Human operators cannot integrate perceptual information across the multiple radar sweeps during this time to produce a meaningful perception of the turn radii. Additionally, when the training proceeds at this slow rate, there is a great deal of training time wasted on a few trials. Compressing the time frame of the perceptual events not only makes the events more perceptible (i.e. effective), but also allows more trials to be presented in a given training session (i.e. efficient).

Roscoe (1980) depicted the trade-off between efficiency and effectiveness as in Figure 1. The dashed line shows the relationship between the amount of transfer from a training system and the fidelity of the system, while the solid line represents the relationship between the cost of the training system and system fidelity. Transfer shows a negatively accelerated relationship with fidelity while cost shows a positively accelerated function. Thus, beyond a certain point, additional costs spent on training systems produce diminishing returns on training effectiveness. Roscoe argues that the practitioner must find the "honey region" that produces the most transfer for the least amount of money.

Principled use of computer-based training can expand the size of the honey region. The increased capabilities of computers along with the development of tutor authoring software expand the honey region by lowering the costs of training systems. Principles of learning derived from well-founded research on training and complex-skill acquisition expand the honey region by increasing the transfer effectiveness of training systems. Principles of learning can also increase training efficiency by determining the dimensions of fidelity that maximize transfer. Focusing costs on those dimensions of fidelity that produce the most transfer can lead to improved training effectiveness and efficiency.

3. PRINCIPLES OF TRAINING

As the discussion above suggests, the effectiveness and efficiency of training systems depend critically on the training principles underlying the training systems. Only when based on principles of training derived from sound empirical studies will training systems produce meaningful transfer *and* cost efficiency.

3.1. Cognitive Task Analysis

To identify critical training needs, one must understand the cognitive, perceptual and motor demands of a task. The first step in understanding these demands is an accurate cognitive task analysis. Cognitive task analysis differs from regular task analysis in that it emphasizes the cognitive, perceptual and motor demands of the task. A good cognitive task analysis does not just indicate what an expert operator does, but how and why the operator does it. As such it forms the basis for identifying the most critical aspects of the task. Once the critical aspects are identified, an assessment must be made about whether the components are trainable. This assessment is critical because training should focus on those critical task components that can be trained.

3.2. Spaced Practice versus Massed Practice

There is a mature literature exploring the relative effectiveness of spaced practice versus massed practice. The bulk of the research shows that practice that is scheduled over several training sessions separated by non-practice periods produces greater acquisition, retention and transfer than training sessions that are not separated by the non-practice periods. The effectiveness of spaced practice has been demonstrated for a wide variety of tasks and for a wide variety of spacing intervals. In general, longer and more frequent spacing between training sessions leads to greater training gains.

There is an abundance of theories of the spacing effect. One class of theories suggests a memory consolidation explanation. These accounts hold that spacing, especially across days, promotes neural processes that serve to strengthen relevant cortical connections and weaken irrelevant ones. Another class of theories holds that the benefits of spaced practice are the result of enriched encoding. That is, spaced practice produces a richer set of encoding cues that promote information access during retrieval. A third class of theories holds that spaced practice, by requiring active reloading of information into working memory, promotes the development of control processes that are used to perform the task. Research is only now beginning to provide empirical comparisons between the theoretical explanations. One prediction that the latter two theories share in common is that the interval between practice periods need not be an empty "rest" interval. This research indicates that filling the interval with cognitive tasks can actually be beneficial.

3.3. Component–based Training

Component-based or part-task training rests on the component fluency hypothesis. This hypothesis assumes that complex tasks can be divided into several components and that efficient performance on the complex task depends on proficiency of the component tasks. Part-task training approaches assume that proficiency on the complex task can be achieved through proficiency on the components. The effectiveness of part-task training depends critically on how the complex task is decomposed and

how the task components interact. One of the more effective methods for decomposing the task is to divide it into different time periods, rather than into components that are performed in parallel. One reason for this difference may be that time-based decomposition keeps the interrelationships between components intact. When parallel components of the whole task are divided into separate components that are practiced individually, the relationship between the components may be lost. Special care must be taken to provide trainees with sufficient understanding of how the components combine and interact in the context of the whole task. This re-integration requires extra effort when parallel components are practiced separately. One way of achieving re-integration is by intermixing component task practice with practice on the whole task. Another way to achieve component practice within the context of the whole task is through *Gopher et al.*'s (1989) procedure of multiple emphasis on components. In this procedure, participants are asked to perform the whole task but are given explicit instructions to focus their efforts on one or two components of the task rather than the whole task. The emphasis is shifted between components throughout training. In this way, trainees focus on component practice but experience how the components interact with each other in the context of the complete task. This procedure may have the additional advantage of training time-sharing skills and attention-switching skills.

3.4. Consistent Mapping

One of the major milestones in training research is the empirical demonstration that the consistency between stimuli and their responses plays a critical role in whether a task can be learned. Schneider and Shiffrin (1977) presented a series of experiments showing the importance of task consistency in training. A task or task component is consistently mapped when the stimulus requires the same response whenever the stimulus is presented. In contrast, when a stimulus is associated with different responses at different times or in different contexts, the stimulus is variably mapped. Research on consistent and variable mapping has clearly established that consistently mapped components and tasks show dramatic improvements in response time and accuracy, indicating learning. On the other hand, variably mapped components show little performance gains, indicating little or no learning. This research has had a monumental impact on training research and applications. Several important training guidelines can be directly derived from this work. A short list of these guidelines is presented below.

3.5. Observational Learning

In the push by instructional designers to individualize instruction, observational learning is at risk of becoming overlooked as a useful training method. There is, however, a place for observational learning in modern training programs including computer-based training. Bandura (1986) proposed a multi-process theory of observational learning that holds that the effectiveness of observational learning depends on how well observers can attend to relevant information, represent the information in memory and produce the modeled responses. Thus, the complexity and salience of the modeled activities influence attention, memory,

and production processes involved in learning. Research on observational learning has shown that when components can be easily extracted and coded, internal models are complete and performance is high without hands-on practice. Recent evidence has expanded the scope of this theory to highly complex tasks, computer-based tasks and operational training centers. The practical appeal of observational learning is that it is an inexpensive training intervention. It can overcome limitations in training budget, hardware, software and manpower. For example, by alternating practice and observation periods on a training task, trainees sharing a single piece of equipment can benefit from modeling each others' behavior while realizing factorial gains in training efficiency.

4. GUIDELINES AND RECOMMENDATIONS

Several training guidelines can be derived from the abbreviated review of research on training presented here. The guidelines presented represent an incomplete list. A more complete list of guidelines is in Schneider (1985). First, practitioners need to consider both the effectiveness and efficiency of training and realize the diminishing returns of increased fidelity. Second, care should be taken to identify those dimensions of fidelity that are most relevant to the operational setting. Third, training should be focused on those tasks that are critical to performance. Fourth, cognitive task analysis has shown promise as a technique for identifying the critical components of tasks and thus should be one of the initial steps in developing training systems. Fifth, practice should be spaced to improve transfer. More importantly, filling the interval between practice periods with cognitive tasks may not be harmful but beneficial. Sixth, component-based training programs hinge critically on accurate identification of critical components. Training should promote an understanding of how the components interact in the context of the complete task. Seventh, training should be designed specifically to promote the development of consistent task components. Finally, social aspects of learning, such as observational learning and modeling, should not be overlooked in the push toward individualized instruction.

United Kingdom: The Ergonomics Society

S.A. Robertson

Centre for Transport Studies, University College London, Gower Street, London WC1E 6BT, UK

1. THE SOCIETY

The Ergonomics Society is the professional body for ergonomists in the UK. It was founded in 1949 as the Human Research Society while a more appropriate name was chosen. And its aim was to foster the interdisciplinary nature of work, because people had realized that a combination of disiplines could achieve more than any individual discipline. Up to 1949 there was no word in common usage to describe such interdisciplinary collaboration.

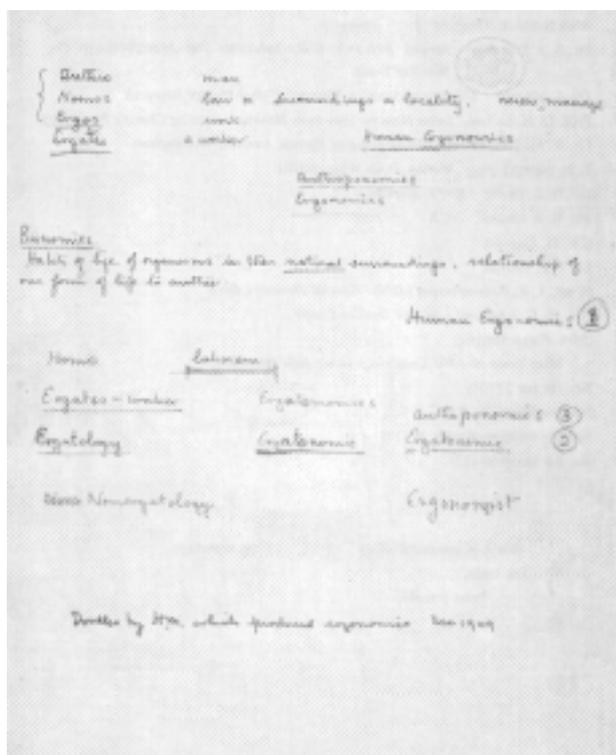
One of the tasks of the early committee was to decide on an appropriate name. A number of suggestions were made, including the Society for Human Ecology and the Ecuminological Society. They even coined a new word æergonomics. Figure 1 shows the original notes made by Murrell when he took part in choosing the name. Eventually the options were whittled down to two, and in a ballot the members chose the Ergonomics Research Society. Not only had a new professional body come into being, but a discipline had been born. In 1977 the society changed its name from the Ergonomics Research Society to the Ergonomics


Figure 1. The development of the word "ergonomics" by K.F.H. Murrell in 1949 (Reprinted, with permission, from Edholm, O.G. and Murrel, K.F.H., 1973, *The Ergonomics Research Society: A History 1949-1970*, Loughborough: Ergonomics Society)

Society, for its members were not only fundamental researchers but also applied ergonomists. In 1991 the Ergonomics Society instituted the grade of registered member, so it could identify competent practitioners.

The society gained strength over the years, and after discussions with Taylor & Francis the journal *Ergonomics* was started in 1957 as its official journal. *Ergonomics* rapidly became a highly respected international journal and was adopted as the official publication of the International Ergonomics Association in 1961.

The Ergonomics Society annual conference is a major event and the scientific papers take a very short time to appear in print. It takes about seven months from submission of abstracts to publication of the proceedings. This makes the annual conference an ideal forum for disseminating cutting-edge research and for researchers to exchange ideas at an early stage of a project. The proceedings have been published by Taylor & Francis as *Contemporary Ergonomics* since 1982.

The Ergonomics Society today has a membership of over a thousand ergonomists throughout the world and maintains a register of professional ergonomists and ergonomics consultancies. Its aims are to promote the awareness, education and application of ergonomics in industry, commerce, the public sector and government, and the public domain in general. The society provides its members with a focus for important matters affecting the profession.

Through various participative committees and interest groups, it addresses short- and long-term issues affecting professional status and the development of ergonomics, including education, practice and legislation. The society represents all these issues both nationally and internationally and coordinates its activities to communicate a cohesive and coherent view of ergonomics to the outside world. It has a growing number of awards targeted at members and nonmembers; details may be obtained from the society.

2. MEMBERSHIP GRADES

To maintain academic standards and to encourage participation from practitioners in fields related to ergonomics, the society implemented a new structure in April 1998. The full professional grade of membership is registered membership, giving the designation Member of the Ergonomics Society (MErgS). This is reached through one of two routes. A graduate member will enter the society having successfully completed a course of study approved by the society and will be eligible for registered member status having gained three years' approved experience after graduating. An associate member who has a qualification which is acceptable to the society but not on the list as a qualification for graduate membership, may attain registered membership on the basis of five years' approved experience.

Associate membership is also open to applicants from related disciplines, such as physiotherapy, but these members would not necessarily be expected to seek promotion to registered membership. Registered members who have contributed significantly to ergonomics and the society may become fellows (FErgS), and honorary fellowship may be awarded to distinguished practitioners and other people who have made special contributions to the society.

The society welcomes new members from the UK and other
countries. Here is the contact address:

United States: Human Factors and Ergonomics Society

Although the origins of the human factors and ergonomics field can be traced to earlier dates, World War II was the key factor in the rapid maturation of the discipline known as human factors engineering in the United States. By the end of the war, a number of centers in the US were involved in human factors research, most of which related directly to military programs and dealt largely with aircraft and electronics equipment design problems. After a wartime program was initiated by Arthur W. Melton, the Engineering Psychology Branch of the Aeromedical Laboratory was established in 1945, with Paul M. Fitts as its chief. Other centers in the United States that were early contributors to the human factors field included the Navy Electronics Laboratory Human Factors Division under Arnold M. Small, the Massachusetts Institute of Technology Radiation Laboratory, the laboratory at Johns Hopkins University, and other universities and government research facilities.

There was little human factors activity, as such, within the aircraft industry during the war. However, a number of individuals were engaged in what was later to be considered human engineering. Most of this activity was concentrated in design organizations labeled as aircraft interiors, furnishings, or cockpit equipment groups. Compelled by the growing complexity of postwar military systems, and stimulated by the pioneering work of government and institutional centers, the aircraft industry began the gradual development of in-house human engineering capabilities.

Much of this work centered in the West Coast, where, in the early 1940s, the Aeromedical Engineering Association was formed as a medium for discussions among engineers, pilots, and physicians. Meetings were held on a regular basis in and around the University of Southern California in Los Angeles. By the mid-1950s most of the major weapon system manufacturers, as well as the military service laboratories, had developed or initiated clearly defined human-factors oriented groups charged with human engineering design or design support functions.

A number of other informal student and professional groups had sprung up around the country by this time, including the Chowder and Marching Club at Ohio State University and the San Diego Human Engineering Society, which formed in 1954. During the 1952 convention of the American Psychological Association (APA), Jack W. Dunlap of Dunlap & Associates chaired a meeting of 45 people to discuss the merit of forming a society and publishing a journal devoted exclusively to human engineering topics. A smaller group met again at the APA convention in 1953. Three more years would elapse before a concerted move was made to form a national human factors society based on the needs and aspirations of a much broader segment of the people engaged in human factors work than that represented by psychologists alone.

In the spring of 1956, Arnold M. Small and Wesley E. Woodson, then with the Convair Division of General Dynamics Corporation in San Diego, dispatched Clair E. Cunningham and Donald W. Conover up the California coast to study the organization of human factors groups within other aircraft firms. Each discussion invariably turned to the desirability of having a national human factors organization. Lawrence E. Morehouse, professor of physical education at the University of Southern California (USC) and the 1956 chair of the Los Angeles Aeromedical Engineering Association, issued a memorandum on 19 June calling for a meeting to consider the establishment of a new human factors organization. The meeting was held in Beverly Hills on 28 June 1956, and resulted in the establishment of a working committee. A follow-up meeting of 100 individuals from Southern California was held in Los Angeles on 25 October, at which time a new organization "The Human Engineering Society" was voted into existence. Morehouse was elected chair pro tem.

In the ensuing months a steering committee consisting of Arnold M. Small (Convair), Lawrence E. Morehouse (USC), Donald W. Conover (Convair), Donald Hanifan (Douglas Aircraft), Wesley W. Woodson (Convair), Stanley Lippert (Douglas Aircraft), John Poppen (an MD and consultant to Douglas Aircraft), Max Lund (Office of Naval Research), Jesse Orlansky (Dunlap & Associates), and Paul M. Fitts (Ohio State University) created the framework for a new organization. The seven committee members from Southern California met in Laguna Beach (halfway between Los Angeles and San Diego) every month or two during the next year to work out the details of what, at the time, was to be called the Human Factors Engineering Society of America. The Human Factors Society of America was voted into official existence on 25 September 1957, at the first official meeting in Tulsa, Oklahoma. About 100 human factors practitioners were in attendance. The name was changed at the 1958 annual meeting to The Human Factors Society, Inc., and then, in 1992, to the Human Factors and Ergonomics Society.

The San Diego Human Engineering Society and the Aeromedical Engineering Association of Los Angeles became the first two local chapters; there are now 36 local chapters and 31 student chapters in North America and Europe. Twenty-one technical interest groups have been formed within the umbrella of the Society, providing further communication links for individuals with similar interests and information needs. Membership in HFES has grown to about 5000 since the first official meeting in Tulsa in 1957, and more than 40 annual meetings have been held around the country since that time. Meetings, held each fall, feature an extensive technical program featuring paper presentations, posters, and hands-on workshops, as well as an annual awards ceremony, exhibits, and technical site tours.

The Society's flagship journal, *Human Factors*, was first published in 1958. *Human Factors* presents original papers of scientific merit that contribute to the understanding of human factors and advance the systematic consideration of human factors. The *HFES Bulletin* has been published monthly since 1959, containing news of conferences, elections, and events within and outside HFES; employment opportunities; editorials; and other items of interest to human factors researchers and practitioners. In 1993, the Society began quarterly publication of an applications-oriented magazine, *Ergonomics in Design. EID* features case studies, interviews, book and software reviews, and editorials. *HFES* has also produced monographs, proceedings

paper compilations, indexes, directories, standards, reports, guides, and videos. Some of the publications will be available online at the HFES Web site, http://hfes.org. In addition, HFES operates an on-line job placement service.

The Society found permanent headquarters in 1964 in Santa Monica, California. It has chapters in the United States, Canada, and Europe, which sponsor local meetings and publications. The Society also has student chapters and 21 technical interest groups.

Universal Design for the Aging

S. Kose

Housing and Building Economy Department, Building Research Institute,
Ministry of Construction, Tatehara, Japan,

1. INTRODUCTION

It is only quite recently that the impact of population aging has gained much attention. What does it mean to our society, and how can we cope with it? What does the expression "universal design" mean in this context, and how can human factors and ergonomics contribute to solve the problems?

2. POPULATION AGING AND DESIGN

Population aging is caused by two major factors: extended life expectancy and reduced birth rate. The means that in developed countries about 80% of populations live to 65 or older — longevity has become a reality due to improved health and medical conditions. Reductions in birth rates result mainly from social attitudes — i.e. the wish of females to continue in work and to have fewer children. In most developed countries, the birth rate is less than 2 per 1000, which means that the total populations of these countries are destined to decrease. Figure 1 illustrates population trends for 65-year-olds and over in selected countries for the years 1950–2050, and shows clearly that in the twenty-first century 20–30% of the populations of developed countries will be in the 65-and-over age group; moreover, the populations of developing countries are following a similar pattern.

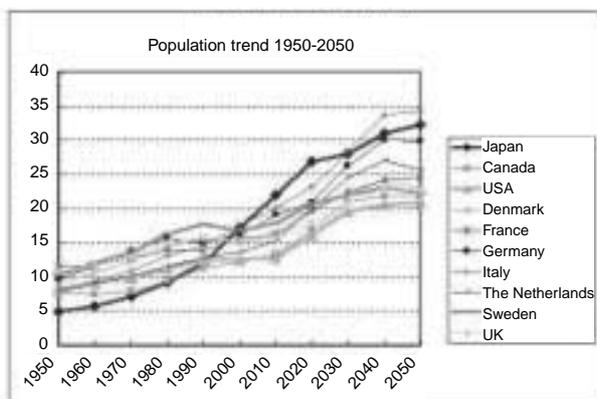
With regard to design, and universal design, since we have to design artifacts, etc., in order to use them, the first question to be asked is: "Who are the users?" Traditionally, we have had average users in mind — both Mr and Mrs Average — and have long assumed that meeting the needs of these average users would suffice. In the past, the few exceptional user groups that designers have specifically targeted have included the disabled. Unfortunately, the aged have been equated with the disabled, and it has been assumed, because only the frail aged were visible, that designs for the disabled would also cover the needs of the aged. But, usually, most of the older members of society who


Figure 1. Population ratio of people aged 65 and over in selected countries 1950–2050
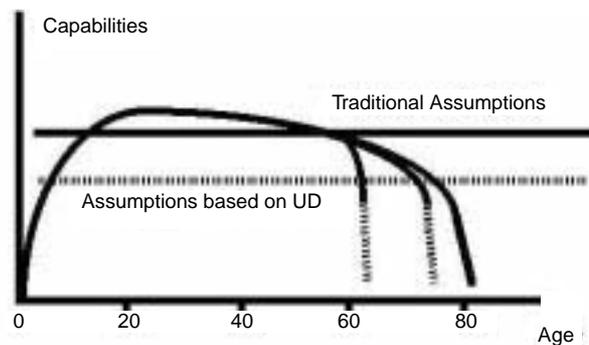

Figure 2. Schematic diagram of the development of human capabilities with age

have none of the apparent problems associated with aging, refuse to admit that they themselves are among the aged.

However, as has already been pointed out, the change in population structure reveals that, by occupying one-fifth or one-quarter of the total population, the aged are no longer a minority group in society but a sizeable segment of it. The problem with this is that the older generation do not necessarily have the capabilities assumed by designers for Mr and Mrs Average, nor can they be equated with the disabled. Figure 2 is a schematic diagram that illustrates reduction of human capabilities with age.

Our capabilities develop from birth onwards so that, between approximately 15 and 54 years of age, we are of "average" or "above average" capability, or at least this is assumed. In figure 2, the upper horizontal line shows what has, in the past, been regarded by designers to be the traditionally accepted level of expectations of capability in the public in general. It does not reveal any critical problems because, until recent years, the 65-year-olds and over occupied only 5% of the total population so that the majority of users were relatively young. Now, however, the situation is completely different, and in order to cover the wider age range, we must lower the line. In other words, we can no longer assume that the majority of people are healthy and robust; the new line has to allow for the changes in the level of capability necessary to accommodate the aging population. How then can we attain this goal of universal design?

3. THE EMERGENCE OF UNIVERSAL DESIGN

The concept of universal design emerged from barrier-free design, which took into account the needs of people with disabilities. The inherent nature of barrier-free design should perhaps have been "design for everybody", but, in reality, barrier-free design provided solutions for people with particular disabilities to offset badly designed products, environments, and systems. Because these have been specific solutions for particular users, they have had no universality. It has been a matter of initial bad designs which then required remodeling — and thus a doubling up on the design contract!

A completely new approach should take into account the needs of *all* users — that is universal design. The idea has long been in existence, but it was not until the Center for Universal Design at the State University of North Carolina issued the "Principles of Universal Design" that the idea received much attention. The message was more evident with the passing of the Americans with Disabilities Act (ADA) in 1990. Although the

rights of people with disabilities are acknowledged, the real pushing force must involve other user groups whose needs differ from those with disabilities.

Design for disabilities sounds too limiting; it also tends to emphasize specific disabilities and can lead to conflict between differing disabilities — for instance, tactile warnings designed to benefit people with visual disabilities can create hazards for people who have difficulty in walking. Universal design tries to solve such contradictions.

The definition of universal design written in The Principles of Universal Design is as follows (Version 2.0, The Center for Universal Design) (please note that no reference is made here to disabilities):

Universal design is the design of products and environments to be usable by all people, to the greatest extent possible, without the need for adaptation or specialized design.

The basis of universal design and barrier-free design therefore is good design — and, in reality, the essence of "design" is to accomplish *good* design.

4. THE ESSENCE OF DESIGN

The essential requirements of good design are: safety, accessibility, usability, affordability, sustainability, and esthetics (Kose 1998, 1999). Among these, barrier-free design emphasizes the first three, while universal design emphasizes the first four. The difference, therefore, is whether or not economic factor is taken into account, and this difference is crucial because, without the support of the general users, designs aimed at all users will not survive in the market. To put it another way, universally designed goods must appeal to the general users, and in particular to the aging population who do not qualify for the legal definition of disabled, or who deny any association with disability, but who suffer from badly designed goods.

Of course, designs suitable for everyone, or to be usable by everyone are goals that are difficult to achieve. What is important is that designers are well prepared from the beginning, and that the effort is sustained to ensure products, environments, and systems are *more* universally applicable in order to cover a larger segment of end-users, with emphasis being given to the aged. It is also important for designers to be prepared to adapt or modify products according to needs.

In addition to this, there will be requests for assistive technologies, designed for special groups. A wheelchair is unnecessary when one can walk; an oxygen container means nothing if one has no respiratory problems (Mace 1998: 25); but these are examples of assistive technologies whose existence are vital for those who need them. However, no one would ever describe them as universal design products. The layers of design policies that are required to meet varying needs are shown in figure 3, and at the pinnacle of the layers lies the support from human resources — personal intervention is often more effective and logical (it would be ridiculous to rely on high-tech devices for everything).

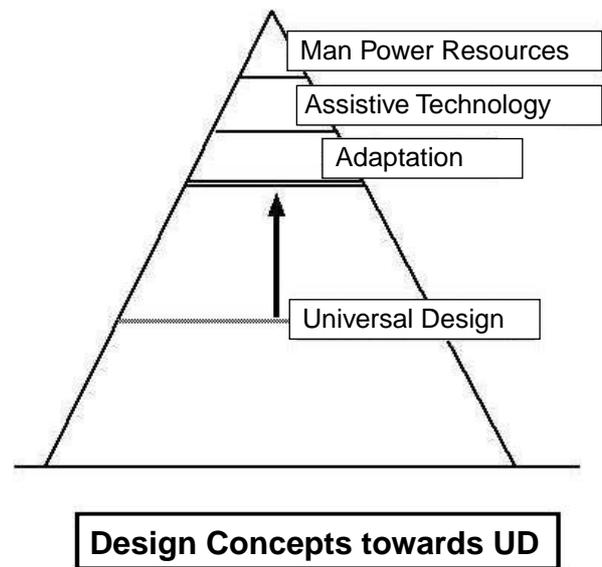
Next, we consider the problem of who will pay and who will benefit. Figure 4 shows the relationships between duration of designed products and environments and their characteristics as to whether they are public goods or private ones. To the bottom left are consumer products and to the upward right are durable goods, then come housing and public buildings, and to the extreme top


Figure 3. Design concepts: universal design and assistive technology

right lie infrastructures such as urban environments and civil structures. Those in the bottom left are cheaper products of short duration that give the users relative freedom of choice: in other words, one can select the most preferred from among the alternatives — for example, the choice of a ball-point pen that best fits one's gripping capacity or a telephone that one can easily dial/push. As one moves towards the top right, opportunities for choice become reduced to the point where it may be that one set of conditions must cover virtually all users — e.g. the railway station must perhaps provide stairs, escalators, and elevators. Nothing can be spared in the majority of cases. The reason for the differences is partly because of the possibilities of providing alternative means, and partly because of the public nature of the designed environments.

5. EXAMPLES OF UNIVERSAL DESIGN CONCEPTS

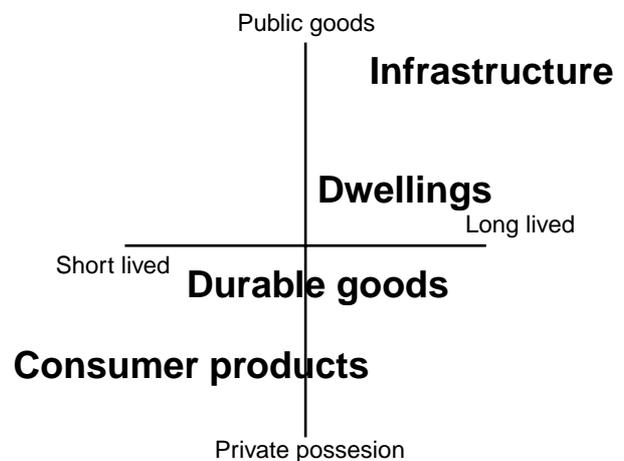
What then are the universally designed products, and what specific requirements does aging put upon us? Microwave ovens, remote controls (for TV, VCRs, etc.), mobile phones, automatic operations in automobiles (such as power assisted steering, power


Figure 4. The relationships of duration and ownership with designed products and environment

windows), and personal computers are all recent innovative technologies that have enhanced most people's lives, including those of the aged and the disabled (see Goldsmith 1997). Microwave ovens assist people by speeding up food preparation and eliminating some of the repetitive work involved; remote controls overcome the distance barrier between the user and the appliance, automatic operations in automobiles eliminate the need for physical strength and simplify adjustments for height and position; while personal computers have simplified communications and empowered people to do many things without undue effort. The crucial point is that such new ideas have integrated universal design features that enable them to be used by everyone — regardless of age or physical ability.

Of course, the design solutions of individual products are not necessarily such that they can be described as of universal design for the aged. Not all remote controls are easy to operate; on the contrary, many are notoriously difficult to use, and VCR timers are among the worst examples of this — it is said that the majority of older people have given up using them. Some of these design errors result from complex operating procedures, while others are due to the alien nature of the products.

6. CONCLUSION

Universal design concepts attempt to solve usage problems by gradual improvements made as a result of user feedback. It is expected that an increased knowledge of the capabilities of older users will add greatly to the improvement of designs — which is where human factors research can make an important contribution. In addition, a cognitive science approach to design (Norman 1990, 1998) will also assist in realizing a better future for all groups of users.

Part 2

Human Characteristics

Alternative Controls

G. L. Calhoun and G. R. McMillan

Air Force Research Laboratory, AFRL/HECP, 2255 H Street, Bd. 33, WPAFB, OH 45433, USA

1. INTRODUCTION

Typically, human interaction with computers involves a keyboard for text entry and a mouse for pointing and selecting text and icons. Trackballs and touch pads are also employed to perform much the same function as a mouse. Each of these controllers involves a manual input. However, there are many alternative controls that have the potential of providing a hands-free means of interacting with computers or computer-based systems. These hands-free controls would be useful for applications in which manual control is less convenient or impossible for the operator to exercise. Examples of the latter include assistive technologies for persons with physical disabilities and instances where operators are required to wear protective gear in hazardous environments, limiting their manual dexterity. Manual control is also not convenient in anticipated wearable computer applications in which a tetherless mobile computer, head-mounted display, and telecommunications systems will allow workers to access information, communicate with others and store information, all while performing their field operations. Even though one-handed keyboards, special purpose mice, trackballs, dials and finger sensors have been designed for wearable computers, there are instances where it is preferable for an operator's hands to remain engaged in their primary task. Use of speech input is one possibility, but is constrained by noise and may not be applicable in some task environments. Non-conventional controllers that do not require a direct mechanical linkage between the operator and the input device are desirable to provide hands-free interfaces that can substitute for or supplement manual control. These emerging hands-free technologies provide operators with a variety of new channels for interacting with computers.

2. CANDIDATE HANDS-FREE ALTERNATIVE CONTROLS

Alternative controls that use signals from the brain, muscles, voice, lips, head position, eye position, and gestures are candidate hands-free means for humans to interact with computers. US Air Force scientists (McMillan *et al*. 1997) have documented a comprehensive description of non-conventional control technology. A NATO Working Group recently reviewed this technology for aerospace applications (Leger 1998). Before discussing application issues for alternative controls, a brief description of several candidate controls is provided below. Each is addressed in more detail elsewhere in this volume.

2.1. Speech-based Control

Speech-based control uses pattern recognition methods to map an input speech waveform into corresponding text or a discrete output. Commercially available speech systems are fairly mature making their application both feasible and cost effective. Despite optimization techniques that can make speech-based control more robust, a key issue is whether speech systems can perform in high and dynamic noise environments (Jennings and Ruck 1995).

Another challenge is efficient dialogue design such that the vocabulary and syntax are manageable, without imposing a great memory load on the operator. Speech-based control must not interfere with operator communications and verbal inputs that can be heard by others nearby must be acceptable in the user's environment.

2.2. Gaze-based Control

For applications in which the operator views a display during control operations, harnessing the direction of gaze promises to be a very natural and efficient control interface. Careful interface design will be necessary, though, to ensure that the operator's head and/or eye movements during task completion are natural and not fatiguing. Rather, natural head and eye movements should be used to provide a direct pointing capability that can be combined with other control modalities to command activation. The task design also needs to take into account the accuracy limits of the gaze measurement system.

2.3. Gesture-based Control

There are a variety of techniques to read hand and body movements directly. Since the body and hands can be involved in other activities, gesture-based control for hands-free computer operation may best involve detecting defined movements or positions of the operator's face or lips. Optical and ultrasonic sensing technologies have been used to monitor an operator's mouth movement. Two candidate control approaches include processing lip movements to provide "lip reading" and translating symbolic lip gestures into control inputs. A related possibility is to employ special mouthpieces, which enable tongue-operated pointing or keypad input.

2.4. Electromyographic (EMG)-based Control

EMG-based control uses the electrical signals that accompany muscle contractions, rather than the movement produced by these contractions, for control. Electrodes positioned on the surface of skin detect these electrical signals (e.g. produced during an operator's clenching of the jaw) and translate them into control inputs. Continued development is required to optimize the signals employed, to assess the stability of the electrode contact over time and to minimize the effect of operator movement and external electrical activity on signal recordings.

2.5. Electro-encephalographic (EEG)-based Control

EEG-based control translates the electrical activity of the brain into a control signal. In one approach EEG patterns are brought under conscious voluntary control with training and biofeedback. Another approach harnesses naturally occurring brain rhythms, patterns and responses that correspond to human sensory processing, cognitive activity or motor control. Although detection of these signals is easily accomplished with inexpensive components, optimization of this alternative control requires minimizing the time required for signal processing and developing easily donned electrodes.

3. APPLICATIONS ISSUES

With perhaps the exception of speech-based control, hands-free alternative controls need further evaluation to specifically assess

their utility for human–computer interface applications (Calhoun and Macmillan 1998). Most are not commercially available and are not configured to facilitate integration with software designed for keyboard and mouse operations. However, given the potential advantages of hands-free control, further research and development are warranted and eventual commercialization is likely. The following are some issues relevant to their application.

3.1. Application Environment

Hands-free alternative controllers need to be operable in the anticipated application environment. Environmental factors include ambient noise, light, temperature, smoke and industrial contaminants. Some controllers (i.e. speech) may not be appropriate when privacy or covertness is a concern. For mobile applications, the input device needs to be operable regardless of operator movement or position and employ wireless transmitter technology as much as possible. Likewise, collaborative use of computing and networking technologies can impact input device choice.

3.2. Target Operator Population

For hands-free alternative controls to be acceptable to any operator population, components need to be lightweight, compact, comfortable and easy to don and doff. Implementation of these controllers will be impacted by whether the general population is targeted or whether the controller can be customized for an individual operator. If the former, the design should assume that the operator has little computer sophistication. For the general population, procedures to employ the controller need to be obvious, natural and amenable to self-training. Likewise, the need for operator calibration and adjustments should be minimized. However, for more specialized military or technical applications it may be acceptable, and even advantageous, to customize the controller and/or utilize a longer training protocol. For example, tailoring signal detection algorithms to an operator's EMG response or training on a speaker-dependent speech recognition system may produce significant long-term payoffs.

3.3. Task Requirements

To date, the control achieved with most hands-free devices can be described as rudimentary. Any application must take into account the limited dimensionality, accuracy, speed and bandwidth of control afforded by these devices. For some applications and target users (for instance, those with severe physical limitations), speed and accuracy of control may be of less concern, since conventional control options are not accessible. Other applications require more rapid and error-free performance. Since hands-free controls do not require associated limb or hand movement, control inputs are typically very rapid, unless lengthy signal processing is required. Rather, it is the precision and accuracy limits of the fundamental human responses and of the controller hardware and software that constrain application. In light of these limitations, efficient procedures are needed for correcting erroneous entries and for safeguarding the system from hazardous control inputs.

The characteristics of the task must also be considered. If the content of the data input is not known in advance, then the input device needs to support arbitrary input. In this case, keyboard surrogates or speech recognizers are likely candidate devices. If the input content is fairly constrained, and user interaction can be reduced to a selection process, then a more limited input device is acceptable. Concurrent tasking must also be considered. If the operator's visual attention is totally occupied by a task, then the use of gaze pointing for control is not appropriate.

3.4. Task–Controller Mapping

In addition to considering the general adequacy of the candidate alternative controls, the specific mapping of the input device to control functions must be addressed. It is unlikely that a single hands-free input device will be adequate for all control functions required in a particular application. A specific input device will be elegantly appropriate for some control functions and clearly inappropriate for others. It is most likely that alternative controllers will be used in conjunction with conventional manual input devices and other alternative controllers. Thus, task–controller mapping must take into account how best to increase overall functionality by using multiple input devices. The following describe some mapping alternatives. Computer-based systems may incorporate more than one of these mapping techniques in the overall control system design.

3.4.1. Single input device mapped to single control function

With this mapping, the "optimal" input device is assigned to each control function. For example, one might use keyboard control for inputting lengthy text information and a hands-free controller for sequencing through display screens or options. The potential advantages of using optimized input devices needs to be weighed against controller cost and potential operator confusion concerning which device to use for each function.

3.4.2. Single input device mapped to multiple control functions

It is doubtful that any hands-free input device will be capable of performing *all* the control functions required for wearable computer operation. To the extent that this can be achieved, controller cost can be reduced. However, the designer needs to avoid the pitfall of compromising overall efficiency for the sake of using fewer devices. For instance, speech-based control currently offers the most capability for this type of mapping. However, use of a speech command to designate a position on a two-dimensional surface can be cumbersome.

3.4.3. Multiple input devices mapped to single control function

Just as operators with desktop computers can navigate with a variety of controllers (mouse movement, arrow keys, tab key), it is possible to implement other computer operations such that several alternative input devices can be used for a single control action. This mapping approach provides the operator with increased flexibility: (1) the operator may have individual preferences for specific input devices, (2) a temporary task or environmental condition may deem one input device more efficient than another and (3) should one device malfunction, the control action can still be performed with another device. Once again, the designer needs to ensure that overall efficiency is not compromised. To map one, less optimal, input device to a control function may require procedures (e.g. a hierarchical menu

approach) that are not optimal for another device (e.g. single speech command). This requires the operator to use different procedures, depending on the active input device, for the same control function. There is a limit, though, to an operator's ability to remember or manage multiple procedural steps.

3.4.4. Mappings that truly integrate multiple input devices

In certain cases a combination of two or more input devices can perform a control function better than either one operating alone. Although little research has been done with integrated mappings, it seems clear that these types of designs will best capitalize on the capabilities of hands-free alternative controls.

One method is to map the input devices to subcomponents of the control action. For example, if hands-free function selection is required, eye gaze can be used to designate a desired control function and a purposeful facial muscle signal can serve as a consent response, commanding the system to act on the function last designated by the eye gaze. It would be difficult to use the individual input devices for this overall function. The use of both input devices capitalizes on the ability of eye gaze to rapidly designate position on a two-dimensional surface and a muscle signal to quickly send a discrete command.

A second method integrates multiple input devices to increase the accuracy or reliability of a control action. For example, the use of lip movement data, together with acoustic signals recorded during voice commands, has been found to enhance speech recognition accuracy in a noisy environment. Similarly, a controller design might require a simultaneous eye blink and muscle signal to minimize the chance of spurious activations.

A third method uses one input device to improve the performance of a second device. For example, eye gaze data might be used to enhance speech processing by restricting the vocabulary search to the most probable verbal commands associated with the current gaze point.

3.4.5. Implicit control and inferencing

The mappings described above focus on applications where controls are used to support conscious and explicit operator actions. Alternatively, these technologies can be used to support implicit actions in which control is largely transparent to the operator. One example is the use of head tracking to change the imagery presented on a head-mounted display in virtual reality environments. Here the controller is responding to an essentially subconscious act of the operator. A suite of alternative controls, coupled with inferencing software, may one day support even higher level implicit control. The combined information available from operator monitoring systems may allow a computer-based system to infer an operator's intent or requirements, such that

information presentation and task allocation can be automatically optimized.

3.5. Frequency of Control Input

Application of an alternative controller should take into consideration the anticipated input frequency. For example, just as extended manual keyboard entry can cause carpal tunnel syndrome, frequent use of jaw clenches to activate EMG-based control can aggravate TMJ (tempero-mandibular joint) disorders.

3.6. Control Evaluation

Laboratory evaluation, together with field testing using the target operators, are essential for the design of effective alternative controls and task–controller mappings. Objective measures of performance (e.g. time to activate the device, task completion time and accuracy, and performance on concurrent tasks) should be recorded, in addition to subjective ratings on the usability, satisfaction and learning associated with the candidate controller.

4. CONCLUSIONS

Creative human–computer dialogue design, together with further development of enabling technologies, human factors research, and field testing are required to evolve a system design that exploits the combined potential of conventional and alternative controls. With careful design, there are many advantages to using alternative controls, either individually or as part of a multi-modal interface. Hands-free operation can be realized for many tasks. Given the variety of available input modalities, there will useful options for any special user population (e.g. those with severe physical limitations). Properly implemented, the human machine interface will be more natural and require less training. In many cases, inputs can be made with more speed and accuracy. Given these advantages, alternative controls have great potential to assist operators in benefiting from the full capabilities afforded by computer-based systems.

Anaerobic Threshold

J. L. Smith

Department of Industrial Engineering, Texas Tech University, Lubbock, TX 79409-3061, USA

Anaerobic threshold (AT) has been defined in several ways, with the most accepted definition being "that point at which blood lactate begins to increase beyond the basal level." This definition implies that AT is determined through analysis of a series of blood samples taken as the exercise or work bout progresses. Some purists might argue that lactic acid accumulation should be examined in the muscle, rather than waiting for lactate to appear in the blood. At the other end of the spectrum, are the non-invasive measurement advocates who recommend that AT be defined by changes in respiratory parameters. The most commonly observed respiratory parameter used to determine AT is the non-linear increase in pulmonary ventilation. Software programs are available to predict AT from respiratory parameters, or the respiratory data can be plotted and determined by fitting two lines to the data and looking at their intersection point (figure 1). There are inaccuracies associated with the graphical analysis of respiratory parameters, but such a method is much less risky than one requiring blood sampling. AT is normally reported as a percentage of VO_{2max}.

Why is AT of interest to the ergonomist? It represents the point at which physiological fatigue is to be expected and where some sort of work–rest scheduling might be required. For untrained individuals, AT typically occurs at ~50–60% of VO_{2max}. With training, not only does the threshold to lactic acid increase, but also the onset of lactic acid accumulation occurs at a higher percentage of VO_{2max} (up to 80–85% of VO_{2max} in highly trained athletes).

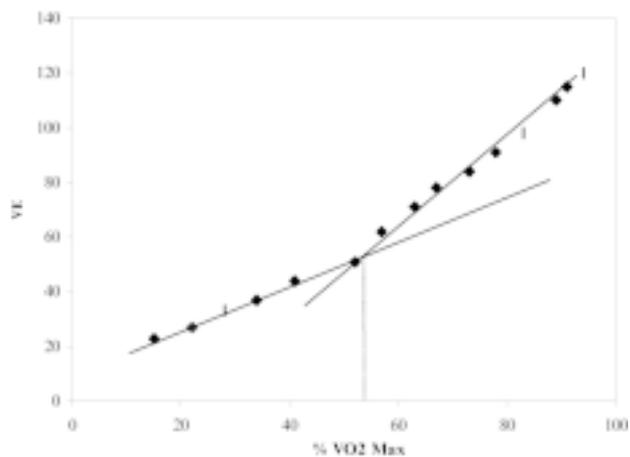
Most ergonomics references recommend that physiological limits for work activities be set at 33% of VO_{2max}. If such recommendations are heeded, then a "safety margin" should exist between the recommended limit of 33% of VO_{2max} and AT, which


Figure 1. Graphical determination of anaerobic threshold

could be expected to occur ~50–60% of VO_{2max}. For most whole-body type activities, where large muscle masses are utilized, the worker would likely exceed the 33% of VO_{2max} recommendation before reaching his/her anaerobic threshold. Proper ergonomics guidelines should call for a "rest break" for workers exceeding 33% of their physiological capacity.

AT is probably of more interest to the ergonomics researcher than to the ergonomics practitioner. For the researcher interested in the development of work–rest schedules, AT provides information related to the physiological limits of work that require no special "rest breaks." Therefore, the ergonomics researcher would like to have knowledge of AT to insure that physiological fatigue is not accumulating, resulting in performance decrements of the worker.

Anthropometric Databases

R.E. Herron

Department of Ergonomics, Colorado State University, Fort Collins, CO 80523, USA

1. INTRODUCTION

Anthropometry literally means the measurement of humans. Although one can measure humans in many different ways, anthropometry focuses on the measurement of bodily features such as shape and size ("static anthropometry"), body motion, use of space and physical capacities such as strength ("functional anthropometry"). A database is simply a compilation of information, generally used for reference purposes.

There are several types of database in ergonomics. They include: (1) much of the published literature itself, (2) bibliographic aids containing citations, abstracts and indexes to the literature and (3) manuals, guides, handbooks and other compilations that summarize the basic data and methods of the field. Anthropometric databases include all of these formats, but the most widely used are in the form of manuals, guides, handbooks and statistical compilations that attempt to summarize the variability in anthropometric characteristics of different human populations or groups. A new type of anthropometric database — the computer-generated human model — is a rapidly growing phenomenon that is leading to major changes in how anthropometric information is used for ergonomic design and other purposes.

2. HISTORY OF ANTHROPOMETRIC DATABASES

Interest in applying anthropometric data to the design of tools, instruments, equipment and systems has a long history. Early human societies employed folk norms for the design of digging, cutting and shaping tools. Natural units of measurement first developed around the hand, fingers and foot and were not replaced with physical units of measurement until many years later. The systematic collection of anthropometric data on large groups of individuals did not occur until the 18th century with the work of Linne and Buffon. The industrial revolution increased the demand for pertinent body dimensions to meet the needs of such mass markets as furniture and clothing. In 1883 Sir Francis Galton undertook a detailed, quantitative survey of anthropometric and other characteristics of over 9000 visitors to the London Health Exposition. However, it was not until World War II, when the human–technology interface reached new levels of complexity, that the need for better anthropometric data for workstation and equipment design became a major focus of attention. Today, there is no longer any doubt that the wide and constantly growing variety of ergonomic design problems calls for more comprehensive, versatile, parsimonious, valid and reliable anthropometric data sets for use in representing the shapes, sizes and functional capacities of target user populations.

3. HOW ARE ANTHROPOMETRIC DATABASES USED IN ERGONOMICS?

In the majority of real-world ergonomic design applications involving the interaction of humans with tools, instruments and systems, there is a need for information about the population of users. Very often the need is for anthropometric data. Differences in body shape, size and physical capacities are among the most obvious manifestations of human variability. It is clearly apparent that people differ in height, weight and arm length, as well as in the other myriad ways in which body form and function can be measured. A well-designed or selected anthropometric database can provide vitally important information for optimizing the human–machine–equipment or system interface.

Creating or selecting and using an anthropometric database effectively is not a trivial matter. There are many hazards, which can undermine the best intentions of the unwary practitioner. First, one has to define which anthropometric parameters are relevant and necessary. Determining which bodily dimensions are important starts with a clear understanding of the task being performed. Then, the user population must be identified and characterized, in terms of homogeneity (e.g. highly selected astronauts) or the lack of it — heterogeneity (e.g. more diverse assembly line workers), as well as other relevant demographic variables, such as age and sex. An initial search should be made to locate a database that matches the target user population as closely as possible. Unfortunately, although hundreds of anthropometric databases are now available, the prospects of finding a good match (from a valid and reliable source) are not good — due to the wide diversity of today's working population, in terms of racial, ethnic, sex, age, nutritional and other variables. This ever-changing diversity is the source of numerous human factors problems, due to the difficulty in defining exactly what the make up of the civilian population really is. Wide-ranging differences in body shape and size of various ethnic groups are of special significance in the design and manufacturing of products for the global marketplace.

But the current utility of anthropometric databases is not all doom and gloom. Notwithstanding the low probability of finding a close match between existing databases and various target populations, informed and useful compromises can be made. This involves supplementing or adjusting the best available data set, using sophisticated methods for estimating or forecasting, to arrive at a description of the desired design criteria — the range of relevant dimensional measurements which would be expected in the target population. While these strategies can be productive in generating usable and useful anthropometric data for design purposes, a well-conceived and executed methodology is essential. Further details about such matters can be found in the references.

4. WHAT ANTHROPOMETRIC DATABASES ARE AVAILABLE?

There is a vast supply of anthropometric databases on military populations, but unfortunately those on civilian populations are fewer. The main sources of military data are publications of government agencies and specialized centers such as the Air Force, Army, NASA and CSERIAC (Crew Systems Ergonomics Information Analysis Center). Many such publications can be obtained from the National Technical Information Service (NTIS) or the Defense Technical Information Center.

The scarcity of good anthropometric databases on the US civilian population is due to a number of limiting factors: (1) inadequate measurement technologies, (2) costs and (3) logistical

problems — such as difficulty in mobilizing and accessing representative populations. Fortunately, the situation is slowly improving. In the meantime, one can locate the best extant anthropometric databases via the references.

5. WHAT NEW ANTHROPOMETRIC DATABASES ARE UNDER DEVELOPMENT?

Better civilian anthropometric databases, which are more representative of today's diverse population, are on the horizon, largely due to a growing demand for anthropometric data and the continuing evolution of more practical computer-based anthropometric measurement instruments.

These new compilations will go far beyond traditional linear (2-D) dimensional data and include the much more comprehensive and informative multidimensional (3-D, 4-D, etc.), biostereometric data.

The use of a biostereometric approach permits the storing of digital geometric descriptions of entire body forms, i.e. 3-D spatial replicas). These archival databases can be mined for an infinite variety of anthropometric data to meet a wide range of user needs. Another advantage is the ease with which such computer-based compilations can be maintained and up-dated to ensure continuing representative fidelity of the total population and various subpopulations.

6. COMPUTER MODELS OF HUMAN FUNCTIONAL CAPACITIES

Another consequence of using a biostereometric approach to the measurement of body geometry is the development of more realistic, animated human models. Such multidimensional models constitute another type of anthropometric database which is changing how anthropometric data are used for ergonomic design applications. However, the biostereometric data on which these models are based do not yet adequately represent the variations in body geometry and motion patterns which are present in the civilian or military populations. This is largely due to the continuing inadequacies of 3-D scanning methods for gathering the basic body geometry and motion data. As these methods become more cost-effective, portable, faster, user-friendly and technologically sophisticated, the current deficiencies will be overcome.

Ultimately, highly representative computer models can be installed in computer-aided design (CAD) platforms and accessed instantaneously to serve a wide variety of ergonomic design functions. The growing availability of such "virtual humans" can overcome many of the problems associated with current anthropometric databases and help promote the proactive use of anthropometric information for improving the human–machine and human–environment design interface.

7. FURTHER READING

There is an extensive literature related to the subject of anthropometric databases. The references constitute but a small sample of the extant sources. However, they should at least provide a point of entry for obtaining further information about an area of ergonomics which is entering its most exciting phase — when anthropometric databases of realistic, multidimensional, human models are found in the computers of every designer who is concerned with ergonomic design for human use.

Anthropometry of Children

E. Nowak

Institute of Industrial Design, Warsaw, Poland

1. INTRODUCTION

From the design point of view, ergonomics can be divided into three areas, which are as follows:

- environment of work
- environment of the home
- environment of the leisure activities

When we wish to adjust these environments to meet human needs, it is necessary to take into account the age of the person or persons using them. In all these environments anthropometric data of children and juveniles play an important role in the design of toys, interior furnishings and furniture, kindergartens, schools, hospitals, playgrounds, etc.

A young and not completely developed organism is extremely susceptible to the influence of the external environment. Furniture, equipment, and toys, wrongly designed and not adjusted to the characteristics of a young child can result in defective body posture and the establishment of pathological states. In order to prevent this, it is necessary to make use of various remedial measures. Besides providing children with proper medical care and correct nourishment, it is necessary for their development to shape consciously the surroundings, including the world of objects. Correct design, taking note of ergonomic criteria, can facilitate good physical development in a child, while the use of harmonious forms and rational solutions helps to form aesthetic feelings and improve the quality of everyday life. Ergonomic values should be apparent in every object designed and intended for the youngest generation.

Anthropometry is one of the important elements that has an effect upon the ergonomics of the child's environment. It provides data concerning the physical development of children and the changes that take place in body proportions with age. It also provides information about the inter-generation differences in somatic features observed in a given population. This is the so-called phenomenon of secular trend. When this phenomenon occurs in a given population, a designer should use current anthropometric data only. In this respect, the Institute of Industrial Design, among others, specializes in the environmental ergonomics of children and the young people, and conducts research to develop anthropometric data characterizing the basic design requirements of children.

This article describes successive phases of investigation involving Polish children and presents their actual somatic characteristics. It also introduces two-dimensional manikins that illustrate to scale the changing physical shape of a child's body with age.

2. CHARACTERISTICS OF SOMATIC DEVELOPMENT OF CHILDREN AND JUVENILES: DATA FOR DESIGNING

Before a proportionally shaped figure of an adult individual is finally formed, it undergoes many intermediate states, which are characterized by different body proportions. This results from the irregular development of the body systems, such as the skeletal and muscular systems, in particular developmental periods, and different growth rates of individual parts of the body. In relation to adults, newborns and, to a lesser degree, infants have large heads, short necks, long trunks and short limbs, especially the lower ones. In the course of development, from the moment of birth to adulthood, the trunk, already proportionately long in infants, increases to three times its original length. At the same time, the mass of muscles also increases. It is estimated that muscular system increases by as much as 42 times its original size.

Apart from this basic information concerning changes in the structure of the human body, designers need to become acquainted with some of the biological phenomena that are directly connected with physical development. These are secular trend phenomenon, the acceleration process, and the pubertal spurt of body growth.

Secular trend is defined as the sequence of changes of human physical features, which occur gradually from one generation to another, tending in a constant direction. These changes concern mainly stature dimensions — e.g. children are taller than their parents and have bigger body size.

Acceleration of development is understood as the intergeneration speeding-up of biological development and puberty, and thus the earlier arrival of consecutive phases of development. The acceleration of development of the whole organism in every successive generation by comparison to the preceding one initially concerns puberty. One of the manifestations of this period is the so-called pubertal spurt, its characteristic being that the yearly increase in height is greater just before the onset of puberty than previously in both boys and girls.

The observations of Polish anthropologists (Waliszko *et al.* 1980; Charzewski 1984; Hulanicka 1990) prove that in Poland both the phenomena of secular trend and developmental acceleration continue to occur. In Poland, the physical development of children and youth is differentiated and depends mainly on social and economic living conditions. According to Polish anthropologists significant differences in this field can be noticed for particular regions of Poland (Hulanicka 1990). Researches carried out by the Polish Academy of Science indicate that there are significant differences between the physical dimensions of children living in city centers, small towns, and in villages, and that these differences are greatest during the time of the pubertal spurt. For example, 14-year-old boys from city centers are, on average, about 50 mm taller than their peers from small towns, and nearly 90 mm taller than those living in villages. In Poland, the greatest environmental differences are seen in the comparison of physical dimensions of children of the Warsaw intelligentsia to those of children living in villages whose parents have elementary education. At the same time, the results of investigations carried out by Polish anthropologists confirm that the biggest development indices are obtained by children and the young people living in the center of Warsaw. Contrary to West European and American cities, where the intelligentsia live mainly on the outskirts of urban areas, in Warsaw the intellectual elite tends to live in the city center rather than the suburbs. This is the most urbanized area of the city, having the highest number of utility premises (commercial, cultural, and medical). In

Table 1. Annual growth values of stature (B-v) in boys and girls from the big town population in 1966, 1978 and 1992 (in mm)

Age	Boys			Girls		
(years)	1966	1978	1992	1966	1978	1992
7–8	51	44	57	49	54	59
8–9	47	52	46	56	45	56
9–10	57	55	45	57	54	48
10–11	34	44	47	55	73	75
11–12	52	62	88	57	70	63
12–13	64	68	56	66	45	44
13–14	47	88	79	29	38	45
14–15	100	49	51	27	14	18
15–16	43	34	37	6	17	12
16–17	22	15	21	5	10	5
17–18	9	14	12	3	14	5

comparison with other districts and regions of Poland, the center of Warsaw is characterized by having the lowest number of people living in a household, and this contributes to their better living conditions.

Taking this into consideration, the Institute of Industrial Design conducted an anthropometric investigation embracing a selected group of children and young people aged 6–18 years. They represented the environment with the highest living standard and were characterized by the highest index of physical development (Nowak 1993). After comparing the results of investigations obtained in 1992 with those of the years 1966 and 1978 (table 1), it can be seen that in Poland the phenomenon of secular trend, manifesting itself by the regular increase of stature dimensions, continues to occur in both boys and girls.

The greatest differences in the body height of boys between the years 1966 and 1978 were observed at the age of 14 and amounted to 95 mm. The difference between the years 1978 and 1992 was lower (31 mm) and was seen at 12 years of age. However, comparison of the years 1966 and 1992 shows big difference in body height. The greatest increase occurs at the age of 14 and amounts to as much as 105 mm. The increase of stature characteristic in girls show a similar tendency, though it is less marked. The analysis of the yearly increase of stature (B-v) and pubic height (B-sy) defining the length of lower extremities, shows that both characteristics confirm the evident *process of pubertal spurt acceleration*. In boys investigated in 1966 this process was observed between the ages of 11 and 12 years. In girls, the pubertal spurt occurred about two years earlier. Based on these investigations, it is possible to indicate directions for designing:

- since secular changes and developmental acceleration occur in the Polish population, anthropometric data based on investigations conducted in earlier years cannot be used;
- the greatest growth acceleration and activity is seen between the ages of 11 and 14. While designing for this age group, one should be extremely careful and take into consideration up-to-date data.

In order to make up-to-date data accessible to Polish designers the Institute of Industrial Design has developed the so-called target standard. It is based on the anthropometric data of children of the highest indices of development. It is assumed that in the

future children from other environments will draw nearer this standard when their living conditions improve. Table 2 presents the dimensions of the target standard of selected stature characteristics of children and young people aged 6 years and 18 years.

3. TWO-DIMENSIONAL MANIKINS OF CHILDREN: MODELS FOR DESIGN

The following criteria were taken into consideration while preparing the manikins: conformability of functional measurements with current anthropometric data, simplicity of the use of models, of their removal and storing, and the lowest costs of production. In order to meet these criteria it was necessary to reconcile many factors important both for anthropometry and design. It is obvious that even the best model is a static arrangement — it cannot present fully the dynamics of the human body, and especially the dynamics of a child's body changing in the ontogeny. To achieve data synthesis the idea of differentiating manikins in respect of sex was given up. The analysis of the development of body height as well as of other height features of boys and girls indicates that the development of these features of boys and girls up to 10 years of age is similar and that differences of somatic features are statistically insignificant (up to 8 mm) and can be neglected for design purposes (Nowak 1989).

The manikins were not prepared for each age class but were divided into groups consisting of several age classes. It was very difficult to separate the above groups since it was impossible to take into account the dynamics of development with the division resulting from the necessity of designing furnishings separately for children in kindergartens, primary schools and secondary schools simultaneously.

The period between 11 and 15 years of age was the most controversial one. This is a period of rapid changes in a child's body due to puberty. This period differs slightly in the case of boys and girls. The pubescent leap is a sign of puberty and results from the hormonal, functional and morphological changes that are taking place in a child's body in preparation for puberty. Although the pubescent leap is common to both boys and girls, its effects differ in intensity and persistence in individual children.

In the case of boys, the leap occurs on average at the age of 14; it is about two years earlier in girls and less intensive. The differences in dimensions between adult males and females result to a certain extent from the differences of their pubescent leap. Since the girls' pubescent leap starts earlier, it is less intensive and as a result the process of body development is completed earlier. On average, girls reach puberty at the age of 16 and, at the same time, their bodies cease growing; in the case of boy, their development process can continue up to 21 years of age.

In view of this, the groups of boy and girl manikins were divided differently, although the divisions were made according to successive stages of child development. These covered post-infantile age (1–3 years), pre-school age (4–6 years), younger school age (7–10 years), puberty (11–14 years), and juveniles (15–18). This division corresponds with the ages of children attending nursery, kindergarten, primary, and secondary schools. Thus, the following seven groups were selected according to age: I: 1–3-year-old boys and girls; II: 4–6-year-old boys and girls; III: 7–10-year-old boys and girls; IV: 11–14-year-old boys; V: 15–18-year-old boys; VI: 11–13-year-old girls; VII: 14–16-year-old girls.

Table 2. Anthropometric measured data in (cm) of Polish boys and girls aged 6 and 18

Dimension	Boys				Girls			
	6 years		18 years		6 years		18 years	
	percentiles							
	5	95	5	95	5	95	5	95
1. Stature	112	127	168	189	111	127	157	178
2. Eye height	101	114	156	175	100	115	147	161
3. Suprasternal height	89	101	137	156	87	101	127	146
4. Elbow height	69	81	109	122	68	79	101	113
5. Pubic height	57	66	88	101	57	66	83	95
6. Head and neck height	23	25	31	33	24	25	30	32
7. Trunk height	30	38	47	56	29	37	43	51
8. Thigh length	25	33	41	51	25	33	37	47
9. Knee height	28	36	45	55	28	35	42	50
10. Upper extremities length	43	57	71	86	42	56	64	79
11. Arm length	17	23	30	37	17	23	27	33
12. Forearm length	14	20	23	37	17	23	27	33
13. Hand length	11	14	18	21	11	14	16	19
14. Arm overhead reach*	130	152	209	232	126	148	188	214
15. Arm reach down*	42	52	69	82	41	51	65	77
16. Arms span*	92	115	146	176	94	116	134	159

* Measurement taken with the hand clenched.

The set of manikins was prepared using the values of 5th and 95th percentiles, to allow the application of threshold percentiles in design. The set consists of 26 models presented in two views: a side view, where figures are in the sagittal plane, and a top view, where figures are in the transverse plane. Each model gives information on sex, age, and its percentile value. The manikins are made of a stiff material, plexiglass, and in a scale of 1:5, and have holes which enables the placing of the figure in a given position or the movement of a given segment of the body. The manikins are fixed by sticking a compass leg or a pin into a hole on the top of head or on a foot. Movement capacities are possible thanks to holes representing the axis of rotation of the following joints: shoulder, elbow, wrists , hip, knee, ankles, as well as head motions (upper and lower joints of head), neck motions (junction of neck and thoracic segments of spine) and trunk motions (junction of thoracolumbar segment). Flexion and extension movements in all these joints can be obtained by means of the manikin developed in the sagittal plane, while the manikin developed in the transverse plane allows the determination of the abduction and adduction movements of limbs and head movements. The model in transverse plane is a simplified shape of a child's figure seen from above. The left side consists of the shoulder, upper limb and breast; the right side consists of the thigh, hip and abdomen. By rotating the manikin along the axis of symmetry, one can obtain the contour of the whole body. Contours of upper limb and reach dimension are obtained by putting the model into the sagittal plane.

Figure 1 shows the application of manikins in the ergonomic analysis of furniture. If the analysis is undertaken while still in the design stage, this reveals any problems in the functional dimensions of furniture to be revealed and corrected.

Anthropometric Terms

K. H. E. Kroemer

Industrial And Systems Engineering, Virginia Tech, Blacksburg, VA, and Eri, Inc., A Consulting Company, PO Box 3019, Radford, VA 24143-3019, USA

- Anterior — in front of, toward the front of the body.
- Breadth — straight-line, point-to-point horizontal measurement running across the body or a body segment.
- Curvature — point-to-point measurement following a body contour; this measurement is neither closed nor usually circular.
- Circumference — closed measurement following a body contour; hence, this measurement is usually not circular.
- Coronal — same as frontal.
- Depth — straight-line, point-to-point horizontal measurement running fore–aft the body.
- Distal — away from the center of the body; opposite of proximal.
- Distance — straight-line, point-to-point measurement between landmarks of the body.
- Dorsal — toward the back or spine; opposite of ventral.
- Height — straight-line, point-to-point vertical measurement.
- Frontal — in a plane that cuts the boy into fore–aft (anterior–posterior) sections; same as coronal.
- Inferior — below, toward the bottom; opposite of superior.
- Medial — in a plane that cuts the boy into left and right halves; same as mid-sagittal.
- Mid-sagittal — in a plane that cuts the boy into left and right halves; same as medial.
- Lateral — to the side, away from the middle (medial).
- Posterior — behind, toward the back of the body; opposite of anterior.
- Proximal — toward or near the center of the body; opposite of distal.
- Reach — point-to-point measurement following the length of an arm or leg.
- Sagittal — parallel to medial (occasionally used as medial).
- Superficial — on or near the surface of the body.
- Superior — above, toward the top; opposite of inferior.
- Transverse — in a plane that cuts the boy into upper and lower (superior and inferior) sections.
- Ventral — toward the abdomen (occasionally used like anterior).

Anthropometry

K. H. E. Kroemer

Industrial And Systems Engineering, Virginia Tech, Blacksburg, VA, and Eri, Inc., A Consulting Company, PO Box 3019, Radford, VA 24143-3019, USA

While all humans have heads and trunks, arms and legs, the body parts come in various sizes and are assembled in different proportions. The science of measuring human bodies is called anthropometry. It uses special terms and procedures described in the relevant literature. The results of anthropometric surveys are described in statistical terms.

In statistical terms, most body data appear in a normal (Gaussian) distribution. Such data set can be explained by the statistical descriptors *mean* (same as *average*), *standard deviation*, and *range*, if the sample size is large enough. Misunderstanding and misuse have led to the false idea that one could "design for the average" (see the chapter on Engineering Anthropometry). Yet, the mean value is larger than half the data, and smaller than the other half; consequently, the "average" does not describe the ranges of different statures, arm lengths, or hip breadths. Furthermore, one is unlikely ever to encounter a person who displays mean values in many or all dimensions. The mythical "average person" is nothing but a statistical phantom.

For more information see Roebuck (1995) and Kroemer (1999).

Body Sizes of US Americans

K. H. E. Kroemer

Professor Emeritus of Industrial and Systems Engineering, Virginia Tech, Blacksburg, VA, USA

The most recent and complete set of information on the body sizes of US Americans, 19 to 60 years of age, is presented in the following table. It contains measurements in mm (weights in kg) taken by Gordon, Churchill, Clauser and co-workers in 1988 (reported 1989) on US Army soldiers, male and female. Their dimensions are close to those of the civilian population which has not been measured comprehensively for decades.

The commentary identifies the measurements and their design implications. The numbers in brackets are the same as used by Gordon et al. (1989), who also provide exact definitions of the anthropometric terms. However, in order to apply this information for design, the data must be converted to reflect actual body positions and motions instead of the standardized postures (all body angles at either 0, 90, or 180 degrees) which the subjects assumed for the measurements. Furthermore, allotments must be made for clothing, shoes, gloves, and other ''real world'' conditions (see this volume, Engineering Anthropometry).

1. Stature

The vertical distance from the floor to the top of the head, when standing. [99]

A main reference for comparing population samples. Relates to the minimal height (clearance) of overhead obstructions. Add height for more clearance, hat, shoes, stride.

2. Eye height, standing

The vertical distance from the floor to the outer corner of the right eye, when standing. [D19]

Origin of the visual field. Reference point for the location of vision obstructions and of visual targets such as displays; consider slump and motion of the standing person.

3. Shoulder height (acromion), standing

The vertical distance from the floor to the tip (acromion) of the shoulder, when standing. [2]

Starting point for arm length measurements; near the center

37. Weight (kg), estimated by Kroemer	58	78	99	13	39	62	85	14

Note: According to Gordon, Churchill, Clauser et al. (1989), who used the numbers in brackets.

of rotation of the upper arm (shoulder joint), reference point for hand reaches; consider slump and motion of the standing person.

4. Elbow height, standing

The vertical distance from the floor to the lowest point of the right elbow, when standing, with the elbow flexed at 90 degrees. [D16]

Reference point for height and distance of the work area of the hand and the for location of controls and fixtures; consider slump and motion of the standing person.

5 Hip height (trochanter), standing

The vertical distance from the floor to the trochanter landmark on the upper side of the right thigh, when standing. [107]

Starting point for leg length measurement; near the center of the hip joint; reference point for leg reaches; consider slump and motion of the standing person.

6 Knuckle height, standing

The vertical distance from the floor to the knuckle (metacarpal bone) of the middle finger of the right hand, when standing.

Reference point for lowest location of controls, handles and handrails; consider slump and motion of the standing person.

7. Fingertip height, standing

The vertical distance from the floor to the tip of the index finger of the right hand, when standing. [D13]

Reference point for lowest location of controls, handles and handrails; consider slump and motion of the standing person.

8. Sitting height

The vertical distance from the sitting surface to the top of the head, when sitting. [93]

The vertical distance from the floor to the underside of the thigh directly behind the right knee; when sitting, with the knee flexed at 90 degrees.

Relates to the minimal height of overhead obstructions. Add height for more clearance, hat, trunk motion of the seated person.

9. Sitting eye height

The vertical distance from the sitting surface to the outer corner of the right eye, when sitting. [93]

Origin of the visual field; reference point for the location of vision obstructions and of visual targets such as displays; consider slump and motion of the seated person.

10. Sitting shoulder height (acromion),

The vertical distance from the sitting surface to the tip (acromion) of the shoulder, when sitting. [49]

Starting point for arm length measurements; near the center of rotation of the upper arm (shoulder joint), reference point for hand reaches; consider slump and motion of the seated person.

11. Sitting elbow height

The vertical distance from the sitting surface to the lowest point of the right elbow, when sitting, with the elbow flexed at 90 degrees. [48]

Reference point for height of an arm rest, of the work area of the hand and of keyboard and controls; consider slump and motion of the seated person.

12. Sitting thigh height (clearance)

The vertical distance from the sitting surface to the highest point on the top of the right thigh, when sitting, with the knee flexed at 90 degrees. [104]

Minimal clearance needed between seat pan and the underside of a structure, such as a table.; add clearance for clothing and motions.

13. Sitting knee height

The vertical distance from the floor to the top of the right knee cap, when sitting, with the knees flexed at 90 degrees. [73]

Minimal clearance needed below the underside of a structure, such as a table; add height for shoe.

14. Sitting popliteal height

The vertical distance from the floor to the underside of the thigh directly behind the right knee; when sitting, with the knees flexed at 90 degrees. [86]

Reference for the height of a seat; add height for shoes, consider movement of the feet.

15. Shoulder—elbow length

The vertical distance from the underside of the right elbow to the right acromion, with the elbow flexed at 90 degrees and the upper arm hanging vertically. [91]

A general reference for comparing population samples.

16. Elbow-fingertip length

The distance from the back of the right elbow to the tip of the middle finger, with the elbow flexed at 90 degrees. [54]

Reference for fingertip reach when moving the forearm in the elbow.

17. Overhead grip reach, sitting

The vertical distance from the sitting surface to the center of a cylindrical rod firmly held in the palm of the right hand. [D45]

Reference for height of overhead controls to be operated by the seated person. Consider ease of motion, reach and finger/hand/arm strength.

18. Overhead grip reach, standing

The vertical distance from the standing surface to the center of a cylindrical rod firmly held in the palm of the right hand. [D42]

Reference for height of overhead controls to be operated by the standing person. Add shoe height. Consider ease of motion, reach and finger/hand/arm strength.

19. Forward grip reach

The horizontal distance from the back of the right shoulder blade to the center of a cylindrical rod firmly held in the palm of the right hand. [D21]

Reference for forward reach distance. Consider ease of motion, reach and finger/hand/arm strength.

20. Arm length, vertical

The vertical distance from the tip of the right middle finger to the right acromion, with the arm hanging vertically. [91]

A general reference for comparing population samples. Reference for the location of controls very low on the side of the operator. Consider ease of motion, reach and finger/hand/arm strength.

21. Downward grip reach

The vertical distance from the right acromion to the center of a cylindrical rod firmly held in the palm of the right hand, with the arm hanging vertically. [D43]

Reference for the location of controls low on the side of the operator. Consider ease of motion, reach and finger/hand/arm strength.

22. Chest depth

The horizontal distance from the back to the right nipple. [36]

A general reference for comparing population samples. Reference for the clearance between seat backrest and the location of obstructions in front of the trunk.

23. Abdominal depth, sitting

The horizontal distance from the back to the most protruding point on the abdomen [1]

A general reference for comparing population samples. Reference for the clearance between seat backrest and the location of obstructions in front of the trunk.

24. Buttock—knee depth, sitting

The horizontal distance from the back of the buttocks to the most protruding point on the right knee, when sitting with the knees flexed at 90 degrees. [26]

Reference for the clearance between seat backrest and the location of obstructions in front of the knees.

25. Buttock—popliteal depth, sitting

The horizontal distance from the back of the buttocks to back of the right knee just below the thigh, when sitting with the knees flexed at 90 degrees. [27]

Reference for the depth of a seat.

26. Shoulder breadth, biacromial

The distance between the right and left acromion. [10]

A general reference for comparing population samples. Indication of the distance between the centers of rotation (shoulder joints) of the upper arms.

27. Shoulder breadth, bideltoid

The maximal horizontal breadth across the shoulders between the lateral margins of the right and left deltoid muscles . [12]

Reference for the clearance requirement at shoulder level. Add space for ease of motion, tool use.

28. Hip breadth, sitting

The maximal horizontal breadth across the hips or thighs, whatever is greater, when sitting [66]

Reference for seat width. Add space for clothing and ease of motion.

29. Span

The distance between the tips of the middle fingers of the horizontally outstretched arms and hands. [98]

Reference for sideway reach.

30. Elbow span

The distance between the tips of the elbows of the horizontally outstretched upper arms with the elbows are flexed so that the fingertips of the hands meet in front of the trunk.

Reference for "elbow room."

31. Head length

The distance from the glabella (between the brow ridges) to the most rearward protrusion (the occiput) on the back, in the middle of the skull. [62]

A general reference for comparing population samples. Reference for head gear size.

32. Head breadth

The maximal horizontal breadth of the head above the attachment of the ears. [60]

A general reference for comparing population samples. Reference for head gear size.

33. Hand length

The length of the right hand between the crease of the wrist and the tip of the middle finger, with the hand flat. [59]

A general reference for comparing population samples. Reference for hand tool and gear size. Consider changes due to manipulations, gloves, tool use.

34. Hand breadth

The breadth of the right hand across the knuckles of the four fingers. [57]

A general reference for comparing population samples. Reference for hand tool and gear size, and for the opening through which a hand may (or may not) fit. Consider changes due to manipulations, gloves, tool use.

35. Foot length

The maximal length of the right foot, when standing. [51]

A general reference for comparing population samples. Reference for shoe and pedal size.

36. Foot breadth

The maximal breadth of the right foot, at right angle to the long axis of the foot, when standing. [50]

A general reference for comparing population samples. Reference for shoe size, spacing of pedals.

37. Weight

Nude body weight taken to the nearest tenth of a kilogram.

A general reference for comparing population samples. Reference for body size, clothing, strength, health, etc. Add weight for clothing and equipment worn on the body.

Control of Rapid Actions: Motor Programming

R. A. Schmidt†, T. D. Lee‡ and D. E. Young†

†Exponent Failure Analysis Associates, Inc., 5401 McConnell Avenue, Los Angeles, CA 90066, USA

‡Department of Kinesiology, McMaster University, 1280 Main Street West, Hamilton, Ontario, Canada L8S 4K1

In the study of movement control, it is often convenient to subdivide actions into two, broadly defined classes: (1) those with brief execution times and (2) those with longer execution times. Brief actions have movement durations of a few hundred milliseconds or less (such as a throw, button press, pedal movement), whereas the longer durations have movement times (MT) > ~5 s and may actually require several minutes for their execution (e.g. juggling). These two classes of actions are sometimes termed "fast" (or "rapid") versus "slow," and this terminology is adopted here. But it should be clear that the defining characteristic is the duration (in seconds), and is not their actual speed (cm/s). While many brief actions are also of very high velocity (e.g. a batswing), they need not be (pressing an accelerator pedal).

These two movement classes follow very different principles. The major difference is that the so-called rapid movements are essentially organized in advance and run off as a unit. The slower actions tend to be more controlled by interactions and compensations for sensory information delivered during the conduct of the action (termed "response-produced feedback," or simply "feedback"), and hence they do not rely (so) heavily on advance organization. Of course, this distinction between the processes in rapid and slow movements blurs at their border. Movements that are in the region near this border (with MT of from ~400 to ~1500 ms) have components that are both pre-organized and feedback controlled (see, e.g., Principles of Simple Movement, Chapter xx in this volume). The factors that determine the relative contributions of these two kinds of control processes have been examined and modeled recently (Meyer *et al*. 1990). But, at the polar extremes, rapid and slow movements appear to be quite differently controlled. We will be dealing with rapid actions in this section. Other sections in this volume deal with those processes in slower actions (see, e.g., Tracking, Chapter yy).

1. FEEDBACK CONTROL IN RAPID ACTIONS

The rationale supporting the idea that rapid actions are organized in advance and run off as a unit are both simple and compelling. Probably the most important reason is the inadequacy of sensory information, or response-produced feedback, to serve as the basis for the action's control (as in a closed-loop system). Feedback-control viewpoints have come in many different forms throughout the 20th century (for a review, see Schmidt and Lee 1999). However, all require that the response-produced sensory information be transduced, travel to the CNS (or at least to the spinal cord), be integrated with other information, be delivered to the muscles, result in a different pattern of contraction, and eventually produce some effect on the movement of bones and joints. The problem is that these processes are generally too slow to be a part of the control of these brief actions, and a 200-ms action is essentially over before the feedback can have any effect on the action.

About 20–30 years ago there was considerable debate about this issue, as it is at least possible for some "reflex"-like activities to be delivered to and from the CNS in from 30–80 ms after a perturbation to a movement was applied, providing some encouragement that the movements were controlled via feedback. More recent evidence and thinking, however, has revealed that these-lower level feedback processes are mainly involved in the maintenance of the already organized actions, and are not the basis (or the origin) of the pattern. Various levels of feedback involvement can be identified, each with various contributions to the motor output (Schmidt and Lee 1999). But the fundamental question has centered on the issue of what was being modified by the feedback information. The answer usually given is that some prestructured, centrally generated pattern of activity is produced, and the feedback modifies it in various ways.

Several other lines of evidence also converge on the idea that at least rapid movements are organized in advance. Earlier work with deafferented monkeys, for whom sensory information from the responding limb was eliminated surgically, revealed that these animals moved very well, and almost normally in some situations. They had particular problems with fine-controlled finger actions, however, suggesting that feedback is a relatively large part of these slower actions. In humans, electromyographic (EMG) patterns from the responding limb in rapid tasks that were unexpectedly blocked mechanically are essentially normal (i.e. like the unblocked movements) for ~150 ms, revealing that the patterning was presumably organized in advance. Importantly, this finding suggests that neither the feedback from, nor dynamics of the responding limb can be responsible for the EMG patterning of brief actions, as such patterning would surely have been massively disrupted by blocking the limb at the beginning. In a different paradigm with humans, the time to prepare an action during reaction time is dependent on the complexity (and/or duration) of the movement to be made, as if the organization of a more complex action required more time for organization before the movement actually starts. Finally, research on animal locomotion uses an analogous concept of central pattern generators (CPG) to account for patterns of action. This concept is quite similar to the idea of motor programs for human motor control. All of this thinking has led to the concept of the motor program, the name most often used for the structure that is presumably organized in advance. See Schmidt and Lee (1999) for a review.

2. GENERALIZED MOTOR PROGRAMS

Given that some sort of motor program is organized in advance and "run off" as a unit, considerable research and thinking has focused on the nature and organization of these structures, particularly using rapid actions in relatively stereotyped environments. One important line of thinking concerns the observation that, at least in its original form, the motor program is very inflexible, so that essentially countless movement programs would be required for all of the motor actions humans can do. This, of course, raised issues about where (and how) in the CNS all of these programs could be stored (the so-called storage

problem). Second, there was concern that such programs could not generate novel behavior (the novelty problem), where the production of an action is "new" and not precisely like any of the similar actions done previously. These ideas have suggested the notion that programming is flexible in various ways, leading to the idea of the generalized motor program (GMP). According to this idea, a given GMP consists of a rigidly defined (or invariant) fundamental pattern that determines the form of an action, but this pattern can be varied — or scaled — in several, relatively superficial ways, each of which allows the action to meet slightly different environmental demands, as described below.

2.1. Relative Timing Invariances

A key observation has been that most actions can be sped up or slowed down easily (e.g. via instructions) without changing the fundamental pattern of action. When speed is scaled, several features remain constant, or invariant. One of these is the order of events. But the most important is relative timing, or the fundamental temporal structure of the action. For relative timing to be invariant, the durations of any subpart of the action must remain in constant proportion to the overall movement time as the action is changed in duration. It is as if the whole action is sped up as a unit, with all parts of the action changing their speed in the same proportion. Relative timing stays roughly invariant over large changes in movement time for tasks that are initially rapid and of short duration. Relative timing is not perfectly invariant, however, and small but systematic deviations from invariance have been documented. However, many have felt that the conspicuous tendency toward invariance provides a good approximation of these processes. If the actions are longer in duration (e.g. juggling, reaching), relative timing sometimes breaks down completely, as one would expect if feedback-based processes were intervening to modify the originally programmed movement pattern. Often, though, relative timing remains roughly invariant even in long-duration tasks of several seconds, such as in typing, certain speech tasks, stair climbing, etc. Such tasks presumably can be programmed, but of course they need not be; and their conduct can be interrupted easily if the action goes awry.

These relative timing invariances have been considered as the fundamental structure, or "signature" of a GMP. Each different class of activity (throwing versus kicking, for example) is argued to have its particular GMP, each with its unique and invariant relative timing. Therefore, as we discuss later, this observation provides a basis for deciding when a particular GMP is being produced (its unique relative timing pattern is observed), or when it has stopped or been replaced by another GMP (with a different relative timing pattern). Extensions of this idea show that two GMP running sequentially can be distinguished using the identification of the relative timing invariances of each (Schneider and Schmidt, 1995).

2.2. Parameters of the GMP

According to this view, when actions are controlled by GMP, they must be parameterized (or scaled) before initiation so that they meet the environmental demands. Research and common observation suggests that actions can be essentially linearly scaled in several ways. The most important of these parameters determines the rate, or the duration of the action, mentioned

above. The changes in movement speed are such that the durations of the subparts remain in constant proportion to the overall movement duration. Another is an amplitude parameter, by which the amplitude of all of the features of an action are increased in constant proportion so that the movement can be varied in size, or can be varied in terms of the masses or frictions encountered, without changing the fundamental temporal structure. Large and small handwriting has been modeled in this way by using a force parameter to scale the sizes of all of the muscular contractions in an action. Finally, many have argued that the GMP requires a limb parameter so that the action can be produced in either the right or left hand, or perhaps even with other effector systems (the mouth, foot, etc.), a phenomenon known as motor equivalence. Because the GMP can be involved in the control of various limbs, it is regarded as an abstract representation of the action patterning, not containing muscle- or effector-specific instructions.

3. WHAT IS CONTROLLED IN MOTOR PROGRAMMING?

Two general models of what is controlled by the motor program have been presented. One view argues that the program controls impulses, while the other argues that the system controls limb position.

3.1. The Control of Impulses

Considerable evidence suggests that a GMP controls impulses. From physics, the impulse is the integral of the force–time curve (or the area "under" the curve), and it has the property that the velocity of an object (starting from rest) after an impulse has stopped acting on it is proportional to the impulse size. Therefore, by adjusting the size of the impulse — either in force or in duration, both of which are physiologically plausible — the system can control velocity simply and indirectly. Further, the GMP under this view controls the temporal distribution of forces to the various musculature, defining when the particular forces are to be applied, for how long and in what order. This viewpoint, wherein a pattern of impulses is distributed over time, is called the impulse-timing view. Furthermore, this pattern of impulses over time can apparently be scaled almost linearly by the various parameters mentioned in the previous section, preserving the fundamental patterning.

3.2. Equilibrium–Point Control

A possible alternative viewpoint for the nature of limb control has been termed the equilibrium-point model (or the mass-spring model). According to this view (e.g. Feldman and Levin 1995), the control of single-joint actions is produced by programming an equilibrium point; the spring-like properties of the muscles on the two sides of a joint then achieve that position for which the torques are equal and opposite (the so-called equilibrium point). In many ways, this is an attractive alternative to impulse-timing views, as no central timing is required for action. However, it appears to have limitations (1) when two-joint actions (e.g. elbow–shoulder) are required, (2) when the action requires sequential control of rapid movements with reversals in direction, or (3) when the action involves the coordination among separate limbs. It appears that some higher-level timing of the contractions is important for control in these situations (for a discussion, see

Schmidt and Lee 1999), and that the equilibrium-point view does not have sufficient generality at present for it to be taken as an effective account of movement control.

4. THE CONTROL OF COORDINATION

Coordination, or the patterning of various limbs together to form a coherent whole action, also appears to differ markedly depending of the duration of the actions. When the actions are slow and continuous, such as swimming or juggling, coordination appears to be related strongly to interactions among the limbs, perhaps with a feedback basis. Presumably, sensory information plays a strong role in on-going control, and the actions are not programmed. On the other hand, rapid coordinated action of the two hands has been modeled recently in terms of the GMP viewpoint described earlier. Here, the GMP is a single structure that provides impulse-timing information for both limbs, so that speeding up the coordinated task speeds both limbs (and all of their subparts) proportionally, and the relative timing both within- and between-limbs remains invariant (Heuer *et al.* 1995, Schmidt and Lee 1999). Such a view has potential generalization to far more complicated tasks involving the upper and lower extremities, where complex actions can be thought of as programmed in the same general way as simpler ones.

5. PRACTICE FOR GENERALIZED MOTOR PROGRAMS AND PARAMETERS

Practice, of course, has strong influences on the control of actions, and this is also understandable in terms of the changes in the GMP and parameters. When we learn such actions, we appear to learn at least two, separate things. First, we acquire some fundamental pattern for the action; in throwing, we learn the coordination patterns among arm, trunk, and legs that leads to an effective throw. Theoretically, we need to acquire a GMP for the class of actions. Second, we learn to scale the pattern so that we can achieve various environmental goals, such as throwing heavy versus light objects, long versus short distances or rapidly versus slowly. That is, we need to learn how to parameterize the GMP. Recent research has suggested that the fundamental learning of these two facets of motor responding are distinct, and that their acquisition follows different principles (e.g. Wulf *et al.* 1993). Some of these differences are highlighted next.

We know from common experience, and also from empirical data, that the acquisition of the fundamental patterning (or the GMP) is the most difficult and time-consuming aspect of practice. When the tasks are new, different from other actions already learned, and complex, it may require considerable time and effort for learners to be able to acquire the fundamental patterning. In a similar way, it requires considerable practice for the learner to change the fundamental patterning once it has been learned, as

in eliminating a "bad habit" in one's golf swing once acquired. And, under conditions of stress or fatigue, the "old" pattern can emerge to replace the "new" one that was just learned. The GMP appears to be acquired most effectively using randomized (or spaced) practice sequences, where feedback is withheld frequently to avoid the learner becoming dependent on it. See Skill Learning: Conditions of Training, Chapter yy, elsewhere in this volume for a summary of the most important learning methods.

Once the pattern is learned, it is almost trivial to scale it to match the environmental demands. On the one hand, it is very easy to change the speed or forcefulness of an already learned GMP. The problem for the learner is that s/he must acquire the capability to scale the parameters of the GMP to match the particular environmental demands. This kind of learning has been termed schema learning, where the individual acquires a relationship, or rule (the schema), defined between the environmental conditions (say, the distance that the object is to be thrown) and the parameter for the GMP required to produce a throw of that distance. Research has shown that the most effective practice leading to schema learning uses many repetitions of the same GMP, but under varied environmental conditions that require different parameters (so-called variable practice). As might be expected, the goal is to practice many variants of the action so that the system can build an effective and accurate rule between the environmental demands and the parameters provided to the GMP. Also, unlike GMP learning, frequent feedback does not seem to be a limitation for parameter learning.

Dynamic Muscle Strength

J. L. Smith

Department of Industrial Engineering, Texas Tech University, Lubbock, TX 79409-3061, USA

Since most industrial activities are dynamic in nature, dynamic strength testing has a great deal of appeal to the ergonomist. Dynamic strength tests are somewhat difficult to perform due to the variety of factors that must be accounted for or controlled. For example, the speed of movement, range of movement and the body posture will all affect the strength test results. Historically, dynamic strength tests have been classified as: isokinetic, isotonic and iso-inertial. Although some have argued over the appropriateness of the names, they are widely used and understood as defined below.

Isokinetic tests refer to testing performed under conditions of moving at a constant velocity. Isokinetic devices restrict the speed of movement. Therefore, when a subject is instructed to move as fast and as hard as possible, the device will limit the speed of movement and the additional muscle force will be recorded typically as a torque curve throughout the range of the motion. Isokinetic devices can be relatively expensive, require trained personnel to operate, and have long set-up times for the subjects, but they can provide an excellent "strength profile" along the path of motion at a fixed velocity of movement.

Isotonic strength tests refer to testing performed under conditions of constant muscle tension. Such devices alter the tension or resistance of the device at different points along the motion path, resulting in a constant tension required by the subject performing the test. Muscles generate different tensions (or strengths) at different lengths of the muscle. For example, if a muscle is stretched or compressed, it will be able to generate less tension than when it is at its resting length. Therefore, the iso-inertial devices attempt to alter the resistance of the strength-testing device in order to require the subject to exert a constant muscle force throughout the range of motion. Isotonic devices do not control speed of movement. Isotonic devices tend to be relatively expensive and are not widely used for industrial strength testing.

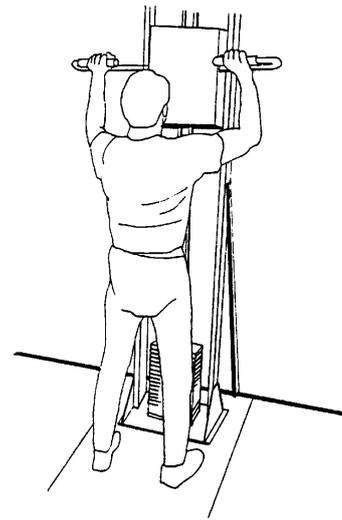
Iso-inertial devices refer to testing conducted on constant external loads. Typical iso-inertial testing devices are free weights and devices that use weights to change the external load. The US Air Force developed an incremental 6 foot lifting machine (figure 1) that was an iso-inertial device that restricted motion of the load to the vertical plane, by having handles mounted to a carriage that rode within two vertical rails (Ayoub *et al*. 1987). Adding or subtracting 10-lb weights on the carriage changed the external load. The subject was instructed to lift a load to a height of 6 feet and then lower the load. The test administrator then added more weight and the subject repeated the task until he/she reached a point where the load could no longer be successfully lifted to a height of 6 feet. The heaviest load successfully lifted to the 6-foot height became that subject's strength score. Test scores from the incremental 6-foot lift were found to be good predictors of manual materials handling capabilities in a variety of tasks. The incremental 6-foot lifting machine is relatively inexpensive, the tests are easy and fast to conduct and requires very little training for the test administrator.


Figure 1. Incremental 6-foot weight lifting machine.

In cases where engineering and administrative controls are not feasible, strength training of workers may be a consideration if their capabilities are exceeded by job demands and the chances of injury are unacceptable. A sound strength training program will adhere to two basic physiological principles: specificity of training and the overload principle. Specificity of training states that the best training is actually using the activity that the worker is being trained for. As an example, a worker involved in lifting objects should be trained on a lifting task under conditions similar to those encountered on the job. Thus, the specific muscle groups and energy systems that will be utilized on the job are the systems being trained. The overload principle states that adaptations will take place and that to see any further increase in strength, more stressful workloads must be encountered. For example, a worker can be trained to lift 20 kg, but will soon adapt to that load and receive no further training benefits until the load is increased.

For dynamic muscle strength, a popular strength training protocol utilizes the repetition maximum (RM) approach. Under such an approach, the maximum amount of weight that can be handled for a fixed number of repetitions is established. For example a 10 RM protocol would require that the maximum amount of weight that can be handled 10 times under a given set of task conditions be determined. The training session would then be for the worker to perform 10 repetitions at one-half of the 10 RM load, followed by 10 repetitions at three-quarters of the 10 RM load, and finally 10 repetitions at the 10 RM load. Such a protocol allows a "warm up" by starting the worker at a lower load and increasing to the maximum load. When a subject can perform more than 10 repetitions at the 10 RM load, a new 10 RM should be established. For greater training effects a 3 or 5 RM protocol utilizing heavier weights could be utilized. By the same account a less stressful 12 or 15 RM protocol would be more conservative and start subjects with a lighter load.

Whether a strength training program would be appropriate depends on the industry and the worker population. However, some sort of strength training incorporated along with skill training could be beneficial in reducing the risk of injury for new employees.

IL 62794-9652, USA

1. INTRODUCTION

Every living system is under the influence of a variety of physical fields. The information about the environmental changes (external and internal) detected by various receptors is transferred to different levels in the nervous system, and the decision to react or not to react is taken. Any human activity in the external environment involves the motor system. The utilization of the motor system allows humans to change their position in space (locomotion) and to interact with the environment in a controlled manner (work). The human motor system is complex, with about 280 biomechanical degrees of freedom (number of coordinates necessary to describe the body's motion in space) and thousands of neural channels. Such a complex system contains many subsystems, inputs, and outputs; it is a multilevel system.

The motor system has the ability to learn and to change its structure. It can act in a very wide range of external conditions while changes to the internal conditions are kept within the small ranges necessary to maintain the basic living functions (homeostasis). There exists no consistent theory to analyze these systems. The properties of the human motor system are described by its biomechanical parameters. The central nervous system (CNS) monitors biomechanical variables such as force, position, and velocity. Intensive studies are currently investigating the manner in which the CNS maintains these variables constant, stable, and reproducible during a variety of motor tasks.

Even though the control rules are unclear, quantification of the human motor system is under intensive development. There are two basic subsystems: structural and functional. The structural system contains morphological passive and active musculoskeletal elements and can be described with a large but limited number of parameters. The functional system describes the spatial and temporal ordering of the structural elements and is practically infinite. Quantitative description of the system can be achieved using its structural and functional subsystems.

The basic structural properties of the motor system include segment dimensions, ranges of motion, segment dynamics (moment of inertia, stiffness, damping), maximum voluntary and reflex activation. At the range of the functional subsystem, the most often quantified human functions include walking, upright standing, initiation of walking, reaching, climbing stairs, and grasping. This article looks at how to quantify human segment dynamics using moment of inertia, stiffness, and viscous damping; then it examines how these parameters are affected by factors such as activation, angular position, and human growth.

2. DYNAMIC PROPERTIES OF HUMAN LIMB SEGMENTS

Human ability to perform any motor task depends on many factors, including biomechanical properties of the body. Segments (rigid parts of the body) operate around their joints through the muscles which are under neural control. The segment endpoint is usually the final executor of any motor task. The segment endpoint moves in space with different tasks, depending on the criteria (time, precision, etc.), or it generates force on the external environment. In return, forces generated by the environment affect the execution of the motor task. The inertial and viscoelastic properties of human limb segments describe the dynamic properties of the system, which is under neural control.

Neural control signals are transformed into motor tasks through the mass, inertial, and viscoelastic properties of joint segments. The active and passive elastic structures were originally defined at the level of the individual muscle by Hill (1940). In human bodies the biomechanical properties can be evaluated at the level of a limb segment and its joint. The viscoelastic passive properties are characteristics of muscle tissue, joint capsule, tendons, and skin (Johns and Wright 1962). The active dynamic properties are related to the state of the segment's muscle activity: relaxation or activation (voluntary or reflex). Knowledge about these properties is important in designing any devices that interact with the environment (ergonomics) and designing compensatory control loops for patients (rehabilitation engineering).

The dynamics of a human limb segment are defined by its generalized equation of motion:

$$Ja'' + (B_p + B_a)a' + (K_p + K_a)a + MgR = Tq \qquad (2.1)$$

or

$$a'' + ba' + wa + g = tq \qquad (2.2)$$

where

$$b = (B_p + B_a)J^{-1} \qquad (2.3)$$
$$w^2 = (K_p + K_a)J^{1} \qquad (2.4)$$
$$g = MgRJ^{1} \qquad (2.5)$$
$$f = FJ^{1} \qquad (2.6)$$

J = moment of inertia around the axis of rotation. Moment of inertia defines the mass distribution along the segment long axis. It is equal to a sum of the element masses multiplied by the square of the radius of rotation

K_p, B_p = passive viscous damping and stiffness of the muscles acting on the joint when muscles are relaxed (nonactive). In static conditions the stiffness may be defined as a ratio between the change in force and the change in motion which was caused by it. Viscous damping can be defined as a ratio between the change in force and the velocity caused by it

K_a, B_a = active stiffness and damping of the muscles acting on a joint; the changes of stiffness are due to muscle activation (voluntary or reflex)

M = segment mass

R = radius of mass

a, a', a'' = angular motion, velocity, and acceleration, respectively

F = external torque (force multiplied by the radius of action)

w = natural free frequency of the segment, $w = (K/J)^{1/2}$

x = dimensionless damping ratio, $x = B/2(KJ)^{1/2}$

2.1 Measuring moment of inertia, stiffness, and viscous damping.

The generalized equation of motion (2.1) is usually reduced in the measurement techniques. The reduction concerns the biomechanical degrees of freedom, the viscoelastic properties of

Table 1

Segment	Axis of rotation	Moment inertia (N m)	Stiffness (N m rad^{-1})	Damping (N m s rad^{-1})	Free frequency, ω (rad s^{-1})
Finger	II metacarpophalanger	–	0.1–0.8	0.005–0.008	30
Hand	Wrist	0.015	4–88	0.04–0.1	16–76
Forearm	Elbow	0.037–0.082	1–12	0.1–0.3	6–16
Upper limb	Shoulder	0.29	10	1.1–1.7	5.8
Foot	Ankle	0.027–0.07	17–58	0.2–0.42	26–46
Lower Leg	Knee	0.32–0.58	10–120	0.35–1.85	5–14

[a]Around proximate axis in flexion /extension plane.

the muscles (relaxation or steady effort) and gravitational forces (unloading or constant loading condition). The methods for identifying the parameters of the reduced equation depend on the choice of structural elements, the complexity of the model, the identification procedure, and the technical methods of force or motion analysis being applied. The identification procedures are based on the analysis of the system response to different types of external stimuli.

Methods based on the geometrical segment dimensions and appropriate anthropometric measures were used in measuring the moment of inertia of different segments in cadavers and in living subjects. Moment of inertia may be predicted from these studies (Conwey 1972) or measured with different techniques. Here are some of them: peak acceleration after quick release of a forearm following a fixed force; acceleration and force of a limb segment undergoing sinusoidal displacement (Allum and Young 1976); and calculation of lower leg moment of inertia from the period of free segment oscillations with additional mass elements.

Static stiffness, defined as a coefficient between the change of force and displacement, has been measured in the elbow, knee, ankle, metacarpophalangeal, and hip joints with the aid of complex torque devices or hand-held force transducers (MacKay *et al.* 1986). An apparatus supplying constant velocity displacement (the inertial properties are negligible in the equation of motion) and measuring force (or vice versa) has been used in ankle joint stiffness measurements. The resistance to sinusoidal movement, or the movement as a result of sinusoidal forces was used to measure interphalangeal, elbow, wrist, ankle, hip, and knee muscle stiffness (Johns and Wright 1962). Force, displacement (step, pulse) or random perturbation functions were used to identify the viscoelastic properties of interphalangeal, wrist, elbow, finger, and ankle joints (Hayes and Hatze 1977). A popular method involves driving the limb system with increasing frequency sinusoidal force to determine its natural frequency.

Dynamic stiffness can be calculated from the free frequency with an estimated or measured moment of inertia. This method was used to identify the stiffness of muscles acting on the ankle, wrist, elbow, knee, and interphalangeal joints (Lakie *et al.* 1981).

3. DYNAMIC PARAMETERS OF DIFFERENT LIMB SEGMENTS.

3.1 Dynamic parameters of selected body segments in adult populations

Table 1 shows dynamic parameters of different limb segments based on results available in the literature. All parameters were measured for joint motion with one degree of freedom, in the flexion/extension direction around the proximal axis of rotation. The discrepancy of the data reported by different authors is re-

lated to the fact that the data sets were collected using different measurement methods and at different ranges of motion. When a joint is stretched from any resting position by external force, its force increases much more rapidly at the beginning. It is reported in many studies (MacKay *et al.* 1986) that the stiffness (K) rapidly decreases with the amplitude (A) for movements up to 0.1 rad (when $K = A^{0.8}$) and then gradually decreases. This observation might be related to the breakdown of a short-range elastic component (Hufschmidt and Schwaller 1987). Segment masses, centers of mass, and moments of inertia can also be predicted from the anthropometric measures (Conwey 1972).

3.2 Changes of viscoelastic properties related to the joint position

Many studies (Hayes and Hatze 1977) have shown that the viscoelastic properties, when studied over the whole range of joint motion, exhibit highly nonlinear properties. Both passive stiffness (figure 1a) and passive damping (figure 1b) increase with the angular position until the passive joint and bone structures limit the range of motion. At the midrange, both parameters exhibit minimal values. The passive stiffness exhibits hysteresis, i.e., the passive moment is different when moving from flexion to extension than when moving from extension to flexion; this indicates energy loss during the displacement cycle. It might be related to plastic changes within the muscle (yielding property, thixotropy).

3.3 Dynamic active parameters of some body segments in adults

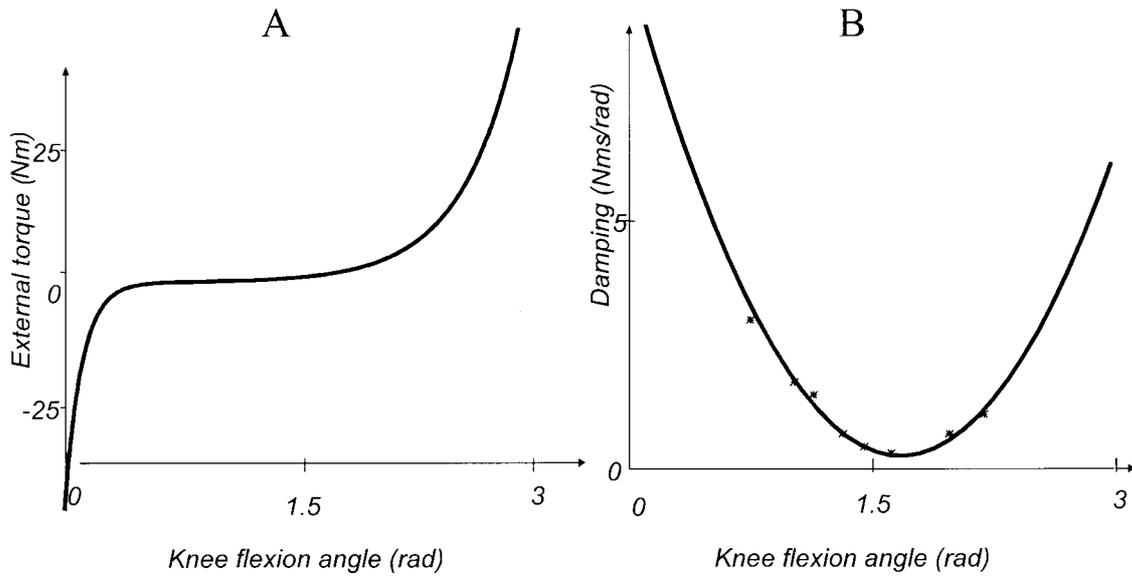
In an isolated animal muscle preparation, the stiffness increases proportionally with muscle activation. The dynamic properties of different segments were measured during muscle relaxation and voluntary and reflex activation. During muscle activation, the stiffness and damping of the limb segment increase as a result of structural changes within the muscle. The increase in stiffness with the muscle activation was found for hand, forearm, foot, leg, and lower leg segments (Kearney and Hunter 1990). The joint exhibits elastic behavior up to yield stress, and viscous behavior above yield stress. The increase in the stiffness (figure 2a) and damping (figure 2b) during muscle activation might be related to the increasing number of elastic cross-bridges formed between myofilaments and the increase in the active areas of sliding myofilaments. However, more data is needed to describe the active dynamics of different joint segments at higher levels of muscle activation.


Figure 1. Knee joint: (a) passive stiffness, (b) passive damping.
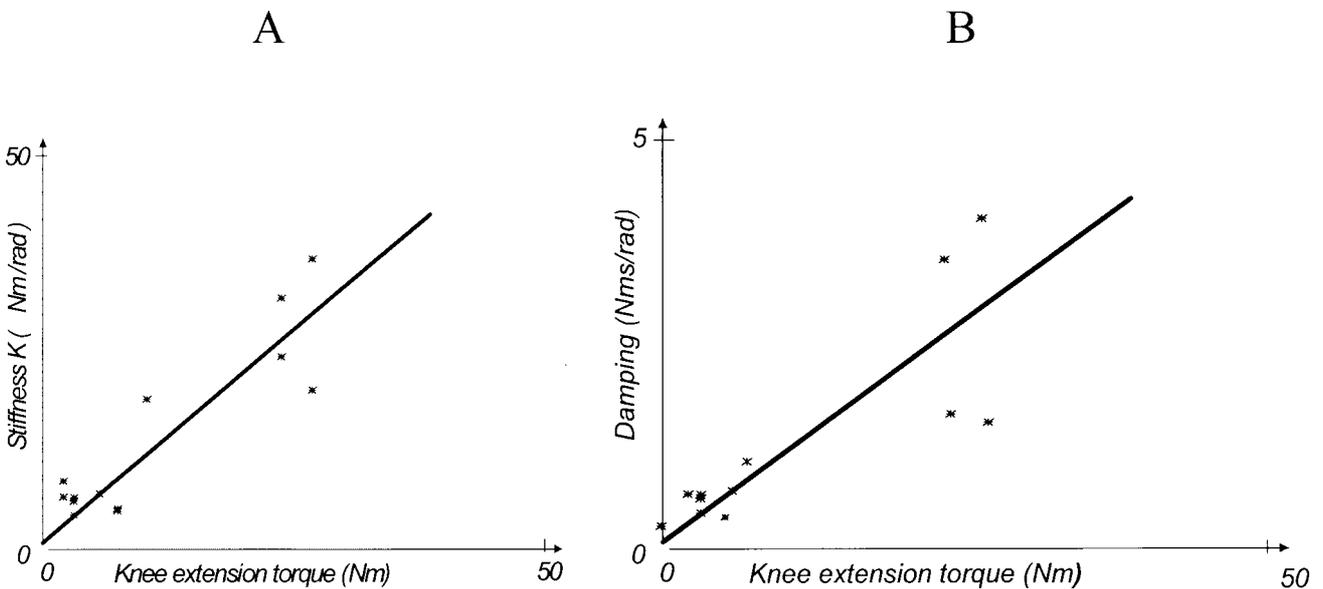

Figure 2. Knee muscles: (a) active stiffness of knee flexors and extensors, (b) active damping of knee extensors.

3.4 Dynamic passive parameters of some body segments in children

The parameters of human motor systems undergo changes during the lifetime as a result of ontogenetic development, aging processes, and diseases. There is very limited data on changes in early development (ages 0 to 6) and aging (above 55 years) (Schneider and Zernicki 1992, Jensen and Fletcher 1994). For lower leg (Lebiedowska and Fisk 1999) and forearm, the moment of inertia (J), stiffness (K), and viscous damping (B) increase as the fifth power of body height in children aged 6 to 18 years.

	Moment of inertia	Passive stiffness	Passive damping
Lower leg	$J = 0.03H^5$	$K = 4.59H^5$	$B = 0.06H^5$
Forearm	$J = 0.0049H^5$	$K = 1.16H^5$	$B = 0.032H^5$

These figures confirm the proportional growth of human body segments in children aged 6 to 18. When the segment's motion

(a) is restricted to the horizontal plane and/or the torque generated by the muscles is much larger than the torque needed to overcome gravity (fast movements), the segment dynamics may be described by the following equations:

Lower leg: $a'' + 2a' + 165a = T_{ext} / (0.03H^5) + aTq_{max} / (0.03H^5)$ (3.1)

Forearm: $a'' + 5.8a' + 219a = T_{ext} / (0.0049H^5) + aTq_{max} / (0.0049H^5)$ (3.2)

Thus, the dynamics are an invariant property of the growing human motor system. Similar motor activity with respect to the shape, amplitude, and duration can be expected as a result of the proportional propelling of a segment. The same activation patterns (3.2) can be used in children during development (age 6 to 18).

Other studies found that the maximal isometric knee torque Tq_{max} (at the midrange) in children changes as the fourth power of body height. Thus, to obtain the same angular joint motion, proportional scaling of activation to body height can be applied. The same linear displacement of the segment endpoint can be

obtained with the same activation. Although not experimentally confirmed, this should also be true in subpopulations characterized by different average body sizes (as long as the body shape is geometrically similar).

On the other hand, the sensitivity of a human operator to external torque (Tq_{ext}) is scaled proportionally to segment inertia or the fifth power of body height. This means that the same torque applied to the same body segment of a smaller person would cause larger motion than in a taller person (scaled by the fifth power of the ratio between their body heights).

3.5 Changes in passive dynamic parameters caused by disease

An increase in passive stiffness was documented in patients with rheumatic diseases and Parkinson's disease. There were several studies investigating the changes in passive stiffness and viscous damping in human spastic paresis. The inconsistency of findings might be related to the application of different measurement methods and different patient populations (Douglas *et al.* 1989, Lebiedowska and Fisk 1999). However, for differential diagnosis of spasticity, it is better to use the changes of active stiffness evoked by application of external force with increasing velocity of stretch.

4. RECOMMENDATIONS

4.1 How to choose a measurement method

Different measurement methods are available at the moment: some of them involve expensive, complex torque devices, and some of them use simple hand-held transducers. When choosing the measurement method, researchers should analyze the aim of the study carefully. In basic research studies choose the more accurate and more complex methods; whereas in clinical applications choose the simpler and less time-consuming methods. The viscoelastic properties exhibit highly nonlinear properties, and special attention should be paid to the range of motion for each measurement method. It is well known that viscoelastic results obtained with a small range of motion can be 10 times larger than results obtained with a large range of motion.

4.2 How segment dynamics limit the maximal voluntary velocity

The range of segment motion is restricted (limited) by the anatomical ranges of motion (joint capsule, bones, skin). The maximal segment velocity (a'_{max}) is limited by the level of muscle activation and segment dynamics. These relations depend on the trajectory of the motion. For motion (a) which is sinusoidal (flexion/extension motion in the same range as A), the relation can be estimated as $a'_{max} = Aw$. This means that the segment free frequency w (2.4) and the range of the motion limit the maximal velocity which can be exerted by the joint. The ballistic movements (from one position to another) at the initial part (generation of maximal velocity) might be considered to be governed by the same rule. Other task criteria (e.g., precision) also modify the maximal velocity of a segment.

4.3 How to use the dynamic parameters of limb segments

The dynamic parameters are necessary to quantify the properties of the human motor system in ergonomics, rehabilitation, and sports medicine. The dynamic parameters collected in different populations might be used in ergonomics to design the optimal workplace. Rehabilitation ergonomics deals with the optimization of different designs, targeting selected patient populations, again characterized by their biomechanical parameters. Quantitative methods are needed in medical rehabilitation to make objective evaluations about the effectiveness and efficiency of different rehabilitation methods, and about the progress of rehabilitation for an individual patient; they also help to choose the best methods of improvement. Rehabilitation engineering uses the motor system parameters to design the compensatory control loops to regain or improve the patient's performance.

Engineering Anthropometry

K. H. E. Kroemer

Professor Emeritus of Industrial and Systems Engineering, Virginia Tech, Blacksburg, VA, USA

People come in a variety of sizes, and their bodies are not assembled in the same proportions. Thus, fitting clothing, equipment or workstations to suit the body requires careful consideration; design for the statistical "average" will not do. Instead, for each body segment to be fitted, the designer must determine the critical dimension(s).

Design for fitting clothing, tools, workstations, and equipment to the body is usually done in steps:

Step 1: Select those anthropometric measures that directly relate to defined design dimensions. Examples are: hand length related to handle size; shoulder and hip breadth related to escape-hatch diameter; head length and breadth related to helmet size; eye height related to the heights of windows and displays; knee height and hip breadth related to the leg room in a console.

Step 2: For each of these pairings, determine whether the design must fit only one given percentile (minimal or maximal) of the body dimension, or a range along that body dimension. Examples are: the escape hatch must be big enough to accommodate the largest extreme value of shoulder breadth and hip breadth, considering clothing and equipment worn; the handle size of pliers is probably selected to fit a smallish hand; the leg room of a console must accommodate the tallest knee heights; the height of a seat should be adjustable to fit persons with short and with long lower legs. (See below how to determine percentiles.)

Step 3: Combine all selected design values in a careful drawing, mock-up, or computer model to ascertain that they are compatible. For example: the required leg-room clearance height, needed for sitting persons with long lower legs, may be very close to the height of the working surface determined from elbow height.

Step 4: Determine whether one design will fit all users. If not, several sizes or adjustment must be provided to fit all users. Examples are: one extra large bed size fits all sleepers; gloves and shoes must come in different sizes; seat heights of office chairs are adjustable.

Determination of percentiles can be done either by estimation or by calculation.

Estimation is used when the data set is not normally distributed or too small. In this case, the data point is estimated by counting, weighing, or sample measurement according to the best possible judgment.

Calculation is used based on statistical considerations.

A normally distributed set of n data is described by two simple statistics:

The 50th percentile is by definition the same as the mean m (also commonly called average)

$$m = Sx/n$$

where Sx is the sum of the individual measurements.

The Standard Deviation SD describes the distribution of the data:

$$SD = [S(x - m)^2/n-1]^{1/2}$$

It is often useful to describe the variability of a sample by dividing the standard deviation SD by the mean m. The resulting Coefficient of Variation CV (in percent) is:

$$CV = 100 \, SD / m$$

To calculate a percentile value p of a normal distribution you simply multiply the standard deviation SD by a factor k, selected from the table below. Then subtract the product from the mean m if p is below the mean:

$$p = m - k \, SD$$

Table 1. Factor for computing percentiles from mean x and standard deviation s.

Percentile p associated with X		
K	X = m – KS	X = m + KS
2.576	0.50	99.5
2.326	1	99
2.06	2	98
1.96	2.5	97.5
1.88	3	97
1.65	5	95
1.28	10	90
1.04	15	85
1.00	16.5	83.5
0.84	20	80
0.67	25	75
0	0.50	0.50

If p is above the average add the product to the mean:

$$m = m + k \, SD$$

Examples:
To determine 95th percentile, use k = 1.65
To determine 20th percentile, use k = 0.84

Ergophthalmology: The Visual System and Work

B. Piccoli

University of Milan – ICP Hospital, Vin San Barnaba 8, 20122 Milan, Italy

1. INTRODUCTION

For quite some time people have been showing interest in the health aspects of the relationship between work and vision. In the past such interest was mainly orientated towards the etiology and treatment of chronic and degenerative diseases, either ocular or visual, connected to the presence in the working environment of large amounts of chemical (lead, sulfur-dioxide, solvents, etc.) and physical (ionizing radiation, UV, IR), pollutants. Consequently, medical intervention in this field has been mainly directed towards diagnosis and treatment of impairments of the visual system.

Over the last 50 years working conditions have greatly improved in technologically advanced countries. Illness and injuries, while not completely eradicated, have been noticeably reduced. However, many new problems have arisen. Among these are aspects of "visual functionality", which are much less worrying in terms of immediate impairment, but are most important in terms of wellbeing and efficiency and are destined to become progressively more widespread.

In truth, this side of the matter is not completely new. The first author to note the possible relationships between refraction and work was Bernardino Ramazzini in Italy in the seventeenth century. In his famous *De Morbis Artificum Diatriba*, he wrote a chapter, No. XXXVI, entitled "De lepturgorum morbis (About illnesses of small-object workers)*,* in which he mentioned specific visual disorders for some categories of workers (watchmakers, copyists, goldsmiths, etc.) and pointed out, for the first time, the possible relationships between near work and ocular/visual disturbances. The topic kindled the interest of other authors like Duke Elder and Kuhn, in the early twentieth century, but it is only in the last 20 years that its importance has been fully appreciated.

Indeed the many and varied interventions of transformation and reconversion implemented in the workplace with the introduction of new techniques, mainly computer-based, have noticeably changed the traditional relationship between man and machine. In the workplace, compared with the past, the effort required of the musculo-skeletal apparatus is clearly reduced, while the demand made upon the perceptive sensory system in general, and the visual system in particular, are correspondingly increased.

In this context, a new scientific field emerged in the early 1980s — *ergophthalmology*. According to the Scientific Committee on Work and Vision of the International Commission on Occupational Health (ICOH), its definition is the following:

Ergophthalmology is a scientific field aimed at analyzing, evaluating and designing simple or complex working systems pertaining to the relationship between work and visual performance. Ergophthalmology makes use of established knowledge derived from ophthalmology, industrial hygiene and occupational medicine, as well as from technology (physics, engineering, architecture, etc.) and social disciplines (psychology, sociology, etc.). The purposes of Ergophthalmology are mainly the prevention and management of discomfort and disease in order to obtain maximum efficiency and effectiveness of visual function in organized work.

2. AN OUTLINE OF THE PHYSIOLOGY OF VISION

The visual system can easily be divided into three well-defined groups of components: a peripheral component (eyeball) with its sensory functions; a central component (visual pathways and the primary visual cortex) with its functions of transmission, elaboration, and integration of the luminous input; a number of accessory components (eyelids, eyebrows, lacrimal film, conjunctiva, etc.), also called *adnexa,* with their mechanical, trophic, and protective functions.

In synthesis, it can be said that light emitted or reflected from the objects present in the surrounding space penetrates the eyeball producing, by means of a photochemical process, nervous impulses which give rise to the visual sensations.

The structure dedicated to ocular motility (extrinsic muscles) and focusing (accommodative system) achieve a wider and more detailed exploration of the surroundings as well as a clearer perception of objects, whether stationary or moving.

Besides the three sensorial functions mentioned above, in human beings the visual system also plays an essential "metabolic" role. Visually perceived light stimulates, via a specific retinal pathway, the synthesis of melatonin, a hormone essential for many physiologic processes. Because of its importance in ergonomics and occupational health, this peculiar function will also be considered.

2.1. The Eyeball

The eyeball is a spheroid (average diameter 24 mm front to back, 23 mm across and 23.6 mm top to bottom) situated in the orbit, a pyramid-shaped cavity of the cranium. About one-third of the eyeball, the "ocular surface", protrudes from the orbit and is in direct contact with the environment. The prominent bony structure (frontal, maxillary, and zygomatic bones) of the external part of the orbit, plus the eye lids, provide excellent protection from injury. These structures also help to reduce visual disturbances such as those caused by bright or undesired light.

Because of its structure and functions the eyeball is often compared to a photographic camera: this example, with a few qualifications, can be usefully employed to explain how it works. It is possible to distinguish three parts in this organ, dividing them according to their function.

The first part, which corresponds to the optical system of a photographic camera, is composed of the structures found in the anterior segment: the cornea, the iris, and the crystalline lens with its associated systems (the ciliary body). Contraction of ciliary body muscles increases the convexity (and consequently the refracting power of the lens), allowing a sharp vision of near objects.

The second part is formed by the vitreous, a gelatinous, transparent, colorless mass which fills the posterior segment of the eye: its function is essentially morphostatic. In a photographic camera this part is represented simply by an empty space, the dark room (*camera obscura*).

Lastly, there is a membranous structure, the retina, which corresponds to the sensitive element of a photographic camera, i.e. the film. The retina can be schematically divided into four components: photoreceptors (100 000 "rods" for nocturnal and twilight vision and 6000 "cones" for daylight vision), elements for the conduction of nervous impulses (bipolar and ganglion cells), elements with associative functions (horizontal and amacrine cells) and, finally, support elements (Mueller cells).

For an adequate understanding of human eye functions that suits ergonomics, it is, however, necessary to clarify a few points.

In the optical system of a photographic camera, focusing is achieved by moving the lens backwards and forwards: in the eye this is obtained, as mentioned above, by a contraction of the ciliar muscle, which allows the lens, by decreasing the tension on its capsule, to achieve a more convex shape, mainly in the central portion. This mechanism, supported by a complex neuromuscular system, is a reflex action and is *automatically* activated whenever the image is not sufficiently sharp. Consequently, every time objects or images appear in the visual field within six meters in an emmetrope subject, (i.e. not affected by refractive defects), focusing occurs *involuntarily* and *unconsciously*. The response to environmental light behaves in the same way, i.e. by a reflex mechanism.

The pupil, mesopically adjusted, has an average diameter of about 3.5 mm. In extreme conditions it can go from 1 mm (maximum miosis) to 9 mm (maximum midriasis), but under normal circumstances it oscillates between 2.5 and 6 mm. Pupillary size changes (dilatation and constrictions) brought about by the action of the sphincter and dilatatory muscles of the pupil are activated in response to the environmental light fluctuations (pupillary reflex). Experimental studies have shown that following repeated light stimulation (50 to 60), the pupillary reflex shows *clear signs of fatigue*, evidenced by prolonged latency, reduced contraction and poor redilatation.

While observing objects placed within one meter, pupillary constriction can also occur regardless of the lighting conditions but following accommodation and convergence changes (synkinesis near response), in order to eliminate as much as possible stray light not pertaining to the object/image under observation from visual field.

Another important difference which distinguishes the eye from a photographic camera is the structure of the sensory elements. Indeed a film has "receptors" that are all the same and uniformly distributed. Its sensitivity is not variable and its resolution power is homogenous in all points.

In the retina, however, the sensorial elements have different characteristics according to type, density, and nervous connections, from which is derived a vast range of retinal sensitivities (from full sunlight to minimum nocturnal light there is a ratio of 1 billion to 1) and a remarkably variable resolution power (from 1 minute of arc to several minutes of arc at the periphery).

The highest retinal resolution power area, called "fovea" or "macula" — which, in the presence of adequate light and perfect focusing enables us to identify the smallest details of an object — is located approximately at the center of the retina and has a diameter of only 5.5 mm. The remaining part of the retina has a function which is similar to that of radar, i.e. very sensitive to moving objects in the visual field but with poor discriminative capacities.

An important consequence for ergonomics of this heterogeneous receptor distribution is that stray light produces *much greater discomfort and visual disturbance* when the *foveal areas* rather than the *peripheral areas* of the retina are involved.

2.2. Ocular Motility

Among the various structures found around the eyeball there is a muscular system which carries out all the eye movements. This system is composed of six small muscles (extraocular muscles) responsible for all the movements of the eyeball. These movements, which are always harmonious and measured, can be very fast (saccadic, up to 400 degrees /sec.) or slow and accurate (pursuit, 30 degrees/sec.), and are able to perform complete and rapid explorations of the surrounding environment as well as a detailed identification of objects of interest.

It is important to point out that the motorial activity of the eyeball is a consequence of, and depends upon, the sensory component of visual processes.

Indeed when we fix an object placed within the binocular field (i.e. the visual field common to both eyes) which captures our interest, two foveal images are sent to the visual cortex but we perceive only one (sensory fusion). This is possible only if the two images sent from the foveas, identical in size, color, and luminosity, simultaneously reach the cortical areas. Consequently, the realization and maintenance of a state of "bifoveal fixation", particularly during the observation of moving objects, implies the activation of very complex nervous and muscular synergistic processes. It is therefore possible to speak of a motor-sensory unit in which the sensory system elaborates and transmits the information received from the environment, while the motorial system, completely at the service of the first, performs the exploration of the surrounding space, allowing maximum visual detail and tridimensional perception of the objects.

Ocular movements can be divided into voluntary and involuntary.

The first are the result of a decision made by the subject and are completely conscious (for instance to turn the eyes to the right or left, up or down, on command).

In the second group some (vestibular) movements established by unconditioned reflexes and coordinated by sub-cortical structures leave the subject completely unaware (maintaining eye position with respect to changes in head and body posture).

Others (saccadic, pursuit, vergence, and position maintenance movements) are activated by the coordination of specific brain structures (supra-nuclear centers), when an image arouses the interest of the subject. By means of fast and precise rotations of the eyeball, the image is then placed onto the fovea and followed if moving.

These involuntary eye movements are not completely "unconditioned" in that to be activated they require a state of "visual attention" (interest) which is only possible with the cooperation of the subject. All this has important implications for staff who work in confined spaces, particularly small offices. Indeed, when an operator is not directly engaged in observing the task-objects, which in offices are very frequently placed within one meter, there are often few possibilities, due to the presence of walls, dividers, cupboards, curtains, etc. to use as far vision.

In fact, in such a situation, practically nothing is placed at a sufficient distance to permit complete disactivation of convergence and accommodation, which remain active, obviously at varying intensities, *for the whole time the operator performs that task*, possibly causing overloading of the functions involved and consequently "visual fatigue".

2.3. The Optical Pathways

The fibers (axons) coming from the ganglion cells of the internal layer of the retina are united into a single bunch (optic nerve)

that emerges from the eyeball and crosses the back part of the orbital cavity penetrating into the cranium. Shortly after, the two optic nerves merge partially together (optic chiasm). Those coming from the nasal hemiretina of each eye pass into the optical tract of the opposite cerebral hemisphere where they reunite with the uncrossed fibers coming from the other eye (semidecussation). Thus, when an individual fixes an object with interest, images from the right (or left) side of the visual field, projected onto the nasal hemiretina of one eye and onto the temporal hemiretina of the other, simultaneously reach the same cortical areas where they are fused into one image (binocular vision).

After, the optic chiasm axons continue on (optic tract) to terminate within the lateral geniculate body where, by very complex synaptic interactions with the geniculate cells, a number of elaborations take place that are not yet completely understood.

From this site a pathway (optic radiations) reaches the striate cortex of the occipital lobe: it is here that the most important and sophisticated elaborations and the most complex visual perceptions are achieved in association with several other cortical areas.

2.4. The Metabolic Function

The effect that visually perceived light can produce on the pineal gland via a specific retinal pathway (retinohypothalamic tract) is now well known.

The pineal gland is located in the brain and synthesizes a specific hormone, melatonin, which is found in blood with high/low levels (with remarkable inter-individual variability), according to the daily dark/light cycle. Melatonin is considered an internal pace-maker ("zeitgeber") which translates light information from the environment to the central nervous system via high affinity binding sites. The exact role of melatonin in humans is not yet fully understood, but the presence of melatonin receptors in the human circadian clock, as well as the ability of humans to respond to melatonin signal with a well-defined circadian phase-response curve, is evident.

The rhythmic melatonin blood-level changes appear to be implicated in a number of physiological phenomena such as body temperature, cortisol blood levels, sleep–wake cycle regulation, and physiopathological situations such as jet lag and seasonal affective disorder syndrome (SADS).

Most circadian rhythms, including that of melatonin production, are driven from an endogenous circadian pacemaker located in the suprachiasmatic nuclei (SCN) of the hypothalamus. Since it is active perinatally and continues its activity throughout life, the SNC generates an approximate 24-hour rhythm that plays a role in most, if not all, the body processes. In subjects experimentally kept away from time cues, the circadian rhythm is still present, but slightly longer (free-running circadian rhythm). Humans seem to require a more intense natural light than other species to activate their physiological day–night melatonin cycle, maybe because of an adaptation to prolonged artificial indoor light exposure.

Pineal sensitivity, which varies in the different species, in humans seems to require *an intensity of 2500 lux* (i.e. the illuminance normally present by a window on a sunny day, but rarely found in indoor work places) to be fully inhibited. Dim light (approx. 300–500 lux) also suppresses nocturnal melatonin production, but to a lesser extent.

A light wavelength of 530 nanometers (green) appears to be the most effective, while 435 (blue) and 660 (red) have poor or no suppression effect. The degree of suppression produced by light exposure duration, other than intensity and wavelength, is so far not completely clear. Nevertheless, the effects caused by prolonged and marked reduction in daylight exposure, in particular for occupational reasons and in young subjects, have to be carefully considered in ergonomics.

3. THE OCCUPATIONAL VISUAL PERFORMANCE

The main function of human vision is to explore the surrounding space and gather detailed information about the objects and images most attracting the subject's interest.

In modern work organization, the visual system is used progressively less as a sensory organ able to satisfy an individual's interest and increasingly as a "work instrument" obliged to make predetermined and repetitive visual efforts for prolonged periods of time. In work places, in fact, the visual function is subject to many constrictions of various nature imposed by organizational necessities (environment features, time and duration, instruments and equipment, procedures, etc.), which can be responsible for discomfort and/or disorders.

Occupational risk for the visual system could be schematically subdivided into: (i) task-related and (ii) environment-related.

3.1. Task–related Risk

The occupational visual effort can be divided into two main categories: (i) requiring mainly *far vision*, and (ii) requiring mainly

Table 1. **Examples of some common near-visual tasks.**

Sector	Task
Aviation	air traffic controller
Bank and insurance press Telephone companies Airport service Design activities in industry	VDU work
Ceramics	decoration
Clothing	quality inspection and mending
Research Laboratories Microsurgery Electronic components industry	work with microscopes
Pharmaceutical industry Food industry	impurity controls
Sheet metal industry	precision mechanics engravers welders
Jewellery industry	bench work
Photographic industry	photo compositors and binders cartographers topographers
Craftsmen (artisans)	decorators sculptors engravers wood carvers lithographers
Movie industry	film editing, splicing, cutting, montage

near vision. From a physiological point of view, the effects that can be induced by different efforts are clearly different.

While far vision is achieved by a natural and well-balanced involvement of the different components of the visual system (nervous, muscular, and refractive), near vision burdens the system particularly with two specific functions: accommodation and convergence. Their activation implies a complex muscular and nervous effort (see 2.1, 2.2)

It is well known that tasks which require near visual effort can cause ocular and visual disturbances (occupational asthenopia) often associated with conjunctive hyperemia and over-lacrimation, rarely found in far-visual tasks and in non-occupational activities.

Studies were carried out mainly in VDUs operators, but it should be mentioned that many other workers are exposed to similar conditions (see table 1).

From an ergophthalmological point of view all these job categories have a common element: they all require a *near*, *prolonged*, and *fixed* observation.

The term *near* is used because the objects and instruments to be observed are usually placed within 1 meter, with an average daily observation distance ranging from 50 to 70 cm.

The term *prolonged* refers to situations where types of tasks and/or techniques used demand near point fixation to be maintained for many hours a day.

The term *fixed* is related to the physical and structural limitations of indoor work places where walls, curtains, wardrobes, dividers, etc., frequently do not allow far vision (i.e. over 6 meters), therefore greatly reducing the physiological alternation of activation and disactivation of accommodation and convergence to their full extent and consequently increasing the amount of contraction, which is mainly isometric, of the muscles involved.

For these reasons in a vast number of operators occupational tasks can produce an overloading of accommodation and convergence which normally represents a major cause of transitory disturbances. The risk of permanent alteration, particularly for long-term near work exposure (over decades), is still matter of dispute. To date the literature reports no clear-cut studies able to confirm or deny this hypothesis.

3.2. Environmental Risks

3.2.1 Chemical pollution

Studies carried out on the Sick Building Syndrome (SBS) and on health effects linked to Indoor Air Quality (IAQ), have demonstrated the presence of a high number of airborne substances in industrial and non-industrial working environments. Indeed, these researches quite often report "eye irritation" as a common or very common complaint in some categories of workers, particularly office operators.

Among the many potential chemical agents found in these workplaces, those that most affect ocular mucosa are: aldehydes (especially formaldehyde, acetaldehyde and acrolein), oxides and nitrogen (NOx), Volatile Organic Compounds (VOCs), Environmental Tobacco Smoke (ETS, i.e. a mixture which includes respirable suspended particles, CO, nicotine, nitrogen oxides, acrolein, nitrous compounds and benzo(a)pyrene), ozone, dust, and fibers.

The source of these pollutants, which are frequently present in higher concentrations in indoor rather than outdoor environments, can be carpets, furniture, painted surfaces, and cleaning agents, as well as photocopying machines, laser printers, facsimile machines and combustion sources (kerosene and unvented gas heaters).

All these chemical agents are potentially able to produce ocular irritation and disturbances when in contact with the outermost part of the eye, i.e. the "ocular surface". The ocular surface is an anatomo-functional identity that comprises lacrimal film, corneal and conjunctival epithelia. Thanks to its versatility and adaptability it is able to sustain adverse indoor air quality conditions, obviously up to a certain limit. Over that limit, which can vary considerably even in normal subjects in relation to age and gender, ocular disorders, such as decreased foam formation, reduced lacrimal film stability (abnormal break-up time test), conjunctival and corneal epithelium alterations can be observed.

3.2.2 Microclimate and Illumination

Microclimate and illumination are the most important environmental sources of ocular and visual disorders. Regarding the first, relative humidity, particularly if below 40%, and air velocity, i.e. eye hit by flows originating from fan-coils, air conditioners, office equipment cooling systems (VDUs, printers, photocopiers), etc., are possible causes of eye irritation. In these circumstances, a corneal flogosis and sufferance can arise due to an excessive evaporation and consequent lack of lacrimal film on the ocular surface.

Environmental lighting today is much more important than in the past due to two groups of interrelated factors:

i. Work activities are carried out increasingly in indoor environments.

ii. Fine work, particularly "computer tasks" are becoming more and more widespread. (In this respect, it is appropriate to note that according to the European Foundation of Living and Working Conditions, in 1997, out of 147 million workers in the European Union, 55 million were using computers.)

There are numerous researches where office lighting is linked to visual discomfort and fatigue (see table 2). Moreover, studies on VDU work, where illumination is unanimously recognized as a major contributing factor, often report a frequency of complaints varying from 25% to 85 % , with an average frequency of 62% (see table 3).

Table 2. Illumination and visual complaints in VDU operators.

Authors	Year	Population studied	Frequency of complaints
E. Gunnarson and O. Ostberg	1977	German VDU operators	76%
A. Cakir *et al.*	1979	Swedish VDU operators	68–85%
L. Ghiringelli	1980	Swiss VDU operators	76%
L. Scullica and C. Rechichi	1980	Italian VDU operators	25%
B.L. Cole, I.D. Breadon *et al.*	1986	Australian VDU operators	50%
R.I. Wibon and L.W. Carsson	1987	Scandinavian VDU operators	70%
H. Lindner	1994	VDU operators	58%
B. Piccoli	1996	Italian VDU operators	70%

Table 3. Office lighting and visual disturbances.

Authors	Year	Detail
A. Cakir, D. Hart *et al.*	1980	Factors able to affect the incidence of visual fatigue. . . The level of illumination
Human Factor Soc.	1981	Incidence of eye troubles is associated with excessive luminance contrast...
ILO	1989	Increased visual disturbances attributed to glare and inadequate lighting....
P. Boyce	1991	... visual enviroment created by lighting can cause discomfort in VDT users..
Sheedy	1992	The most common complaint of VDT users is glare.
H. Lindner	1994	Asthenopic complains frequently occur in conjunction with illumination...
IES	1995	Discomfort may be caused by viewing a light source or a reflection...

There could be several causes for this high prevalence of occupational visual disturbances reported as illumination-related:

(a) a wide distribution of self-compiled questionnaires where the data are biased by subjectival factors;

(b) a synergistic link with overloading of visual functions and/or with non-lighting environmental-related aspects;

(c) inadequate indoor work-place lighting design, both in theory and in practice.

Regarding the last point a few observation are in order.

The main parameter referred to when a lighting system is being designed is almost always the *illuminance,* measured by the luxmeter. This kind of photometer does not seem adequate to furnish measurements congruent with human anatomy and physiology for two reasons:

1. Its measurements are strongly influenced by the incidence angle of straylight ("cosine effect"), while this does not happen in the eye (figure 1);

2. The photovoltaic cell of the luxmeter detects light over a large angle (i.e. includes straylight originating from a wide portion of space), while for most operators, particularly when involved in near work, due to the characteristics of ocular structure and functions, the light which actually affects the eyes, and namely the fovea, comes from a very limited area of the surrounding space (figure 2).

Actually, a photometric evaluation able to detect light over small angles (< 5°) can be carried out by using a luminance photometer (telephotometer or video-based photometer).

Both approaches have their validity. The first is appropriate for lighting control strategies (energy saving, minimum maintained levels, daylight factor component, esthetic applications, etc.). The second seems more adequate for a reliable evaluation of light actually involving the operator's visual system.

3.2.3 Microbiological agents

Bacteria, fungi, and viruses are often found in indoor environments and, according to the numerous SBS investigations reported in the literature, they are believed to have a role in the

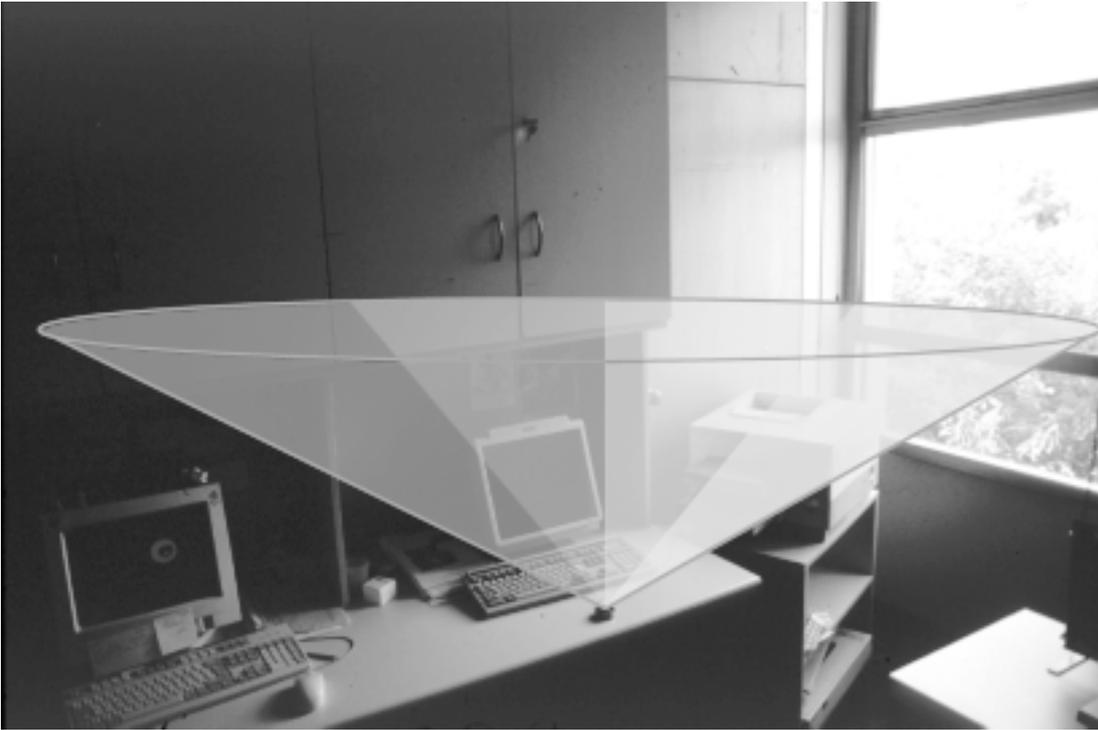
Figure 1.


Figure 2.

development of certain respiratory and skin disease of the occupants.

The origins of microbial contamination are usually outdoor air (bacteria and fungal spores) and humans. They are sustained or worsened by poor maintenance of air conditioners, fan coils, and humidifier systems, as well as by carpets and office equipment, including keyboards and computer mice.

We should also consider the numerous microrganisms normally present in the working environment, which can play a pathogenic role if they come into contact with specific organs and mucosa of the human organism (for instance *Pseudomonadaceae*).

The ocular conjunctiva and cornea, due to their external position, can be easily contaminated by microrganisms present on periocular tissues and hand skin. In everyday clinical practice, infective diseases of the ocular surface (conjunctivitis, cheratitis, dacriocystitis, etc.) are quite common and symptoms normally include burning eye, photophobia, lacrimation, gritty feeling. Due to the fact that these symptoms are also commonly reported by office operators ("VDU asthenopia"), it is quite likely that, unless specific ophthalmological examinations are carried out, the origin of these infections will be misinterpreted.

General preventative measures can be recommended:

(a) worker education (good personal hygiene and restriction of food consumption at work);

(b) cleaning procedure using an appropriate antimicrobial product;

(c) environmental investigations and ophthalmological check-ups in cases of high prevalence of ocular surface infections in a specific working population or recurrent ocular infection in individual operators.

3.2.4. Preventive measures

The following essential primary and secondary preventive measures, concerning job organization and environmental and medical issues, can be recommended:

(a) implement working procedures and task sequences where near (< 1 m) vision sessions are interrupted by breaks or far-vision activities;

(b) make it possible to look into the distance from each workstation and wherever possible with outside view;

(c) keep luminance ratios in the environment generally, and inside the "occupational visual field" particularly, to a minimum with specific regard to computer-based equipment operators;

(d) avoid relative humidity being lower than 40% and eliminate constant air-flows towards the operator's eyes;

(e) minimize ocular-irritative airborne substances;

(f) provide antimicrobial cleaning procedures when multi-user work equipment (particularly keyboards, mice, telephones, etc.) is present;

(g) carry-out appropriate eye examinations before commencing work in order to evaluate the compatibility of the operator's visual capacity with the performance required (job-fitness evaluations);

(h) activate health surveillance programs for: (i) prolonged near-work operators (computer-aided design, precision mechanics, goldsmiths, etc.) particularly if under 18 years old; (ii) operators involved in high attention and intense cognitive performances (airline pilots, crane drivers, air traffic controllers, nuclear power station operators, etc.); (iii) hypersusceptible subjects (refractive, binocular, and ocular surface alteration carriers, frequent task-related asthenopia cases).

The application of these measures will not only reduce injury and health risk, but will also have a positive influence on the morale of employees, thus becoming ethically appropriate and highly cost effective.

Event related Potentials

A. Yagi

Department of Psychology, Kwansei Gakuin University, 1 Uegahara, Nishinomiya, Hyogo, Japan

1. INTRODUCTION

Some brain potentials (e.g. EEG, spontaneous brain wave; ERP, event-related brain potential) can be measured from electrodes placed on the scalp. ERP is a sequence of electrical changes elicited by sensory or perceptual stimuli, and cognitive events. ERP technology has some advantage compared with other psychological methods such as questionnaire and performance indices. ERP changes can be measured objectively, quantitatively, in real time and temporally. The potentials to an unconscious (subliminally) stimulus and to an ignored stimulus can be measured in the study of attention. Aims of research on ERP in ergonomics are classified into two categories. The first is basic laboratory studies on the nature of ERP in relation to human information processing. The second is studies aimed at the application to field settings. Studies have been conducted that are applied to the assessment of environment and mental workload in ergonomics. At an early period (the late 1960s) in the history of ERP, the potential was called the evoked potential (EP) or the evoked response, because the potential was recognized as evoked by sensory stimuli. However, since similar potentials are elicited not only by sensory stimuli, but also by such subjective events as attention, decision-making and language process, and by the voluntary movement, the potential is now referred to as the event-related potential (ERP).

2. MEASUREMENT OF ERP

Since ERP is a very small change in electrical activity of the brain, direct observation of ERP is difficult since it is intermingled with EEG. EEG must be recorded to obtain the ERP. Regular EEG amplifiers can be used but an amplifier with a long time-constant is preferred because the ERP includes lower frequency components. To obtain an ERP, successive stimuli or a sequence of events have to be presented to a subject. The EEG is triggered by the onset of a stimulus or event and EEG epochs associated with the onsets are averaged (Figure 1). Because the spontaneous EEG is assumed to be a random process, the averaged EEG gradually approaches zero. On the other hand, ERP linked to the events become increasingly clear as the number of trials averaged increases. Visual, auditory and tactile stimuli have been mainly used in ERP studies. Therefore, to obtain an ERP, signals associated with repeatable stimuli, responses or events are required to trigger EEGs for averaging. Some of the ERP occur not after the stimulus onset but before the event onset (e.g. the readiness potential and the motor potential).

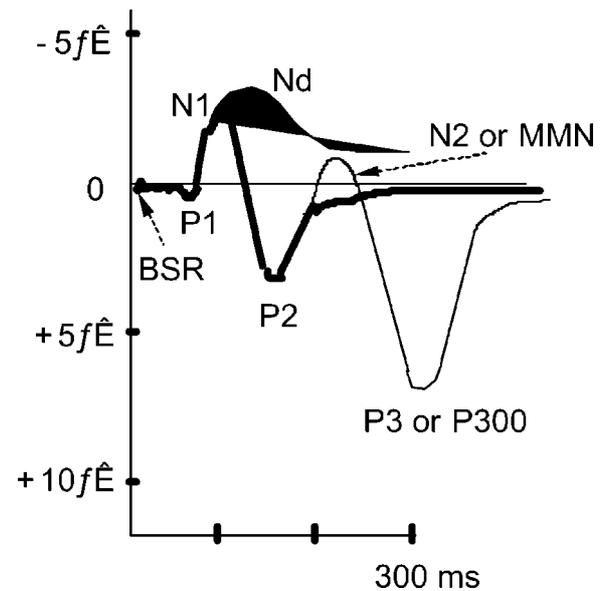
3. VARIETY OF ERP
3.1. Endogenous and Exogenous Components
ERP is classified into several groups based on the stimulus modality used, the paradigm of a task, latency (the time from stimulus onset to the peak of the potential), and the distribution


Figure 1. Model of auditory ERP. ERP consists of several components. Upward negativity.

of the potentials on the scalp. Further, each component can be classified into subordinate components. Some well-known ERP related to ergonomic issues will be discussed here.

A unique component, one which is specific to the modality and which changes with the physical property of the stimulus, is called an exogenous component. A component elicited by a psychological or physiological event is called an endogenous component. For instance, when a stimulus is unexpectedly omitted in a sequence of stimuli presented regularly, a large amplitude-positive deflection appears, in spite of the absence of an external stimulus. This component appears at the moment when the stimulus was expected. This is a typical endogenous component. An exogenous component may be used in the assessment of sensory or perceptual events (such as sensation and discrimination) in ergonomics. An endogenous component is expected to be most useful in ergonomic studies concerning mental workload, attention, decision-making, vigilance, etc. The Nd wave, the mismatch negativity, P300, the eye fixation-related potential, the contingent negative variation, the readiness potential and the motor potential are slow potential changes occasionally applied in ergonomics studies.

3.2. ERP by Auditory Stimuli
Figure 2 shows a model ERP recorded at the vertex of the head evoked by auditory stimuli. The waveform consisted of several components. Upward deflection in the potential is traditionally used to demonstrate increases in negativity in both EEG and ERP studies. The components, which appear very early (< 10 ms) after onset of auditory stimuli, are called the brain stem response (BSR). They reflect the progress of neural signal through the auditory nervous system. The responses used for the diagnosis of deficits in the auditory system. The components with latency of > 100 ms are related to psychological events. N1 with latency of ~100 ms, is an exogenous component, which changes with intensity of the auditory stimulus. When a subject attends to a given stimulus, the Nd wave extends beyond N1. When attention

is directed to an unexpected stimulus, a large amplitude positive component (P300) occurs after the stimulus onset (see below).

3.3. Visual Evoked Potential (VEP)

VEP, which is observed predominantly at the occipital region, is a transient potential evoked by a flash, pattern and color. VEP changes with such stimulus conditions as luminance, contrast, the spatial frequency, the wavelength, stimulus duration and the visual field. The slow negative wave and/or P300 may, as is true of auditory stimuli, also occur at the vertex of the head depending upon the nature of the event. The VEP has been principally applied to studies in clinical settings rather than in ergonomics,

because movements of eyes have to be restricted in measurement of these VEP.

3.4. P3 or P300

When auditory or visual stimuli are presented after the subject had to guess the modality of the upcoming stimulus, a late positive component with a peak latency of ~300 ms occurs in ERP to both auditory and visual stimuli (Sutton *et al.* 1967). The component is called P300 or P3, which is the third major component of the ERP. P300 is affected by psychological parameters such as stimulus probability, target discrimination (Figure 3), relevance, discriminability, response requirement, refractory period, age, performance task and etc. A widely used paradigm in the ERP (P300) study requires the subject detect infrequently occurring target or 'oddball' stimuli occurring unpredictably in a sequence of standard stimuli. Therefore, many researchers deal with P300 as an index of mental workload, attention, etc. in ergonomics.

3.5. MMN or N2

If, following a series of auditory stimuli, the stimulus suddenly changes, a negative wave at ~200 ms occurs. This component is called the mismatch negativity (MMN) or N2 (Naatanen *et al.* 1978). MMN occurs with any change in the physical property of the repetitive stimulus. MMN occurs to stimulus change even if the subject is not aware of the change because attention is directed elsewhere. The amplitude of MMN varies with the degree of the difference from the repetitive standard stimuli. When the subject is aware of the change, MMN is followed by P300.

3.6. N400

When a subject is asked to read silently a word completing a sentence (e.g. 'He spread the warm bread with socks'), which is

NT ——— TG ·······

Oz

LR

P3

5 μV

0   400   800

Time (ms)

Figure 3. Example of the lambda response (LR) and P3 in EFRP. The lambda response is followed by P3, when a target signal is detected in a situation requiring visual search. NT: EFRP to eye fixations at non targets. TG:EFRP to eye fixations at detected targets. OZ: occipital region on the scalp. Time zero (0) shows onset of eye fixations. Upward negativity.

presented one word at a time on a CRT, a prominent negative component peaking ~400 ms (N400) is elicited by an unexpected and semantically anomalous word. However, words that are semantically appropriate but physically deviant from the rest of the sentence elicit a late positive component similar to P300. Thus, the processing of any semantic stimulus that is unpredictable and unprimed may be associated with N400.

3.7. Eye Fixation-related Potential (EFRP)

When a subject looks at something, the eye movement record shows step-like pattern identified as saccadic eye movements with eye fixation pauses between such saccades. Information concerning the nature of the visual object is sent from the retina to the brain during the fixation pause. When EEGs are averaged time-locked to fixation pause onset, i.e. offset of saccades, the eye fixation related potential (EFRP) is obtained (Figure 2). EFRP is an ERP measurable in situations requiring eye movements. EFRP like ERP consists of several components. The most prominent component with latency of ~100 ms is called the l response. Some components of EFRP, especially the l response, change as a function of stimulus properties, e.g. spatial frequency, contour and the brightness of the stimulus, as well as subjective factors, e.g. attention, signal detection and language processing. The l response is followed by P300, when a signal is detected in a situation requiring visual search (Figure 3). It is thus the possible to apply the EFRP in ergonomic studies.

3.8. Contingent Negative Variation (CNV) and Readiness Potentials (RP)

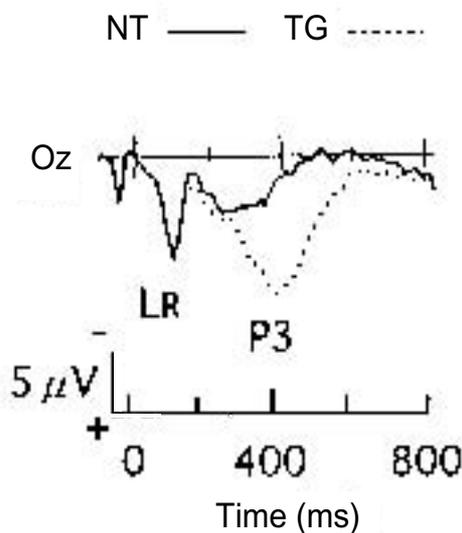
CNV is a relatively long-lasting negative shift, which develops between the presentation of a warning signal (S1) and a second stimulus (S2) that requires a response. The CNV begins within 200 to 100 ms after S1 and reaches its peak within 100–900 ms if the S1–2 interval is 1000 ms. The amplitude drops suddenly when S2 is presented. A simple pairing of stimuli without response requirements results in no appreciable negative shift. The CNV reflects a state of expectancy. CNV indicates an intention to act, subject motivation or attention. The readiness potential (RP) begins at ~500–1000 ms before a voluntary movement and peaks at the moment of response (Figure 1). The last part of RP includes the motor potential (MP) which initiates a voluntary movement.

4. QUANTIFICATION OF ERP

Indices for quantification used in ERP studies are: peak amplitude of a specific component from the base line, the peak-to-peak amplitude between neighboring components, the area of a component, and peak latency from stimulus onset. Another index of ERP in cognitive studies is the similarity (or inverse variability) that can be calculated by measuring the correlation between two ERP waveforms. The distribution of those values is displayed topographically to observe mutual relations of ERP recorded from many regions on the scalp. Further, new procedures have been developed to identify electric dipoles of ERP in the brain to identify the location from which the electrical event is triggered.

5. COGNITIVE FUNCTIONS AND ERP

5.1. Attention and ERP

There are studies that deal with the relationship between attention and ERP. When the subject pays attention to a specific auditory


stimulus, the N1–P2 component increases in amplitude. However, attention is an ambiguous term that has many meanings, such as selectivity, concentration, vigilance, search, arousal level, etc. The effect of selective attention on ERP has been an issue of controversy for a long time. The criticism suggests that an increase of N1–2 amplitude at the vertex reflects a nonspecific arousal effect produced in response to the task relevant stimulus rather than selective attention. In a selective attention study, it is required that ERP should be measured under the condition where non-specific arousal does not affect ERP. For example, the subject is asked to attend to one channel and to respond to a stimulus change under conditions where auditory stimuli are delivered rapidly and to the two ears (Hillyard *et al.* 1973). Nd is obtained by subtracting ERP in an unattended channel from the ERP to those same stimuli while they are being attended. Nd is a neural sign of stimulus processing that follows stimulus set selection. When the task requires visual attention, the subject is asked to fixate on a fixation point in the center of the visual field. The subject attends to flashes presented to either side of the light or to only one side to detect target flashes that deviated in brightness, size or color from the non-targets. In the occipital region, positive and negative components with latency between 100 and 300 ms are elicited to the flashes in the attended field. The Nd-like slow negative wave is observed at the frontal region in the visual task. Thus, in a visual ERP study, the subject is asked to fixate eyes on a special point and not to move eyes.

5.2. Mental Workload and ERP

Recording the ERP to stimuli in an unattended channel can provide a measure of how fully those stimuli are being processed, without disrupting the subject's attentional strategy. In the early years of the 1970s the first application of ERP (to auditory stimuli) to the study of mental workload started in dual task situations on the assumption of the single channel theory. In 1980, it was found that the P300 varied with the demands made on perceptual rather than response resource (Isreal *et al.* 1980). An auditory oddball sequence as a secondary task has been used to probe cognitive processing during joystick tracking of visual target. Increasing the perceptual demands of the tracking task by increasing the number of visual targets to be tracked attenuated the P300 to the oddball stimulus. P300 reflects an allocation of resources to stimulus evaluation. There are many studies on P300 in the dual task method. For instance, the technique is applied to assess the workload in a radar operation and an instrument board.

5.3. Signal Detection and ERP

In signal detection task, the subject makes decision concerning the presence or absence of a stimulus. Vigilance is one of the first themes on ERP studies. The ERP waveform to detected stimuli is different from that to missed signals. When the subject reports the confidence of detection judgment, the P300 and a negative wave with peak latency of ~100–200 ms increases in amplitude and decreases in latency as a function of the level of confidence. The ERP is measured to assess responsiveness to the warning signal.

5.4. Application of EFRP

EFRP is applicable as an index of a visual task under eye movement situations. The waveform of the EFRP changes with the type of screen (positive or negative) on the CRT. When subjects enjoy performing a computer graphic task, EFRP increases in amplitude. On the other hand, the amplitude decreased when subjects are tired or when the arousal level decreases. Variations of EFRP are related to attention and arousal level during task performance.

Intermittent visual stimuli are required to measure ERP related to a visual environment. However, such intermittent lighting is different from usual illumination. EFRP can be obtained under the majority of lighting conditions by measuring EOG and EEG. EFRP is a useful index for assessing changes in the lighting environment. Latency of the lambda response in EFRP changes with the luminance of the work area. The stability (inverse variability) of the waveform of EFRP reflects the level of concentration of attention to the tasks under the various lighting conditions (Yagi *et al.* 1998).

Early components in the EFRP change in amplitude with complexity of textile patterns. The result suggests that EFRP may be applicable as an index to evaluate complexity of textile patterns and visual environments. Thus, EFRP has major possibilities for application in ergonomic studies.

6. CONCLUSION

Because EEG is a very small electrical signal, noise or artifacts seriously compromise results in field studies. To reduce such noise the worker's body and eye movements are often restricted. Therefore, ERP as perceptual or cognitive indices is mostly studied in the laboratory. Current developments of very small EEG amplifiers and a telemetry system make it possible to measure EEG in industrial settings and in outdoor situations. Since new analysis procedures are being developed to allow for the extraction of usable signal from noisy data. This will allow for the application of ERP technology to many more areas in ergonomics.

Force Exertion: Pinching Characteristics and Strengths

S. N. Imrhan

Industrial and Manufacturing Systems, Engineering Department, University of Texas, Arlington, TX 76019, USA

1. INTRODUCTION

Grasping and squeezing objects and manipulating them with the fingers are common workplace activities. However, it is widely accepted that they cause or contribute to hand overexertion disorders, known as cumulative trauma disorders (CTDs). Three main factors have been implicated in the prevalence and severity of these disorders: great muscular contractions in squeezing, repetitive muscular contractions in maintaining high rates of work (even if they are not of great magnitude), sharp bending of the wrist, and inadequate rest. In order to prevent or minimize CTDs, these factors must be carefully analyzed. This article examines the strength of the fingers in pinching. Like hand gripping, pinching has been deemed one of the main factors responsible for CTDs of the hand, such as carpal tunnel syndrome, trigger finger, and other forms of tendinitis. This article discusses pinching. No attempt is made to explain the details of CTDs of the hand since that topic is discussed elsewhere.

In this article, the term "strength" is defined as the maximum force or torque that a person can generate at the hand-handle (object) contact while gripping and squeezing the handle or object. Such strength is measured from a maximum voluntary muscular contraction (MVC); that is, the maximum a person is willing to exert during a 4-6 s maximal effort without suffering from pain or significant muscular discomfort. This technical definitions is widely accepted within the discipline of ergonomics but other definitions and interpretations have been used in other disciplines (e.g., physiological studies and exercise and physical fitness studies) and by the general public.

The terms "grasp" and "grip" will be used interchangeably. Existing definitions of grasping have identified two types — prehensile and nonprehensile grasps. Both types are defined in my article on handgrip characteristics and strength. In pinching, an object is grasped between the pad of the distal phalange of the thumb and the pad of the distal phalange of one or more of the other fingers. In finger torquing, the object being torqued (e.g., a small jar lid or electrical connector) is pinched and a rotary (turning) force applied either in a tightening or loosening mode.

2. TYPES OF PINCH

The pinch terminology in the clinical field (Smith 1985) has been adopted by ergonomists. It refers to one-handed pinching. Work tasks typically use the following types of pinch:

- *Lateral pinch*: the thumb opposes the lateral aspect of the index finger (which acts as a buttress) with the fist clenched.
- *Pulp pinch*: the thumb opposes one or more of the other fingers.
- *Chuck pinch*: the thumb opposes the index finger and middle finger simultaneously.
- *Four-finger pinch*: the thumb opposes the index, middle, and ring fingers.
- *Five-finger pinch*: the thumb opposes the other four fingers.

There are different types of pulp pinch depending on which finger opposes the thumb: pulp 2 pinch uses digit 2 (index finger); pulp 3 uses digit 3 (middle finger); pulp 4 uses digit 4 (ring finger); and pulp 5 uses digit 5 (little finger). The pulp 4 and 5 pinches are uncommon for work tasks.

3. PINCH STRENGTH TESTS

The strengths of some of these pinches have been measured in several experiments by different researchers. The typical method of measurement is the clinical one in which the two lips of a pinch gauge are gripped with the thumb and other finger(s) with all finger joints in low to moderate flexion. The hand is held at elbow or shoulder height with the forearm in mid-orientation. The lips of the pinch gauge are then squeezed by the fingers maximally for 4–6 s and the peak or middle 3 s mean force recorded. Most published pinch strength data uses peak values. Mean values are about 10–15% lower than corresponding peak values for the same pinch. There is very little motion of the lips when squeezing on the pinch gauge. So for practical purposes, the exertion may be considered as static.

Dynamic pinching has yet to be investigated. For all except the lateral pinch, pinching involves flexion of all the fingers. There is a limited amount of data using a variation of this method in which the thumb is hyperextended (Imrhan and Rahman1995); this reflects what happens in many work tasks. It is wise to check these points in order to avoid misinterpretation or misapplication of published data.

The method of pinch testing described above has disadvantages for ergonomics because much pinching in the workplace is performed differently and on objects that are of different physical characteristics (size and shape) from those of the typical pinch gauge. Some pinch gauge lips have limited area (2.0–1.4 cm), each smaller than the area needed to accommodate more than one finger comfortably in a large percentage of the population; and these lips are separated by a fixed width (separation distance between thumb and the other fingers) of 1.6–1.8 cm. These limitations preclude the measurement of pinch strength at all except this fixed width. It is also important to remember that almost all published pinch strength data is based on one-handed exertions using the clinical method of pinching. My two-handed pinch data will soon be published in the ergonomics literature.

4. PINCH MAGNITUDES

Because of differences in pinch conditions and subject samples in different experimental studies, pinch strength magnitudes vary widely among the different studies. But if we omit data from studies which show much greater or smaller magnitudes (somewhat extreme) than the other studies, the following generalizations may be made about static pinch strength magnitudes.

4.1. Traditional (Clinical) Pinching Method

For traditional methods the lateral pinch is 8.2–10.1 kgf (80.4–99.0 N) in males and 6.4–8.0 kgf (62.8–78.5 N) in females. The other pinches may be expressed as ratios of the lateral pinch as

follows. Handgrip strength is about 4.5 times lateral pinch strength.

Five-finger	1.3
Chuck	1.0
Pulp 2	0.7
Pulp 3	0.7
Pulp 4	0.45
Pulp 5	0.3

4.2. Nontraditional Pinching Method

For the nontraditional pinching methods in which the thumb is allowed to hyperextend, pinch strengths are significantly greater. For this method, at large pinch widths, chuck pinch is 16.9–18.4 kgf (165.7–180.4 N) for 2.0–5.6 cm width range, lateral pinch is 12.8–14.2 kgf (125.5–139.3 N), and pulp 2 pinch is 11.0–11.7 kgf (107.9–114.7 N). At greater widths all three pinches decrease steadily from these values. Chuck and pulp 2 decrease to 9.0 kgf (88.3 N) and 5.7 kgf (55.9 N), respectively, at 14.0 cm width, and lateral pinch to 8.0 kgf (78.5 N) at 9.2 cm width.

5. FACTORS INFLUENCING PINCH STRENGTH

MVC pinch strength magnitudes are strongly influenced by the method of pinching and the characteristics of the object being pinched. These two factors include wrist position (or wrist bending), forearm orientation, forearm position in the coronal plane, forearm support, elbow angle, body posture, finger joint position, position of inactive fingers, use of gloves, and personal factors such as age, sex (or gender), and anthropometry. The nature and extent of these these influences are discussed below. Unless otherwise stated, pinch strength below refers to static exertions using the traditional (clinical) method.

5.1. Types of Pinch

The various types of pinch commonly used for work tasks have been listed above. People know from experience that pinches are not all of equal strength, and several studies have been conducted specifically to determine which pinches are greater or less than others under similar pinching conditions. Swanson *et al.* (1970) and Mathioweitz *et al.* (1985) are two of the earliest large-sample studies. Most of these studies have concentrated on the lateral, chuck, pulp 2, and pulp 3 pinches since they are the most commonly used in the workplace, and they are customarily tested for clinical applications. The results have indicated that pinch strength magnitudes may be arranged in the following order, from strongest to weakest:

Five-finger and four-finger
Chuck and lateral
Pulp 2 and pulp 3
Pulp 4
Pulp 5

The individual pinch strengths within the pairs, such as five-finger and four-finger pinches, are not significantly different from each other. Some studies have found that the chuck pinch is stronger than the lateral pinch whereas others have found near equality of the two pinch strengths. The disparity is most likely due to variations in pinching conditions. However, the accumu-

lated evidence indicates near equality of strength for lateral and chuck pinches.

5.2. Types of Test

Pinch strengths measured by traditional (clinical) methods have yielded different results from those measured by nonclinical methods, both in the absolute magnitudes and in relative magnitudes among different pinches. When people pinch (i) with greater finger-object contact area, (ii) with freedom to hyperextend the thumb (for chuck and pulp 2 pinches), and (iii) with the hand at about worktable surface height (instead of at elbow or shoulder height), then they achieve greater MVC strengths and the chuck pinch is stronger than the lateral pinch at any pinch width. Moreover, at great pinch widths (greater than or equal to 6.8 cm) the pulp 2 pinch is stronger than the lateral pinch. Only pulp 2, chuck, and lateral pinches have been tested at large pinch widths.

5.3. Wrist Bending

The strongest pinches may be obtained when pinching with the wrist in its natural position — the hand at 15–35° dorsiflexion (also called extension, bending toward the back of the hand) relative to the forearm, depending on the person. Slight bending of the wrist away from this wrist position does not change strength significantly but sharp bending degrades strength appreciably (Imrhan 1991, Dempsey and Ayoub 1996). The amount of decrease depends on the direction of bending, with palmar flexion (flexion toward the palm of the hand) producing the greatest decrease, followed by dorsiflexion, ulnar deviation, and radial deviation in decreasing order of effect. In other words, up/down wrist bending is worse than sideways bending. Degradation due to flexion is about 24–43% and degradation due to extension is 9–31%, depending on the research study. Considering that wrist bending has been implicated as one of the major causes or contributing factors in carpal tunnel syndrome, tool and job designers should design such that sharp bending of the wrist is avoided.

5.4. Finger Joint Position

One study has found that the pulp 2 pinch is much stronger when the nonpinching fingers are flexed than when extended, with greater differences in females than in males.

5.5. Anthropometric Variables

Ergonomists have always been fascinated by the hope of developing a predictive equation for strength from one or more other variables that are easy to measure, such as anthropometric variables. Several of these variables, such as stature, body weight, and hand length are significantly correlated with various pinch strengths. However, attempts have been unsuccessful to find models that can predict pinch strengths from anthropometric variables accurately enough for ergonomic applications. Variables such as height, body weight, hand length, hand breadth, forearm circumference, biceps circumference, and grip diameter have all been explored. This means that pinch strength values for ergonomic engineering applications must be obtained from tables. Anthropometry-strength relationships are stronger in children than in adults and the elderly; this is most likely due to the parallel growth in body dimensions and muscle size.

5.6. Forearm Orientation and Position, Elbow Angle and Glove Use

A few studies have tested how pinches are affected by forearm orientation (pronated, supinated, and mid-orientated), forearm position in the coronal plane (from left to right of the body), external forearm support, elbow angle (90° and 180°), and glove use. Though differences were reported for these variables, they were either too small (2.5% and 3% for elbow angle, and 6–7% for forearm support) or too inconsistent across studies (forearm orientation and body posture) for these variables to be deemed influential; that is, some studies have shown an increase, decrease, or no effect for one or more of these variables. Moreover, biomechanical theory does not indicate that these variables should exert significant influences.

The single study on forearm position difference reported that the strongest position is with the forearm in front of the body with a decrease on either side; that is, an increasing/decreasing trend across the body. Use of gloves has been tested on the chuck pinch but it appears to be uninfluential; other pinches have not been investigated but it is unlikely the results will be different as long as the glove is not bulky enough to obstruct the pinch grip. Also, it is likely that pinch strength on sharp edges would be painful and weak, and it would be enhanced by using gloves of appreciable thickness to prevent pains but not thick enough to obstruct proper gripping.

5.7. Relationships with Other Manual Strengths

As expected, pinch strengths are strongly correlated with other types of hand strength, such as handgripping, pinch/pulling, and manual torquing, all of which use pinching muscles partly. Lateral pinch strengths have high correlation coefficients with torque strength on large-diameter cylinder handles, and lateral and chuck pinches have strongly correlations with pinch/pull strengths.

6. CONCLUSIONS

There are different types of pinch depending on which fingers are used. Their strengths vary considerably and any reference to pinch strength at work should specify clearly the type of pinch. Many factors influence pinch strengths and it would be simplistic and misleading to make reference to "pinch strength" as if it were a single entity. The conditions under which pinching occurs, such as pinch width, wrist angle, and use of gloves must be specified. Almost all the pinch strength data available in the literature is for static pinching with one hand using a restrictive method (clinical method) that does not reflect many pinching tasks in the workplace. Caution must therefore be exercised in applying this data to the design of work or hand tools for the workplace, and in assessing the severity of tasks. A few small data sets exist for methods of pinching resembling real tasks more closely. Since pinch strengths among studies vary widely (due to differences in subject samples and test methods), caution must also be employed in accepting data from any single study.

Force Exertion for (Consumer) Product Design: Information for the Design Process

B. J. Daams

Delft University of Technology, Department of Industrial Design Engineering, Jaffalaan 9, 2628 BX Delft, The Netherlands

Presently at: Daams Ergonomie, Mauvezand 17, 1251 JC Laren, The Netherlands

1. INTRODUCTION

First, a summary is given of design activities and accompanying ergonomic aspects. Next, a number of rules of thumb are given and some examples of application. Then, more precise data on force exertion are given. Finally some tips on measuring force exertion for design purposes are given.

2. DESIGN PROCESS

In a nutshell, the process of incorporating force exertion in design is the following.

First information should be gathered and analyzed. Existing products should be investigated. The function of the product, the target user group, the situation and the behavior of the users should be established or estimated. For design purposes, the weakest users are often more relevant than the strongest, and beginners more than experienced users. The result of the information and analysis phase is a program of requirements.

Then the implications for the design should be considered. Some elementary knowledge of physics and human force exertion, and some logical thinking are indispensable. Rules of thumb may be very useful in this stage. This may result in a schematic idea for the product with the most comfortable, efficient or maximal force exertion.

After the choice of the best concept the chosen idea will be detailed. Then it can be inferred which detailed information on force exertion is needed, to check whether the rules of thumb are right in this case, and to learn how high the exerted forces will be. This information must then be gathered from somewhere. A private investigation into force exertion with the right subjects and the desired postures is advised, but if there is not enough time, literature can sometimes give an indication of the range of forces involved. Now, knowing the limits within which the product should function, the program of requirements can be completed with operational requirements concerning force exertion.

Then the product can be designed. The first prototypes should be tested with subjects and evaluated, and the product should, if possible, be improved accordingly. This is important, especially if the information forming the basis for the program of requirements is obtained from literature.

If the required information on force exertion cannot be found, the probable forces involved cannot be predicted, but only very roughly estimated, and the design can neither be adapted beforehand to the needs of the users, nor be adequately tested and evaluated on the basis of a prototype. In most design projects, neither time nor funds are available to conduct experiments, and sometimes experience and enthusiasm are also lacking (except perhaps in cases where force interaction is a key topic for the design). So in general, designers have to rely on existing literature, which is so scarce that it takes much time to find details on the required force, if such information is to be found at all.

Thus, the information that is needed for the design consists of two parts:

- general information (rules of thumb) for the early stage of design; and
- detailed information (exact forces) for the detailing stage of design.

These rules of thumb are important, because they force the designer to think about a good design concept. If no effort is put in this first stage, it is no use to detail an ergonomically basically bad design.

3. RULES OF THUMB

The following rules are deducted from literature and physics. The concerning literature can be found in Daams (1994).

3.1. Users

- Women can exert on average two-thirds of the maximal force of men.
- For the lower extremities the ratio female/male maximal force is relatively larger, for the upper extremities it is relatively smaller.
- Maximal force is exerted between ~20 years and ~60 years of age.
- For different ethnic groups, maximal force may differ.
- People with rheumatism or arthritis (a common condition of old age) prefer push buttons over twist buttons. They do not like to hold buttons any longer than necessary.

3.2. Posture

- With two hands, more force can be exerted than with one hand (but not as much as twice).
- With the whole hand, more force can be exerted than with a (few) finger(s).
- With a support or a bracing possibility, more force can be exerted than without.
- With push and pull, most force can be exerted between shoulder and elbow height.
- With torsion and grip force: the closer to the body, the more force can be exerted.
- Use of body weight can lighten a heavy task.
- Pulling and pushing vertically down, maximal force is limited to the body weight of the user.
- Neutral joint position is to be preferred. Joints should not be held in extreme positions for a long time, and heavily loaded joints should not be held in extreme positions anyway.
- Moment = Force x Arm. A shorter arm with the same force thus results in a lower moment and vice versa. These simple calculations can help designing a lighter task.
- Maximal torque, but not maximal force, increases with increasing diameter of knobs and lids.
- Maximal forces exerted while standing with the feet close together are lower than those with one foot in front of the other.

● In free posture, more force can be exerted than in standardized or restricted posture.

3.3. Force, Time and Velocity

● Heavy work is lightened by rest periods.
● The longer a force is maintained the lower the maximal force.
● With low forces that are endured for a long period, the load caused by posture (especially the weight of the limbs) should be taken into account.
● The larger the movement, the more tiring it is.
● Large force exertion and precise positioning or handling do not go well together.
● With dynamic forces, eccentric forces are larger than concentric forces (eccentric is when the muscle lengthens during force exertion, concentric is when the muscle shortens during force exertion).
● Dynamic concentric forces are lower than maximal static forces in the same situation. The faster the movement, the lower the possible maximal force is.
● Endurance time of comfortable forces range from 0.4 (at 80%) to 0.2 (at 15%) of endurance time of maximal forces, when endurance time of comfortable force is defined as the "time to the first change of hand" (Daams 1994).

3.4. Grip

● Good diameter of a grip for lifting and carrying is 3–4 cm.
● Good grip span to exert grip force is ~4.5–5.5 cm wide.
● Grip should have no curvature, no sharp corners, edges, ridges, finger grooves or protrusions.
● Surface should be soft and non-slip.
● Grip force should not be a prerequisite for torsion, so the grip for torsion is preferably not round but has protrusions. The larger the protrusions, the less grip force is required for torque. A paddle or handle is best.

4. EXAMPLES OF THE APPLICATION OF RULES OF THUMB IN PRODUCT DESIGN

Questions concerning the forces that could be exerted on a product can never receive a standard, ready-to-use answer. Rules of thumb can help to configure a basic design that is easy to operate or to use. Some examples are given to illustrate this scope.

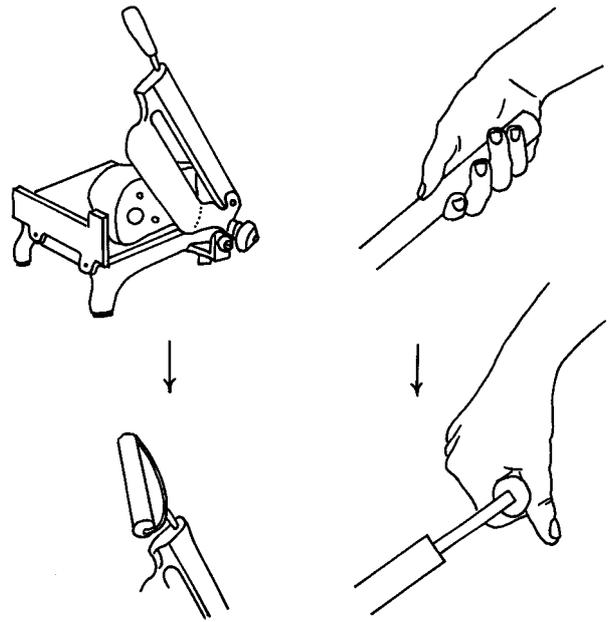
The first example concerns a large professional cheese slicer, as used in supermarkets (Figure 1). Present cheese slicers are fitted with a handgrip at the end of a blade that rotates around a pivot. The larger the blade (or the arm of the moment), the less force is needed to slice, but also the larger the movement of the hand. The handgrip is positioned in the same direction as the blade, so that the wrist is in an uncomfortable position when exerting force. The slicer is usually positioned on a table or bench, so that the force is exerted on the handle from about shoulder height to about elbow height. The users are women and men aged between 18 and 65. Instead of trying to find out how much force can be exerted in such a situation, thought is given to a more comfortable way to slice. Suggested improvements include lower positioning of the equipment, so that the force is exerted with the hand at elbow height and lower and body weight can be utilized, and a change of the handgrip so that the wrist need not be flexed to extreme degrees. If possible, the movement should be a translation instead of a rotation, so that force needs to be


Figure 1. Suggestion for improvement of a professional cheese slicer (Daams 1994).

exerted in one direction only. The optimal length of the arm, weighing the length of the stroke against the force needed to operate the cheese slicer, may be determined experimentally.

The second example concerns a wheelchair for children in Sri Lanka who suffer from the consequences of polio. Their legs are paralyzed, so the vehicle has to be moved by using the arms. How much force can they exert? For some mechanical reason, force was to be exerted in one direction only. Deciding on a force direction based on the direction in which the greatest force can be exerted is in this case not advisable. When pulling in a horizontal direction, the child will tend to pull itself out of the seat, which is uncomfortable and prevents maximal force exertion, even if the subject were to be strapped to the back of the seat. On the other hand, when pushing, the child will be able to brace itself against the back of the seat, which is more comfortable, and allows more force to be exerted. Therefore, if a choice has to be made, pushing against the back of the seat is preferred. It should be noted, however, that to exert force in both directions in a cyclic movement is better for the development of the muscles. Uneven development of muscle groups may lead to incorrect loading of the joints and related problems in the future. The use of two arms instead of one will, of course, allow more force to be exerted, and will also stimulate better physical development in the subject. To know the maximal forces, they should be measured for the actual children concerned. Although there are some data on maximal pushing and pulling abilities of European children in literature, this information can not be used, as it can not be assumed that children who are disabled and children from different ethnic groups exert equal maximal forces.

Third example: how much force is exerted on a paper punch? This can easily be measured with a weighing scale on a table. Place the punch on top of it and the exerted force can be read from the scale of the weighing scale. The maximal force that can be exerted is limited by the weight of the user. The results of a

small experiment showed that this theoretical maximum is not attained by any of the subjects, their maximal force being slightly lower.

The fourth example: for the design of a portable or rolling easel, information on maximal exertable push, pull and carry forces were asked. The easel is intended to be used for outdoors painting and should be easily transportable by a person on foot. The target group consists of elderly people, so the required force forms an important aspect of the design. Carrying is no option, because it will certainly require more force and energy than simply rolling the easel along. Rather than pushing it, a wheeled object is preferably pulled along because this makes it easier to negotiate ramps and kerbs (this is everyday experience and can be backed up with statics). The force necessary to stabilize and maneuver the easel should be as small as possible, because energy and attention should not be diverted from the main activity, pulling the easel along. The question then arises how much force elderly people can exert when pulling something along. If the lowest part of the distribution (say the P_1) of elderly women is included in the target group, the force that can be exerted is near to zero, for these people have barely sufficient strength to walk about unsupported, and will not have much force left to pull easels around. Therefore, the less force is needed to pull the easel, the better.

The fifth example concerns a hand-held device to suck venom from insect bites. The device had to be operated with two hands. Much force had to be exerted pulling vacuum, while at the same time the device had to be positioned on the skin. When operated by the person who was stung, it could only be applied to half of the body. Advice was given to separate force exertion and positioning in time, for heavy force exertion does not go well with precise positioning. The resulting product was constructed according to this advice. The vacuum is first built up, and it is released by pressing the device down with one hand on the skin. Both force exertion and positioning are now easier. Added advantage is that the product can be positioned single handed, which improves the accessibility of the body when used by the person who was stung.

The conclusion is that, with some rules of thumb, no measuring is needed to come to a design principle which is ergonomically sound concerning force exertion.

5. DETAILED DATA ON FORCE EXERTION

After the concept phase of the design, the details should be looked into. How much force can be exerted by the envisaged user group? Or better, how much force can be exerted by the weakest users?

This question must preferably be answered by research, but usually there is lack of time, money and/or interest to do so. Therefore the question about the force that can be exerted can only be answered by literature. Adequate information on force exertion in literature is very scarce, because a situation in which force exertion is investigated seldom corresponds with the situation in which a product is expected to be used, and even less with the real situation. An attempt to gather design-relevant information and to present it in a way useful for the designer can be found in Daams (1994). A choice from these tables is given in

the articles "Push and Pull data" and "Torque data". They comprise pushing and pulling force of adults, children, elderly and disabled.

6. SOME TIPS ON MEASURING FORCE EXERTION FOR DESIGN PURPOSES

For research, intended to provide information for (consumer) product design in general: measure in free posture. Measure discomfort of hand forces by change of hands (Daams 1994). Measure not only young and healthy males, but also children and elderly disabled women and everything in between.

For research, applied to one specific product: measure in the situation of envisaged product use. Measure in free posture if that is appropriate. Have subjects from the envisaged user group (preferably the weakest/smallest, etc. because then possible problems will show easier) Measure only what you need to know.

Provide the subjects with clear instructions on the purpose, duration, expectations etc. of the experiment. During the actual exertion of force, allow them a few seconds to increase their force to the required level. If maximal force for a short time is measured, follow the Caldwell regimen (2 s increase, 4 s maximal, the average of the four seconds is the maximal force; Caldwell et al. 1974). Do not encourage the subjects before or during the measurements and do not provide them with any feedback (except during measurement of endurance times). For submaximal forces at a low level (40% of maximum, and less), measurement of maximal endurance can take up to > 30 min.

If research on force exertion is published, relevant information should be mentioned in the publication. Indispensable information include, for example, description of subjects (number, sex, age, anthropometric data, and health status and occupation if relevant), direction of exerted force, shape and size of handle or contact surface, position of handle in relation to the subject, posture (if possible with picture), bracing possibilities and method of measurement. All this information is indispensable.

7. CONCLUSION

It must be emphasized that the general way of considering and approaching force exertion and using rules of thumb is even more important than specific and accurate data, as proper, logical reasoning will in itself lead to better designs. Probably even the fact that designers are giving the problem serious thought would lead to some improvement. The right data can provide the finishing touch in realizing a good design principle.

1. INTRODUCTION

Ergonomics is the science and the art of adapting a product, machine or environment to its users. The product should be comfortable, safe, and effective and efficient to operate, handle or use. It should meet these requirements in a number of ways, one being the force required to use the product.

This article focuses on forces exerted on consumer products. As an introduction, the problems with force exertion on products are illuminated. In two other articles by the same author attention is given to the relation between design, ergonomics and research, and to information for the design process.

2. CONSUMER PRODUCTS AND THEIR USERS

Characteristic for consumer products is that they are used voluntarily, by a variety of non-specialist users with different backgrounds, different levels of education and of varying strength. Generally speaking, they are used less than 8 hours a day, 5 days a week, all year round. The relative importance of consumer products for the user ranges from "essential" to "just for fun." Usually the person buying a product is also one of its users. If the consumer is not satisfied with the product, it may be replaced or just remain unused, and it will certainly not be bought again.

3. IMPORTANCE OF DESIGN FOR FORCE EXERTION

Users, even the physically weakest, should be able to operate, use or handle a product designed for them. A designer should therefore take into account the physical capabilities of weaker users, like the elderly, women, children and the handicapped, if they are targeted as future users. This is especially important in view of the "gray wave" of elderly people that is now flooding industrialized countries, and will continue to do so for the next few decades. The ability of the elderly to handle everyday products in and around the house determines how long they will remain able to live on their own. This ability depends not just on the people themselves, but also on the proper design of the products in their immediate surroundings. About half of the people in The Netherlands who move into a home for the elderly do so because they become can not to do their own housekeeping (De Klerk and Huijsman 1993). Products designed for this special group would help them to remain self-sufficient longer if they so choose, from which both they and the community would benefit. Even if a product is not especially intended for the elderly, a designer should realize that physical strength varies widely among individuals and that products intended for the general public will be used by different people, varying from those who are almost incapable of exerting any force at all, as is the case with the ill and elderly, to those with more than three times the average strength, as with young, healthy and well-trained men. Many individuals belong to relatively weak categories, and the lack of information on the characteristics and abilities of these groups is conspicuous.

On the other hand, very strong users should not be able inadvertently to damage or break a product. If this happens, the product may still be functioning, in which case the damage will be no more than a minor annoyance. However, it may happen that the product is broken and cannot be repaired. In the worst scenario, depending on the product and the situation, a breakdown will cause serious injury. This, of course, is something a designer must try to avoid. For some products, safety standards and regulations are defined; for others the designer has to find out what the acceptable limits are.

It can be argued that in these modern times products are becoming increasingly mechanized, servo-assisted and equipped with electronics. Less and less force is required for interaction with a product. Soon, one will require hardly any force at all to use the products the modern world offers. Why bother then about the forces people can exert? Because this reduction of force needed to operate or use products does not come about spontaneously, but has to be brought on by the designers of new products. It is therefore necessary to know about the capabilities of future users. Furthermore, if a product is designed with a more sophisticated view to force exertion, servo-assistance may not always be needed, which consequently makes it less complicated, cheaper and possibly less damaging to the environment.

Although large mechanical resistance and the corresponding necessity of large force exertion should be avoided in products, some force will always be required. For most products, this is inevitable as some functions inherently require force. For some products, resistance is indispensable for proper positioning. Without resistance, positioning would be awkward and overshooting would easily occur. All continuously variable controls, for example those on electronic equipment, therefore require some built-in resistance. For other products, resistance is indispensable to provide feedback, as for example with rotating dimmer switches, where increased resistance indicates the point where moving the knob any further will switch off the lighting completely.

In itself, it is a good thing that products require some force to operate them, as it is very healthy to do some physical exercise in daily life. In a domestic environment in which everything can be controlled at the flick of a switch, the inhabitants through lack of exercise will run the risk of losing their physical condition due to atrophy of the muscles and the cardiovascular and respiratory systems. One example of this is the use of the increasingly popular power-assisted bicycle. For the elderly, the ability to open a can with a normal can-opener can decrease through the use of an electric machine. This deterioration of health due to the use of products that require little or no force mainly applies to people who do not take regular exercise. This may eventually result in deterioration of health on a national or even international scale.

4. EXAMPLES

Some products are renowned for their resistance to consumer

efforts. These cases indicate the consequences of bad design-for-force-exertion. The list of problematic products includes a large diversity of products, among which the nutcracker, the train door and the jam jar feature prominently.

An interview with eight Dutch elderly ladies who do their own housekeeping gives some insight in the kind of products they can not operate (Daams 1987). Some of the women have problems turning water taps or radiator valves not fitted with knurled knobs, medicine jars, toothpaste tubes, and hand-operated can-openers because they require too much force. None can open jam jars or bottles of lemonade by hand. They must ask someone stronger than they to open these products, or resort to a variety of tools and tricks (although the use of tools does not always guarantee success). With some corkscrews, extracting the cork from a bottle is very difficult, but the double-lever type of corkscrew will easily do the trick. Most of these women had electric watches and alarm clocks, but those with mechanical clocks had problems winding them. Winding a watch is mainly difficult due to the small size of the crown.

Jam jars that are almost impossible to open will be a familiar phenomenon to most people. It is the traditional example of a form of packaging that is difficult to open. It is referred to as such in newspapers and popular magazines. A patient can even attempt to open a jar of peanut butter, and in the struggle strain the muscles of an arm, as experienced by Dorrestein (1993: 128–9). Problems with opening jam jars also received attention in research (Berns 1981, Daams 1987, Imrhan and Loo 1988) and design (Schoorlemmer 1989).

The nutcracker is a popular though problematic product. Many different mechanisms have been tried, none perfect. Cracking a nut takes too much force, not only for weak persons, and certain types of nut will resist any force applied to them. With several nutcracker systems the result is often nut pulp mixed with pieces of shell. Some nutcrackers, however, require so much force to operate that even persons of average strength will not succeed in using them properly.

Door-closing devices are designed to keep doors shut against draughts or to comply with fire regulations. Some perform so well that it becomes extremely difficult to open the door. Kanis (1991) describes a door in a train passage that automatically closes with such force that the elderly are hurt.

In many cases, operating the push button to flush a lavatory requires not only a minimum force, but also a minimum speed to succeed. This severely increases the degree of difficulty of the operation. In one case, the only way a healthy young woman could get the flusher to work was by applying a karate kick.

Opening the lid of some large photocopiers ought to be prohibited by law. The lid is very heavy and must be opened by pulling a handle positioned so that the wrist is supinated maximally and the hand is in near-maximal dorsal flexion. Pain in the wrist is the price to pay for a few good copies.

Another interesting product of which use is complicated by a lack of feedback is the car handbrake. It is hard to tell whether the brake is pulled sufficiently. Weaker subjects are stuck with the fear that their efforts were not sufficient and they will find their vehicle several meters from where they parked it (and hopefully undamaged). A stronger but not exceptionally strong subject is known to have broken off a brake handle with a seemingly gentle pull.

Disabled people who require the temporary aid of crutches can, after some exercise, move around quite swiftly and can sometimes even continue business as usual. Only then do they find out how great a force is applied by most door-closing devices. It is hard to open automatically closing doors while standing on one leg, and it requires some dexterity to keep them open long enough to pass through. Doors with less powerful closing devices are much easier to cope with, and apparently perform equally well in all other respects.

Latchkeys can be a problem too. An old woman had to make herself a tool for turning the key to her front door — something she could not do otherwise by hand.

Lighting a gas fire or a geyser can be quite tricky. To get the pilot flame going a button must be pushed or turned and held for as long as five minutes, or even more. This is certainly not an easy task with a spring-loaded button that requires much force.

Child-resistant closures are another category of products in which the required force is an important factor determining the rate of success. On the one hand, children up to a certain age should not be able to open the closure, while on the other hand the elderly must open it without problems. A complicating factor is that the maximal grip force of most 4-year olds exceeds that of many of the elderly. As the closures should be easy to open by the latter, the resistance to opening by children is often further improved by using a combination of two forces (like pushing and turning at the same time) to open the closure. Nevertheless, this still requires too much force of the weakest elderly person who must wrestle regularly to obtain their daily medicines or to open bottles of household detergents.

The examples of man struggling with various types of packaging, apart from the notorious jam jar, are many, notably with coffee-creamer cups (Kanis 1989a), milk cartons (van Putten *et al.* 1990), complimentary sachets of bath foam in hotels (den Uyl 1979) blister packaging, plastic wrapping, certain juice cartons, shrink-wrapped cucumbers (Stephan and Daams, personal communication, 1999) and slices of luncheon meat hermetically sealed in plastic. In those cases the packaging material is so smooth that the friction between packaging and hand is very small, and in addition the shape is often such that it is hard to get a good grip on it. Consequently, although a subject may exert sufficient force, he or she can not transfer it to the packaging.

Some products are not as easy to handle or operate as they could be. A good design may require investments, and when the benefits are not directly visible such improvements find little support. The cost aspect is especially important in packaging and may explain why a relatively large number of complaints originate from that area.

For some products, the cause of the problems can be bad maintenance (like those with the latchkey), or bad adjustment (like the toilet push button). This does not make the problem less serious for the user. Designers should allow for bad maintenance and bad adjustment in the design of their products.

5. CONCLUSION

It is of vital importance for designers to take the physical capacity of the users into account when designing a product.

Force Exertion for (Consumer) Product Design: Research and Design

B. J. Daams

Delft University of Technology, Department of Industrial Design Engineering, Jaffalaan 9, 2628 BX Delft, The Netherlands

Presently: Daams Ergonomie, Mauvezand 17, 1251 JC Laren, The Netherlands

To clarify the discussion on force exertion on consumer products, some characteristics of their relation are given, as is their respective relationship with ergonomic research. For more information on these subjects, see Daams (1994).

1. FORCE EXERTION AND CONSUMER PRODUCT DESIGN

The two main differences between consumer products and professional products are that consumer products are used voluntarily and by a broad group of users, with much variation in characteristics and background. Users of professional products are aged between 18 and 65, are generally healthy and for some occupations are predominantly male. Consumers include children, the elderly, the physically disabled and the world's largest minority group — women. Users also range from the mentally handicapped to the highly gifted. With regards to the force required to operate a product, the capacities of all groups must be taken into account. Everyone should be able to operate the product — or even better, enjoy operating it.

To the user, the relative importance of consumer products varies from "essential" to "just for fun." Many products range somewhere between those two extremes. For essential products, the most important thing is that the product can be operated, whereas for fun products enjoying their use is the main requirement. If the consumers do not like the product, they will not buy it again. Usually a consumer who buys a product is one of the users, whereas in the professional world different individuals often handle the decision to purchase, the purchase, payment and use. It could well be that satisfaction of the user contributes more to the sales figure for consumer products than for professional ones, for which, for example, efficiency and safety may be more important to the decision-makers. Therefore, the subjective experience of the consumer is an important factor in the assessment of what is an acceptable force for operating a product. The information on the maximally exerted force is in this view less important than information on the experience of the user during exertion of submaximal forces. The time of exertion must also be taken into account. Forces on consumer products can be exerted for any period, but they are usually not operated with the intensity and frequency of a full working day (8 hours a day, 5 days a week, all year round). Therefore, the necessity to prevent injury through excessive exertion during work is not the first priority in the research into force exertion on consumer product design.

Force can be exerted both statically and dynamically. It is estimated that with products in general, dynamic force exertion occurs probably more often than static force exertion. Mostly, force is exerted to create a certain effect, like opening, turning on, fastening, propelling or adjusting. By moving a handle, a knob or even the whole product, the desired effect may be obtained. Some forces are initially static, like those exerted on the lids of jam jars, but in the end the idea is that the lid should move.

2. FORCE EXERTION AND ERGONOMIC RESEARCH

Research on physical strength and force exertion is found in several areas of ergonomics.

The first place is industrial ergonomics. Emphasis in research is put on lifting and carrying, or "manual materials handling" as it is called. The aim is to establish the maximum workload, so that laborers will survive an 8-hour working day, 5-day working week, without physical problems. Research is geared to prevent injury and improve efficiency. Research on cyclic work is necessary. Subjects are aged between ~18 and 65.

Second is military ergonomics. Research for military purposes focuses mainly on the control and maintenance of vehicles and aircraft. Subjects are predominantly young and male.

Third is healthcare. Forces are measured to establish the progress of disabled people. Static grip force is a favorite in this area, and research is often done to establish standards for various groups of people, to which the patient's grip force can then be compared. The maximal force is the maximum score of a short, maximal exertion. Subjects are recruited from all age groups, varying states of health and both sexes.

The last group is sports. The aim of research here is to monitor the condition of athletes and to establish the effect of training schemes. In this case, dynamic force and staying power are investigated rather than static force exertion. The measures used to determine these are the maximum oxygen uptake (aerobic capacity) and power output. Subjects are usually younger people, both athletes and others.

Every area has its own research purposes, methods and subject groups. Research of forces on products is scarce, and in general is too specific, and directed towards one product or a select group of products. Research on force exertion according to a more general product-oriented principle, with a large variety of subjects, could make the results more valuable for designers.

3. PRODUCT DESIGN AND ERGONOMIC RESEARCH

The relation between design and research is a controversial and tricky one. This applies not only to ergonomic aspects, but also to other areas of industrial design engineering. The cause is sometimes attributed to bad communication between researchers and designers, but at close inspection it is clear that there are many discrepancies between their activities. Researchers are often interested in the cause of a phenomenon, whereas designers need data and care little where these come from or what the reasoning behind them is. Researchers extract information from the surrounding world. Designers analyze information to generate a new idea for a product. Thus, to researchers information is the goal of their efforts, whereas for designers it is the starting point.

To designers, the gathering of information should be quick, easy and to the point, in order to get on as quickly as possible with the design work. They prefer not to indulge in statistical analyses or to linger at the deeper causes of the results. To researchers, experiments carried out that way are considered "quick and dirty." Although researchers and designers may agree that research should be to the point, researchers are usually not familiar with the way a product is designed or the problems encountered by the designer. Consequently, they are ill-equipped to judge the relevancy of their research to design practice.

If a way can be found to show researchers how to gear research for design purposes and to show designers how to interpret data correctly and with the right degree of caution, it will greatly improve their ways of communication and mutual understanding and, consequently, the results of their work.

4. DESIGN AND RESEARCH ON FORCE EXERTION

Research on force exertion is usually conducted in one specific situation, with only a few variables varied each time. The daily use of products, on the other hand, has the potential of an enormous variety of situations, of which the designer can anticipate only the most common. The number of possible combinations of postures and force directions is nearly unlimited, and the research that has been done in this area lacks system and is rather thin on the ground. Furthermore, the usefulness to designers is not taken into consideration when the research is set up. A situation in which force exertion is investigated seldom corresponds with the situation in which a product is expected to be used, and even less with the real situation. Postures are standardized and mainly static, maximal forces are measured for ~4 s, whereas in practice only the position of a handle or control is known and subjects will exert static or dynamic submaximal force for any time and in any posture they feel like, and to some extent with different muscle groups. And even if the usefulness to designers is taken into consideration, usually only one (type of) product is investigated so the results are too specific to be of much use for other product areas.

Research should be geared to generate those results useful to designers. Designers know the product they are going to make, they can target certain user groups and can estimate the situation in which the product is likely to be used. Armed with this information, they should find out how much force can be exerted.

Gaze-based Control

G. L. Calhoun

Air Force Research Laboratory, AFRL/HECP, 2255 H Street, Bd. 33, WPAFB, OH 45433, USA

1. OVERVIEW

Human beings naturally look at objects that they want to manipulate or use. For applications in which an operator is controlling a computer-based function or device, harnessing the direction of the operator's gaze promises to be a very natural and efficient control interface. With such control, the computer initiates a predefined action once it receives an input based on the operator's point-of-gaze. Based on the assumption that an operator looks in the general direction that the head is pointing, "gaze-based" control has already been employed for several applications. These systems translate the position of an operator's head into a system input, enabling "head-based control." More recently, "eye-based control" has become commercially available, enabling the eye point-of-gaze to be translated into a system input. Unless the head is stationary (or, with some tracking systems, held within a small motion box), determining the eye gaze point also involves tracking the head position/rotation. For gaze-based control to be useful, it is important that the operator's eye and/or head movements remain natural and not involve any unusual blinking, lengthy fixations or fatiguing inputs.

One common approach to implementing gaze-based control is to combine line-of-sight position data with line-of-sight dwell time criteria. The operator selects an item on a display simply by looking at it for the criterion time. Using dwell time to initiate the control action is particularly useful if the operator's gaze is only being utilized to call up additional data. In this manner, the operator's sequential review of a series of icons can be made more rapidly, with detailed information popping up, as the gaze briefly pauses on each icon. Typically, required dwell times range from 30 to 250 ms. Longer dwell times tend to mitigate the speed advantage of gaze-based control. However, shorter dwell times increase the likelihood of a "Midas touch," with commands activating whereever the operator gazes.

One solution to this potentially distracting problem is to require a consent response. Such a response can also be used to reduce dwell time requirements and minimize the inadvertent selection of objects. With a consent response step, gaze-based control is similar to the operation of a computer mouse and button press. The gaze position (or mouse) indicates the response option on a display and the consent response (or button press) triggers the control action. Different types of consent responses have been evaluated and it is recommended that a dedicated, conveniently located button be employed as a universal consent response, unless the application environment dictates a hands-free option.

Another possible implementation enables object selection either by satisfying the dwell time requirement *or* by pressing a button, whichever occurs first. Alternatively, dwelling on an object for about 30 ms can cause it to be highlighted, while a button press or voice command is used to select it. This highlighting may be maintained, without requiring constant gaze on the object, so that the operator can make the consent response while performing another task.

2. HEAD-BASED CONTROL

2.1. Applications

Since humans can position and hold their head with relatively good accuracy and stability, head-based control can be used to place a cursor on a selectable item or object. For instance, the helmet-mounted sights in aviation environments use head position and orientation in this manner. Fully integrated sights allow the pilot to lock radar and weapon systems onto targets without maneuvering the aircraft. The sighting reticle provides a fixed line-of-sight with respect to the head and this feedback is critical for precise head pointing. The pilot performs these operations simply by looking (i.e. pointing the head) to align the sight on the target, and executing appropriate manual consent commands. In rehabilitation applications, physically limited operators who still have head mobility can interact with a computer-based system by aiming a pointing device with head positioning. In these applications, head-based control is useful for tasks short in duration or when traditional input devices cannot be employed. However, for typical human computer interactions, head-based control is not ideal. For these applications, able-bodied operators would find the frequent and precise head movements tiring and unnatural to perform.

Head-based control is well suited to non-command-based applications (Adams and Bentz, 1995). For example, the head-mounted display systems used in simulated and virtual environments seamlessly update the displayed scene based on the user's head position. In "visually coupled" airborne systems, helmet-mounted display components present task-critical information, regardless of where the pilot is looking. In these examples the operator does not produce an explicit command to change the display viewpoint or information. The system senses the change in gaze direction as an implicit signal to take this action.

2.2. Head Tracking Methodology

Mechanical, acoustic, electro-optical, and magnetic technologies have been employed in head tracking systems. Two of these approaches, electro-optical and magnetic tracking systems, have been used most extensively. Optical trackers generally use light-emitting diodes located on the object to be tracked. Multiple cameras are used to measure the location of each light source. Magnetic trackers include a transmitter that is made up of three coils radiating electromagnetic fields in a radius of a few meters. The three coils in the sensor (located on the tracked object) receive varying signals depending on its position relative to the transmitter. Both of these approaches employ sensors mounted on the head and externally mounted transmitters. Magnetic trackers require the mapping of ferromagnetic and metal conductive surfaces in the user's environment. Some of the performance parameters, as well as the strengths and weaknesses of each approach are summarized in Kocian and Task (1995). Magnetic systems (accuracy ranging from 0.75 to 2.5 mm translation and 0.15–0.5° orientation) have probably seen the widest use and can be considered a relatively mature technology.

More recently, advancements in micro-fabrication techniques have made accelerometers and gyroscopes available for consumer markets. These inertial "transmitterless" sensors utilize the earth's gravity and magnetic fields as reference and do not require external receivers/transmitters. They do, though, require frequent

drift correction. Also, inertial systems cannot monitor an operator's absolute position in space, as only linear acceleration and rotational information are sensed. With their small size and modest cost, application of inertial trackers in computer systems will undoubtedly increase, as already seen in a variety of cordless mouse controllers with embedded inertial sensors.

The ideal choice of a head tracking approach for a specific application depends on a number of factors including the operational environment and performance requirements (e.g. accuracy, precision, resolution, range, and delay). The last factor, in particular, is difficult to quantify, as the operator experiences the overall delay in the head tracking process which is a function of a several variables (e.g. number of update cycles required to obtain an adequate measurement, type of movement pattern being tracked, and degree to which time is required for graphics processing and image display). Considering all of these factors, system throughput delays with magnetic trackers can be as high as 400 ms. Usually, the delay is ~40 ms as most trackers sample at 120–240 Hz. To improve overall system performance, head position prediction algorithms can be employed. Another promising approach is to augment magnetic or optical system data with information from inertial sensors which require only a fraction of the processing time (~1 ms) since they measure changes directly. Moreover, a hybrid system consisting of inertial sensors and one or more other head tracking systems also provides absolute positional information.

3. EYE–BASED CONTROL

3.1. Applications

The visual system is the primary channel for acquiring information. Because of its speed, accuracy, and stability, it may be advantageous to use the direction of eye gaze as a control input. In other words, if the operator is looking at a control-related function, it is more efficient to use the operator's eye line-of-sight to inform the system, rather than align the head or manually slew a displayed cursor, over the function. In this manner, eye-based control can increase the speed of control operations. However, moving one's eyes is usually a subconscious act, and it is relatively difficult to control eye position consciously and precisely at all times. Therefore, there is an increased likelihood of unintentional activity in the eye-line-of-sight signal for control. For this reason, a fully "eye-driven" mouse is not practical. Rather, natural eye movements should be used to provide a direct pointing capability that can be combined with other interface modalities to command activation. Application of eye-based control also needs to take into account the accuracy limits of the eye-tracker (Calhoun, Janson and Arbak, 1986).

The majority of commercial eye trackers are used in laboratories or in the home as a communication device for individuals with motor control disabilities. It is anticipated that once developers capitalize on advances in optics, sensor and processing technologies, eye-tracking systems will become affordable for a variety of home and work environments. Moreover, efforts toward miniaturizing eye tracking components will facilitate their integration into head mounted displays.

3.2. Eye Tracking Methodology

Methods for tracking the eye (Jacob 1995) can be classified into those that: (1) measure the electrical potential of the skin around the eyes, (2) involve image processing of one or more features that can be optically detected on the eye and (3) employ a special contact lens that facilitates eye position tracking. The latter method is too intrusive for most applications. The first method is probably the least expensive and easiest to implement. However, the drift inherent in electro-oculography (EOG) measurements makes this technology more suitable for measuring eye velocity and acceleration profiles rather than measuring eye point-of-gaze. It is possible that EOG tracking would suffice if the eye-based control operations only required detecting whether the operator is looking generally left, right, up or down.

The most practical line-of-sight measurement technique involves illuminating the eye with a near infra red source, capturing an image of the eye with a solid state video camera, and tracking one or more features that can be optically detected on the eye. The most often used features include the limbus (boundary between the iris and sclera), the pupil, movement of the lower eyelid, the reflection of a light source from the cornea (1st Purkinje image or corneal reflex) and the reflection from the rear surface of the eye lens (4th Purkinje image). However, these video-based methods, besides being more complex and costly to implement, are very sensitive to the placement of tracking components.

Tracking a single feature on the eye does not enable one to discriminate between eye rotation and eye translation caused by movement of the head. This ambiguity can be resolved by tracking two features, which are at different radii from the eye center of rotation. The two sets of features most commonly employed are (1) the pupil center and 1st Purkinje image and (2) the 1st and 4th Purkinje images. Two-feature eye trackers thus permit a small amount of head motion, assuming that the user stays within the field of view of the video camera observing the eye. Some table-mounted systems also employ a servo-controlled camera or mirror, which follows the operator's eye as the head moves. Such systems permit head motion within a volume of ~0.03 m^3. To permit essentially unlimited head motion, head-mounted eye tracking is required. The eye tracker data are used to determine eye position with respect to the head and are combined with head position data to compute line-of-sight in the environment.

Commercially available systems permit eye-tracking accuracies of ~1° of visual angle. At the typical 61 cm viewing distance, this translates into a resolution of ~1 cm on the surface of a computer monitor. Eye tracking, therefore, provides much coarser operation than a mouse or trackball. Unless a head-mounted system is employed, the range over which eye movements can be tracked is limited to about the area of a 48-cm monitor. Another important constraint is the temporal resolution of the eye tracker. The feature-tracking systems are video-based and typically operate at 60–120 Hz frame rates. Total throughput delays of 25–50 ms can be expected which includes updating the eye position every 8–17 ms, filtering the data and computing the eye position.

4. FUTURE DIRECTIONS

In summary, head-based control is not the best substitute for manual inputs in human–computer interaction. Head mass, head-tracker delays, and the need for frequent, precise head movements all tend to degrade operator performance. However, there are several applications where head-based control is beneficial,

especially for non-command based applications. Eye-based control is a promising alternative for numerous applications in which high control resolution is not a requirement. Ware and Mikaelian (1987) evaluated eye line-of-sight control for computer inputs and found that object selection and cursor positioning tasks were performed approximately twice as fast with an eye tracker as with a mouse.

While some applications will continue to employ head- and eye-based control in an explicit command mode, it is clear that this does not fully exploit the capability of gaze-based control. Seamless interpretation of head and eye movements to infer operator interest, needs and desires appears to be a much more powerful, albeit challenging, path.

Both head and eye trackers would benefit from enhancements that enable faster measurements and transformation of these measurements into input signals for human computer interactions. Future improvements in the accuracy and resolution of head and eye trackers are not likely to be major factors in enhancing control operations. Head trackers are already quite good in this regard and adequate for most applications. Eye trackers are approaching the 1° useful limit imposed by the size of the fovea. Improvements are needed, though, in the stability and repeatability of eye tracking so noisy eye signal data or momentary signal loss does not impact eye-based control. Additionally, the video-based eye tracking systems are not particularly robust in high or variable illumination environments.

Gesture-based Control

G. R. McMillan and G. L. Calhoun

Air Force Research Laboratory, AFRL/HECP, 2255 H Street, Bd. 33, WPAFB, OH 45433, USA

1. INTRODUCTION

Hand and body gestures are an important component of interpersonal communication. Gesture-based control seeks to exploit this channel for human–machine communication (Baudel and Beaudoin-Lafon 1993). Most currently available input devices only make use of discrete pieces of data produced by an operator's movements. This sometimes stems from the use of intrinsically discrete devices, such as a keyboard or numeric keypad. Even with continuous input devices, such as mice, only specific events and data points (e.g. the coordinates of the pointer when the operator clicks) are taken into account by most applications (Bryson and Levit 1992). Gesture-based interaction attempts to take advantage of the continuity and dynamics of an operator's movements, instead of extracting only discrete information from these movements (Brooks *et al.* 1990). Although the terms are sometimes used interchangeably, *gesture* formally refers to dynamic hand or body signs, while *posture* refers to static positions or poses.

2. GESTURE MEASUREMENT TECHNOLOGY

Gestures can be measured using a variety of hardware devices. Contact devices, besides classical ones such as mice, trackballs and touch screens, include a variety of more exotic items such as spaceballs and three-dimensional (3-D) mice. The head, hands and body can be localized in space using trackers, video techniques, gloves or suits. Trackers are devices that allow one to measure the position and orientation of a body part in space. Video techniques use image processing in order to identify a specific body part and then reconstruct its position, orientation and posture from two-dimensional (2-D) video images. Gloves and suits allow one to measure the relative positions and angles of body components. A comprehensive directory of manufacturers of gesture capture devices is available in Buxton (1998).

2.1. Contact Devices

This category includes devices such as light pens, touch screens and mice. They typically move in 2-D and operate through a straightforward translation into 2-D screen space. Such devices can, however, be used for more advanced purposes, such as 2-D gesture or handwriting recognition. The most serious limitation of these devices is that operator input is quite constrained. One hand is generally completely involved with the contact device.

2.2. Trackers

These devices allow one to measure, in real time, the position of an object in space. They can be used for tracking the head, hands or other body components. They have also been used for body posture recognition, although the number of devices affixed to the body can make such systems awkward.

- *Mechanical* systems connect the tracked object to potentiometers, or other sensors, using rods or cables. This allows very high update rates and very low latencies. It is also an inexpensive approach. On the other hand, the usable range is small and the apparatus impairs free movement.

- *Electromagnetic* trackers include a transmitter made up of three coils radiating electromagnetic fields in a radius of a few meters. The sensor, located on the tracked object, is also made up of three coils. It receives varying signals depending on its position relative to the transmitter. These trackers are moderately expensive, but on the whole they are the most precise and popular of non-contact techniques. They also offer a large operating range. One must account for metallic objects and other sources of electromagnetic interference in the tracking region. Also, there must be an electrical connection between the sensor element and the electronic unit. This can limit free movement.

- *Ultrasonic* trackers make use of ultrasonic pulses to compute distances based on time propagation measurements. The main advantage of these trackers is that they work seamlessly in metallic environments. They also tend to be less expensive than electromagnetic systems. However, ultrasonic trackers must have a direct line-of-sight between the emitter and sensor. The latency is greater than with other trackers since it includes the propagation of ultrasonic waves.

- *Optical* trackers generally use light emitting diodes or reflective dots located on the object to be tracked. Multiple cameras are used to measure the location of the light source or reflective marker. The 2-D marker positions detected by each camera are correlated to compute the 3-D coordinates. These devices face the same line-of-sight constraint as ultrasonic trackers, and the usable range is similarly limited.

Recently, a variety of low-cost *transmitterless* trackers have begun to appear using principles similar to aircraft and missile inertial guidance systems. The sensing components may include inclinometers, Hall-effect compasses, gyroscopes or accelerometers. Some of these devices use telemetry to communicate with the electronic control unit, so no cables encumber the operator. While they are often not as accurate as the devices discussed above, many are inexpensive and have satisfactory capabilities for selected gesture measurement applications.

2.3. Computational Vision Systems

These systems use classical image recognition techniques to find silhouettes of the hands or body and to identify gestures. The computational problems are even more challenging than with optical tracking systems, if real-time operation is required. Limited camera resolution necessitates a compromise between adequate recognition of small elements, such as fingers, and the large field of view necessary for free movement. Obstruction of the fingers by the hand or other body segments is another problem. Nevertheless, this approach is inherently unobtrusive and has been successfully employed.

2.4. Gloves

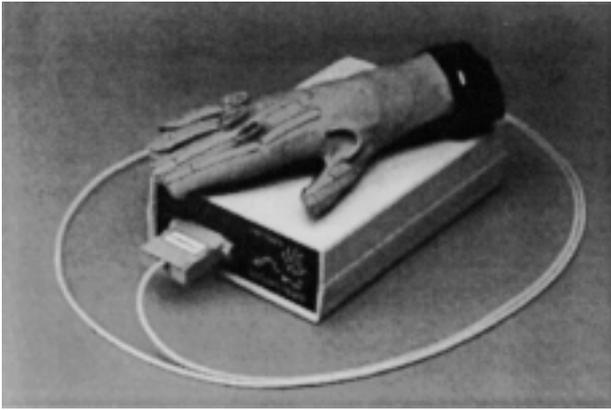
Gloves measure hand and finger angles and movements of the fingers relative to the hand. Most can be equipped with a position tracker in order to measure global hand position. Numerous sensors are needed and the resulting data rate can be high. Various measurement technologies have been used including optic fibers, Hall effect sensors, resistance variation or accelerometers. The main problems encountered are repeatability, precision and reliability. Almost every glove needs calibration before each use,


Figure 1. The CyberGlove. Photo: courtesy Virtual Technologies, Inc., Palo Alto, CA, USA.

since the manner in which it is worn greatly affects the measurements. A sophisticated example, the CyberGlove, employs 18- or 22-foil strain gauges to measure finger, thumb and palm relationships (Figure 1).

2.5. Some Issues in Measurement Device Selection

The optimal gesture measurement device depends not only on the task, but also on the environment in which the device is used. A positional hand tracker might be the preferred device in a relatively benign environment, but might become unusable under the acceleration and vibration levels found in a fighter aircraft or helicopter. A contact device would have the advantage of supporting the hand, but the space needed to integrate such a device must then be considered. Glove-based gesture recognition might be incompatible with safety equipment or might interfere with other tasks requiring fingertip sensitivity. System lags that are tolerable in a laboratory experiment might become problematic when the operator has to attend to several tasks at once. Environmental and integration issues such as these must guide the choice of gesture measurement devices.

3. GESTURE RECOGNITION

The algorithms for determining fundamental positions and angles, based on the sensor inputs, are provided with the systems described above. With glove-based systems, some individual operator calibration is required (Fels and Hinton 1993). Magnetic trackers require the mapping of ferromagnetic and metal conductive surfaces in the operator's environment, but no individual operator calibration. For interactive applications that employ rapid body movements, one may need to add or modify movement prediction algorithms to compensate for system delays. Although general-purpose posture recognition software is becoming available for glove-based systems, the development of algorithms to recognize specific postures or gestures is often left up to the system designer. These algorithms tend to be application specific, although some general approaches are common. For example, the recognition of a fixed set of hand postures is often based on look-up tables that contain acceptable ranges of values for each position and joint measurement.

Gesture recognition is a much more challenging problem since pattern analysis must be performed on moving body

segments. Many approaches compare the motion vectors for each body segment to reference vectors representing the target gesture. This match must be within error tolerances and these tolerances are weighted by the contribution of each motion vector to gesture discrimination. For robot control applications one must address the kinematic differences between the human hand and the robot hand. Algebraic transformations have been employed to perform this human-to-robot mapping. Alternatively, the kinematic differences can be resolved by determining the 3-D position of the operator's fingertips and driving the robot's fingertips to match. It is also a challenging problem to identify the beginning and end points of a gesture. Typical solutions require the operator to take a "default" posture between gestures, which serves as an anchor for the system.

Still another issue to be addressed is the "immersion problem." If every movement is subject to interpretation by the system, the operator can be deprived of interpersonal communication for fear that a movement will be acted upon by mistake. The solution is to provide an effective and unobtrusive way of detecting whether a gesture is addressed to the recognition system or is a part of normal interpersonal communication. "Charade," a system for control of computer-based presentations to an audience, addressed this issue by creating an active zone in which gestures were effective. Gestures performed in a defined area in front of the screen were recognized, while gestures directed toward the audience were ignored.

4. MODES OR STYLES OF CONTROL

Given that a specific gesture can be reliably discriminated from other activity, one still must determine how it will be used for interaction with a system. First, one can choose to use discrete or continuous features of a gesture. Within each of these categories, three styles of input may be considered:

- *Direct* — Features of the gesture or posture generate kinematically similar actions in the task domain. One-to-one control of a robot hand is a good example of this style of interaction.
- *Mapped* — Features of the gesture or posture are mapped in some logical fashion to actions in the task domain, but there may be no kinematic similarity between the features and actions. For example, the number of raised fingers might indicate which level of force should be applied by a hydraulic press.
- *Symbolic* — Features of the gesture or posture are interpreted as commands to the system. While this may be similar to the mapped style, it may also be significantly more abstract and may employ knowledge-based reasoning to determine the intention or emotional state of the operator. Most uses of facial expressions would fall into this category.

5. FEEDBACK REQUIREMENTS

In many applications the only feedback that is provided, or required, is the system's response to the recognized gesture. Examples include simulated movement in the direction toward which the operator is pointing and synthesized speech following recognition of a sign language gesture. Feedback requirements for simulated object manipulation, vehicle control and robot operations are still the subject of research and development. In each of these cases tactile and kinesthetic feedback play an

important role in normal human–system interaction. These cues are absent in most gesture-based systems. Significant progress is being made in the development of force-reflection and tactile stimulation systems that can provide this feedback through normal sensory modalities. In addition, there is evidence that substitute feedback can be provided using vibratory, auditory and electrical stimulation. The importance of feedback depends on the specific task, experience of the operator, availability of substitute visual and auditory cues, and implementation of the artificial feedback. Until additional parametric studies are performed, it is difficult to provide specific guidelines. Nevertheless, it seems clear that some form of tactile and kinesthetic feedback will be required for object manipulation and tool operation tasks in many robotic applications.

6. APPLICATIONS

6.1. Sign Language Interpretation

Sign language interpretation continues to be a significant area for gesture research and development. Scientists at the University of Toronto, for example, developed a hand gesture to speech system using a neural network. Performance of a single "speaker" with a vocabulary of 203 words was evaluated following a network training phase. With near real-time speech output, the system successfully translated the gestures > 90% of the time.

6.2. Robot Control

In one study sponsored by the National Aeronautics and Space Agency (NASA), a glove system was used to control a robot arm in a task that required retraction, movement and insertion of a block in a test panel. The researchers compared these results to another study that used a conventional 6°-of-freedom hand controller as the input device. They concluded that robot control performance with the glove compared favorably with the "standard" device and that it provided a natural and intuitive operator interface.

6.3. Virtual Reality

Several examples are provided by computer generated displays in which the operator can touch, grab and move objects by pantomiming these activities with glove-based sensors. In these applications the operator actually sees a rendering of their hand performing the object manipulations. Researchers at the NASA/Ames Research Center have used this approach in a virtual wind tunnel to explore simulations of computational fluid dynamics. Aeronautical engineers can put their hands and head into a simulated fluid flow and manipulate the patterns in real time. The GROPE project at the University of North Carolina was among the first applications to use force feedback for interacting with a computer simulation. GROPE displays the interactions between complex molecules using a force-feedback-manipulating rod. When the operator modifies the position of a molecule by moving the rod, the simulation computes intermolecular forces and reflects them back through the feedback system.

6.4. Aircraft Control

A series of experiments carried out by the US Air Force required true 3-D selection of targets from a head-down, 3-D tactical map. An electromagnetic tracker located on the back of the hand sensed hand position. The tracking volume was remote from the actual map so that hand movements were actually made in a space close to the aircraft controls. The hand tracker worked well and was, in general, a faster and more accurate way to select targets than a 3-D joystick.

7. FUTURE DEVELOPMENT

A significant disadvantage of current gesture measurement devices is that most of them limit the operator's freedom of movement (Hale 1992). This results from limited sensor range, wires attached to sensors, or the need to grasp a sensor component. Progress in component miniaturization and telemetry continues to reduce this problem. Static posture recognition has made great progress and allows reasonably high recognition rates, provided that the operator performs a standard procedure such as pointing at a target area or assuming a default posture BEFORE issuing a command. This is not yet true for dynamic gesture recognition and software techniques are still developing in this field. The main difficulty is segmentation, i.e., detecting gesture beginning and end points. Despite these challenges, gesture-based applications are beginning to take advantage of the dexterity and natural coordination of the human body, and to permit less constrained forms of operator input.

In addition to using this technology for explicit control applications, gesture may also play an expressive role in future human–machine communication (Reising *et al.* 1993; Sturman and Zeltzer 1993). Interface designers are beginning to explore the recognition and application of facial expressions and other emotive inputs. Here unconstrained gesture recognition will be required, and an effective system will undoubtedly integrate the inputs from a variety of operator monitoring systems.

Hand Grip Strength

S. K. Adams

Department of Industrial Engineering, Iowa State University, Ames, Iowa, USA

1. INTRODUCTION

Hand grip strength is an important limiting factors in many occupational tasks as well as in general activity. Grip strength is affected by many factors. Some of these are tasks related including grip span requirements, grip surface geometry and friction hand orientation, force–frame requirements, movement of the hand during the grip effort, task repetition, and the use of gloves. Other factors relate to individual subject or worker strength characteristics as affected by age, gender, hand size and muscular strength acquired over time through occupational, domestic, and recreational activity. As is true for any type of strength, hand grip strength is highly individualistic. Population means and standard deviations should be developed for a given class with workers or product users whenever this is feasible to assure human/ equipment compatibility.

2. FACTORS AFFECTING HAND GRIP STRENGTH

2.1. Importance of Analyzing Hand Capabilities

Most occupational work, as well as many domestic and recreational activities, are performed with the hand, generally employing the hand–wrist–forearm system in combined and coordinated motion. Understanding the strength and motion capabilities of the hand and wrist, as well as methodologies for determining them, are important in designing tasks to minimize the frequency and severity of work-related upper extremity disorders. These cumulative injuries and functional losses, defined as cumulative trauma illnesses by the US Bureau of Labor Statistics, account for 11% of all work-related musculoskeletal disorders (illnesses) in the US. The National Safety Council (1998: 56) listed the total cost of injuries and cumulative trauma to the arm and wrist in the US at $12 billion for the two-year period covering 1995 and 1996. Hand and finger injury and trauma costs were $7.46 billion for the same period.

The versatility of the human hand in performing tasks is remarkable, including activities that involve large loads as well as very fine and delicate manipulations with the fingers. When large forces and torques are required to perform a task that includes the hands, these must be absorbed and transmitted through the hands and wrist, often resulting in high biomechanical stresses that may occur many times. Only the legs and feet transmit more force than the hand and wrist as working limbs. Since the hand is a delicate and complex biomechanical structure, designing tools, equipment and tasks to protect its many structures and systems from cumulative trauma is important.

2.2. Anthropometric Structure of the Hand and Wrist

The skeletal structure of the hand consists of three segments: the carpus or wrist bones, the metacarpus or bones of the palm, and the phalanges or bones of the digits. There are eight bones in the carpus, arranged in two rows. The upper row, progressing from the radial (thumb) to the ulnar (little finger) side includes the scaphoid, semilunar, cuneiform, and pisiform. The lower row (fingers down) includes, in the same order, the trapezium, trapezoid, os magnum, and unciform. These are as small as the fingertip segments and have complex shapes. The metacarpus comprises five long cylindrical bones, one for each digit. These connect the digits with the carpus. The phalanges comprise the fourteen bones of the fingers. There are two in the thumb and three for each finger. The finger phalanges are designated as being proximal, medial or distal according to their position. Gray's classic book on human anatomy provides complete descriptions and drawings of the anatomical and muscular structures of the hand, wrist, and forearm (Gray: 1977).

Numerous muscles are attached to the lower row of carpal bones as well as to the metacarpals and phalanges. Space does not permit an enumeration of their names and points of attachment. These muscles provide forces for precision movements in the hand. Larger forces required for power gripping are provided through tendons connecting strong flexor muscles located in the forearm to the fingers and thumb. Of special importance in work task design and analysis is the carpal tunnel bounded by the carpal ligament on the palmar side through which these tendons pass, along with the median, ulnar and radial nerves. The median nerve activates the muscles which flex the forearm, wrist and fingers and also those which pronate the forearm. The median nerve also provides control feedback from the thumb, first two fingers, and half of the feedback for the third finger. The ulnar nerve controls the fourth and fifth fingers. The radial nerve supports the ulnar (toward the little finger) side of the thumb and also the fingers. Repeated or sustained overstress through torque (high-grip tension), or rapid rotations of the wrist can interfere with the lubrication of tendons in their sheaths causing in swelling and a compression of the median nerve resulting in carpal tunnel syndrome, estimated to occur at an incidence rate of from 0.5% to 3.0% among adults (Moore 1992).

2.3. Hand and Wrist Mobility and Strength

2.3.1 Mobility

The hand, operating through motions of the wrist and forearm, can rotate in three planes. These include: extension and flexion (upward and downward motion of the hand with the palm down), adduction and abduction (rotation of the hand toward and away from the trunk with the palm down), and rotation of the wrist about the major axis of the forearm (as in turning a doorknob) caused by rotating the forearm. These rotational capabilities for adults are summarized in table 1 from Kroemer *et al.* (1994: 57).

Significant differences exist between the 5th and 95th percentiles for both genders for all three planes of rotation. Data are given in degrees of rotation. Gender-related differences (female–male) are also significant and quite large in a few instances. Significance in this case is defined at an alpha level of 0.05 and is based on 50th percentile values.

Neese and Konz (1989: 698) investigated the effects of age (16–88) on wrist mobility for a general adult population (40 males and 83 females) and concluded that overall, females have a 5% to 15% greater range of motion than males, averaging approximately 10%. Maximum flexion was 57 degrees for females and 56 degrees for males. Maximum extension was 53 degrees and 50 degrees for females and males, respectively. Adduction

Table 1. Comparison of elbow-forearm and wrist mobility data for college-aged males and females

Joint	Movement	5th Percentile		50th Percentile		95th Percentile		Difference*	
		Female	Male	Female	Male	Female	Male	Female	Male
Elbow–forearm	Flexion	135.5	122.5	148.0	138.0	160.5	150.0	+10.0	
	Supination	87.0	86.0	108.5	107.5	130.0	135.0	NS	
	Pronation	63.0	42.5	81.0	65.0	99.0	86.5	+16.0	
Wrist	Extension	56.5	47.0	72.0	62.0	87.5	76.0	+10.0	
	Flexion	53.5	50.5	71.5	67.5	89.5	85.0	+4.0	
	Adduction	16.5	14.0	26.5	22.0	36.5	30.0	+4.5	
	Abduction	19.0	22.0	28.0	30.5	37.0	40.0	–2.5	

* Listed are differences at the 50th percentile at an alpha significance level <0.05
Data adapted from Staff, K. R., *A Comparison of Range of Joint Mobility in College Females and Males*, 1983, unpublished M.S. Thesis, Department of Industrial Engineering, Texas A & M University, College Station, TX. Data are in degrees of rotation from the standard neutral orientation for each limb axis and plan.

was 24 degrees for both genders. Abduction was 55 degrees for females and 57 degrees for males. Pronation was 139 degrees and 130 degrees for males versus females. Supnation was 89 degrees for females and 78 degrees for males. Pronation capability increased significantly with age according to the formula:

Pronation angle = 89.2 + 0.94 (age in years)

2.3.2 Grip strength

Many factors affect hand and wrist strength as measured in laboratory or field studies. These include, but are not limited to:

- orientation to the work surface
- plane of rotation of the hand
- working position
- resisting force dynamics
- repetition
- obstructions (barriers to motion)
- grasp interference
- grasping method (many partial- and full-grip variations)
- grip diameter and surface area
- surface roughness or coefficient of friction
- use of gloves
- gender
- worker

Since only a few of these can be varied in a given study (typically 2 or 3), experimental results from laboratory or field studies are limited to the application and conditions tested. Generalizations can often be made despite these limitations from functional relationships and the prioritization and interactions that occur in a given set of experimental results. Grip strength resulting from a wrap around or power grip results from forces generated by all of the fingers acting together. Fransson and Winkel (1991: 881) conducted a study that included both traditional and reversed (inverted, jaws backward) grip on a pair of multiple slip joint pliers on which they measured individual finger forces together with full grip force for males and females. While the overall optimal hand grip space for maximum force at approximately 750N occurred at approximately 6 cm, optimal grip span varied for different fingers, suggesting a new approach to handle profiling for hand tools, based on individual finger strengths. Radwin and Oh (1991: 843) measured finger and palmar forces independently in determining optimum grip span length for maximum grip for a simulated pneumatic power tool. Exertion level (defined as actual exertion force divided by maximum voluntary contraction strength) was related by a U-shaped function to handle span and was minimized for a span between 5 cm and 7 cm. An extended trigger resulted in

lower finger and power grip forces. Handle size preferences for subjects were directly related to their hand lengths.

2.3.3 Wrist flexion and extension strength

The flexion and extension force capability of the wrist muscles (unassisted by the forearm) varies with the flexed or extended position of the wrist. Hallbeck (1994: 379) performed a study using 30 male and 30 female right-handed seated subjects ranging in age from 20 to 30 years in which horizontal flexion and extension hand forces generated by wrist muscles only (the forearm being held in a sagittal plane direction (forward) by a padded clamp) were measured over a range of plus and minus 90 degrees from the neutral (forward) position.

Flexion forces varied from approximately 90N (105N for males, 75N for females) at a 90 degree flexion angle (toward the body) to approximately 45N (50N for males, 40N for females) at a 75 degree extension angle (away from the body) with a slight increase of 10N at 90 degree extension angle. Flexion forces decreased over the entire range from the maximum flexion to maximum extension position. Extension forces remained fairly constant, averaging approximately 55N (65N for males, 50N for females) with an increase to 67N (75N for males, 60N for females) at an extension angle of 90 degrees. Female flexion strength averaged 76.3% of male flexion strength while female extension strength was 77.4% of male extension strength. Extension forces averaged 83.4% of those generated in flexion for the entire group of subjects.

2.3.4 Repetitive wrist flexion and extension

Snook et al. (1995: 1488) used psychophysical methods to determine maximum acceptable forces for several types and frequencies of repetitive wrist motion, employing 15 female subjects. Four adjustable work stations were built to provide simulated repetitive wrist flexion using a power grip, wrist flexion with a pinch grip, and wrist extension with a power grip. There were no significant differences in maximum acceptable torque on a day-to-day basis. A 36.3% decrement on average maximum acceptable torque did occur for a five-days per week seven hours per day exposure as compared with a two-days per week seven hours per day per week exposure. The five-days per week experiment lasted 23 days. The two-days per week experiment also lasted 23 days. Under the assumption that other repetitive motions are affected similarly with respect to maximum acceptable torques tables were developed for female wrist flexion (power grip), wrist flexion (pinch grip) and wrist extension (power grip). These are presented in simplified form in tables 2, 3 and 4, which

Table 2. Maximum acceptable forces for female wrist flexion (power grip) (N) (Newtons)

Percentage of Population	Repetition rate				
	2/min	5/min	10/min	15/min	20/min
90	14.9	14.9	13.5	12.0	10.2
75	23.2	23.2	20.9	18.6	15.8
50	32.3	32.3	29.0	26.0	22.1
25	41.5	41.5	37.2	33.5	28.4

show the effect of work rate (exertions per minute) as well as duration.

The most frequently reported health-related symptom in this study was muscle soreness (55.3%). The most frequently reported locus of pain was in the hand or wrist (51.8%). In addition, numbness in the palmar side of the fingers and thumb was frequently reported (69.1%) as well as stiffness on the dorsal (top with palm down) side of the fingers and thumb (30.6%). The number of symptoms increased consistently over the seven-hour, five-day work shift and were 2.3 times as numerous after the seventh hour of work than after the first hour of work. The incidence rate was 2.4 times as high after the seventh hour of work than after the first hour of work in the seven-hour, two-day work-shift.

3. METHOD OF MEASUREMENT

Hand grip strength is typically measured using an adjustable length hand dynamometer which measures force mechanically, hydraulically, or as electrical voltage change from one or more load cells containing strain gages. Conversion of signals to provide direct digital readout is often done for convenience in recording data. Graphic output is desirable when the distribution of force over time (linear impulse) is of interest as, for example, determining force or grip strength requirements or capabilities when a sustained exertion is required or when the maximum peak grip force is an important factor.

Hand grip strength measurement of a given individual performing a given task is a function of two important basic types of variables: those associated with the type of strength being measured and the method of measuring it, and those associated with the type of grasp employed along with factors that affect biomechanical effectiveness in exerting the muscular contractive effort required.

3.1. Types of Muscular Strength

Chaffin and Andersson (1991: 40) describe five types of muscular contraction: isometric, isotonic, eccentric isometric, and isoinertial. An isometric contraction is one in which the muscle length does not change during the contraction. No motion (or negligible motion) of the hand occurs and the task is therefore static (another term for this type of motion). Static hand grip or torque apply to this definition. The grip length of the dynamometer or simulated hand tool handle does not change with the applied grip force. No work or power can be calculated since there is no movement of the applied force. An isotonic (or concentric) contraction is one in which the internal force within the muscle is constant and the muscle shortens. In this case work is performed against a constant resistive force (e.g. friction). In actual work settings, the resistive force changes with limb segment position, so this type is rare.

In general, isotonic strength is approximately 80% of isometric strength, but the ratio between the two varies with the rate of decrease in muscle length. An eccentric muscle contraction is one in which the external resistance force is greater than the internal muscular force. Therefore, the muscle increases in length while maintaining tension. In doing this, the muscle merely controls the movement and the muscular effort is in resisting work done on the muscle in contrast to work performed by a muscle in overcoming the resistance force in concentric contraction. An isokinetic contraction is one in which joint motion occurs at constant velocity, representing a task in which the speed of motion is controlled. While isometric, isotonic (concentric) and eccentric motions occur commonly in all human activity, isokenitic contractions do not normally occur although they can be produced in the laboratory using an isokinetic dynamometer.

Lehman *et al.* (1993: 715) used an isometric dynamometer to measure grip strength under forearm flexion and extensions at angular velocities from zero to 175 degrees per second. Mean grip force for the hand decreased for all angular velocities above 5 degrees. Forces varied from 311 N under no motion (data averaged for five males and five females) to 178N at 5 deg/sec and to 133N for angular velocities of 25 deg/sec or higher. Male and female grip forces averaged approximately 170N and 98N respectively, a difference attributable to the combined effect of gender and hand size. Larger grip forces were provided during forearm flexion than during extension. Grip forces were also higher during radial to ulnar motion (abduction) than during ulnar to radial motion (adduction) of the forearm. Average grip

force decreased from approximately 356N under no motion to 280N for angular velocities ranging from 5 to 115 deg/sec. Although this study shows important dynamic properties of grip strength, it should be considered a pilot study because of its small size.

Isoinertial contractions are those in which the muscle contracts against a constant load. Acceleration of the body segment and any object being moved will occur if the force generated by the muscle is greater than the resistance. In this case, muscular performance evaluation requires the additional measurement of acceleration and velocity. While nearly all research studies of hand grip and hand grip torque strength have involved isometric or static muscle contractions, isotonic (concentric) and eccentric muscle strength can also be determined when this is of interest. Isokinetic strength has no known application in hand grip or grip torque strength testing. The evaluation of isoinertial contractive strength requires extensive instrumentation and has little or no practical value in ordinary applications.

3.2. Types of Grasp

Kroemer *et al.* (1994: 386) list ten types of grasp or coupling mechanisms between the hand and the object being held. These are illustrated and described in figure 1. Grip strength depends upon the type of contact made between the hand and the object being grasped. Numerous factors affecting overall grip strength are listed in section 1.3.2, including grasping method. Biomechanically, the grip span surface area of contact with the hand flexion or extension position and the ability to employ the large flexor muscles in the forearm are major factors affecting grip strength. The number of fingers employed is also, obviously, a major factor. Only a few of the ten types of grip have been investigated to determine strength capabilities.

3.3. Grip Force Dynamics

Whenever strength is measured by the exertion of muscular force, the force delivered to the handle or other contact surface in a given tool varies over the duration of the exertion. Thus, many measures of strength are possible including peak force, average force, linear impulse (force multiplied by its duration), sustained force over a given interval, or any other definition involving force and time. (Caldwell *et al.* (1974: 201) developed a general procedure for defining static strength which has become a standard used by many investigators. Minor modifications of the procedure are often done to adapt the definition to particular applications and instrumentation. The Caldwell standard static strength measurement procedures are described in terms of data recording; instructions to subjects; experimental conditions including body position, support and coupling; subject description; and data reporting including the mean, median or mode, standard deviation, skewness, maximum and minimum values, and sample size.

The proposed standard measurement of static strength is as follows:

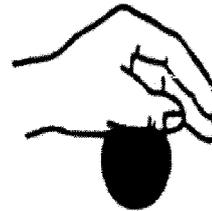
i   Static strength should be measured during a steady exertion lasting four seconds.

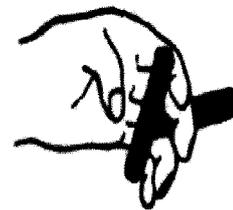
ii The transient periods of one second preceding and one second following the four-second exertion should be disregarded.

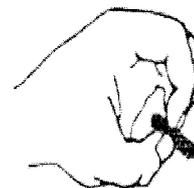
iii The measure of strength for the exertion is the mean score recorded during the first three seconds of the four-second exertion.

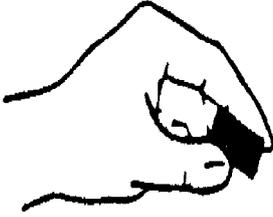
This procedure should be followed, with possible minor

Coupling #1.   Digit touch:
One digit touches an object.

Coupling #2.   Palm touch:
Some part of the palm (or hand) touches the object.


Coupling #3.   Finger palmar grip (hook grip):
One finger or several fingers hook(s) onto a ridge, or handle. This type of finger action is used where thumb counterforce is not needed.


Coupling #4.   Thumb–fingertip grip (tip pinch):
The thumb tip opposes one fingertip.


Coupling #5. <u>Thumb–finger palmar grip (pad pinch or plier grip):</u>
Thumb pad opposes the palmar pad of one finger (or the pads of several fingers) near the tips. This grip evolves easily from coupling #4.


Coupling #8. <u>Thumb–fingertips enclosure (disk grip):</u>
Thumb pad and the pads of three or four fingers oppose each other near the tips (objects grasped does not touch the palm). This grip evolves easily from coupling #7.

Coupling #9. <u>Finger-palm enclosure (collect enclosure):</u>
Most, or all, of the inner surface of the hand is in contact With the object while enclosing it. This enclosure evolves easily from coupling #8.

Coupling #6. <u>Thumb–forefinger side grip (lateral grip or side pinch):</u>
Thumb opposes the (radial) side of the forefinger.

Coupling #10. <u>Power grasp:</u>
The total inner hand surfaces is grasping the (often cylindrical) handle which runs parallel to the knuckles and generally protrudes on one or both sides from the hand. This grasp evolves easily from coupling #9.

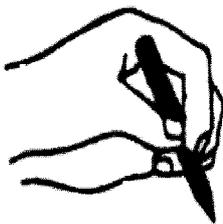
Coupling #7. <u>Thumb–two- finger grip (writing grip):</u>
Thumb and two fingers (often forefinger and middle finger) oppose each other at or near the tips.


Figure 1. Couplings between hand and handle. Adapted from Kroemer, K.H.E, Coupling the hand with the handle: An improved notation of touch, grip and grasp, *Human Factors*, 28(3), 1986. Reprinted with permission. Copyright © 1986 by The Human Factors and Ergonomics Society. All rights reserved.

modifications to meet specific testing or data processing requirements, in measuring static grip or grip torque strength.

3.4 Selected grip strength data

Grip strength is a function of several basic task and tool design variables. Among the more important ones whose effects on grip strength have been studied are: handle width or span, forearm rotation (palmar-dorsal), wrist flexion or extension, elbow flexion,

and contact area of the hand (including the number of fingers used). Chaffin and Andersson (1991: 423) citing Greenberg and Chaffin (1976: 55) present typical grip span data derived from 50 men and 50 women employed in a large electronics component manufacturing plant shown in figure 2. The optimum grip span resulting in maximum grip strength (measured in Newtons) is approximately 8 cm. Fransson and Winkel (1991: 881) describe the effects of grip span, grip type, and the contributions of

individual finger strengths on total hand grip strength (discussed in section 1.3.2). Terrell and Purswell (1976: 28) found significant decreases in grip strength for a grip span of 5.25 cm as a function of forearm orientation and wrist flexion–extension. For forearm orientation, grip strength was highest for supine (palm up) orientation, and lowest for prone (palm down) orientation. Mid-position strength was slightly lower than supine strength. Grip strength for prone orientation was 87% of strength measured in the supine position. Decrements from the neutral position (hand parallel with the forearm) for wrist flexion (45 degrees), extension (50 degrees), radial flexion (20 degrees) and ulnar flexion (20 degrees) were 30%, 22%, 18% and 15%, respectively. Grip strength (force) in the neutral position varied with forearm position from 356N (supine position) to 422 N (prone position).

Marley and Wehrman (1992: 791) investigated grip strength as a function of forearm rotation and elbow posture for 10 male and 10 female subjects using 90 and zero degree elbow flexion and seven positions of forearm rotation ranging from 90 degree (complete) pronation to 90 degree (complete) supination. Maximum grip strength occurred with no forearm rotation (thumb up) with the elbow flexed at 90 degrees and at a 60-degree supination angle with no elbow flexion (zero degrees, arm straight) for males. Female subjects produced similar data except that maximum grip strength was produced at a supination angle of 30 degrees. Severe decrements in grip strength occurred for all prone or supine deviations in forearm rotation angle from the neutral (thumbs up) position as a function of the angle. Less severe decrements occurred for deviations from the maximum strength forearm rotation position with zero degree elbow flexion. Data from this study were gathered and tabulated in detail by the authors. Radwin and Oh (1991: 843) investigated the effect of

Figure 2. Maximum linear grip strengths for various handle openings (maximum grip span) in a random population sample. The grip span was measured at the illustrated grip axis – the middle of the hand at the beginning of closure of the test fixture. From Greenberg, L. and Chaffin, D.B. *Workers and Their Tools: A Guide to the Ergonomic Design of Hand Tools and Small Presses,* **1976, Pendell Publishing Co., Midland, MI, p.55 (adapted in Chaffin, D.B. and Andersson, G.B.J.** *Occupational Biomechanics, 2nd ed.***, 1991, p.423). Reproduced with kind permission of the authors.**

handle grip span and trigger length upon grip strength as it applies to power tool operators.

3.5. The Effect of Gloves on Grip Strength

Whether the use of gloves results in an increase or decrease in grip strength has not been clearly indicated. Gloves affect friction and grasp closure. These factors affect the interaction of biomechanical forces with the test handle or object being grasped. Moore *et al.* (1995: 582) found in a pilot study that latex medical examination gloves had no effect on three-jaw chuck pinch strength or power grip (full grasp) strength. Bronkema-Orr and Bishu (1996: 702) in another pilot study found that the amount of surface friction of a glove with the grasped surface affects the amount of force that a person feels is necessary to grasp an object. A high frictive force results in a lower grasping force. Their study also indicated that thicker gloves with a coefficient of friction similar to that of the bare hand tend to result in grip-related task performance similar to that occurring when using the bare hand. Special types of gloves that must be pressurized, such as space suit gloves, produce a significant decrement in grip strength. Roesch (1987: 786) compared hand grip strength with the bare hand to strength using a pressurized space suit glove with a 0.5 psi differential and one with a 4.3 psi differential. The smaller pressure differential resulted in a 35% grip strength decrement compared with bare hand. For the larger pressure differential, the strength decrement was 42%. Strength for the bare and gloved hand was positively correlated with hand size, body weight, height, and forearm circumference. Strength decrements were larger for larger-handed subjects because of the pressure differential acting over a greater area thus creating a higher resisting force against the grip.

4. RECOMMENDATIONS

i   The 4-second hand grip force exertion measure with sampling of grip force over the last 3 seconds of exertion as recommended by Caldwell *et al.* (1974: 201) should be used as a procedural guide in measuring hand grip strength.

ii   A hand grip span between 5 and 7 cm should be used when high grip forces are required. The span providing maximum grip strength for males is approximately 6 cm and for females approximately 5.5 cm.

iii The forearm should be kept in the neutral position (thumb up) or in the supine position (palm up) for tests requiring large grip forces. Grip strength is maximized in the supine position. With the forearm pronated (palm down), static grip strength is only 87% of the level attainable with the forearm supinated.

iv   The wrist should not deviate from the neutral position (parallel with the long axis of the forearm) in a radial or ulnar direction or be flexed or extended from the neutral position for maximum static grip strength.

v   A wrist flexion angle between 75 and 90 degrees is recommended when high wrist flexion forces are required.

vi   A wrist flexion angle between 45 and 60 degrees and a wrist extension angle between 45 and 75 degrees should be avoided in tasks requiring high wrist extension forces.

vii The hand should be stationary when high grip forces are required since isokinetic grip strength is lower than isometric grip strength.

viii When feasible, an adjustable grip span should be provided to accommodate a broad range of hand sizes.

ix An extended trigger handle permitting grip by several fingers (all if feasible) is desirable to minimize repeated exertions using only the forefinger.

x A high level or coefficient of friction should exist between the hand or glove and the handle or object being grasped.

xi When thick gloves are used, their coefficient of friction with the handle or object being grasped should be similar to that of the bare hand.

xii When latex examination gloves are used, they should fit the hand closely. Latex examination glove usage does not affect three-jaw chuck pinch strength, power grip strength or manual dexterity.

xiii Significant allowances should be made in hand grip strength and flexion–extension torque requirements based on task duration per day and number of repetitions of grip exertion per minute. A decrease in grip strength and flexion–extension torque up to 36% from maximum single effort strength can be expected for high repetition and prolonged task duration. The data and recommendations of Snook et al. (1995: 1488) should be used as a guide in establishing standards for tasks that include grip exertion.

Hand-grip Torque Strength

S. Keith Adams

Iowa State University, USA

1. INTRODUCTION

Hand-grip torque strength is important over a broad range of manual tasks that involve the tightening and loosening of fasteners using powered or un-powered hand tools. This strength is also a necessary capability in assembly tasks that include the tightening and loosening of threaded parts or connectors by unaided hand torque. A number of studies have been conducted to model, measure and predict hand-grip torque strength under specified conditions. These studies have revealed ways in which task and hardware design variables interact with biomechanical action and effective torque strength.

2. FACTORS AFFECTING HAND-GRIP TORQUE CAPABILITY

2.1. Factors affecting Hand-grip Torque Strength

All of the factors that affect grip strength (listed in the article on 'Hand-grip Strength' by the same author) also affect hand-grip torque strength. Every task requiring torque based on hand-grip contact contains some combination of these factors. Only a few factors can be studied in a single laboratory investigation. Since the hand must rotate in a dynamic task or exert rotational torque in a static task, factors affecting friction as well as grip force are important. These include the diameter of the object grasped, surface coefficient of friction, knurling or indentations, shape, type of grip (full wrap-around, two-finger pinch, three-jaw chuck), orientation of the hand, and interference with segments of the hand involved with the grasping or torque effort. Direction of torque (clockwise or counter-clockwise) can also affect strength. The use of gloves is another factor. As in any task involving hand strength, hand size and gender have significant effects with larger hand sizes and males typically producing higher torques, provided that adequate clearance exists to permit a high grip force and sufficient contact area with the surface.

2.2. Hand-grip Torque Strength for Circular Electrical Connectors

Adams and Peterson (1988: 733) investigated hardware and task design factors affecting hand-grip torque strength in tightening or loosening circular electrical connectors used to attach and detach multiwired electrical cables on US Air Force aircraft using simulated connectors. Circular electrical connectors consist of a male and female section. After the respective electrical terminal pins that connect the circuits are aligned with and inserted into their receptacles, a threaded female connector ring is hand-tightened onto the corresponding male threaded shaft on the other half of the connector thus securing the connection. The connector ring must fit tightly to prevent inadvertent disconnection from vibration or acceleration forces. Thus, tightening and loosening require a secure grip and high hand torque. The use of hand tools as an aid when torque requirements exceed the hand torque strength of the technician is undesirable since their misalignment or misuse could damage the connector casing or cause rotation of two connector halves in opposing directions thereby breaking connecting pins. This results in very costly and time-consuming replacement and repair. It is, therefore, important that hand torque capabilities be known for this task for a variety of connector sizes and task configurations. Such knowledge permits the proper design of connectors and task configuration.

Adams and Peterson (1988: 733) investigated the effect of connector size (2.3, 3.8, 5.1 cm tightening ring diameter), grip type (full thumb and forefinger wrap-around, thumb tip and forefinger tip), grip orientation (frontal plane, sagittal plane (right side) and reverse frontal plane facing away from the subject), height (60 and 80% of maximum reach height), glove use (no glove, work glove, and chemical defense glove), and direction of torque (clockwise, counter-clockwise) for 20 male and 11 female

Table 1 Mean hand-grip torque (NM) and standard deviation for males and females as a function of independent variables

Variable	Condition	Male(N=20)				Female (N=11)

right-handed subjects in standing position. Results of the study are summarized in Table 1. Minus signs on torque values in the table denote loosening or counter-clockwise torque. Data are given in Nm. A modified Caldwell procedure (Caldwell *et al.* 1974: 201) was used as a measure of strength with data obtained from a torque measuring load cell and converted from analog signals acquired in 0.1 sec. intervals to direct digital readout and computer disc storage. Grip torque strength increased with connector size and was higher for right-side grip and reverse frontal orientation than for frontal orientation. The use of chemical defense gloves and work gloves resulted in slightly higher torque strength than the use of the bare hand. Strength gradients among varied conditions were approximately equal for tightening and loosening torques. Torque strength for males was significantly higher than for females.

Adams and Ma (1988: 642) investigated the effects of interference with hand and finger grip and torque in a study employing 18 male and 16 female standing subject, all right-handed. Torque measurement methods were identical to those used by Adams and Peterson (1988:733). In this study, the effects of four configurations of obstructing adjacent electrical connectors or flat surfaces upon hand-grip torque strength were determined for six behaviorally defined levels of interference. The effects of electrical connector size (2.3, 3.8, 5.1 cm diameter) and the use of work gloves were also measured in the study. The four conditions of interference were as follows:

i.   Interference by an identical connector located to the right and left of the grasped connector.
ii. Interference by an identical connector located to the right and left and also above and below the grasped connector.
iii. Interference from a flat rigid surface obstruction to the right of the grasped connector.
iv. Interference from a flat rigid surface obstruction below the grasped connector.

The six behaviorally defined levels of interference were as follows:

i.   Unobstructed
ii. First noticeable effect
iii. Moderate obstruction for full grip
iv. Loss of full grip
v.   Moderate obstruction for fingertip grip
vi. Limit of fingertip grip

The respective behavioral criteria for these interferences are as follows:

i.   No noticeable (by subject) interference with full grip (full wrap-around grasp)
ii. First detectable interference (by subject) with full grip; first contact with obstruction
iii. Very noticeable interference with full grip; some compromising necessary on full wrap-around grasp
iv. Subject forced to change grip to fingertip grasp using thumb and forefinger
v.   Very noticeable interference with fingertip grasp using thumb and forefinger
vi. Minimum clearance for which a fingertip grasp is possible using thumb and forefinger

In all cases, the grasped connector was located at 60% of the subject's reach height (maximum fingertip reach height above the floor). Its forward position was ahead of the right foot at a

Table 2 Hand-grip torque and separation distance as a function of level of interference

Level of Interference	Male		Female	
	Torque in NM	Separation (mm)	Torque in NM	Separation (mm)
1 Noninterference	1.53	34.5	1.01	29.8
2 First noticeable full grip	1.28	28.9	0.89	24.7
3 Significant, full grip	1.01	23.4	0.74	20.8
4 Switch to fingertip grip	0.74	18.8	0.57	16.7
5 Significant fingertip grip	0.68	14.8	0.52	13.9
6 Limit of fingertip grip	0.62	11.3	0.46	11.1

distance equal to one-half of the maximum grip distance. The maximum grip distance is defined as the displacement range between the center lines of two cylindrical handles, one held by a full grip at arm's length and the other held by a full grip against the sternum. Hand-grip torque was sampled in 0.1 sec. intervals over a period of 4 seconds and measured over the final 3 seconds according to a modified adaptation of the Caldwell procedure (Caldwell *et al.* 1974:201) as used previously by Adams and Peterson (1988:733).

Results are presented in Tables 2 to 5. Table 2 shows the effect of level of interference on hand-grip torque in Nm and the separation distance between connectors in mm necessary to achieve the indicated torque. All strength level differences shown in Tables 2 to 5 are significantly different at an alpha level of .05 using the Duncan test except those connected by a vertical line on the right side. The data in Table 2 are averaged over condition of interference (type of obstruction), connector size and the use or nonuse of work gloves. A significant difference averaging approximately 18% is shown between male and female hand torque strength, female strength averaging 72% of male strength. Strength differences are high under the higher torque conditions. A large compromise to hand torque strength occurs between levels 2 and 3, suggesting a minimum spacing of 25–30 mm. Higher male torque capability does not permit significantly greater torque under close crowding of connectors because of more limited grip contact area for larger hands. The relationship between torque strength and separation distance varies with the type of obstruction.

Condition of interference (type of obstruction) also produced significant differences in hand-torque strength and separation distance effects when averaged over the six levels of interference, three connector sizes and the use or nonuse of work gloves. The effect of obstructions on hand torque is shown in Table 3. Differences between male and female strength are evident, but do not vary as much by type of obstruction as by level of interference (Table 2). Under conditions 3 and 4, providing the highest torque strength, male and female strength are in reverse order as a function of condition. These differences are not statistically significant. Interference from a flat rigid surface located to the right side or below the grasped connector caused a much smaller decrease in torque strength than interference from

Table 3 Hand-grip torque and separation distance as a function of condition (type of obstruction)

Condition	Male Torque in Nm	Separation (mm)		Female Torque in Nm	Separation (mm)
3 Surface on right	1.08	27.4	4 Surface on bottom	0.76	25.2
4 Surface on bottom	1.07	23	3 Surface on right	0.75	20.6
2 Connect on L, R	0.93	21.5	2 Connect on L, R	0.69	18.8
1 Connect on on L, R, T, B	0.83	15.8	1 Connect on L, R, T, B	0.60	13.5

adjacent connectors. Connectors located on the right and left side produced a smaller strength decrement than connectors located on all four sides (right, left, top, bottom). For design of equipment, a minimum clearance from any flat rigid surface of 23–25 mm is desirable. Somewhat less clearance is acceptable between connectors, but only with a significant compromise in torque strength.

Table 4 shows the very significant effect of connector size on torque strength, averaged over all other conditions. This effect is to be expected since torque is directly related to diameter and a higher surface contact area results in a higher surface friction force. Male–female strength differences are smaller for small- and medium-sized connectors than for large connectors. Higher strength provides limited benefit when grasping is difficult. An important principle for equipment design that can be derived from this table is that minimum separation distance increases as connector size decreases. Nearly 40% more surface-to-surface separation distance was required for 2.3 cm diam. than for 5.1 cm diam. connectors. Nearly 20% more separation was required for 3.8 cm diam. than for 5.1 cm diam. connectors. The data in Table 4 suggest a minimum surface separation distance between connectors of 25 mm.

The use of work gloves increased hand-grip torque strength slightly for all subjects, as shown in Table 5. Work gloves also required significantly more clearance for all conditions of interference. These data also suggest a minimum surface separation distance between connectors of 25 mm.

Table 4 Hand-grip torque and seperation distance as a function of connector size

Connector Size	Male Torque in NM	thing Seperation(mm)	Female Torque in Nm	hiinggng Seperation(mm)
Large (5.1 cm diam.)	1.55	18.3	1.06	16.5
Medium (3.8 cm diam.)	0.95	22.0	0.72	19.4
Small (2.3 cm diam.)	0.42	25.5	0.32	22.6

2.3. Torque Strength for Cylindrical Handles

Replogle (1983: 412) investigated the relationship between hand torque strength and the diameter of a smooth phenotic fiber cylinder with a diameter ranging from 0.95 to 8.89 cm. and developed a mathematical model predicting torque as a function of handle diameter, gripped area, and relative grip force (proportional to gripped circumferential angle). Torque strength increased with the square of handle diameter up to approximately 2.5 cm, the "grip-span diameter" at which the fingers just reach the base at the palm in encircling the handle. Beyond 2.5 cm, torque strength increased at a decreasing rate to a maximum diameter of approximately 5 cm. The hand torque at this point was approximately 1.5 times the torque exerted on the 2.5 cm handle.

Female torque strength was 40% of male torque strength. Grip span and maximum torque diameters did not differ significantly between males and females, suggesting that the same size handles can be used for both genders for tools such as screwdrivers for which hand torque constitutes the primary effort required. A deviation in handle diameter at plus or minus 1 cm from the 5 cm optimum (for maximum torque) does not reduce torque strength significantly. For diameters below 2.5 cm or above 7.5 cm, hand torque strengths significantly reduced. The proposed mathematical model was verified accurately in a laboratory study using 20 subjects.

2.4. Torque Strength for Hand Tools

Pheasant and O'Neill (1975: 205) performed research on the effect of the diameter, shape, and amount of hand contact area of screwdriver handles on grip torque strength. They also compared screwdriver handles with smooth and rough steel cylinders for this effect. Handle shape was found to be unimportant. Handle diameter and the effect of contact area and friction were important factors. Hand torque strength normalized against each subject's mean torque strength over seven polished steel handles ranging in diameter from 1 to 7 cm in 1 cm increments increased linearly up to a diameter of 5 cm, at which point the rate of increase dropped although linearity was maintained up to 7 cm. A total of 24 subjects served in this study. Normalized thrust force and shear force (equal to torque divided by handle diameter) were both maximum for a handle diameter of 4 cm. The contact area between the handle and the hand was maximized for a handle diameter of 5 cm. A knurled cylindrical handle 5 cm in diameter is recommended as a design for maximum torque strength.

Mital and Sanghavi (1986: 283) compared maximum voluntary torque in the use of five different hand tools for 55 subjects (30 male, 25 female), for 2 postures (seated and standing), 3 work heights, 3 reach distances and 6 angles relative to the mid-sagittal plane (plus or minus 15, 45 and 75 degrees). Moment arm effect among the five tools (short and long screwdriver, socket wrench spanner (crescent) wrench and adjustable vice-grip) produced widely differing torque capabilities. The mean torques exerted for the latter three tools were 27.8, 23.6 and 20.9 Nm, respectively. Mean torque values for the long and short screwdrivers were only 2.7 and 3.1 Nm. For screwdrivers, torque strength was a function of hand-grip contact area while for wrenches, torque strength depended upon the length of the wrench. The socket wrench enabled higher torque than the spanner wrench (27.8 versus 23.6 Nm).

Higher torques were produced in a sitting posture for screwdrivers and in a standing posture for wrenches. Peak torque exertion for female subjects averaged 66% of peak male torque. Work height and angle effect were of no practical significance. Higher torque strength occurred in the standing position (23.5–33.3 Nm) for the socket wrench, spanner wrench and vice-grip) than in the sitting position (17.6–27.4 Nm). Reach distance also affected torque strength with maximum torque (18.5 Nm) exerted at a distance to the work surface of 33 cm and minimum torque (13.1 Nm) at a distance of 71 cm. The decrease in torque strength resulting from reach distance was the same for sitting and standing postures (2.2 versus 2.4 Nm) for an increase of 25 cm in reach distance.

Torque strength in this study was measured using the basic recommended procedure (Caldwell 1974: 201) with a 3-sec. build up in torque exertion followed by a 1-sec. hold at the peak exertion. Torque produced during this final second was used as the measure of torque strength. Among several isometric strength measures taken, shoulder strength appeared to limit torque exertion capability of subjects in this study.

2.5. Torque Strength for Small Knobs

Swain, Shelton, and Rigby (1970: 201) conducted a study in which 96 civilian and 24 military personnel in two age groups, one 29 years of age or under, the other over 29 years of age, exerted grip torque with and without gloves in a standing position on small diamond-knurled knobs 3/8, 1/2, and 3/4 inches (0.95, 1.27, 1.90 cm) in diameter located in front of and on the side of the preferred hand. Maximum single effort exertions were used as a measure of torque strength. No significant differences in torque strength were attributable to age or civilian versus military subject group. Mean and standard deviation data were developed for each of the knob sizes with and without the use of gloves. For the 3/4 in. knob, mean frontal bare-handed torque strength was 0.52 Nm with a standard deviation of 0.127 Nm with the 5th percentile equal to 0.31 Nm. The side mean torque strength for the 3/4 in. knob was 0.55 Nm with a standard deviation of 0.124 Nm and a 5th percentile value of 0.34 Nm. The use of gloves reduced the mean torque values slightly to 0.45 and 0.47 respectively for front and side torques but did not affect the 5th percentile value.

For the 1/2 in. knob, mean torques for the front and side were 0.65 and 0.66 Nm with standard deviations of 0.150 and 0.159 Nm respectively. The 5th percentile values were both equal

to 0.40 Nm. The use of gloves reduced torque strength to 0.57 and 0.59 Nm with standard deviations of 0.104 and 0.116 for front and side torque exertions respectively. The 5th percentile value remained at 0.40 Nm for both orientations.

For the 3/4 in knob, mean torques for the front and side were 1.11 and 1.14 Nm with standard deviations of 0.260 and 0.266 Nm respectively. The 5th percentile torque values were 0.68 and 0.70 Nm respectively. The use of gloves reduced mean torque strength for front and side exertions to 0.92 and 0.93 Nm with standard deviations of 0.170 and 0.178 Nm respectively. The 5th percentile value for both front and side torques was reduced to 0.64 Nm.

These data show increased torque capability as a function of knob diameter, a slight reduction in unobstructed knob torque strength resulting from the use of gloves, and significant variability among subjects not attributable to age. Torque strength also did not differ significantly between civilian and military personnel. The variation in strength among subjects suggests the use of the 5th percentile values as a general design upper limit value for torque requirements when specifying the sizes of knurled knobs used in the study.

3. RECOMMENDATIONS

i. A 4-second hand-grip torque exertion measure with sampling of torque over the last 3 seconds of exertion as recommended by Caldwell *et al*. (1974: 201) should be used as a procedural guide in measuring hand-grip torque strength.

ii. Hand tools requiring high torque exertions should have a handle diameter of approximately 5 cm.

iii. Hand tools requiring high torque should not have handles with diameters below 2.5 cm or above 7.5 cm.

iv. Since grip span diameter (the diameter at which the fingers just reach the back of the palm in encircling the handle) and maximum torque diameter do not differ significantly between males and females; the same sized handle for hand-grip torque can be used for both genders.

v. Hand contact area with the handle should be maximized in the design of screwdrivers.

vi. For small knurled knobs requiring hand torque exertion, strength should be considered to be related to knob diameter.

vii. In specifying hand torque strength requirements for tasks, it should be assumed that women can exert approximately 66% of male hand torque strength.

viii. Right-handed operators can exert stronger hand-grip torque on the right side than in a forward or rearward work surface orientation because of more effective use of flexors and extensors affecting wrist and forearm motion and because of additional torque provided by the upper arm. Based on this fact, components requiring high torque should be accessible from a right-handed operator's right side when feasible.

ix. The height of an electrical connector or other object to which hand torque is to be applied does not affect grip torque strength provided that its height does not affect the type of grasp used. Therefore, adjustments in hand-grip torque strength requirements based on task height are, in most cases, unnecessary.

x. Gloves often increase hand-grip torque strength provided there is sufficient clearance to accommodate the glove. Work gloves or chemical defense gloves are effective in increasing

hand-grip torque strength. Whether gloves are used or not used, good surface friction with the grasped object should be provided.

xi. For the case of circular electrical connectors or other grouped objects such as knobs, torque strength depends upon adequate clearance, which varies inversely with connector or object size. Therefore, wider spacing is needed for smaller connectors or objects to provide the conditions for adequate grip torque. When gloves are used, sufficient clearance for their use should be provided.

xii. The minimum clearance between connectors, knobs or other objects, or between these and a nearby rigid surface should be at least 25 mm when a full grip is required. For connectors or objects 3.8 cm or less in diameter, a surface separation distance of 30–35 mm is recommended for a full grip.

xiii. For a fingertip grip torque, large connectors or objects (5.1 cm diameter or larger) should be spaced at least 15 mm apart, surface to surface. Medium connectors or objects (approximately 3.8 cm diameter) should be separated, surface to surface, by a distance of at least 20 mm. Small connectors or objects (2.3 cm diameter or less) should be separated, surface to surface, by at least 25 mm.

xiv. When interference in applying hand-grip torque to tighten or loosen circular electrical connectors occurs at or beyond Level 2 (first detectable interference with a full grip), required torque should be no more than 1.35–1.70 Nm for a large connector (5.1 cm diameter), 0.90—1.10 Nm for a medium connector (3.8 cm), and 0.35—0.45 Nm for a small connector (2.3 cm).

Handgrip Characteristics and Strength

S. N. Imrhan

Industrial and Manufacturing Systems, Engineering Department, University of Texas, Arlington, TX 76019, USA

1. INTRODUCTION

Of all human physical activities none is more pervasive and perhaps more important than grasping and manipulating objects with the hand. While grasping was necessary in early human development for fashioning crude hunting tools and for accomplishing other basic necessities of life, today it is a precursor to more sophisticated tasks, especially in the workplace. The ways objects are grasped and manipulated largely determe the quality of task performance and the associated level of strain on the body.

For convenience early classifications of grasping (Napier 1956) have identified two main types(prehensile and nonprehensile. In prehensile grasping an object is seized partly or wholly within the compass of the hand, whereas in nonprehensile grasping the object is pressed with the flat surface of the hand or fingers. Two major types of prehensile grasp have been identified:

- *The power grasp*: the object is held in the palm of the hand with the force of the thumb opposed by the combined forces of the other fingers.
- *The precision grasp*: the object is held between the flexor aspects of one or more fingers and the opposing thumb of the same hand. This article deals with the strength of the power grasp (power grip).

2. TYPES OF HANDGRIP

Common usage of the term "handgrip" is synonomous with "power grasp" and will be used in this context here. Other synonyms are hand grasp, hand squeeze, and grip. Power grasping may be accomplished in different ways, depending on the size and shape of the object being grasped. Here is a practical classification of the main types of power grasp:

- *Spherical grasp*: the hand grasps a spherical object in the palm of the hand. The object is large enough to allow contact with the palm and fingers, as in holding a baseball or spherical doorknob.
- *Disk grasp*: the fingers encircle the perimeter of a disk-shaped object such that the thumb lies along the grasp surface (perimeter), as in trying to open or tighten a lid on a jar with great force.
- *Cylindrical grasp*: the fingers are wrapped around the surface of a cylinder or similarly shaped object such that the long axis of the object runs along the width of the hand, as in grasping a hammer handle.
- *Hook grasp*: the handle of the object is hooked by the index, middle, ring, and little fingers at the region of the knuckles, as in carrying a briefcase, but the thumb does not apply counter force to these fingers.

3. PROBLEMS WITH STRONG GRIPPING

Power gripping with great forces is common during task performance; great grip forces, especially when applied repetitively, may produce significant muscular strains in the hand and should be avoided as a task requirement. One solution has been to use powered tools, but the advent and proliferation of powered hand tools have not eliminated overexertion problems of the hand. On the contrary, in some cases, new problems have been created, such as the need to maintain more powerful grips on tools to stabilize them from impact motions and vibrations, or to maintain them at specific positions in space against gravitational pull (their weight). Moreover, developing countries routinely use manually operated hand tools and their populations experience many ergonomic problems. The use of manual pliers and screwdrivers is ubiquitous in developing countries. One needs, therefore, to understand the nature of hand gripping in order to prevent or eliminate manual muscular overexertions and enhance task performance. This kind of understanding may also lead to improvements in hand tool design, work design and evaluation, and personnel task assignment.

One of the most important aspects of gripping is strength — (the maximal force that can be achieved by squeezing voluntarily on an object with the hand as hard as possible without feeling pain or significant discomfort (MVC exertion)). This article examines the nature of MVC grip strength. Applications of grip strength will not be discussed except to help readers comprehend a particular aspect of strength.

4. GRIP STRENGTH MEASUREMENT

The standardized method of measuring grip strength involves gripping and squeezing the handle of a handgrip dynamometer. The typical handle comprises two straight or slightly curved parallel bars (ostensibly shaped to fit the contours of the enclosed hand) which are squeezed toward each other but which can accommodate only one hand. Some dynamometers allow a slight movement of one of the bars whereas others show no perceptible movement. For practical purposes, these grip forces are considered as static forces. Grip strength is taken as the peak or middle 3 s mean grip force during a maximal voluntary effort (MVC force) that lasts 4–6 s. Usually the subject is allowed to adjust the separation distance of the two bars over a narrow range to obtain their most comfortable grip. Most adults select a width of about 5.0 cm. The result is a power grip with some resemblance to a hook grip. This method of measuring handgrip strength has its origins in the clinical field in which the data is used mainly for evaluating the effects of injuries and the progress of rehabilitation of injured hands rather than for work task applications.

5. FACTORS INFLUENCING HANDGRIP STRENGTH

Grip strength, like almost any other kind of strength, is not a constant. It varies according to the conditions in which it is exerted. Many of the variables that define these conditions have been investigated experimentally. The results show that among the most influential are grip size, posture and joint angle, type of grasp, use of gloves, anthropometry, and sex (or gender). These factors are discussed below. Unless otherwise stated, the

discussions pertain to one-handed (the preferred hand) static strength measured on a standard handgrip dynamometer as described above.

5.1. Grip Size

Grip size refers to how much the fingers are opened in gripping an object. It may be measured as the diameter or perimeter of the handle being gripped or, for the bars on a handgrip dynamometer, as the distance between the surfaces of the bars in contact with the hand. Grip strength seems to be highest at grip widths in the range 5.0–6.5 cm for males and 4.5–6.0 cm for females. It is lower outside these ranges. This constitutes an increasing/decreasing trend. Research results also suggest that similar optimal ranges exist for other types of one-handed grip: 5.0–6.0 cm for pistol grip; and 6.4–8.9 cm for dynamic contractions on angulated handles (such as those found on sheet-metal shears) and 5.0–6.5 cm for static contractions (Fransson and Winkel 1991). However, not all types of grip have shown an increasing/decreasing trend. One study on gripping cylinders has shown a steady decrease as the diameter of the cylinder increases (within the 5.0–7.0 cm range). One study on two-handed gripping (Imrhan 1999) also found that, for flat surfaces, grip strength followed a linear trend with grip width (distance between the surfaces).

These ranges seem to be the grip sizes where the fingers are about midway between full flexion and full extension and the finger flexor tendons are at about their greatest mechanical advantages; that is, where the torques generated by the finger flexor muscles about finger joints are maximized. These torques translate into grip forces at the hand(handle contact.

5.2. Body Posture and Joint Angle

There seems to be no credible reason to expect a difference in grip strength among sitting, standing, and lying down postures, but one study has reported that grip strength is 6% stronger when standing compared to sitting and 4% stronger when sitting compared to lying supine.

Given the anatomical nature of gripping, it is reasonable to expect that grip strength is influenced by biomechanical variables such as wrist angle and wrist orientation. Experimental data has shown this is indeed the case: grip strength is significantly weaker when the wrist is sharply deviated away from its natural position or when the forearm is sharply rotated (Terrell and Purswell 1976). Thus hand tools and workplaces that impose these constrained wrist and forearm positions can cause people to exert unduly great muscular efforts to produce required grip forces for various tasks. This loss of grip strength or increase in muscular effort is most likely due to (i) excessive shortening or lengthening of the flexor muscles and consequent loss of some of their tension-producing capabilities, (ii) pressure of the tendons on the carpal wall within the bent wrist resulting in pain in the wrist, and (iii) loss of grip effectiveness.

Experimental data has confirmed that handgrip is strongest when the wrist is in its natural position (hand dorsiflexed 15–35°), followed by ulnar and radial deviation, dorsiflexion (hyperextension), and palmar flexion, in decreasing order of magnitude. The losses of strength in these positions compared to the natural position are about 15% for ulnar deviation, 18% for radial deviation, 22% for dorsiflexion, and 30–40% for palmar flexion. This ordering assumes the wrist in any of its unnatural positions

is bent as sharply as possible while still maintaining a reasonably good power grip on a dynamometer handle. These strength–angle relationships do not necessarily hold under all gripping conditions. One experimental study has shown that, for a hook grip, the 30° ulnarly deviated position was stronger than other deviated positions. Gripping with the forearm in pronation is about 12% weaker than in supination or mid-orientation (natural orientation). Supination and mid-orientation seem to be about equally strong.

5.3. Type of Grasp

From a biomechanical viewpoint, grip types that vary sharply should yield significantly different grip strengths, but there is little empirical data for comparing different types of grasp under similar conditions. One study found that a forward grasp on an angulated metal shear handle was stronger than a reverse grasp for grip spans of 4.1–6.7 cm, but at greater spans there was no difference in strength.

5.4. Use of Gloves

Gloves are used for protecting the hands from mechanical injuries (cuts and abrasions), corrosive chemicals, dirt and grease, heat and cold, and vibration. In many cases the gloved hand must grip and squeeze hand tools and workpieces but the extra effort that may be required to stretch and crumple thick, stiff, or close-fitting gloves while flexing the fingers may lead to some loss of grip strength. Research has shown that grip strength is reduced by about 7–30% when wearing regular working gloves, and by about 50% when wearing pressurized gloves used for extravehicular space activities.

5.5. Anthropometry

Body dimensions, especially body weight, height, hand length, forearm circumference, and various other arm dimensions, are significantly correlated with handgrip strength. But either alone or in combination, they cannot predict handgrip strength (standardized or task related) accurately enough for ergonomic designs.

5.6. Sex or Gender

On average, female grip strength is about 50–60% of male grip strength. This is smaller than the percentages for the strengths of most other body parts. Because of the smaller size of the female hand, an optimal hand size for grip strength should be smaller in females than in males. However, experimental results have not established this male/female difference unequivocally; some results indicate that both sexes have the same optimal range whereas others indicate that the female optimum is smaller. Perhaps this apparent contradiction is due to the characteristics of the subject samples in these studies; it is likely that the male/female hand size difference was not great enough to result in different optimal ranges.

5.7. Gripping and Torquing

The nature and strength of gripping is of paramount importance in manual torquing. In many tasks, gripping is not an isolated activity but is often combined with other kinds of muscular exertion. In some cases, such as turning a screwdriver, the necessary output is the torque generated at the tool (object

interface. This torque, however, is a function of the grip force (in addition to other variables) on the screwdriver handle (Pheasant and ONeill 1975). Other influences being equal, torque increases proportionally with grip force. In other tasks, such as pushing/pulling a cart, grip strength may also make an important contribution to push/pull strength, but its importance here is not as great as in torquing. Designs that prevent gripping overexertion or that enhance the magnitude of grip force for a given level of muscular exertion can help to prevent strains and enhance task performance; for example, cylindrical handles of 4.5–6.5 cm diameter. Because other tool/object or task factors (e.g., surface texture, shape, orientation) interact with handle size, it is not always true that the optimal range of handle diameter (or perimeter) for torquing is also optimal for gripping and squeezing.

6. RELEVANCE OF HANDGRIP STRENGTH MEASUREMENTS

Handgrip strength measurement in the field of ergonomics has adopted the clinical method, often without justification. For many manual tasks in industry, for activities of daily living, and for leisure activities the gripping methods may differ significantly from the clinical test grip. At work people often grip and squeeze with two hands; the shape and contours of objects vary considerably and the types of grip employed vary accordingly; the varying sizes of object may lead to widely varying grip widths. Because of these differences in grip strength between real tasks and standardized tests, one must be careful in applying published grip strength data to the design of tasks and equipment for the workplace as well as for living and leisure activities. One study has shown that when gripping and squeezing flat surfaces, grip strength declined linearly as the width increased from 3.8 cm to 16.5 cm; and two-handed grip strength in females was 1.6 times as strong as one-handed grip strength.

7. GRIP STRENGTH MAGNITUDES

Reported one-handed grip strengths have mostly fallen in the range 450–600 N for adult males and 250–300 N for females. Two-handed strengths have been reported as about 1.6 times as strong in females and 1.3 times in males.

8. CONCLUSIONS

Handgrip strength information is important for designing hand tools and other work equipment, and for designing and evaluating work tasks. Among the most important information are strength magnitude, how other variables influence strength, and the nature of gripping objects. Users should exercise care in applying handgrip data because most data is based on a method of measurement which differs significantly from the way people grip real task objects. Even for similar tests, published data varies widely.

In the human, there are three types of muscle. *Cardiac muscle* brings about contractions of the heart. *Smooth muscle* works on body organs, such as by constricting blood vessels. *Skeletal muscle* is under voluntary control of the somatic nervous system (Kroemer *et al.* 1997, 2000) and serves two purposes. One is to maintain the body's postural balance; the other is to cause local motion of body segments by pulling on the bones to which the muscles are attached, thereby creating torques or moments around the body joints which serve as pivots.

There are several hundred skeletal muscles in the human body, identified by their Latin names. The Greek words for muscle, *mys* or *myo*, are often used as prefixes.

Muscles actively perform their functions by quickly and temporarily developing internal lengthwise tension. This is often, but not always, accompanied by shortening, therefore the action is generally called contracting. Muscle my also be lengthened passively beyond its resting length by a force external to it; in response, muscle tissue develops internal tension both by elastic resistance and by attempted active contraction.

The main components of muscle besides water (~75% by weight) are proteins (20%). Collagen, an abundant protein in the body, constitutes the insoluble fiber of the binding and supportive substance in muscle tissue. The proteins actin and myosin form rod-shaped polymerized molecules that attach end-to-end into thin strands.

These actin and myosin filaments are the contracting microstructure of the muscle. As seen in a crosscut through the muscle, several actin molecules surround each myosin molecule. Lengthwise, the thin actin strands are wound around the thicker myosin in form of a spiral (double helix). At rest, separate actins and myosins are separate. For a contraction the actin strands temporarily connect with the myosin via so-called cross-bridges that serve as temporary ratching attachments by which the actins pull themselves along the myosin rod.

Between 10 and 500 muscle filaments are packed tightly into a bundle known as fibril. Along the length of each fibril, lighter and darker stripes appear in a repeating pattern mostly indicating the density of actin and myosin molecules. This banding or striping has led to the name "striated" muscle. Fibrils, in turn, are packed into bundles wrapped by connective tissue called fascia. Bundles of fibrils packed together constitute the muscle fiber. This is a cylindrical unit, 10^5–10^6 Angstrom in diameter and 1–50 mm long. Each is a single large cell with several hundred cell nuclei located at regular intervals near its surface. They contain the mitochondria, the "energy factories of the muscle" where chemically stored energy is converted for use by the muscle to generate physical energy.

Between 10 and 150 muscle fibers constitute the so-called primary bundle (fasciculus). Several primary bundles are packed into a secondary bundle, again wrapped in connective tissue. Secondary bundles, in turn, are grouped into tertiary bundles, and so forth until the structure called a muscle is formed. It usually has several hundred thousand fibers in its middle and tapers off towards its ends, traditionally called origin (proximal) and insertion (distal).

The bundles and the total muscle are wrapped in perimysium, tough and dense collagenous membranes which, at origin and insertion, develop into tough, bendable, slightly elastic tendons. On its other end, the tendon usually attaches to the outer membrane of a bone. Many (but not all) tendons run through slippery tissue tubes, called tendon sheaths, which keep the tendon in position and guide it around a bend while it slides within the sheath, with synovial fluid serving as lubricant for smooth gliding.

For more information see any book on physiology or kinesiology, or Kroemer *et al.* (1997, 2000).

Information Processing

C. M. Carswell and E. C. Stephens

Department of Psychology, University of Kentucky, Kansas, KS, USA

1. INTRODUCTION

Information processing (IP) is one approach used to describe how minds (human and otherwise) operate. Its core assumption is that basic mental operations select and transform incoming information in goal-consistent ways. The IP approach evolved in the mid-twentieth century in part due to the work of early military human factors researchers. Today, IP concepts and models are widely used by human factors and ergonomics specialists, especially those interested in enhancing human comprehension, decision-making and problem-solving.

2. INFORMATION PROCESSING MODELS

2.1. From Black Box to White Box Models

Psychology in the first half of the twentieth century, especially in North America, was dominated by models of human behavior that included no descriptions of hypothetical mental activities. Researchers working in this behaviorist tradition objected to such concepts either because they were unobservable, and thus unscientific, or because they were considered unnecessary adequately to predict human performance. Such models described how human responses were adapted to environmental stimuli and often included elaborate and careful measurements of stimulus–response relationships. Organismic events occurring between the stimulus and response were said to take place within a 'black box' that was assumed to be impenetrable by the methods of science. Stimulus–response models were, thus, sometimes called "black box models."

By the 1950s, some researchers were exchanging the black box in their models for a series of intervening mental operations. Their models were often presented as flow charts, usually a series of labeled boxes connected by arrows that indicated the proposed flow of information. These "white box models" became the standard format for presenting proposals about information processing. One example from the human factors literature is shown in Figure 1.

2.2. Central IP Concepts

IP models similar to the one shown in Figure 1 have been used to describe human performance in a variety of complex tasks such as reading, maintaining situation awareness, wayfinding and selecting from computer menu options. Regardless of the specific application, most IP models share a number of features (Lachman *et al.* 1979).

2.2.1. Computer metaphor

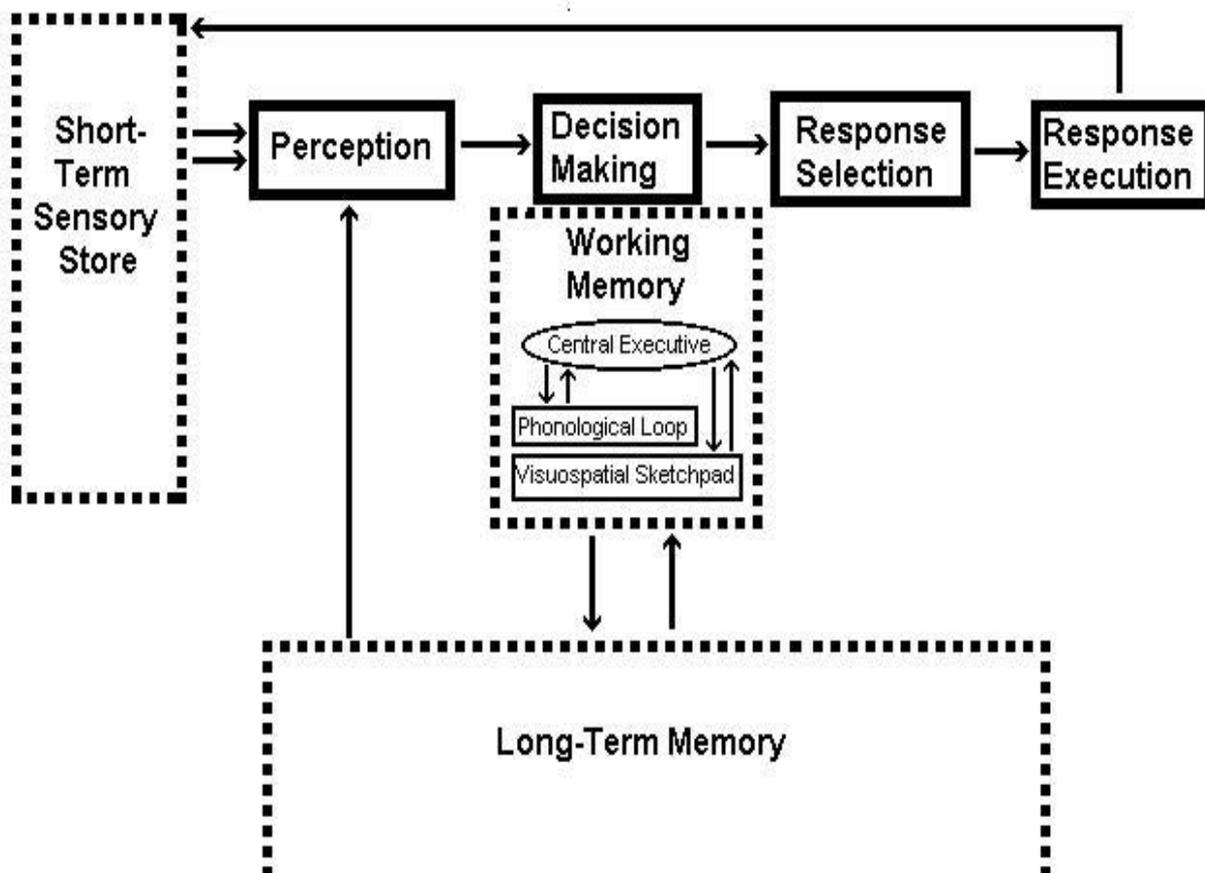
IP diagrams and terminology owe much to the emergence of the digital computer. The traditional IP approach assumes that there are strong similarities between human thought and the way


Figure 1. An example of a typical information processing model, combined from the work of Atkinson and Shiffrin (1968), Baddeley (1997), and Wickens (1992)

computers operate. For example, computers, like humans, have different types of memory stores that can be accessed or searched in different ways. Computers also have specialized input and output devices that might be comparable with the specialized sensory and response modalities of humans.

2.2.2. Processing stages

Most traditional IP models propose a sequence of stages through which information passes. At each stage, information from previous stages is manipulated, transformed or combined with information from memory before being passed to the next stage. The overall cognitive performance of a person on a task is determined both by the number and type of stages required as well as by the efficiency with which the operations at each stage are accomplished. Thus, IP models are often used in human factors as a framework for isolating the "location" of cognitive performance problems. For example, researchers may ask whether a person is having difficulty recognizing a critical stimulus or holding this stimulus information in memory long enough to act on it.

2.2.3. Mental representations

All IP models must deal to some degree with the way information is coded and organized. For example, information relevant to a specific task could be stored as a list, a network, a hierarchy, a series of auditory or visual images, or some combination of the above. Research on display design and decision-support systems, in particular, often attempts to develop displays that are compatible with the probable mental representations of the users. The more similar the physical (display) representation is to the user's mental representation of information, the fewer the number of transformations that are necessary to convert incoming information into a usable form.

2.2.4. Capacity limits

An appealing aspect of IP models for human factors applications is their emphasis on the processing limits of the operator. Just as computers are limited in both their storage capacities and processing speeds, humans too must be limited in how much information they can handle in a given interval. Designers need to be aware of these limitations to ensure that their product, device or procedure does not exceed the operator's capacity. While early IP models tended to focus on identifying the location of processing bottlenecks (e.g. Broadbent 1958), more recent research has focused on training and design techniques that reduce the impact of such limits (for a review, see Wickens 1992).

3. INFORMATION STORAGE IN IP MODELS

Most IP models make use of one or more information storage units. Figure 1 uses a tripartite storage system similar to the model originally proposed by Atkinson and Shiffrin (1968) and incorporated in many other IP models since then. The three units vary in terms of how much information each can hold, the durability of the information once stored, and the effort required to maintain stored information.

3.1. Sensory Registers

The initial memory storage unit for incoming stimuli is referred to as the sensory register. In this register, a large amount of sensory information is stored, but this information can only be held for < 1 s. Presumably a sensory register exists for each of the senses, although the iconic (visual) and echoic (auditory) registers have been the most widely studied. Information in the sensory register decays rapidly, and if attention is not devoted to this information it is lost and replaced by new information.

Functionally the sensory registers are important because they may serve as a pre-attentive system that alerts attention-demanding perceptual processes to select stimuli for further consideration. The sensory register can thus be seen as a brief 'second chance' window on a rapidly changing world. As a result, designers sometimes find that periodic breaks in a stream of information can enhance subsequent processing by allowing the operator to make use of information currently in the sensory register.

3.2. Working Memory

When sensory information is attended it is then processed by working memory (WM). Unlike the sensory register that receives information from the environment, WM receives information internally. The traditional view of WM claims it is a memory buffer of limited capacity (five to nine units of unrelated information) and brief duration (~20 s if not rehearsed). The classic example of using WM is looking up a phone number and keeping that number active in memory until dialing. If the number is not rehearsed, the ability to recall it decays rapidly.

WM has also been described as having two storage subsystems called the visuospatial sketchpad and phonological loop. These two storage units serve a central executive system that coordinates information (Baddeley 1997). The visuospatial sketchpad is dedicated to maintaining information in WM for use as mental images and for spatial reasoning. The phonological loop is dedicated to maintaining verbal information in an acoustical form by actively rehearsing this information vocally or subvocally. Both subsystems have a limited capacity and duration.

The limits of WM are generally assumed to be among the most severe bottlenecks in information processing. As such, WM poses a particular challenge to human factors design. Many researchers suggest that no more than four unrelated units of information (whether visuospatial or phonetic) should be presented to users for short-term recall. For example, voice mail menus should be kept to four or less options. If more options are needed, designers should take advantage of familiarity, identifying options by meaningful letters rather than unassociated numbers. Thus, saying "For savings account information press S" is preferable to saying "For savings account information press 1." Further, designers should avoid requiring users to hold information in WM while waiting for the opportunity to use it. Rather than forcing voice mail users to wait until the end of the menu list to respond, they should be allowed to enter their choice as soon as they know it.

3.3. Long-term Memory

Long-term memory (LTM) is where information is stored for later use. LTM has little or no capacity or duration constraints. However, failures of LTM do occur and are generically called 'forgetting.' There are two main causes of forgetting. First, forgetting may occur because the desired information was never successfully encoded. Some information is encoded with little

effort, whereas other information requires active and effortful memorization. Strategies such as placing the to-be-remembered information in the context of familiar information can facilitate encoding. However, even when information has been successfully encoded in LTM, it can still be forgotten. The second reason for forgetting involves retrieval problems, including interference from irrelevant information and lack of associations with easily retrieved memory cues.

Human factors professionals should design products, instructions, and procedures to minimize both encoding and retrieval failure. To minimize encoding failures, products should be designed to accommodate effective encoding strategies. For example, instructions should make use of pictures of familiar objects where relevant because pictures lead to more elaborate encodings than words alone. To minimize retrieval failure, research indicates that recall is enhanced when information available at the time of retrieval is similar to that available at the time of encoding. Thus, an accident investigation team is likely to get more accurate reports from victims returned to the scene of the accident.

4. COMMON IP STAGES AND OPERATIONS

4.1. Perception

In this stage, information from the sensory register is parsed to form separate objects that can then be identified. The arrow extending from LTM to the perception box in Figure 1 indicates that information stored in permanent memory is matched to the visual representation being processed by the perceptual subsystem. If the long-term information matches this representation, it is recognized as a familiar feature, pattern or object.

Perception is, as discussed above, guided by incoming sensory information. However, higher-order or 'top-down' processes including expectancies, beliefs and motives also guide perception. Human factors specialists must acknowledge the influence of top-down processes by attempting to create designs that accommodate user expectancies. Owing to top-down processing, responses to unexpected events are known to be slower and may even go unnoticed by operators. Therefore, unexpected events should be made salient to the operator. If a restaurant often changes its menu, then menu designs should incorporate factors that facilitate accurate sensory processing (e.g. larger fonts, greater contrast). These factors will be somewhat less important for a more predictable (rarely changed) menu.

4.2. Decision-making

After a stimulus has been perceived, it must be integrated with other task-relevant information, and possibly transformed, to allow the operator to select a response. This stage of processing is often called decision-making or thinking and is conceptualized as the manipulation of information in WM. Sometimes called the 'central executive' or 'central processing unit,' this stage of processing is the one most often associated with consciousness.

The central executive must coordinate the integration of many types of information. A mechanic troubleshooting an aircraft malfunction must integrate numerous pieces of evidence. A consumer deciding to buy a computer must weigh the pros and cons of several makes and models. An interior designer may mentally move a sofa in a room before deciding to expend the

effort physically to relocate it. Because WM, and especially the central executive, is constrained by severe capacity limits, the task of the human factors engineer is to make some of the required integrations easier or even unnecessary. For example, when considering two or more brands of over-the-counter medication, the consumer may need to combine information about dosage, number of doses per container, and overall price per container for each brand. However, some of this information could be combined for the consumer by presenting price per dose or number of daily doses per container.

4.3. Response Selection and Execution

As shown in Figure 1, once a decision has been made, the operator must decide how to respond based on this consolidated information. This requires an understanding of the response alternatives which, in turn, draws upon current perception or stored information. For example, when approaching a yellow traffic light, experienced drivers understand that their response options include stopping (pressing the brake pedal) or speeding up (pressing the gas pedal). They will make their response selection based on a decision, integrating their perception of how long the light has been yellow and the probable presence of law enforcement officers. Assuming that they decide to stop, they must still execute the response. This requires knowledge of the location and force required to use the braking system.

The distinction between response selection and execution is an important one for designers. Users frequently complain that they know what they want to do but may not understand how (or do not have the skill) to do it. Novice computer users may know the option they want to select, but they may not yet have the motor skills necessary to execute a 'double click.' Designers should pay attention to both making obvious the alternatives available to the user as well as reducing the difficulties in carrying out the response (e.g. reducing the motor precision required, adhering to population stereotypes).

5. TRENDS, CHALLENGES AND CONTRIBUTIONS

While the computer metaphor, with its associated flow charts, still influences most IP models found in human factors, cognitive psychology, and related disciplines, an alternative metaphor based on neuronal units and brain physiology has been achieving increasing acceptance. These parallel distributed processing (PDP), connectionist or neural network models propose that information processing takes place as the result of the activation and inhibition of networks of neuron-like units (e.g. McClelland and Rumelhart 1986). These models provide a more detailed explanation of how storage units and processing stages might actually operate.

In addition to the development of IP theories based on alternative metaphors, the IP approach as a whole has met with several challenges. One of the predominant limitations of IP models seems to be their focus on serial, discrete processing of stimuli. Various authors have indicated the importance of the continuous fluctuation of stimuli in a natural, as opposed to a laboratory, environment. Both ecological and control theoretic models have emphasized responses to the continuous flow of stimuli, a flow brought about both by changes in the environment as well as the continuous movement of the operator (see Wickens and Carswell 1997 for comparisons with the traditional IP approach).

Despite the search for an appropriate IP metaphor and challenges from other theoretical approaches, the traditional IP approach still provides a useful overall framework for considering the limitations of thought processes within the operator. Contributions of the IP approach involve its use to perform detailed task analyses that may highlight particular performance problems and suggest design solutions. A more detailed account of IP models and their applications to human factors and ergonomics is found in Wickens (1992) and Wickens and Carswell (1997).

Lifting Strategies

D.H.K. Chow

Jockey Club Rehabilitation Engineering Centre, Hong Kong Polytechnic University Hung Hom, Kowloon, Hong Kong

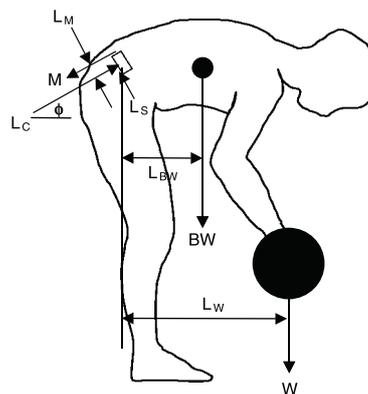
1. INTRODUCTION

Low back pain (LBP) is one of the most serious and persistent problems in occupational medicine. Epidemiological studies have shown that about 60 to 80% of the population experiences LBP at some time during their active life. The associated costs of LBP in term of loss of productivity, replacement training, and individual suffering are unacceptably high. LBP can develop suddenly or gradually, with or without an initiating event. Although the majority of LBP has no particular etiology, the incidence of reported pain, injury, loss of work, and disability is higher among those who are employed in occupations with a high level of exposure to physical loading. It is therefore essential to understand the ergonomic factors as well as the basic biomechanics related to LBP.

In human beings the spine is held in a vertical position during walking and working hours. In the erect posture, the loads on the spine increase progressively down to the lumbosacral region. The loads produce mechanical, physiological, and psychological responses such as tissue deformation, altered metabolism, and altered circulatory patterns. Depending on the duration and intensity of the loads and recovery time, the responses may cause discomfort and impair performance. If the loads are large enough or last long enough, acute tissue damage will occur. Although damaged tissue stimulates a healing response, healing may not occur if the loads continue to be applied. As the lumbar spine is the main load-bearing area and the most common site of pain, studies of spine loads have focused on this region.

2. BASIC BIOMECHANICS

Manual material handling is a common situation wherein loads applied to the vertebral column may be so high as to damage the spine. The loads on the lumbar spine are produced primarily by body weight, muscle activity, and externally applied loads (figure 1). Although the biomechanics of manual material handling and lifting are based on Newton's laws of motion, a number of biological factors complicate their application. For example, the distance between a muscle's line of action and the joint about which it acts changes with joint position; at the extremes of joint movement the active muscle group is necessarily shortened while its stretched antagonist exerts maximal passive tension.

Further difficulties arise with human motion, since the body is seldom quite still, especially at the start or completion of a lifting or handling task. Moreover, coordination of a handling task involves the constraint of many components. Consider the number of muscles involved in a task, and the need to coordinate their torque production with changing joint dynamics. The neuromuscular system experiences particular difficulty in heavy manual lifting as the trajectory of the load is required to be precisely controlled and any stress to the joints has to be minimized. The difficulty in meeting these requirements is reflected in the high incidence of injury to the back when lifting moderate to heavy loads.


$$L_C = \frac{BW \times L_{BW} + W \times L_W}{L_M} + (BW + W)\sin\phi$$
$$L_S = (BW + W)\cos\phi$$

where

L_C	=	Compressive load on the lumbosacral junction
L_S	=	Shear load on the lumbosacral junction
BW	=	Body weight above the lumbosacral junction
L_{BW}	=	Distance between the centre of gravity of BW and the lumbosacral junction
W	=	Weight of the lifted object
L_W	=	Distance between the centre of gravity of W and the lumbosacral junction
M	=	Tension in the back muscle
L_M	=	Distance between the muscle's line of action and the lumbosacral junction
ϕ	=	Inclination of the lumbosacral junction

Figure 1. **"Manual Material Handling" as the third index phrase.**

Despite this complexity, the loads on the lumbar spine in performing most lifting and handling tasks can be roughly estimated using a simplified free body technique for coplanar forces. Several factors influence the loads on the lumbar spine during lifting activities: (1) the position of the object relative to the center of motion in the spine; (2) the size, shape, weight, and density of the object; and (3) the degree of flexion or rotation of the spine. In general, holding the object close to the body instead of away from it reduces the loads on the lumbar spine.

3. GENERAL PRINCIPLES OF LIFTING

It is generally recommended that lifting should be done with the knees bent and the back relatively straight to reduce the loads on the spine, but this technique must be followed correctly. Lifting with bent knees and a straight back allows smallish objects to be held closer to the trunk and to the center of motion in the spine, closer than when lifting with the trunk flexed forward and the knees straight. However, the loads are not reduced if the object is held out in front of the knees.

Loading of the spinal tissues is not harmful unless the endurance of the tissues is exceeded. This excess may be caused by sudden overload or fatigue in repeated loading. Gradual increase in loading has a training effect; and muscles, tendons, and also vertebrae adapt to endure heavier loads. Weight lifters have less degenerative changes in the lumbar spine than men in heavy physical work. However, LBP can be caused by prolonged overstretching of the ligaments and soft tissues of the lumbar spine. Lifting excessive weights can cause overstretching and damage to the supportive spinal ligaments. This type of injury cannot easily be avoided as it can occur unexpectedly and without any

warning signs. Usually it is the ligaments that become damaged first and give rise to pain.

Overstretching of the surrounding ligaments and retaining walls for the intervertebral disk may affect the disk's ability to act as a shock absorber between the vertebrae. When the ligaments surrounding the disk are injured to such an extent that the disk bulges outwards or even bursts through the outer ligament, the disk may lose its ability to absorb any shocks and it can lead to severe pain. Worst of all is when the disk bulges far enough backwards to compress the sciatic nerve, causing severe pain, numbness, or even weakness.

Although many studies have indicated that LBP is related to heavy physical work, there are also studies in which this relationship has not been detected. It has been argued that for those studies with positive correlation, work was classified as heavy on the basis of general impression but without detailed analysis of the loads on the lumbar spine. In some studies the data on the heaviness of work was based on subjective perception. This may be influenced by the occurrence of LBP.

4. SYMMETRY VERSUS ASYMMETRY

For lifting tasks, conditions of asymmetry have been studied in vitro, by simulation, and in vivo; it has been clearly demonstrated that asymmetry may be harmful to the lumbar spine. Asymmetric posture combining forward bending and twisting of the trunk increases the loads on the lumbar spine. In vitro studies predicted that twisting and bending are likely to cause disk prolapse and possibly damage to the capsular ligaments. Dynamometric studies revealed that the worker's trunk extensor capability decreases with asymmetric trunk angle. These results demonstrate the importance of symmetry in relation to handling tasks; heavy lifting with asymmetric posture should be avoided.

5. HABITUAL EFFECTS

Although people have been trained to lift with a straight back (leg lift) instead of a rounded back (back lift), there are still many back injuries caused by improper manual lifting. One explanation is that leg lift is infrequently used because it requires a greater expenditure of energy than back lift, due to greater body weight being displaced vertically. People tend to be reluctant to lift in a way that they feel unnatural and always try to minimize their energy expenditure. As fatigue is induced earlier in using leg lift, this may encourage people to adopt a poor posture in lifting, especially after a period of continuous work. Moreover, people with degenerative changes in their knees often find difficulty with the high loads that leg lift places on the knees. Although there is no clear indication that the degenerative changes in their knees are actually caused by leg lift, it is obvious that a single lifting method does not suit each individual in all situations.

On the other hand, it is important to consider the habit that people adopt during lifting. In general, movement may be produced by two basic systems of control: feedback (closed-loop control) and feedforward (open-loop control). Movements requiring feedback are usually complex and discrete, requiring a degree of accuracy, such as a visual-motor tracking task. Feedback control is required during early skill acquisition and probably accounts for the slow movement execution during this stage. Once the task is well learned, it can be performed accurately without sensory feedback. The control of movement fluctuates between feedback and feedforward modes.

Rapid movements and well-learned movements are performed with feedforward control. Although the sensory information is available during a rapid movement, this information cannot be used because the movement proceeds faster than the nervous system can process and use it. Thus, it appears that well-learned, rapid, and automatic tasks may not require feedback for their execution. If people adopt the movement strategies that they use for lifting light objects, they may wrongly apply these adopted strategies in lifting objects that are neither light nor heavy. The risk that an improper strategy is used to lift a relatively heavy object will be increased.

It is unlikely that the loads induced to the lumbar spine for lifting objects of medium weight using improper movement strategies are the single cause of LBP injury. However, if improper movement strategies are frequently used, the cumulative effects may lead to injury or pain. In a clinical or laboratory setting, it is difficult to document people's lifting habits as they will be assessed under a conscious situation. It is advised that people should keep conscious in performing manual handling tasks. The movements should be performed slowly enough to receive internal sensory feedback that will control and modify the postural requirement. Repeated and rapid lifting should be avoided.

6. SUDDEN UNEXPECTED EFFECTS

Epidemiological data suggests that sudden unexpected maximal efforts are particularly harmful to the back. However, there have been very few investigations into the effects of unexpected loads on the back. Unexpected loads can take many forms; they can be a sudden load application or a release condition. It has been proposed that a sudden release of load, perhaps when a load slips, can generate an unexpected acceleration and a very large muscle force which may damage the tissues of the spine. The back muscles tend to overrespond to regain equilibrium under unexpected events.

Slips or falls in the workplace are relatively common and account for about 50% of accidental back injuries. In an experimental investigation, a subject held a box in a standing position and a designated weight was suddenly dropped into the box. The mean muscle force for the unexpected cases exceeded the mean for the expected cases by nearly 2.5 times, and the peak muscle forces were on average 70% greater in the unexpected cases. The lumbar muscle activities were not fast enough to cope with the sudden change of loading and this produced an increased swaying of the trunk, which in turn induced a load on the lumbar spine.

7. RECOMMENDATIONS

- Minimize loads on the lumbar spine to reduce the risk of low back pain.
- A simplified free body technique can be used to make rough estimates of the loads on the lumbar spine in symmetric lifting.
- In general, holding the object close to the body instead of away from it can reduce the loads on the lumbar spine.
- Leg lift is not always better than back lift.

- Avoid lifting with an asymmetric posture.
- Be conscious in performing manual material handling.
- Avoid repeated and rapid lifting.
- The loads on the lumbar spine can be dramatically increased under sudden unexpected conditions.

Maximum Holding Times of Static Standing Postures

M.C. Miedema and M. Douwes

TNO Work and Employment, PO Box 718, 2130 AS Hoofddorp, The Netherlands

1. INTRODUCTION

Many work situations require standing postures which have to be maintained for a long period of time (e.g. machine operation, assembly work, VDU work). Depending on the posture and the duration of holding the posture, there is a risk of acute discomfort and long-term health effects (musculoskeletal disorders). Static work load can be diminished by improving the working posture (by optimization of the workplace and the equipment), by reducing the holding time of postures and by supplying sufficient and properly distributed rest pauses.

A posture can be maintained for a limited period of time. The Maximum Holding Time (MHT) is the maximum time that a posture, with or without external force exertion, can be maintained continuously until maximum discomfort, from a rested state. Acute discomfort can be considered as an independent evaluation criteria for static postures (Miedema 1992; Dul *et al.* 1994; Miedema *et al.* 1996). Several studies have shown a linear relationship (at group level) between the duration of a continuous static task, and the level of discomfort as measured with the Borg rating scale (Manenica 1986; Bishu and Wei 1992). To avoid uncomfortable durations of static postures discomfort do not exceed score 2 or 3 on a 10 point rating scale (Hagerup and Time 1992; Douwes *et al.* 1993)

EVALUATION METHOD FOR HAND POSITIONS

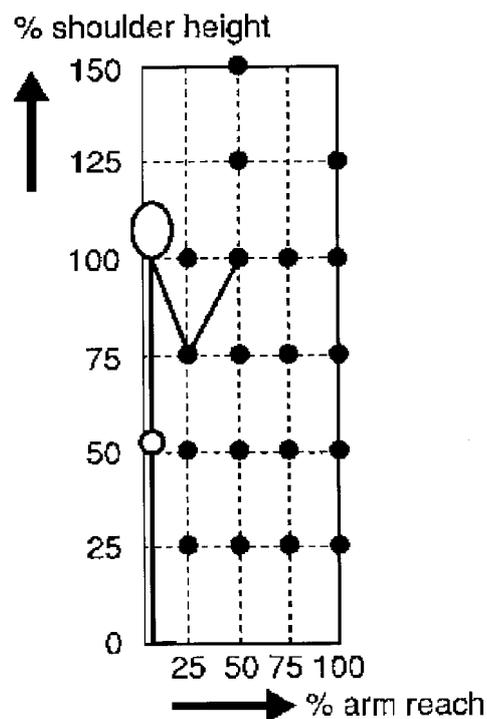
Due to the increment of discomfort in time, holding time (% MHT) can be taken as a measure for making recommendations concerning the maximum duration of static postures. In seven studies information was gathered about the MHT of 19 different standing postures which were maintained without rest pauses and without external load (Corlett and Manenica 1980; Hagberg 1981; Boussenna *et al.* 1982; Milner 1985; Taksic 1986; Manenica 1986; Meijst *et al.* 1995). All postures were defined by two parameters, i.e. the horizontal distance (% shoulder height) and vertical distance (% arm reach) of the position of the hands with respect to the feet in upright standing posture. Shoulder Height (SH) is defined as the distance from acromion to the floor in the upright position. The Arm Reach (AR) is defined as the maximum distance from the knuckles to the wall when standing upright with the back against the wall and the shoulder in 90 degrees anteflexion. The 19 postures differ in the combination of 25, 50, 75, 100, 125 or 150% SH and 25, 50, 75 or 100% AR and are shown in figure 1. In all studies the participants were asked to maintain the posture as long as they could. In almost all studies the subjects had to perform a task while holding the posture. These tasks implied television games, spot-tracking or tapping tasks. During maintenance of the posture, location and amount of perceived discomfort was registered. The experiments ended when maximum discomfort was reached (score 10 on a 10 point rating scale; Borg 1990).


Figure 1. The 19 postures found in literature are indicated with ●. Posture is defined by the horizontal and vertical hand position. The vertical hand position is expressed as a percentage of the shoulder height and the horizontal hand position as a percentage of the arm reach in the upright standing posture.

There is much variation in MHTs of similar postures within and between studies. In spite of this variation a ranking of the 19 postures was made, based on the mean MHT from all available data. These ranked postures are shown in figure 2. The posture 75% SH/50% AR has the highest MHT (35.7 min.) and the posture 25% SH/100% AR has the lowest MHT (2.7 min.).

The ranked postures can be arbitrarily classified into three groups: "comfortable", "moderate", and "uncomfortable" postures, with relatively large, medium, and small MHTs, respectively. Uncomfortable postures are defined as postures with a MHT smaller than 5 minutes, which implies that maintaining an uncomfortable postures will lead to a relatively quickly increased feeling of discomfort. All postures with an extremely low or high working height (25% and 150% SH) appear to be uncomfortable postures. According to the classification the postures with a combination of a moderate working height (50%, 75%, 100%, and 125% SH) and small working distance (25% and 50% AR) are comfortable postures (MHT longer than 10 minutes). Postures with a moderate working height (50%, 75%, 100% and 125% SH) and a large working distance (75% and 100% AR) appear to be moderate postures (MHT $ 5 and #10 minutes).

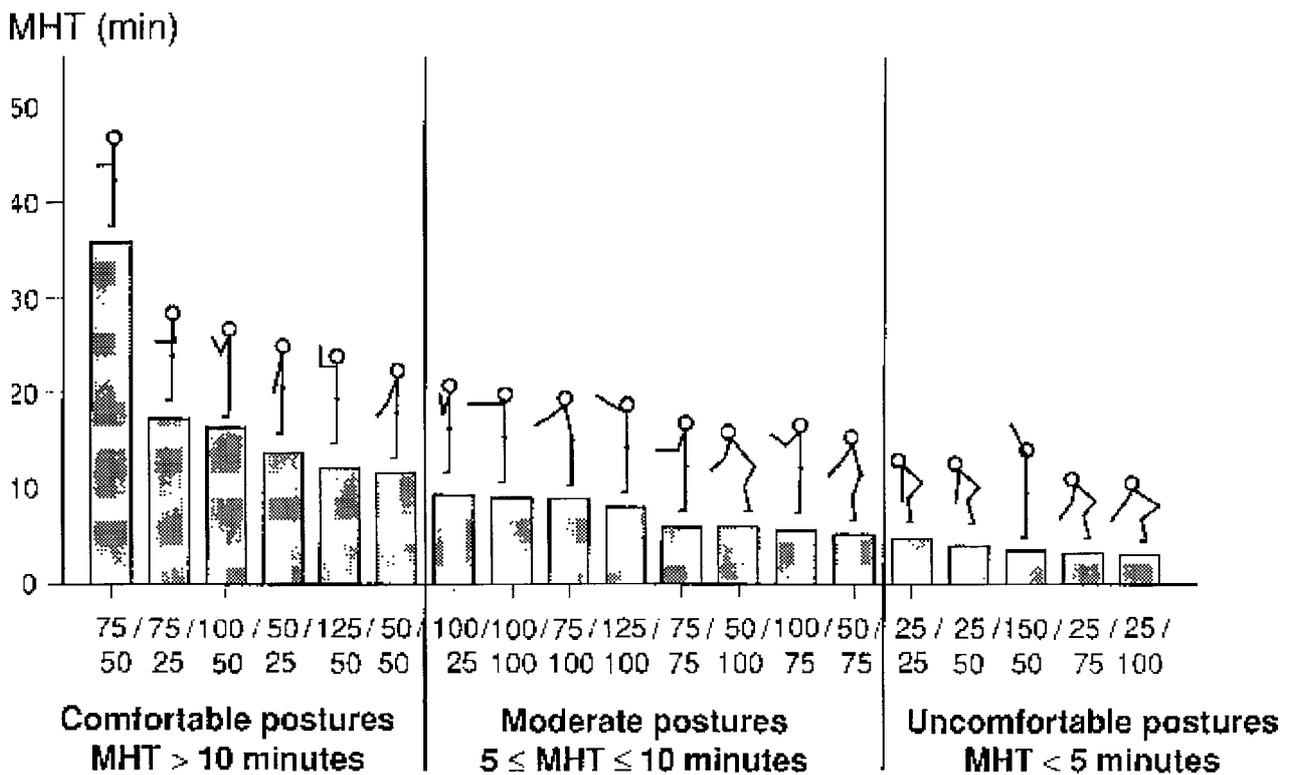
Holding a comfortable, moderate, or uncomfortable posture for the maximum period of time causes extremely strong (maximal) discomfort in (a part of) the body. By limiting the actual holding time of a posture, discomfort can be limited, even in uncomfortable postures. As mentioned, we propose that for a group of individuals the maximum acceptable holding time is 20% of the MHT, corresponding to a discomfort score of 2 of the


Figure 2. Ranking of the postures on the basis of the mean values of Maximum Holding Time (MHT) of available data. The recommended holding time is 20% of MHT.

Borg scale (weak discomfort). To calculate the maximum acceptable holding time of a posture the MHT has to be divided by 5. To make the recommendations safe for all postures in the three classes, the maximum acceptable holding time valid for each class of hand position corresponds with the lowest maximum acceptable holding time of that class (most uncomfortable posture of that class). Thus, comfortable postures with a MHT of more than 10 minutes are recommended to be maintained 2 minutes maximally. Following the same procedure for a moderate posture the maximum acceptable holding time is 1 minute and an uncomfortable posture is not acceptable. In figure 3 the possible hand positions are divided into three areas corresponding to these recommendations (area 1: 2 minutes; area 2: 1 minute; area 3: 0 minutes). It is estimated that for a mean discomfort of 2, 95% of the population will have less than "strong discomfort" (score 5 on the 10 points scale).

The body part(s) in which discomfort is felt, depends on the posture. All healthy subjects who adopt the same posture (independent of the study) perceive discomfort in approximately the same body part(s). Postures with hand positions at or below 50% SH are terminated by discomfort in the lower back and legs. In postures with hand positions at or above 100% SH the shoulders and arms are the critical body parts. Also, it appears that a larger work distance results in a higher discomfort in shoulders and arms.

APPLICATIONS AND LIMITATIONS OF THE METHOD

The evaluation method for hand positions relates to:
- standing postures
- postures without external force
- postures that are symmetric in the sagittal plane
- postures that are maintained without rest pauses (static work)
- healthy, young adults.

The classification can be a guidance in practical situations for occupational health officers, designers, labour inspectors and ergonomists to match the working time to the working posture.

The method has been developed for pure static postures without body motions. In most working postures minor changes in posture and loading may occur. This may result in partial recovery due to changing the critical muscle group or variations of the muscle effort. Another point of attention is that in many work situations body parts are supported by a table, an arm rest, or a machine. This support unloads the muscles and the joint. It can be assumed that the MHT of a "dynamic" or supported posture is longer than the MHT of a static posture. For these kind of working situations the recommendations are expected to be relatively safe.

Models of Attention

R. W. Proctor and L. E. Read

Department of Psychological Sciences, Purdue University, West Lafayette, IN 47907-1364, USA

1. INTRODUCTION

Most research on attention is concerned with either the selectivity of processing or the capacity to perform multiple tasks concurrently. Experimental research on attention has been conducted since the earliest days of psychology. However, contemporary research is usually dated from the early 1950s. Interest in attention arose in part because of the increasing performance demands of technology growing out of World War II. Also, around this same time, the shift from behavioral to information processing approaches began to occur.

The information-processing approach provided a descriptive language for conceptualizing the nature of attention. Using the computer as a metaphor, early models of attention viewed processing as serial. Hence, theoretical issues were concerned with the point at which attention intervened in the processing sequence. Research on attention continues to be guided by metaphors, including attention as an allocatable resource supply, attention as a spotlight, and attention as "glue." Although the dominant metaphors tend to capture some aspects of attention and to direct research toward solving particular issues, there is still debate as to what metaphor, if any, best captures the nature of attention. Though many issues regarding the nature of attention remain unresolved, much has been learned about attention that is relevant to applied system design through a better understanding of the contexts and conditions conducive to efficient task performance.

2. THE FIRST FORMAL MODELS DEFINING ATTENTION

2.1. Bottleneck Models

Bottleneck models propose a structural limitation on processing at some point in the human–information-processing system. Donald Broadbent developed the first major bottleneck model, filter theory, in the 1950s. Filter theory was developed to explain results of studies examining performance limitations in listening tasks implying that only one message at a time could be processed. The primary assumption of this model is that the nervous system acts as a single communication channel. Therefore, for the sequential nature of processing to be most efficient, Broadbent argued that the system must perform a selection operation at an early stage. He postulated that information is first received in a pre-attentive temporary store of unlimited capacity. This information is then selectively filtered to allow only one input to enter the limited-capacity channel. Selection is based on physical features such as the intensity, pitch, and spatial location of sounds. Although Broadbent's original filter theory is no longer accepted as providing an adequate characterization of attention, it is a useful model for the design of human–machine systems because it is simple and captures many of the aspects of attention that are of consequence for human performance.

The primary reason for rejection of Broadbent's filter theory was numerous findings demonstrating that the meaning of an unattended message can influence performance. To accommodate these findings, Ann Treisman reformulated filter theory in the 1960s, developing what is called filter-attenuation theory. According to attenuation theory, early selection still precedes stimulus identification. The filter does not entirely block out the unattended information, but attenuates the information on unattended channels. If expectancies or familiarity cause recognition units to have low thresholds, the attenuated signal may still be sufficient to trigger recognition.

An extreme opposite of Broadbent's early-selection filter theory is late-selection theory, proposed initially by Deutsch and Deutsch, also in the 1960s. According to late-selection theory, within sensory limitations, all stimulus information is identified fully regardless of whether it is attended. The bottleneck is presumed to occur subsequent to stimulus identification. The central issue differentiating filter-attenuation theory and late-selection theory is whether meaning is always analyzed fully. This issue has been debated to the present without resolution. Pashler (1998b) recently concluded from a review of the literature that early attenuation does occur, but that it is an optional strategy rather than a structural limitation.

2.2. Resource Models

Bottleneck models are based to a large extent on selective attention studies in which one message is to be attended and others ignored. Divided attention tasks require concurrent processing of multiple sources of information and are more amenable to models that view attention in terms of resource limitations. Unitary resource models, of which Kahneman's (1973) is the most cited, view attention as a single pool of resources that can be distributed in various amounts to different tasks depending on task demands and voluntary allocation strategies. This is operationalized in performance operating characteristic curves representing a smooth tradeoff for concurrent performance of two tasks as a function of emphasis changes. Unitary resource models provided the impetus for dual-task methodologies and mental workload analyses that are used widely in Human Factors. Accordingly, multiple tasks should produce interference and mental overload when their combined resource demands exceed the available capacity.

Unitary resource models imply that the difficulty of tasks that are to be performed concurrently should be the primary determinant of performance. However, numerous studies have demonstrated that two tasks are easier to perform together when the stimulus or response modalities differ than when they do not. Furthermore, performance is better when one task requires verbal codes and the other visuo-spatial codes than when the same type of code is required for both tasks. These modality-specific patterns of interference have provided the basis for multiple resource models of attention, of which Wickens's (1984) is the most cited in Human Factors. Multiple resource models presume that there are distinct pools of attentional resources for different sensory-motor modalities and coding domains. Multiple resource theory provides a useful heuristic for predicting which display and control combinations can be performed efficiently together and which cannot. The primary criticism of multiple resource theory is that new resources can be proposed in an *ad hoc* manner to accommodate any finding of specificity of

interference. The fact that distinctions beyond broad modality and code differences can produce similar patterns of results has led some to conclude that the multiple resource view is insufficient.

3. CONTEMPORARY MODELS

Whether a structural bottleneck or limited capacity processor, a central issue in the study of attention was, and still is, the degree of processing that occurs with or without attention. Because of a shift in emphasis from auditory tasks to visual tasks beginning in the 1970s, the primary phenomena that many of these models attempt to explain involve processing of visual stimuli.

3.1. Models of Attention in Perception

One metaphor that has been widely used is to characterize attention as a spotlight. The main idea behind this metaphor is that attention serves to focus processing on a location within the visual field. The spotlight is presumed to have a spatial extent such that anything within the spotlight is attended, but attention cannot be directed to different, non-contiguous locations in the visual field. Although the direction of attention is often the same as the direction of gaze, evidence indicates that it is possible to direct attention independently of fixation. A distinction is made between exogenous and endogenous cueing of attention. An exogenous cue is the onset of a visual event in the field that involuntarily attracts the attentional spotlight to that location. An endogenous cue is a central signal, such as an arrow pointing to the right, that requires a voluntary shift of attention to the cued location.

A spatially based theory that has been particularly influential is Treisman's Feature Integration Theory (FIT). It was developed primarily to explain results from visual search studies in which a subject must indicate whether a target stimulus is present in an array. For feature search, in which the target is distinguished from distractors by a basic attribute such as color, the number of distractors has little effect on response time. However, for conjunctive search, in which two or more attributes must be conjoined to distinguish the target from distractors, response time increases as an approximately linear function of the number of distractors.

As with the early selection models, FIT assumes that basic features of stimuli are coded automatically and in parallel at the perceptual level. Each feature is then mapped onto specific "modules" in the brain. Detection of single features is automatic. However, attention is required for conjunction of features, proper selection of feature combinations, and matching them to previously stored representations. Treisman coined the focal attention needed in the conjoining of features as "glue."

Whereas FIT, in its original formulation, is an entirely space-based theory of attention, numerous authors, most prominently, John Duncan, have developed object-based models of attention that do not treat location as unique. Proponents of object-based theories argue that attention is drawn to perceptual groupings of stimulus elements, rather than to spatial locations. Among the findings cited as evidence for object-based models are the following: (1) identifying several targets in a complex visual display is facilitated if the targets form a perceptual group; (2) search for a conjunctive target is much more efficient when the distractors are homogeneous rather than heterogeneous; and (3)

it is easier to make judgments about two attributes from a single object in a display than about attributes from two objects, even when spatial separation of the attributes is controlled.

Treisman has modified FIT considerably to accommodate findings such as those described above. In a recent formulation (see her chapter in Baddeley and Weiskrantz 1993), a variant of the attentional spotlight, termed the attentional window, has been introduced. In the original formulation, though the theory was meant to explain object recognition, spatial location took precedence. Feature locations were implicitly coded, but attentional focus made feature location explicit. In the current formulation, though location takes precedence, there is parallel processing of both "what" and "where." Hence, dependent on prior specification, either objects or locations can direct control of attention. However, without prior specification, the system adjusts the attentional window to the task and searches serially.

3.2. Models of Attention in Response Selection and Initiation

The issue of whether response selection or initiation requires attention has been investigated extensively using the psychological refractory period (PRP) effect. Two discrete choice–reaction tasks must be performed by the subject, with the stimulus for the second task presented at varying stimulus onset asynchronies (SOA) relative to the stimulus for the first task. Second-task responses typically are slowed at short SOA, and it is this phenomenon that is called the PRP effect. Various types of models of attention have been evaluated with the PRP task, but most of the research has been conducted from the perspective of bottleneck models. The experimental results have been interpreted with what is called locus of slack logic. The basic idea is that if a Task 2 variable has its effect prior to the bottleneck, there will be an underadditive interaction with SOA. That is, at short SOA, the "slack" period during which post-bottleneck processing cannot begin can be used for continued processing for the more difficult condition. If a Task 2 variable has its effect subsequent to the bottleneck, the effect will be additive with SOA.

The most widely accepted account of the PRP effect since the 1950s has been to place the bottleneck at response selection. Pashler (1998b) has been the most vocal advocate of this position in recent years. The primary reason for accepting this locus for the bottleneck is that perceptual variables tend to show underadditive interactions with SOA, whereas post-perceptual variables tend to show additive effects. One exception to this pattern was obtained in a study by Karlin and Kestenbaum that manipulated whether Task 2 involved simple or choice reaction time. The effect of this manipulation showed an underadditive interaction with SOA; assuming that the variable has its effect on response selection, these data can be interpreted as implying that response selection occurs prior to the bottleneck. Hence, an alternative model was offered by Keele, who placed the bottleneck at response initiation. De Jong has recently proposed that bottlenecks exist at both response selection and response initiation, and Meyer and Kieras (1997) have argued that there is no structural bottleneck and that the locus of the bottleneck can vary depending on the strategies adopted to perform the assigned tasks.

3.3. Selection for Action

Recent theorizing takes the view that cognitive psychology cannot be complete without an understanding of both mind and brain. This has lead to an increased melding of the disciplines of neuroscience and cognitive psychology (for example, Pashler 1998a, Styles 1998). The bridge between neuroscience and information processing approaches has been aided by linking studies of animal visual systems with the findings from human behavioral studies of attention, including changes during development or as a consequence of brain damage. Localization of intact brain function has also been aided by brain imaging techniques such as positron emission tomography and functional resonance imaging. The temporal properties, as well as implied spatial localization of brain function, are studied by conjoining behavioral techniques with measures of brain activity, event-related electrical or magnetic potentials.

The selection for action approach, described in detail by Styles (1998), is consistent with the emerging use of the brain as metaphor for models of attention, and in the advances in computer models that more closely mimic brain function. Selection for action is a direct contrast to theories postulating structural bottlenecks or limited capacity. Apart from the constraints set by the sensory systems, the brain is considered to be of unlimited capacity. The processing of information is viewed as parallel and distributed. Information regarding attributes as well as possible actions is coded in separate dissociable systems throughout the brain. Attention is needed for perceptual integration, as well as for control of appropriate actions. In this sense, selectivity of attention prevents "crosstalk" or interference among competing activation from multiple streams of informational input. The coupling of relevant input and the blocking of irrelevant competing actions accomplish this. The only limitations are in the actual translation of input into action, in that usually only one action can be performed at a time with any effector.

3.3.1. A computational model

Recently, selection for action has been elaborated and translated into a more concrete analysis of attentional processes within a detailed computational model developed by Meyer and Kieras (1997). The model is implemented within the EPIC (Executive-Process Interactive Control) architecture, a comprehensive framework that includes perceptual, cognitive and motor components. This model, called the Strategic Response-Deferment, was formulated specifically to account for attentional processing in multiple-task performance, specifically PRP tasks. It includes a step-by-step analysis of the processes involved in the performance of each individual task, as well as of the executive control processes that coordinate joint performance. Attention begins at the perceptual level, orienting focus (i.e. moving the eyes) on sensory input. Limits in the systems are attributed to the sensory and motor effectors, as well as individuals' strategies for satisfying task demands (e.g. making sure that the responses for the two tasks are made in the instructed order). The model allows for flexible scheduling in the processing chain during dual-task performance, thus accounting for the effects of response–selection difficulty and SOA on observed reaction times without need of a central, structural bottleneck.

The EPIC architecture resembles the Model Human Processor

architecture developed in the early 1980s by Card, Moran and Newell. However, it has the advantages of being implemented in a computational model and describing in greater detail the operation of the perceptual and motor processes. Also, it has a larger processing capacity and, therefore, can model multiple-task performance without cognitive resource limitations. These features, along with the emphasis placed on sensory-motor limitations and the control strategies that a person can use to accomplish task goals, should make the model attractive to Human Factors specialists.

3.3.2. A neural network model

Neurophysiological evidence has demonstrated attentional inhibition in both intra-cellular recordings of primate cortex and human electrophysiological measurements. Behaviorally, the significance of inhibitory processes of attention is demonstrated with the phenomena of inhibition of return and negative priming (see Milliken and Tipper's chapter in Pashler 1998a). Inhibition of return refers to the finding that although an exogenous cue facilitates processing of a target stimulus at the cued location when the cue–target interval is short, it inhibits processing when the interval is longer. This phenomenon reflects a bias toward novel events and may be a consequence of automatic activation of the oculomotor system. Negative priming refers to the finding that, in selective attention tasks, if the distractor on one trial becomes the target on the following trial, responses are slowed. This effect has been demonstrated with objects and locus of attention. It can also occur with semantically related items and when the stimuli are presented in different perceptual modalities. Negative priming is used as evidence that irrelevant information is processed beyond the perceptual level. Inhibitory effects may not be modality specific but necessary for the coordination of perception and action by assisting enhancement of the selected stimulus and reducing interference.

Houghton and Tipper (1994) have successfully demonstrated both negative priming and inhibition of return in a neural network model that treats the excitatory and inhibitory properties of selective attention as an opponent process mechanism. Inhibition is placed in the flow of activation between perceptual systems and motor planning and execution. Attention requires the matching of a target stimulus with its internally maintained representation. Situated in the frontal lobes, inhibition is a self-regulating mechanism allowing non-targets to achieve an equilibrium activation below that of targets, thus allowing enhanced activation of the target. Negative priming and inhibition of return are viewed as the result of inhibitory rebound and suggest that this effect of the opponent mechanism is not confined to ignored inputs but can happen to selected inputs as well.

4. AUTOMATICITY

It has been customary to distinguish processing that requires attention from processing that does not, which is usually called "automatic" processing (see Proctor and Dutta 1995 for a review). Starting as early as the 1890s with Bryan and Harter, automatic processes were thought of as habits, or spontaneous chains of behavior initiated by environmental stimulus events and not subject to conscious control. The concept of automaticity received renewed interest in the 1970s due to the popularity of limited-capacity models of attention. The general reason for this was

numerous findings suggesting that under many circumstances there is no limitation on information processing for highly overlearned tasks and activities, as well as little if any control over them. One example from laboratory tasks is the well-known Stroop color-naming effect, in which the time to name the color in which a stimulus is printed is much longer if the stimulus spells a conflicting color word than if it is neutral elements or a congruent color word. Phenomena such as these led to the view that automatic processing is qualitatively different from controlled, attentional processing. Its defining characteristics include occurrence without intention, lack of conscious awareness, and lack of interference with other mental processes.

Shiffin and Schneider developed the most prominent dual-process theory of controlled and automatic processing. Their theory was developed primarily to explain results from search tasks in which the number of items in visual displays and the size of the target set held in memory were varied. A central distinction made was between tasks for which the mapping of stimuli as targets or distractors remained consistent (i.e. a member of the target set on one trial could not occur as a distractor on another) versus tasks for which the mapping varied. Their major finding was that the set-size effects were very small in consistent mapping tasks compared to varied mapping tasks. However, once a person became skilled at a consistent mapping task, considerable negative transfer occurred when the target and distractors were switched. Shiffrin and Schneider proposed that performance with highly practiced consistent mappings occurs in an automatic mode that operates in parallel across the display, whereas performance with a varied mapping occurs in a controlled mode that operates serially across the display.

The major implication of the dual-process view is that some tasks require controlled attentional processing, whereas others do not. Not too surprisingly, individuals who have questioned the value of the limited-capacity resource assumption have tended to question whether there really is a qualitative distinction between automatic and controlled processing. The general nature of the critiques has been to argue that "automatic" processes are not independent of intentions, that they may show signs of interference if responses are similar, and that they can show evidence of control when the task demands change. In short, these individuals see the automatic-controlled distinction as excess baggage in the same way as the concept of limited capacity.

Rather than assuming that attention is discarded as a person becomes practiced at a task, an alternative view is that it is more important to consider the change in attentional control strategies and the organization of behavior. For example, in keeping with the selection for action view, practice is seen as constraining the parameters of action. Hence, less attention is needed for the processing of a response. Automatic processing is seen as a quantitative grading of attentional control through the acquisition of attentional skills or procedures for action stored as schemata in long-term memory.

A third viewpoint of automaticity, Logan's instance theory, does not concentrate on the response but the overall processing of stimuli. Attention is seen as the interface between encoding and retrieval. Attention to a stimulus obliges encoding of that instance as well as retrieval of past instances associated with the stimulus. Further, each encounter with a stimulus creates an independent trace. With experience, the accumulation of these traces leads to a transition from algorithmic-based to memory-based processing. Logan's theory relies on individual memory traces rather than on a change in strength of associative links. Performance variability and task-load effects will diminish with practice not because of a qualitative change but because direct memory retrieval can eliminate the slower, step-by-step algorithmic process. This account both predicts the power function speed-up seen in skill acquisition as well as the poor transfer effects to novel situations.

5. IMPLICATIONS FOR HUMAN FACTORS

1. As captured by Filter Theory, information intake is often serial and little is remembered regarding the meaning of unattended messages. Selection between streams of information can be performed efficiently on the basis of physical distinctions such as location.

2. As implied by filter-attenuation and late-selection models, meaning of unattended information can be processed and influence performance, under at least some circumstances.

3. Unitary resource models provide an algorithm for depicting the trade-off between two tasks, as represented by performance operating characteristic curves.

4. Multiple resource models provide a useful heuristic for determining which combinations of stimulus and response modalities and codes will likely lead to optimal performance in multiple-task contexts. They also provide a rationale for varying the tasks used for assessment of mental workload with secondary-task procedures to provide a complete profile of task demands.

5. Models of visual search make clear that selection of information from visual displays is more efficient if done on the basis of distinctive features, perceptual groupings, or object properties.

6. Response competition is a major factor influencing performance in many situations, and models emphasizing limitations in response selection and initiation are useful in deciding the timing structure between multiple tasks.

7. The selection for action approach emphasizes the importance of control strategies adopted by operators in order to coordinate action in complex task environments. The procedural and connectionist models developing out of this approach are promising tools for describing and simulating task performance.

8. Attention often has inhibitory as well as facilitatory effects on performance that must be taken into consideration in any assessment of performance limitations.

9. Models of automaticity present guidelines for the conditions of efficient time-sharing. Most important is that automaticity develops when a consistent mapping of task elements is maintained.

Multiple Resources

D. B. Boles

Department of Philosophy, Psychology, and Cognitive Science, Rensselaer Polytechnic Institute, Troy, NY 12180, USA

1. INTRODUCTION

Multiple resources are mental entities that permit the processing of information in more than one channel simultaneously. Resources were originally conceived as specifically attentional in nature. Most recently they have been identified with mental processes more generally. The exploitation of multiple resources can allow more than one task to be performed together with minimal interference, a matter of great importance in the design of complex human–machine interfaces.

Comprehending the nature of multiple resources requires understanding how the resource construct evolved in the fields of cognitive psychology and human factors. To some extent earlier versions of resource theory are still viable, in the form of possible "layers" of resources (Wickens 1984: 305) that vary from a generalized pool usable by any task, down to numerous specialized resources associated with specific mental processes.

2. RESOURCES AS ATTENTION
2.1. Single Channel Theory

Early attentional theory held that the human could be modeled as a single channel when first attending and subsequently processing information through to response (Broadbent 1958). On this view every attended task would require completion before any other task could be initiated beyond anything but the most rudimentary pre-attentional processing. Thus, attention was conceived as a limited-capacity resource required in every conscious action, and the simultaneous performance of multiple tasks was stated, in effect, to be impossible.

The single-resource viewpoint, however, soon proved problematic when instances were found of parallel processing. For example, it was discovered that people could usually recognize different digits presented simultaneously at the two ears, and they could detect their name when it was unexpectedly presented at the ear opposite to a continuous message requiring close monitoring. Such results implied that multiple sources of information could be processed simultaneously, a seeming violation of single-channel theory.

Attentional theorists proved adept at amending single-channel theory to account for the new findings, variously proposing that attention can switch rapidly back and forth between inputs; that all events can be processed to some extent for meaning, although only one is actually attended at a time; or that attention operates subsequent to processing for meaning. Nevertheless, all such alterations abandoned the notion that complex human performance could be sufficiently modeled using a single channel resource called attention, whose operation was limited in real time.

Because it had been demonstrated that multiple channels could sometimes be processed together, the question became how best to characterize the nature, capabilities and limitations of those channels. This question was addressed first by positing the existence of a generalized resource pool that could be drawn upon by multiple tasks, and later by proposing the existence of multiple resources.

2.2. Resource Pool Theory

Kahneman (1973) among others proposed that attention was best conceived as a pool of undifferentiated resources that could be parceled out to one or more tasks as required. Multiple-task performance was, therefore, possible using multiple channels without substantial interference up to the point where aggregate demand on the pool exceeded the supply.

Although resource pool theory proved useful in accounting for breakdowns in human performance as multi-tasking became more demanding, problems developed as it became clear that certain pairings of tasks or task components resulted in less mutual interference than other pairings. Brooks (1968), for example, showed that a task embedding visuo-spatial and auditory–verbal components produced much less interference than a task embedding either two visuo-spatial or two auditory–verbal components. Accordingly it appeared that interference could not always be predicted by aggregate demand on a single pool of resources.

2.3. Multiple Resource Theory

Wickens (1984) drew on an increasing empirical base of studies investigating dual-task performance, to derive an explicit resource model. His multiple resource theory (MRT) incorporated three orthogonal dimensions: (1) stages of processing (encoding/central processing and response stages); (2) modality (visual and auditory on the encoding end of processing, and manual and vocal on the response end); and (3) processing code (verbal and spatial). Each cell of the model was proposed to have resources dedicated to it, allowing relative predictions of interference between pairs of tasks by examining overlapping characteristics. Little interference was predicted if the two tasks used completely different cells, for instance with one task requiring visual, spatial and manual processing, and with the second task requiring auditory, verbal and vocal processing, especially if the execution of each task was most demanding at a different stage of processing (e.g. central processing for one versus responding for the other). Experimental tests using dual tasks showed that the model faired well: interference generally increased as resource overlap increased.

Although MRT was framed in terms of type of processing, it is important to note that it was developed within an attentional context, and made the implicit assumption that resources underlying the different types of processing were attentional in nature. This formulation essentially preserved the "attentional pool" of Kahneman by fractionating it, and then predicted interference in cases where two tasks drew on the same pool or pools out of multiple possible pools.

Wickens (1992) made minor alterations to MRT, for example by suggesting that interference between two visual tasks might be due more to physical scanning demands than resource competition. However, the bulk of the model remained implicitly attentional in nature.

3. RESOURCES AS PROCESS

Boles and Law (1998) recently proposed a reinterpretation and expansion of MRT. They noted that while the theory had been

described in an attentional context, it may correctly predict dual task performance due to interference in resources either attentional or structural (e.g. by competing for structural areas of the brain devoted to particular mental processes, or for peripheral effectors). They suggested that a more general viewpoint might be to identify resources with particular processes and to leave aside, for the moment at least, the question of whether resources are better viewed in attentional versus structural terms. Finally, they proposed that orthogonal mental processes have orthogonal resources, a principle that if true could potentially require a substantial expansion of MRT.

Putting the orthogonality principle to an empirical test, Boles and Law conducted a series of experiments in which dual tasks

Table 1. Some Probable Process-Specific Mental Resources.

A. Encoding/central processing resources

1. **Auditory emotional** (Boles and Law 1994): resources associated with recognizing emotional tones of voice, using auditory input

2. **Auditory-spatial** (Wickens 1984): resources associated with generalized spatial processing, using auditory input

3. **Auditory-verbal-linguistic** (Wickens 1984, Boles and Law 1998): resources associated with generalized verbal processing, using auditory input

4. **Tactile figural** (Boles and Law 1998): resources associated with recognizing shapes, using tactile input

5. **Visual-spatial** (Wickens 1984): resources associated with generalized spatial processing, using visual input

   a. **Facial figural** (Boles and Law 1998): resources associated with the processing of faces or facial emotions, using visual input

   b. **Planar categorical** (Boles 1998): resources associated with simple left-versus-right or above-versus-below relationships, using visual input

   c. **Spatial attentive** (Boles and Law 1998): resources associated with the deployment of attention in space, using visual input

   d. **Spatial concentrative** (Boles 1998): resources associated with recognition of the density of clustering of numerous objects, using visual input

   e. **Spatial emergent** (Boles 1998): resources associated with the separation of figure and ground, using visual input

   f. **Spatial positional** (Boles and Law 1998): resources associated with the identification of precise locations, using visual input

   g. **Spatial quantitative** (Boles and Law 1998): resources associated with the recognition of analog numerical quantities, using visual input

6. **Visual temporal** (Boles and Law 1998): resources associated with the recognition of the timing of events, using visual input

7. **Visual-verbal** (Wickens 1984): resources associated with generalized verbal processing, using visual input

   a. **Visual lexical** (Boles and Law 1998): resources associated with recognizing words, letters, or digits, using visual input

   b. **Visual phonetic** (Boles and Law 1998): resources associated with evoking verbal sounds, using visual input

B. Responding Resources

1. **Facial motive** (Boles and Law 1998): resources associated with responding with facial movement unrelated to speech or emotion

2. **Manual** (Wickens 1984): resources associated with responding with the hands

3. **Vocal** (Wickens 1984): resources associated with responding with the voice

either did or did not use orthogonal perceptual processes as deduced from prior factor analytic research. In general they found that competition for the same process resulted in substantially degraded performance compared with the use of orthogonal processes. Furthermore, multiple visuo-spatial processes found to be orthogonal in factor analytic work yet not differentiated by MRT, were among those that did not selectively interfere. Evidence was likewise found for resources associated with temporal processing that were not encompassed by MRT. Using inductive logic, the authors concluded that orthogonal processes do have orthogonal resources, and that any complete MRT requires a full accounting of them.

Because the processes investigated by Boles and Law were drawn from a larger set determined to be orthogonal from factor analysis, the inductive conclusion is that each of the larger set most likely has resources associated with it. Combining these resources with those of Wickens' MRT, and with more recent factor analytic work (Boles 1998), it is possible to list a fairly large set of process-specific resources, with the often more specific resources of Boles and Law, and of Boles, typically nested under the more general resources of Wickens. It should be understood that any such tabulation can only be as complete as our current taxonomy of orthogonal processes (Table 1).

It should also be noted that besides process-specific resources, some type of general resource may have influenced performance in the experiments of Boles and Law. Dual-task pairings resulted in substantially lengthened reaction time (RT) compared with single-task RT as measured in equivalent experiments. This outcome may indicate competition for generalized resources, resulting in interference even when two tasks use dissimilar processes. In short, there is good evidence for multiple resources that correspond to multiple processes, yet a full accounting of multiple-task performance will need to consider the possible existence of "layers" of resources that are less process-specific (Wickens 1984: 305). Candidates for such layers include Kahneman's general pool and Wickens' "stage of processing" resources, which were proposed to be available to all processes within a given stage.

4. PRIVILEGED LINKAGES BETWEEN RESOURCES

Beyond describing a specific model of multiple resources, Wickens *et al.* (1983) proposed that privileged linkages exist between certain of the model's cells. Specifically, verbal processing was proposed to be best served by auditory input and vocal output, and spatial processing by visual input and manual output. Such stimulus-central processing-response (S-C-R) compatibility was viewed as a natural expansion of earlier S-R compatibility concepts, when applied to complex systems requiring that the operator maintain a mental model using a substantial amount of central processing resources.

Empirical support for the privileged access proposal is based on studies examining both single- and dual-task performance under varying S-C-R arrangements. Of these, single-task performance provides the less ambiguous test. Wickens *et al.* (1983) found that spatial acquisition of a target stimulus was performed best when its identity was cued visually and its acquisition was confirmed manually, and performed worst when identity was cued auditorily and acquisition was confirmed vocally. The opposite result was obtained in a verbal command

task. Further confirmatory results were found in a dual-task study by Wickens *et al.* (1984), who investigated performance over a continuum of tasks in which predicted resource competition and predicted S-C-R incompatibility were negatively correlated (i.e. as one increased, the other decreased).

While these and similar results support the existence of privileged linkages between resources, it is presently unclear how expanded conceptions of multiple resources might affect their expression. As noted, Boles and Law (1998) found empirical evidence for multiple spatial resources, and they cited factor analytic evidence arguing for multiple verbal resources as well. It remains to be seen whether all spatial processes have privileged access to visual input and manual output, and whether all verbal processes have privileged access to auditory input and vocal output. It is possible that S-C-R compatibilities will be found to differ depending on the exact spatial and verbal resources involved.

5. APPLICABILITY OF MULTIPLE RESOURCES

From a human factors perspective, the value of the multiple resources concept is determined by its applicability to real-world design. Generally speaking, most situations in which the concept should be of value are those in which humans perform multiple tasks simultaneously. However, the concept also has implications for the measurement of workload and for training.

5.1. Multiple-task Application

One of the major areas for the application of multiple resource concepts is that of flight control, due to the extensive multi-tasking required of pilots. Wickens and Liu (1988) examined a simplified simulation of flight under threat conditions. Participants were asked to manually track a moving target while either categorizing the threat represented by spatial (vector) depictions of enemy aircraft, or selecting a weapon based on verbal (digital) depictions of the probability of its reaching its target. Responses to the categorization and selection tasks were made either manually or vocally, providing a manipulation of predicted response-level interference with the tracking task. In general, performance was found to be lower when the spatial tracking task was paired with the spatial threat task, and when responses to both the tracking and the other tasks were made manually, compared with conditions in which spatial and verbal processes or manual and vocal processes were paired. Thus, MRT was supported.

Generally speaking, any dual-task setting requiring high levels of performance and separate responses for the two tasks, could be expected to benefit from design influenced by multiple resource considerations.

5.2. Workload Application

Wickens *et al.* (1988) pursued the intriguing possibility that multiple resource concepts could be extended to the measurement of workload. In their study, a single expert rated the degree of overlap in resource demands incurred by multiple flight tasks. Predictions of interference based on the overlap in demand on multiple resources were then compared with the predictions of workload models variously based on the total number of tasks performed, the number of tasks performed per unit time, and the total resource demand. The overlap (multiple resources) model performed remarkably better than the others at predicting

flight performance. However, the other models performed much better than the overlap model at predicting overall subjective workload as rated by the participants.

What the Wickens *et al.* (1988) results appear to indicate is that a multiple-resource-based approach holds promise if one wishes to measure objective workload as it impacts on actual performance. On the other hand, if one is interested in subjective workload as it is perceived by participants, a more global measure may be a better choice.

5.3. Training Application

Recently Boles (1997) suggested that training programs can also benefit from multiple resource concepts, if resources are thought of as separately trainable components that can be used flexibly in a variety of tasks. The training of a complex task might therefore benefit from targeting critical resources, even if a task very different from the complex task is used during training. Empirical support for this idea came from an experiment in which participants made quantitative judgments based on either bargraph or numerosity (dot cluster) representations, both types of judgment using the same spatial quantitative resource according to prior research. It was found that training in numerosity judgments benefited bargraph judgments nearly as much as training in bargraph judgments themselves, and much more than training using verbal representations of number. Thus, a training task may not require high fidelity with respect to a more complex end task, as long as the same resources are used.

5.4. Limitations on Application

Of equal importance to the applicability of mental resources are indications that its applicability has limits. Attempts to implement the resource construct outside the limits may prove unsuccessful.

Although as indicated, dual-task design benefits from the use of separate resources in the two tasks, this may be true only when they require distinctly separate responses. Boles and Wickens (1987) found that when subjects responded separately to two numerical indicators, performance was better when the indicators were formatted to use separate perceptual resources than when they used the same resource, a replication of the multiple resource advantage in dual-task design. However, if a single response was required, the multiple resource advantage was eliminated. Indeed, in an integration task requiring a single judgment of whether either indicator exceeded a criterion value, there was actually an advantage when they used the same resource. Most likely the outcome derived from a translation cost incurred when different-format indicators had to be compared with the same criterion and the results combined prior to the single response.

Boles and Ruffles (1987) explored a further limit to applicability when comparing experimental conditions in which two numerical indicators had values that were either uncorrelated or highly correlated ($r = 0.9$). Subjects making separate responses to the indicators performed better when they were formatted to use separate resources, congruent with multiple resource concepts, but only when the indicators had values that were uncorrelated over trials. When a high correlation existed, the separate-resource advantage was eliminated. However, performance became better overall, in accordance with the authors' prediction that correlated indicators would encourage subjects to integrate them, generally improving performance but

eliminating the multiple-resource advantage because of translation costs.

Both these results and those of Boles and Wickens illustrate the risks involved in applying multiple resource concepts outside of true multiple-task situations. If multiple tasks become less so, either by reducing response requirements to a single response or by using correlated information sources, translation costs appear to overwhelm any advantage that might otherwise accrue from the use of separate resources. In a true multiple-task situation where information sources and responses are distinct, translation is a moot issue and multiple resource considerations apply. Wickens (1992: 379) drew similar conclusions from research on tracking performance, suggesting that multiple resource considerations are less important when dual tasks require the same mental set, processing routine or timing mechanism.

6. RECOMMENDATIONS

The multiple resource construct holds considerable promise in the prediction of multi-task performance, in workload measurement, and in training. The following recommendations may help fulfill that promise.

Ascertain whether the multiple resource construct is appropriate before applying it in a given context. In the prediction of multi-task performance, the multiple resource construct is most likely to be appropriate if the tasks are intended to be processed independently. Caution should be exercised in situations that might by design or circumstance reward the integration of information across tasks. Examples include the integration of multiple information sources into a single response; the use of correlated information sources; and convergence of multiple information sources onto a common processing routine. In such cases, the savings from multiple resource use may be overwhelmed by the costs of translating information sources into a common format prior to their integration.

In appropriate multi-task situations, consider designing tasks using a dissimilarity heuristic. Because the only complete multiple resource model is one that includes resources associated with all possible mental processes, it may be some time before a complete model is approximated. Nevertheless, in multi-task situations it should be possible to take advantage of multiple resources simply by designing tasks to be as dissimilar as possible. Very often a given task can be achieved through alternate input and output modalities, and sometimes it can be achieved through alternate perceptual and cognitive processes. A judicious selection of these to make multiple tasks as dissimilar as possible should reduce interference between them.

Consider implementing possible S-C-R compatibilities in both single- and multi-task design. Verbal processing may best be served by auditory input and vocal output, and spatial processing by visual input and manual output. Other factors being equal, it may be beneficial to employ these linkages in both single- and multi-task design. However, all such designs should be thoroughly tested since it is presently unclear whether all spatial (or all verbal) processes interact similarly with input and output modalities.

In workload assessment, consider using or developing a multiple-resource-based measure if performance is to be predicted. There is some reason to believe that multiple-resource-based measures of workload more accurately predict performance than global measures. Among MRT-influenced approaches are

W/INDEX and the Workload Profile (North and Riley 1989, Tsang and Velazquez 1996). Alternatively, more complete measures could presumably be developed to include workload associated with task-critical processes not in the original MRT.

Consider supplementing target task training with resource training if economic or risk considerations favor it. A target task may benefit from the training of resources used in performing it. This becomes a particularly desirable strategy if training on the target task itself is expensive or risky. The training of resources may be found to show considerable transfer to the target task, and thus can be used to supplement a reduced program of target-task training.

Finally, it should be noted that further empirical work is needed to more fully identify the set of process-related resources to be included in a multiple resources model. Such work should include empirical assessments in applied settings to identify, if possible, those resources that might be discarded for the sake of parsimony, versus those most important in multi-tasking, workload assessment, and training.

Muscle Strength

K. H. E. Kroemer

Department of Industrial and Systems Engineering, Virginia Tech, Blacksburg, VA, and Director, Eri, Inc., A Consulting Company, PO Box 3019, Radford, VA 24143-3019, USA

Muscle strength, the capability to generate lengthwise tension (force) between its origin and insertion, depends on the cross-sectional thickness of the muscle (i.e. its number of fibers), on the types of fibers, and the geometric arrangement of its fibrils and fibers.

The frequency of contractions and their strength are controlled by the frequency of exciting nervous signals. This is called rate coding. Recruitment coding determines how many motor units of a muscle contract simultaneously; the more, the higher the contractile strength exerted by the total muscle. Thus, nervous control of muscle strength involves a complex pattern of rate and recruitment coding.

1. MUSCLE FATIGUE

If, after contraction, not enough time is provided for relaxation and recovery before the next contraction, the muscle becomes 'fatigued'. (It experiences an oxygen deficit, lactic acid is not removed sufficiently, potassium ions accumulate while sodium is depleted in extracellular fluid, phosphate accumulates in intracellular fluid, and ATP rebuilding is hindered — see the references for details.) Fatigue reduces muscle force and endurance capabilities. Muscular fatigue is overcome by rest, during which accumulated metabolic byproducts are removed.

Muscle fatigue depends on the frequency and intensity of muscular contraction, and on the period of time over which it is maintained. The larger the portion of its strength that a muscle must exert, the shorter the period through which this exertion can be maintained. As a practical rule, maximal muscle strength can be maintained for only a few seconds; 50% of strength is available for ~1 min; < 20% can be applied continuously for long times.

2. MUSCLE LENGTH AND TENSION

Under a 'no-load' condition, in which no external force applies and no internal contraction occurs, the muscle is at its resting length. Sufficient nervous stimulation causes the muscle to contract and, in doing so, exert force against any resistance. In its smallest possible length, the actin proteins are completely curled around the myosin rods; this is at ~60% of resting length. In this position, the muscle cannot shorten any farther nor develop any further active contraction force.

Stretching the muscle beyond resting length by external forces between insertion and origin lengthens it passively. When the muscle is stretched to 120–130% of resting length, the cross-bridges between the actin and myosin rods are in optimal position to generate a contractile force. But elongating the fibrils further reduces the overlap in the cross-bridges between the protein rods. At ~160% of resting length, so little overlap remains that no contraction force can be developed internally. Thus, the curve *active contractile force* developed within a muscle is zero at ~60% resting length, ~0.9 at resting length, at unit value at ~120–130% of resting length, and then falls back to zero at ~160% resting length. (These values apply to an isometric, or static, contraction — see the chapter on Static and Dynamic Strength.)

Passive reaction force to external stretch also occurs, as in a rubber band. This passive stretch resistance increases strongly from resting length to the point of muscle or tendon (attachment) breakage. Thus, above resting length, the total tension in the muscle is the sum of active and passive strain. This explains why we "preload" muscles by stretching them for a strong force exertion, as in bringing the arm behind the shoulder before throwing.

3. VISCOELASTIC BEHAVIOR

In engineering terms, skeletal muscles exhibit viscoelastic properties. They are viscous because their reaction depends both on the amount by which they are deformed, and on the rate of deformation. They are elastic in that, after deformation, they return to their original length and shape. These behaviors, however, are not pure in the muscle, because it is non-homogeneous, anisotropic, and discontinuous in its mass. Nevertheless, viscosity and nonlinear elastic theory can be used to explain major features of muscular performance. This includes the reasons why the muscle tension that we can develop statically by holding a stretch is the highest possible, while in active shortening (a dynamic concentric movement) muscle tension is decidedly lower. The higher the velocity of muscle contraction, the faster actin and myosin filaments slide by each other and the less time is available for the cross-bridges to develop and hold (Schneck 1992). This reduction in force capability of the muscle holds true for both concentric and eccentric activities. In eccentric activities, however, where the muscle becomes increasingly lengthened beyond resting length, the total force resisting the stretch increases with larger length, owing to the — just discussed — summing of active and passive tension within the muscle.

Muscle Terms – Glossary

K. H. E. Kroemer

Industrial And Systems Engineering, Virginia Tech, Blacksburg, VA, and Eri, Inc., A Consulting Company, PO Box 3019, Radford, VA 24143-3019, USA

- Activation of muscle — see contraction.
- Co-contraction — simultaneous contraction of two or more muscles.
- Concentric (muscle effort) — shortening of a muscle against a resistance.
- Contraction — literally, "pulling together" the *Z* lines delineating the length of a sarcomere, caused by the sliding action of actin and myosin filaments. Contraction develops muscle tension only if the shortening is resisted. Note that during an isometric "contraction" no change in sarcomere length occurs and that in an eccentric "contraction" the sarcome is actually lengthened. To avoid such contradiction in terms, it is often better to use the terms activation, effort or exertion.
- Distal — away from the center of the body.
- Dynamics — subdivision of mechanics that deals with forces and bodies in motion.
- Eccentric (muscle effort) — lengthening of a resisting muscle by external force.
- Fiber — see muscle.
- Fibril — see muscle fibers
- Filament — see muscle fibers.
- \n Force — as per Isaac Newton's Third Law, the product of mass and acceleration; the proper unit is the Newton, with $1\,N = 1\,kg\,m\,s^{-2}.$ On Earth, 1 kg applies a (weight) force of 9.81 N (1 lb exerts 4.44 N) to its support. Muscular force is defined as muscle tension multiplied by transmitting cross-sectional area.
- Free dynamic — in this context an experimental condition in which neither displacement and its time derivatives, nor force are manipulated as independent variables.
- Iso — prefix meaning constant or the same.
- Iso-acceleration — condition in which the acceleration is kept constant.
- Isoforce — condition in which the muscular force (tension) is constant, i.e. isokinetic. This term is equivalent to isotonic.
- Iso-inertial — condition in which muscle moves a constant mass.
- Isojerk — condition in which the time derivative of acceleration, jerk, is kept constant.
- Isokinetic — condition in which muscle tension (force) is kept constant. See isoforce and isotonic; compare with isokinematic.
- Isokinematic — condition in which the velocity of muscle shortening (or lengthening) is constant. (Depending on the given biomechanical conditions, this may or may not coincide with a constant angular speed of a body segment about its articulation.) Compare with isokinetic.
- Isometric — condition in which the length of the muscle remains constant.
- Isotonic — condition in which muscle tension (force) is kept constant — see isoforce. (In the past, this term was occasionally falsely applied to any condition other than isometric.)
- Kinematics — subdivision of dynamics that deals with the motions of bodies, but not the causing forces.
- Kinetics — subdivision of dynamics that deals with forces applied to masses.
- Mechanical advantage — in the context of muscle terms, the lever arm (moment arm, leverage) at which a muscle pulls about a bony articulation.
- Mechanics — branch of Physics that deals with forces applied to bodies and their ensuing motions.
- Moment — product of force and the length of the (perpendicular) lever arm at which it acts. Mechanically equivalent to torque.
- Motor unit — all muscle filaments under the control of one efferent nerve axon.
- Muscle — bundle of fibers that can contract or be lengthened. Striated (skeletal) muscle moves body segments about each other under voluntary control.
- Muscle contraction — result of contractions of motor units distributed through a muscle so that the muscle length is shortened. See contraction.
- Muscle fibers — elements of muscle, containing fibrils which consist of filaments.
- Muscle fibrils — elements of muscle fibers, containing filaments.
- Muscle filaments — muscle fibril elements, especially actin and myosin (polymerized protein molecules) capable of sliding along each other, thus shortening the muscle and, if doing so against resistance, generating tension.
- Muscle force — product of tension within a muscle multiplied with the transmitting muscle cross-section.
- Muscle strength — ability of a muscle to generate and transmit tension in the direction of its fibers. See also body strength.
- Muscle tension — pull within a muscle expressed as force divided by transmitting cross-section.
- Myo — prefix referring to muscle (Greek *mys*, muscle).
- Mys — prefix referring to muscle (Greek *mys*, muscle).
- Proximal — towards the center of the body.
- Repetition — performing the same activity more than once. (One repetition indicates two exertions.)
- Statics — subdivision of mechanics that deals with bodies at rest.
- Strength — see body strength and muscle strength.
- Tension — force divided by the cross-sectional area through which it is transmitted.
- Torque — product of force and the length of the (perpendicular) lever arm at which it acts. Mechanically equivalent to moment.

Definitions are adapted from Kroemer (1999) by permission of the publisher.

Musculo-skeletal System

K. H. E. Kroemer

Industrial And Systems Engineering, Virginia Tech, Blacksburg, VA, and Eri, Inc., A Consulting Company, PO Box 3019, Radford, VA 24143-3019, USA

Following Giovanni Alfonso Borelli (1608–79), the human body is modeled as volumes (masses) built on a structure of solid links (the bones) connecting in joints (the articulations with various degrees of freedom); the body segments are powered by muscles that cross joints.

Many body components may be well considered in terms of engineering analogies, for example:

- Articulations — joints and bearing surfaces.
- Blood vessels — tubular transport network.
- Body contours — surfaces of geometric bodies.
- Bones — lever arms, central axes, structural members.
- Flesh — volumes, masses.
- Muscles — motors, dampers or locks.
- Nerves — control and feedback circuits.
- Organs — generators or consumers of energy.
- Tendons — cables transmitting muscle forces.

The human skeleton is normally composed of 206 bones, with associated connective tissues and articulations. The main function of human skeletal bone is to provide an internal framework for the whole body. The long, more or less cylindrical bones that run between body joints are the lever arms at which muscles pull.

Several types of tissues connect parts of the body:

- Muscles are the organs generating force and movement between bone linkages.
- Tendons are strong yet elastic extensions of muscle, connecting it with bones.
- Ligaments connect bones and provide capsules around joints.

Cartilage is visco-elastic flexible material at the ends of the ribs, as discs between the vertebrae, and in general as articulation surfaces at the joints.

The mobility of body joints depends on the shape of the bones at their articulations, the encapsulation of the joint by ligaments, the supply of cartilaginous membranes, and the provision of discs or volar plates, together with the action of muscles.

Some bony joints have no mobility left, such as the seams in the skull of an adult; others have very limited mobility, such as the connections of the ribs to the sternum. Joints with "one degree of freedom" are simple hinge joints, like the elbow or the distal joints of the fingers. Other joints have two degrees of freedom, such as the loosely defined wrist joint where the hand may be bent in flexion and extension, and pivot laterally (deviate). The capability to twist (pronate and supinate) is located in the forearm, not in the wrist. Shoulder and hip joints have three degrees of freedom.

Synovial fluid in a joint facilitates movement of the adjoining bones by providing lubrication. For example, while a person is running, the cartilage in the knee joint can show an increase in thickness of ~10%, brought about in a short time by synovial fluid seeping into it from the underlying bone marrow cavity. Similarly, fluid seeps into the spinal discs (which are composed of fibrous cartilage) when they are not compressed, e.g. while lying down to sleep. This makes them more pliable directly after getting up than during the day, when they are "squeezed out" by the load of body masses and their accelerations. Thus, immediately after a bed rest, one stands taller than after a day's effort.

The term mobility, or flexibility, indicates the extent of angular displacement that can be achieved voluntarily in a body articulation. The actual range depends on training (use), age and gender. It is usually measured as the enclosed angle between the smallest and largest excursions achieved by adjacent body segments about their common joint.

For more information see any book on physiology or kinesiology, or Kroemer *et al.* (1997).

Physical Ability Testing

C. K. Anderson

Advanced Ergonomics, Inc., 5550 LBJ Freeway, #350, Dallas, TX 75240, USA

1. INTRODUCTION

Physical ability testing allows the identification of individuals who will have the physical ability to perform a particular job. This approach is a complement to the traditional ergonomic approach of designing the job to fit the worker. Occasions arise where the traditional ergonomic approach is technically or economically infeasible, at least in the short-term. In those instances, testing may be one of the few options available for achieving the benefits of worker–job matching. As an example, it is possible to reduce the risk of injury by 20–40% and to improve performance through the appropriate use of physical ability testing (Anderson 1998).

Physical abilities that might be considered could include ability to reach a particular distance, manually to handle a specific weight, to maintain a certain energy expenditure level for a given period, to tolerate a particular posture for a prolonged period or repetitively to perform a specific movement, etc. Typically, the focus of a testing program would be on those physical abilities for which a considerable number of individuals have difficulty demonstrating the level required to perform the task. Obviously, there could be a significant difference in capability if one is considering military recruits as opposed to individuals returning to work after back surgery. Hence, when designing a physical ability testing program, it is important to consider the nature of the tasks at issue and the population from which individuals will be drawn. Two basic categories of testing will be considered. The first is the type of testing used to evaluate individuals in the general population for placement on a specific job. This will be of primary focus. The second is associated with testing a specific individual who is temporarily or permanently disabled, which often means that the individual has capabilities that are distinctly different from the overall population.

2. USES

2.1. Placement

From an ergonomics perspective, the most common use for physical ability testing would be in the assignment or placement of individuals relative to alternative tasks. The basic idea would be to compare an individual's specific physical abilities to the specific physical job requirements.

2.1.1. Validity

Typically, one or both of two questions are being addressed: "does this individual have the physical ability to perform this task?" and "does this individual have a higher risk of injury for themselves or others if performing this task than others would?" In the past, some employers have made decisions about people's ability to perform the job or risk of injury simply on the basis the employer's beliefs or stereotypes about the physical abilities of women or older individuals, for instance. In general, it is true that, for instance, females have ~60% of the strength of males and 70% of the aerobic capacity (a measure of ability to sustain particular levels of energy expenditure for extended periods). It is also true that the average aerobic capacity of a 40-year-old male is ~70% of the aerobic capacity of a 20-year-old male. These facts do not warrant the blanket exclusion of women or individuals > 40 years of age from physically demanding jobs. As a side note, a number of the pieces of the employment-related legislation in the USA (e.g. the Americans With Disabilities Act, the Age Discrimination in Employment Act, and Title VII of the Civil Rights Act) have come about in reaction to employers who were making placement decisions on the basis of unfounded stereotypes regarding the capabilities of females, older individuals or those with disabilities. The more appropriate approach, which is the approach advocated in these pieces of legislation, is individually to assess each candidate and base a decision on the physical ability s/he has demonstrated relative to the job's physical requirements. It is important to rely on tests that are accurate indicators of the individual's ability to perform the job and/or risk of injury to self or others. The accuracy of a test in predicting these outcomes is an indication of its validity.

In many countries it is illegal to make employment decisions on the basis of results from test batteries that have not been demonstrated to be valid, particularly if groups protected from employment discrimination, such as females, older individuals or individuals with disabilities are more adversely impacted than their counterparts. Adverse impact is generally assessed by determining whether the pass rate for the protected group, such as females, is lower than the rate for their unprotected counterpart, which in this case would be males. Given the facts stated above regarding the relative strength and endurance of males and females, for instance, it is common to find adverse impact with physical ability test batteries. Said another way, if the task demands are at least moderate, it can be expected that the pass rate for females, and perhaps older individuals, will be lower. Hence, it becomes critical in many countries, for at least legal reasons, to take the necessary steps to validate the test battery before it is implemented. Even if there is not a legal imperative for validating a test battery, the information is valuable to the employer in assessing the cost-effectiveness of the test battery. Obviously, the employer would want to invest in a battery for which the cost to implement can be demonstrated to be heavily outweighed by the benefits received in terms of reduced turnover, injuries, etc.

The evidence needed to demonstrate the validity of the test battery differs substantially depending on the question being considered (Miner and Miner 1979). The strongest form of validation evidence is a statistical study that demonstrates a significant relationship between test scores and indicators of job performance such as productivity, turnover, supervisor evaluation or injury experience. Studies of this sort can be difficult to perform for technical or economic reasons. An alternative is to evaluate "content validity" of a battery. This basically involves assessing whether the content of the job is reflected by the content of the tests, and whether the test cutoffs represent the job requirements. Any evidence from statistical studies of a battery's validity for jobs with similar demands can be useful in determining the content validity of a test battery for a particular job.

2.1.2. Job analysis

There are two key elements essential when developing a battery that will have a high degree of validity. The first is a thorough ergonomic job analysis; the second is the utilization of tests that have a high degree of relation to the tasks that are most physically demanding. One would expect that the most demanding tasks would be the ones that limit the ability of some people to successfully perform the job. Success in identifying physical ability tests that are highly job-related is contingent, in large part, on the accuracy of the ergonomic job analysis.

The first step in the job analysis is to identify those tasks that are physically difficult to perform for a substantial portion of the population from which one would draw. It is important to underscore the point that the labor pool may be larger than what is reflected by the composition of the current workforce, particularly if there has been a hiring bias regarding the characteristics of individuals, such as size, gender, age or disability. For instance, police departments had traditionally hired large males. An analysis of tasks that would be difficult for a population of large males may overlook tasks that would be difficult for a population of smaller females, which is a group these departments are being encouraged additionally to consider for employment.

Tasks that would be of particular concern are heavy lifts, pushes, pulls and carries. Particular postures or movements can also be of concern, such as going through small openings or areas with tight clearances. In some cases, the performance-limiting factor is the overall stamina or endurance required to perform all of the activities involved over the course of a shift. Any one task, such as lifting 1 kg, may not be particularly demanding, but the combined effect of high repetition or large amounts of body movement such as walking or climbing, may yield a high-energy expenditure requirement over the course of a shift. A second factor to consider in the assessment of the energy expenditure requirement is the period over which the energy expenditure must be maintained (Rodgers and Yates 1990).

The second step in the job analysis is to evaluate the degree to which the physically demanding tasks identified in the first step are essential to satisfactory performance of the job. Considerations in this assessment might be the frequency with which the task is performed, the degree to which assistance might be available (such as with a heavy lift), the opportunity to assign the task to someone in another job classification or whether the physical demands of the task can be reduced or eliminated through redesign of the work organization or process.

2.1.3. Test battery design

Once the essential functions that have high physical demand have been identified, it is possible to move into the phase of designing the test battery. There are three key issues to consider in identifying the tests that will be used in the battery. The first issue is the degree to which the test reflects the task in question. The ideal test is the job task itself, though this may be difficult to incorporate into a test battery. For instance, a test of ability to lift 20 kg from floor level to table height could actually be the demonstration of lifting a case from floor level to table height. The safety of the test could be enhanced by starting with a negligible weight and increasing the weight up to 20 kg on later repetitions. In contrast, for some jobs the main question is whether the individual can maintain a given energy expenditure level for the entire shift day after day. One way to assess an individual's ability to do this would be to have them perform the job for a number of days, but this could be rather impractical. An alternative is assess the individual's aerobic capacity, which can be accomplished in < 15 min, and use that to determine the individual's likelihood of being able to perform the job on an ongoing basis. The greater the similarity between the task and the test, the easier it is to validify the utility of the test in assessing an individual's ability to perform the job.

The second consideration is the safety of the test itself. Clearly, it is not desirable to have individuals perform a test that may put them at increased risk of injury. For instance, in the lift-test example above, there would be no reason to have test participants demonstrate the ability to lift > 20 kg on the test, since the job itself would not require the ability to lift > 20 kg. As a general statement, individuals should only be required to demonstrate what the job requires, as opposed to the maximum ability that they have, since the risk of injury typically increases with the degree of exertion.

A third consideration is the objectivity of the test. It is useful to incorporate tests that yield quantified results that are repeatable from test administrator to test administrator as well as stable from day to day. Tests that involve subjective evaluations on the part of the test administrator, such as an assessment of lifting technique, can be unduly influenced by the test administrator's personal judgment of proper behavior, which may or may not have any real bearing on ability to perform the job.

2.2. Norm–based Comparisons

It needs to be briefly mentioned that physical ability tests are sometimes used to compare an individual to particular populations, such as "healthy" individuals or individuals with similar health conditions. This application of physical ability testing can yield very different types of tests since the emphasis is not on determining whether an individual can perform particular job-related tasks. Tests, such as range-of-motion in the low back, may fall in this category. The test can be useful as a measure of impairment, but its use for placement purposes can be questionable since one's low-back range-of-motion may not have a lot of bearing on the ability to perform a particular task. For instance, it may be possible to perform the task even with a limited range-of-motion if an alternative posture is used. The critical point to be made here is that care must be taken when considering the application of tests designed for one purpose, such as impairment rating, for another purpose, such as job placement.

3. SUMMARY

Physical ability testing can be a useful injury control strategy in conjunction with other ergonomic interventions. Research indicates that testing has the potential to reduce injuries to new-hires by 20–40%. The effectiveness of a testing program is a function of the physical difficulty of the job and the degree to which the tests are able accurately to assess an individual's ability to meet or exceed those physical requirements. Critical steps in the implementation process are the job analysis and test battery design.

Physical Strength in the Older Population

S. N. Imrhan

Engineering Department, University of Texas at Arlington, USA

1. INTRODUCTION

The ratio and number of people over 60 years of age (older people) in the technologically developed world has been steadily increasing. In the USA, the population over 60 years of age increased by 20.5% from 1980 to 1989 to reach a total number of 31 million (US Bureau of Census 1991), and the trend is expected to continue. The favorable conditions producing such a trend — enhanced medical care and consequent longer lifespans — are expected to propel the percentage further. A concomitant overall population growth is not expected and so older people are expected to work longer into their lifespans to offset a relative decrease in the population of younger workers. There is, therefore, an increasing need to design work, equipment, consumer products, and the environment, in general, to accommodate older people.

2. FUNCTIONAL CAPACITIES IN OLDER PEOPLE

As people become older, beyond adulthood, many physical and mental functions tend to decline. Among the most important are sensory perception, psychomotor skills, memory and learning, balance, cardio-respiratory strength and endurance, and muscular strength and endurance. While the exact causes and rates of decline of these functions are debatable, both objective scientific measurements and personal observations indicate clearly that the older population, in general, does not perform many types of tasks as well as younger cohorts. Tasks that require great physical resources, heavy sensory load, a high level of manual dexterity, or rapid responses tend to decline with increasing age in older workers. In the industrial workplace, for example, they require more intense illumination levels than young adults to read and cannot lift loads as heavy as those lifted by their younger cohorts. However, some types of performances tend to improve with age — especially those that require a high level of skill, experience or decision-making.

Few people would doubt that, except for special designs targeted at special sub-populations, many tasks and equipment for work or daily living were designed to benefit younger adults more than any other age group. The arguable point is whether it was done consciously or not. A widely held belief among ergonomists and other work design professionals is that the older population would be able to perform tasks at work and at home significantly better if, at the design stage of those tasks and associated equipment, the reduced functional capacities of the older population were taken into account. This chapter discusses muscular strength in older populations and how task design and performance are affected by strength.

3. MUSCULAR STRENGTH AND AGING

Scientific data confirms and quantifies what is known from personal observations and anecdotal evidence — that muscular strength in people declines gradually after adulthood and not suddenly at any particular age. People seem to be strongest at about 30–35 years of age and maintain most of that strength into the late forties as long as they are physically active and free of diseases and other debilitating ailments. The decline in strength seems to be accelerated by lack of physical activity and is common soon after people retire from their jobs and assume a relatively inactive lifestyle. The main physiological cause of strength decline is (gradual) atrophication and loss of some of the fibers that make up the muscles. Research has shown that between ages of 30 and 80 years the loss may be as much as 30% with greater losses in the less active muscle groups. Loss in muscle size is also accompanied by a decline in muscular movements and coordination which affects body balance and tone, and speed of contraction.

Muscle strength in older people is used for the same purpose as in any other age group. A certain minimum strength is necessary for moving the whole body or a body segment from one place to another, maintaining body posture, or effecting small movements for changing posture. Greater muscular strength is required for moving or stabilizing objects during manual materials handling. Manual materials handling tasks comprise mostly lifting, lowering, pushing, pulling, carrying and holding objects. Pressing down on objects, gripping and squeezing with the hands (handgrip) or the fingers (pinching), and turning or twisting objects with the hands may also require considerable strength, especially for job tasks. A comprehensive database and profound knowledge of strengths in older people are, therefore, required to assess how well this segment of the population may be able to perform existing physical tasks, design new tasks, or redesign existing tasks to conform to their strength levels. Unfortunately, because the working population has relatively few people beyond 60 years of age, research related to work tasks has traditionally been concentrated in adults below 50 years of age. Research in strength capacities in older people has also been avoided because of their greater susceptibility to physical injuries. The result is that few data sets and empirical models of strength exist for this segment of the population for use in the design of work tasks, equipment, living environments, products for activities of daily living, or products for leisure activities.

Many of the available strength data sets (mostly small ones) on older people were gathered from clinical studies designed to explore basic theories of aging, rather than from ergonomic studies on work capabilities. They have been concentrated mainly on strengths of single joints or basic easy-to-measure strengths, such as elbow flexion/extension, knee flexion/extension, pinch, handgrip, etc., and do not relate to work task variables. The data are, therefore, almost useless to ergonomists and other work designers.

4. HANDGRIP STRENGTH

Hand gripping is a precursor to many tasks, activities of daily living, or leisure activities. In the workplace, great or sustained gripping forces may be required to operate hand tools and the older population may be at a disadvantage in those tasks. In home and leisure activities, tasks requiring grip strength, which may not normally present problems for the adult population, may prove to be stressful for older people. Opening medicine bottle caps and food jars and tearing plastic wrappers are examples of such tasks. Unfortunately, there are no published data for grip

strength in the older population on objects (e.g. jar lids) associated with these tasks, but grip strength from standardized tests using dynamometers are available. These tests have shown mean strengths (per sample of subjects) of 294–352 Newtons (N) in males and 113–204 N in females among 60–80 years olds (9.81 Newtons (N) = 1 kilogram force); in this age group, grip strength decreases steadily with age. These strengths are 60–80% as great as the corresponding strengths of younger adults 20–40 years old.

Grip strength in both older people and adults follows an increasing–decreasing trend over a (sufficiently wide) range of grip widths — weaker strength for small or large grip widths and the greatest strength for intermediate widths. However, there is some evidence that the trend is more pronounced in the older people than in younger adults. The reason is not clear but it seems that the decrease in biomechanical leverage in the closed or widely opened hand (small or large width) has a greater detrimental effect on hand muscle contraction in older people.

When gripping, while turning or twisting an object with maximal strength (as in exerting torque on a circular handle), the grip force may not necessarily be maximal. Data for such forces are rare but one set of published data (Imrhan and Loo 1989) indicate that the grip force varies little at small to medium size grips (31–74 mm diameter) and then falls rapidly beyond 74 mm.

5. PINCHING AND PULLING WITH THE FINGERS

As in other human age groups (adults and children) pinch strength in older people depends on the type of pinch. The order of magnitude for the different types is same as for adults and children — that is, (i) lateral, (ii) chuck, (iii) pulp-2 and pulp-3, (iv) pulp-4 and (v) pulp-5 in decreasing order of magnitude, as measured on a standard pinch gauge. The difference between the strengths of the lateral pinch (thumb pressing on the lateral aspect of the index finger, as when using a flat key) and chuck pinch (thumb versus index and middle fingers) is small. The weakest pinch (pulp-5, thumb versus little finger) is about one-quarter as strong as the strongest pinch (lateral) which is about one-quarter as strong as handgrip; the strongest pulp pinch (pulp-2 or pulp-3: thumb versus index or middle finger) is two and a half times as strong as the weakest pulp pinch but only two-thirds as strong as the lateral pinch; and ring finger (pulp-3) pinch is about two-thirds as strong as lateral pinch. The relative magnitudes among the various pinch and handgrip strengths in older people are about the same as in any other age group. It is important to note, however, that these relative magnitudes were derived from standardized tests in which pinching is executed in a restrictive manner unlike the way in which it is executed in many work tasks. Recent research has shown that the chuck pinch is significantly stronger than the lateral pinch under pinching conditions that are different from those in standardized tests, and that the lateral pinch becomes weak for great pinch widths (for thick objects) — beyond 5.6 cm. Standardized pinch tests have been performed at pinch widths of 1.6–1.8 cm.

6. PINCHING AND PULLING

Pulling while pinching with the fingers is necessary for opening some types of packages such as plastic wrappers and glass bottles with flexible metal caps. While pinch-pull strength data would

be useful for the design of such products, there is no empirical data for older people to guide designers. However, data for adults are available and if it is assumed that older people are only about 0.63 times as strong as adults, on average, they (older people) would be expected to pull maximally with a force of about 63 N with the lateral grip, 41 N with the chuck pinch and 28 N with the pulp-2 pinch.

7. PUSHING AND PULLING WITH THE HANDS

On average, older people can be expected to pull toward the body with one hand with a force of about 71 N with the fingers in a hook grip (as when holding a briefcase) on a handle. When using the power grip (fingers wrapped around the handle) the increase in strength is insignificant. However, research has shown that strength depends on the mode of living. People living independently have been found to be 1.4 times as strong as those who have assistance with daily tasks (91.6 N versus 64.9 N). These forces, however, are not much greater than the forces required to perform certain common activities of daily living, such as opening refrigerator doors (32.5 N) and oven doors (36.9 N). This implies that these two tasks would be difficult for some older people, especially when performed frequently.

Tests by this author have shown that the pull forces required to open doors in public buildings average about 64 N. This requires an enormous effort for most older people.

8. GRIPPING, TURNING AND TWISTING

Torquing strength of the hands for opening or closing and tightening circular lids (discs) have been investigated in older people. This kind of strength is important for designing containers (food jars and medicine bottle caps, for example) which are difficult for small children to open yet easy enough for older people. Test results have shown that older males can produce maximal torques on circular jar lids in the range 1.5–7.9 Nm depending on lid diameter, and females 0.9–4.4 Nm. Also, older people are significantly stronger than children in respect of jar lids with diameters above 64 mm than below 48 mm. This implies that child-resistant lids should preferably be above 64 mm in diameter rather than below 48 mm. Other important findings about torquing strength in older people are: (i) torque strength on circular (jar) lids increases with diameter up to a point; (ii) the trend is linear up to about 74 mm diameter for both rough and smooth-surface lids; but (iii), above 74 mm the trend is monotonic increasing (slower increase) for rough lids, and increasing—decreasing with a maximum at about 83 mm for smooth lids; and (iv) roughness on the grip surface of commercial jar lids does not enhance torque generation with the hands.

There is also some torque strength data for opening faucets. Properly designs faucet handles can produce three times as much manual torque as poorly designed ones. For the best handles the strengths fall in the range 5.7–10.0 Nm, and for the worst ones 2.7–3.7 Nm, the exact amount depending on hand laterality, direction of torque application and body posture. The best commercial handles for torque exertion are the paddle types with a significant lever arm for the fingers, and the worst are spheroid-shaped ones with ridges. By comparison, torques required to close a sample of faucets were found to be in the range 2.0–2.2 Nm, indicating that certain handle designs were biomechanically stressful on the hands.

9. LIFTING, LOWERING AND CARRYING

Research indicates that lifting, lowering, and carrying tasks in industry are among the most strenuous physical tasks. Injuries and cumulative strains to the back are common, and are costly and debilitating to the industrial population. Older people are less likely to be assigned to these stressful tasks. However, if tasks and equipment are designed to accommodate their (reduced) strength capacities they would be more useful and employable. Activities of daily living also require lifting, lowering, and carrying, and can be made safe and achievable only if the objects to be lifted are designed within their strength capabilities. Unfortunately, empirical data to guide designers of these jobs are almost non-existent for people beyond 60 years of age. The only practical solution is to use subjective estimates of lifting, lowering or carrying strength with extreme caution. Kovar and La Croix (1987), in a questionnaire study for the National Center for Health Statistics, found that 36% of women and 18% of men aged 60–74 years had difficulty in lifting or carrying 25 pounds; and 11% of women and 6% of men had difficulties with 10 pounds. This information underlies the importance of exercising care in designing objects that must be manually moved or tasks requiring the application of muscular forces, and the urgent need for empirical task-related data on muscular strengths.

For manual material handling applications (lift, lower, hold, carry, push and pull) maximal single effort (MVC) strength is not typically used for task or equipment design. Instead, the maximal acceptable loads (or force) people are willing to exert during a work shift is used. This is determined psychophysically while people perform a simulated task. It is much less than MVC strength — typically 25–35% MVC. The psychophysical method for determining maximal acceptable work loads is strenuous and it is unlikely that such strength data will be available in large sets from the US population in the near future.

10. CONCLUSIONS

Strength data in older people are needed for designing tasks and equipment, placing workers in tasks, pre-employment screening, predicting or assessing task performance, and evaluating functional impairment. It is doubtful whether there is any biomechanical or statistical model to predict strengths in the older population accurately enough for ergonomic applications. Also, very little empirical (tabulated) data exists for these purposes. Almost all of the data on task-related strengths in older people are for static exertions — that is, the object or body part does not move from the muscular contractions — and are for manual performance only. Many work activities are, however, dynamic in nature and involve the whole body. More research is therefore needed to generate dynamic strength data simulating task performance.

Physical Work Capacity (PWC)

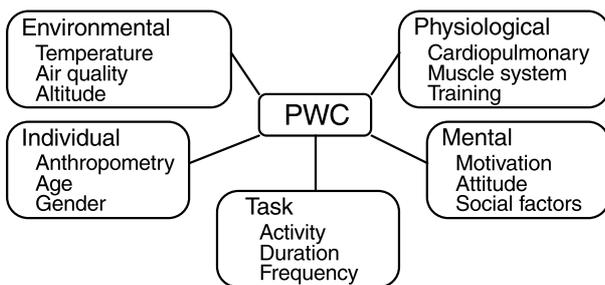
J. L. Smith

Department of Industrial Engineering, Texas Tech University, Lubbock, TX 79409-3061, USA

Physical work capacity (PWC) implies the determination of a physical limit of performance. However, the term is used in ergonomics to refer to a physiological limit of human capabilities (as opposed to biomechanical limitations). Thus, PWC is defined as the maximum level of physiological exertion that can be achieved by an individual. The measurement of PWC is generally given in terms of oxygen consumption (e.g. liters of oxygen consumed per min). PWC is used synonymously with aerobic capacity, or VO_{2max}.

PWC depends on several factors (figure 1). The three examples of each of the factors identified are not meant to be exhaustive, but rather are shown to indicate the potential level of complexity in determining an individual's PWC. In the assessment of PWC for an individual, one must determine which of the factors shown in figure 1 are appropriate and should be accounted for in arriving at a PWC value for that individual. The work environment will determine many of the factors that must be considered.

PWC can be assessed in a number of different ways, depending on the accuracy required and the level of risk willing to be assumed. The most common definition of PWC is the point at which an increase in workload does not produce a corresponding increase in oxygen consumption or heart rate. Such a definition implies that the physical task demands must be continually increased until the worker is no longer showing an increased physiological response to work, which indicates that he or she has reached his/her capacity or VO_{2max}. Taking an individual to their physiological capacity is normally done during a stress test in a clinical environment under the direction of a physician. However, in the industrial environment, it is generally not felt that the benefits of obtaining more accurate capacity data outweigh the risks of subjecting an older, less well-trained population of workers to maximal testing. Therefore, a variety of submaximal techniques have been developed over the years to predict PWC.

Most submaximal techniques to assess PWC involve the worker performing a standardized test (e.g. riding a cycle ergometer, or walking on a treadmill) at a constant workload


until steady-state physiological conditions have been established. As shown in figure 2, physiological responses to changes in work demand are not instantaneous. As the workload is increased, a new set of steady-state physiological responses, notably heart rate (HR) and oxygen consumption (VO_2), will be reached. In most cases, a level of steady-state physiological response will be reached in 3–4 min after changing a workload. This process could be continued until the individual's capacity (HR_{max} and VO_{2max}) is reached. However, if one assumes a linear relationship between HR and VO_2, one can use linear regression to estimate VO_{2max} from a set of submaximal workloads. A common technique is to find three steady-state HR and VO_2 combinations and determine the least-squares linear relationship for the data. Then, based on an estimate of maximum heart rate, VO_{2max} (PWC) can be estimated for that individual. A commonly used, simple estimate for maximum heart rate is:

$$HR_{max} = 220 - Age. \tag{1}$$

For example, assume that a 37-year-old female worker is tested on a cycle ergometer at three workloads of 75, 100 and 125 watts. Her heart rate and oxygen consumption are monitored during the test and recorded for the three steady-state levels of work:

Workload (watts)	Heart rate (bpm)	VO_2 (l min^{-1})
75	121	1.2
100	136	1.5
125	151	1.7

Calculating a linear regression line for the three steady-state data pairs above (HR, VO_2), the regression equation

$$VO_2 = 0.01667 \cdot HR - 0.8$$

is obtained. The worker's maximum heart rate is estimated as $220 - 37 = 183$. Substituting 183 into the regression equation for the HR, VO_{2max} is estimated as 2.25 liters min^{-1}.

Using the submaximal regression technique described above requires that oxygen consumption and heart rate be measured. Heart rate is easily measured through palpation or by using a relatively inexpensive commercially available heart rate monitor. However, oxygen consumption measurement requires more sophisticated and costly equipment. Over the years, a number of researchers have established models to predict oxygen consumption from measurements that do not require oxygen consumption data. Perhaps the most famous of the VO_2 or VO_{2max} prediction models is the nomogram developed by Astrand and Rodahl (1986). The nomogram allows the user to predict VO_{2max} from a variety of input data. VO_{2max} can be predicted from a single steady-state condition using HR and oxygen consumption.

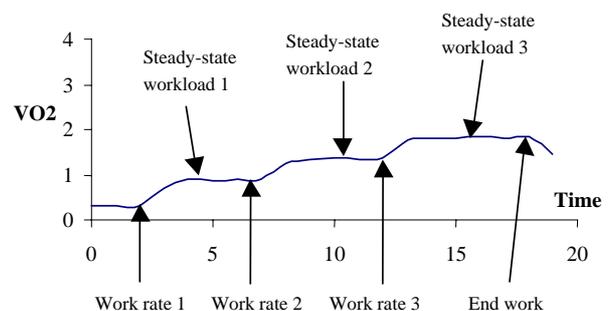
Figure 1. Factors affecting physical work capacity


Figure 2. Physiological response to work

However, VO_{2max} can also be predicted without requiring the use of oxygen consumption data. The Astrand nomogram does require HR and one other parameter to estimate VO_{2max}. The other parameter could be work rate in watts from a standard source such as a cycle ergometer, or body weight if using a step test as the work source. The VO_{2max} obtained from the Astrand nomogram must be adjusted for age. Astrand and Rodahl (1986) states that a 15% standard error exists for using the nomogram for moderately trained individuals of different ages.

Another alternative to the Astrand nomogram is to utilize a step test that is less strenuous than that recommended by Astrand and Rodahl (1986). Such step tests can be based on a model developed by the American College of Sports Medicine (ACSM) (1991). The ACSM model is based on step height and stepping frequency and can be expressed as:

$$VO_2 = 0.35 \cdot f + 2.395 \cdot f \cdot h, \tag{2}$$

where f is the frequency of stepping in steps·min^{-1}, h is height of the step (m) and VO_2 is steady-state oxygen consumption (ml·kg^{-1}·min^{-1})

Thus, for a step height of 0.25 m and a stepping frequency of 20 steps·min^{-1}, the predicted oxygen consumption for that task is 12.675 ml·kg^{-1}·min^{-1}. Multiplying that by the individual's body weight (kg) and dividing the result by 1000 ml·l^{-1} gives the predicted oxygen consumption (liters·min^{-1}). That VO_2 along with the steady-state HR at the given workload can be utilized in the Astrand nomogram to predict the individual's VO_{2max}. Again, an age correction adjustment must be made.

Once an individual's PWC is determined, it can be compared with the physiological demands of the job to determine whether the worker is being overworked and needs additional rest breaks. The most widely accepted standard is that the work should require no more than 33% of an individual's VO_{2max} without additional rest breaks.

1. INTRODUCTION

Human beings are the only remaining bipedal hominids to walk the surface of the Earth. The upright posture and bipedal gait that characterize modern man have a long evolutionary history. In Laetoli, East Africa there is a set of fossilized footprints that it is thought to have been made 3.7 million years ago by early hominids known as *Australopithecus afarensis*. Reconstruction of the walking patterns from the footprints, using data on modern human gait, indicates that *Australopithecus* was fully bipedal. According to anthropologists such as Lovejoy (1988), *Australopithecus* had a cranial capacity similar to that of a modern chimpanzee and weighed ~30 kg, but its pelvis, femur and lumbar spine resembled those of modern man. Both the human and the australopithecine bones are very different from those of a chimpanzee. The former are adapted to enable the animal to walk on two legs rather than four and to stand upright with the weight of the upper body balanced on top of the bones of the spine, pelvis and femur.

Clearly, humans are well adapted to an upright, bipedal posture. If this has enabled them to develop for > 3.5 million years, why is it that postural faults and posturally related musculoskeletal pain are so common, particularly in the workplace?

2. FUNDAMENTALS OF THE STANDING POSTURE

2.1 Bones and Joints

The upright posture of bipedal hominids is illustrated in Figure 1. It is a general solution to the problem of rotating the trunk with respect to the ground from a parallel (quadrupedal) position to a perpendicular position in an energy-efficient way.

In upright standing, the pelvis is held in an anteriorly tilted position by the iliopsoas muscles and the hip joint is free to extend, as happens during the stance phase of gait when the superincumbent body parts move ahead of the planted foot. The trunk and head are rotated until they are vertically above the legs. This is achieved by extension of the lumbar and cervical spines. This is why the vertically held spine is s-shaped in humans whereas in quadrupeds it is c-shaped and held horizontally to the ground.

In the erect posture, the line of gravity of superincumbent body parts passes through the lumbar, sacral and hip joints and in front of the knee and ankle joints. This places an extension torque around the knee joint, which is resisted because the joint is already fully extended. The flexion torque around the ankle is resisted by the plantar flexors.

2.2 Muscles and Ligaments

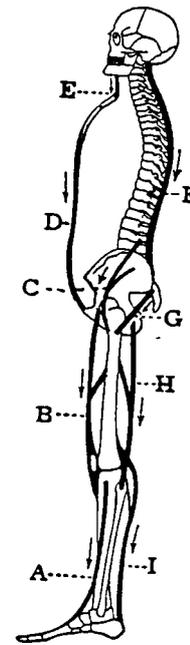
A person standing erect under the influence of gravity is never in a state of passive equilibrium. The body can be conceived of as a pillar of segments stacked one on top of the other and linked by


Figure 1. Upright posture in man. A, Tibilalis anterior; B, quadriceps femoris; C, iliopsoas; D, abdominals; E, neck flexors; f, spinal extensors; G, gluteus maximus; H, hamstrings; I, soleus gastrocnemius. (From Roaf 1997. Reproduced woth kind permission.)

joints. The pillar is momentarily balanced when the resultant effect of all forces acting on it is zero. The system is designed to minimize any displacement of the line of action beyond the base of support described by the position of the feet. Compensatory mechanisms come into play to maintain balance immediately when this happens.

Muscles and ligaments play a stabilizing role by means of the active and passive torques they exert around joints to correct small, fleeting displacements of the lines of action away from the joints. A "good" posture may be defined as one in which destabilizing moments are minimized and the posture is maintained by the resistance of the relatively incompressible bones (as well as interleaved soft tissues such as the intervertebral discs).

When the body is pulled "off-balance" by the requirements of badly designed jobs or workspaces, the anti-gravity muscles come into play and a new equilibrium position is established, but with the associated cost of isometric muscle activity.

2.2.1 The erector spinae muscles

These are the main extensors of the trunk; they also control flexion. In relaxed standing very little muscle activity occurs since the lumbar lordosis minimizes the trunk flexion moment. When the trunk is flexed even slightly forwards or when a weight is held in front of the body, the erector spinae muscles come into play. Work situations that set up static loading of these muscles include:

1. Working with the hands and arms held away from the body.
2. Holding a tool or a weight.
3. Standing with the trunk flexed to reach for work objects placed too far away or made inaccessible due to a lack of foot space.

Fatigue of the back muscles may be experienced as low back pain. Recent electromyographic research suggests that people with chronic pain in the low back have back muscles that fatigue more quickly than those of people without pain.

2.2.2 The leg muscles

The soleus and gastrocnemius muscles are true postural muscles in the sense that they are always "switched on" when standing. When leaning forward, the activity of the gastrocnemius muscle increases. Prolonged standing causes significant localized leg muscle fatigue and is one of the causes of leg discomfort. Research indicates that "anti-fatigue" mats for standing on do not delay the onset of leg muscle fatigue, although they do reduce discomfort in the lower legs, feet and back. This is consistent with the view that the mats work by cushioning the feet and by reducing the impact forces that are passed up the kinetic chain when workers move. Mats would not be expected to lower the postural load on the gastrocnemius muscle.

If workers can place one foot on a footrest, this reduces pressure on the tissues of the foot and leg and allows the leg muscles to relax. It releases the ipsilateral iliopsoas muscle and helps prevent excessive lordosis (by up to 15°). Essentially, footrests for standing workers encourage them to stand on one leg and to increase the load on the supporting leg. Such devices should be designed to allow workers to alternate their posture and in this way to change the static leg load into a periodic regime of load and rest.

2.2.3 The abdominal muscles

There is very little abdominal muscle activity in standing. These muscles may help to maintain a proper relationship between the thorax and pelvis by preventing excessive anterior pelvic tilt and hyperlordosis. The abdominals certainly play a role in manual handling by contracting to increase the intra-abdominal pressure which is thought to exert an extension moment (although this is controversial) and may help stiffen the joints of the lumbar spine. The abdominals can prevent trunk extension, caused, for example, by loads placed high on the back (or when putting on a backpack, for example) or when walking down steep hills.

2.2.4 The hamstring and gluteal muscles

The hamstring and gluteal muscles are hip extensors. The gluteal muscles exhibit hypertrophy in man and their function is to stop the trunk from "jack-knifing" forwards over the legs — unlike in quadrupeds where the trunk is already jack-knifed and the gluteals are used for locomotion. The gluteals are, however, used for locomotion in ladder or stair climbing. Activity in the hamstrings is slight in the standing position but increases when the stander leans forward, holds a weight or pulls.

2.2.5 The iliopsoas muscles

Psoas major and iliacus are hip flexors and are constantly active in normal standing as they prevent extension of the hip joint (the trunk jack-knifing backwards over the legs or loss of lumbar lordosis if the head position is maintained). The iliopsoas muscles act against the hip extensors. Factors that upset the balance between these two muscle groups cause abnormal lumbar curvatures. If the iliopsoas weaken relative to the hip extensors, the pelvis rotates posteriorly over the hip joint and the lumbar curve is flattened; if the iliopsoas strengthen with respect to the

hip extensors, the lumbar curve is exaggerated. This is discussed further in the section on sitting posture.

2.2.6 The adductors and abductors of the hip

When standing on two feet, these muscles provide lateral stability, preventing translation of the pelvis in the frontal plane. When standing on one foot (and also during the stance phase of gait), the pelvis tends to tilt in the direction of the unsupported side. The hip abductors on the side of the supporting leg contract to keep the pelvis level.

3. PHYSIOLOGY OF STANDING

The increase in energy expenditure when a person changes from a supine to a standing position is only ~8%. However, erect standing imposes a hydrostatic handicap that makes people liable to peripheral circulatory collapse. Peak plantar (foot) pressures of 137 kPa exceed the normal systolic pressure of 17 kPa, resulting in occlusion of blood flow through the foot. Venous and circulatory insufficiencies in the lower limbs also contribute to the discomfort that results from prolonged standing. It has been shown that venous reflux is more common in symptom-free surgeons (who stand for long periods) than in a comparison group who experience discomfort in standing.

Prolonged standing causes physiological changes including peripheral pooling of blood due to the influence of gravity, a decreased stroke volume and an increased heart rate, diastolic and mean arterial pressure, peripheral resistance and thoracic impedance. Lying supine brings an increase in whole-body electrical impedance, blood and plasma volume, and lower serum potassium levels. Standing-up from a supine position is accompanied by an increase in the dimensions of the nasal passages.

Constrained standing for long periods causes venous pooling and is particularly troublesome for older workers or for those with peripheral vascular disease or varicose veins. Poor health, obesity, tobacco smoking and any other factors that increase circulatory inefficiency magnify these effects. The "venous muscle pump", which returns blood to the heart, is activated by moving and by postural sway. Fidgeting is a preconscious defense against the postural stresses of constrained standing or sitting. Its purpose is to redistribute and relieve loading on bones and soft tissues and to rest muscles.

4. POSTURAL BEHAVIOR

Much postural behavior and many of our attitudes towards posture are culturally determined. Cross-cultural surveys do enable a few fundamental conclusions to be drawn. First, humans are capable of adopting > 1000 comfortable resting positions but, when unconstrained, they never adopt any posture for any length of time. Postural behavior is, therefore, a process of continual adaptation to changing internal and external circumstances. Second, although humans are adapted to stand on two legs, they are not adapted to stand still. In many cultures, people who have to stand for long periods (such as shepherds, sentries, etc.) use standing aids such as poles, "shooting sticks" or chinstraps, or prop themselves up against external objects. "Natural" standing tends to be tripedal rather than bipedal with the third leg providing extra stability and enabling the weight to be periodically taken off the other legs.

Constrained standing without the use of standing aids or sufficient rest squashes the intervertebral discs, reducing the vertical distance between adjacent vertebrae and increasing the load on the facet joints. It may cause inflammation of the tendon sheaths and chronic degeneration of joints in the form of arthritis.

Standing may be symmetrical or asymmetrical. Asymmetrical standing occurs four times as often as symmetrical standing. Body weight is supported almost entirely on one leg while the other helps maintain balance with its knee slightly flexed and its foot anterolateral to the supporting leg. The pelvis tilts towards the resting leg and the lumbar spine flexes laterally and is concave to the supporting limb. Asymmetrical standing seems a postural strategy aimed at reducing static loading of the spine, pelvis and lower limbs.

The body can be thought of as an open chain of linked segments that, in the absence of external stabilization, is maintained in position by tonic or postural muscle activity. People constantly seek to turn the open chain into a closed one by means of postural strategies such as folding the arms, crossing the legs or cradling the chin in the hand. These behaviors, far from being maladaptive, increase the energy efficiency of posture and facilitate muscle relaxation. It has been demonstrated that leg crossing in the seated position lowers electromyographic activity in the oblique abdominal muscles. Workstations should be designed to encourage postural behavior of this sort.

5. FUNDAMENTALS OF THE SEATED POSITION

When a person flexes their hip and knee joints to sit down, the iliopsoas muscles immediately shorten and the hip extensors lengthen, resulting in an abnormal lumbar curvature as described above. The balance of antagonistic muscle forces that kept the pelvis in its anteriorly tilted position is changed and the pelvis tilts posteriorly almost immediately and continues in proportion to the flexion at the hip. To keep the head erect, the lumbar spine flexes to compensate for the tilting pelvis and the lumbar lordosis diminishes and eventually disappears. The spine of a person seated erect now resembles that of a quadrupedal animal attempting to stand upright, there is a single c-shaped curve in the thoraco-lumbar region and an increased flexion moment about the lumbar spine. This puts the posterior spinal ligaments under tension and causes the intervertebral discs to be "wedged" anteriorly and to protrude into the intervertebral foramen.

6. SEATED POSTURES FOR RESTING AND WORKING

In most cultures and throughout history people either sit on the floor, cross-legged or in other ways, or squat. Squatting is the habitual resting position of the chimpanzee and of young humans of all cultures.

In squatting, the line of action of the body center of gravity passes through the foot support base and some of the weight of the upper body is born on the legs. Humans exhibit great developmental plasticity and can continue to sit comfortably in this and other ways into old age. However, when deprived of practice, these postural options are lost, as happens to modern-day Western children when they start school and sit all day on seats.

Sitting on chairs with the trunk erect and with 90° of flexion at the trunk–thigh and knee joints "takes the weight off the legs"

and puts it onto the back in the form of an increased flexion moment. Modern thinking suggests that conventional chairs should be designed to enable seated workers to recline with a trunk–thigh angle of 105°. Backrests should be fitted with a convexity in the lumbar region to prevent the lumbar spine flexing further. Some researchers have suggested that seats should slope forward (with or without the knee rest found on "kneeling chairs") so that sitters have an upright trunk and a trunk–thigh angle > 105°. This design philosophy is essentially a compromise, or half-way measure, that attempts to take the weight off the legs while preserving a sufficient amount of lumbar extension to allow the trunk to be held erect without a backrest. There is evidence that the concept is valid but its widespread use would depend on it being able to overcome user habits, preferences and usability issues, which are beyond the scope of the present discussion.

7. WORKING POSTURE

7.1 Postural Adaptation

As far as the lumbar spine is concerned, a good working posture is one in which the spine is towards the mid-point of its range of movement and the trunk is unconstrained (i.e. free to move anteriorly and posteriorly). Figure 2 presents a range of postures varying in extremity and constraint.

In practice, postural adaptation in the workplace is a result of the interaction of three classes of variables:
1. Task requirements (visual, postural and temporal).
2. Workspace design.
3. User characteristics.

The position of the head is a major determinant of posture and is determined by the visual requirements of the tasks. If the main visual area is a flat desktop or workbench > 30° below the "straight ahead" line of sight, people will fixate it by flexing the neck. This causes seated workers to slump forwards and it increases neck flexion, particularly in standing workers. Solutions are to tilt the worksurface ~15° towards the user or to provide document holders to lessen the visual angle. Check also that illumination levels and the quality of lighting are adequate and that workers with visual defects wear appropriate corrective lenses.

7.2 Visual Cues and Standing Balance

In the healthy young person balance is achieved by means of feedback via stretch receptors in the muscle spindles and from the vestibular system. Vision plays a secondary role. Restoration of lost balance is achieved by means of control strategies at the ankle and hip joints. With age (in those > 50 years), proprioceptive feedback degrades and visual feedback becomes more important. When investigating cases of slipping, tripping and falling, one area of investigation is the analysis of the foot–floor interface and the task and organizational factors at the time. Another is the analysis of the visual environment. It has been stated that people are quite capable of walking on ice if they know about it. A more thorough analysis might also look for appropriate visual cues in the work environment and to check whether prevailing light conditions were adequate for revealing them.

7.3. Manual Factors

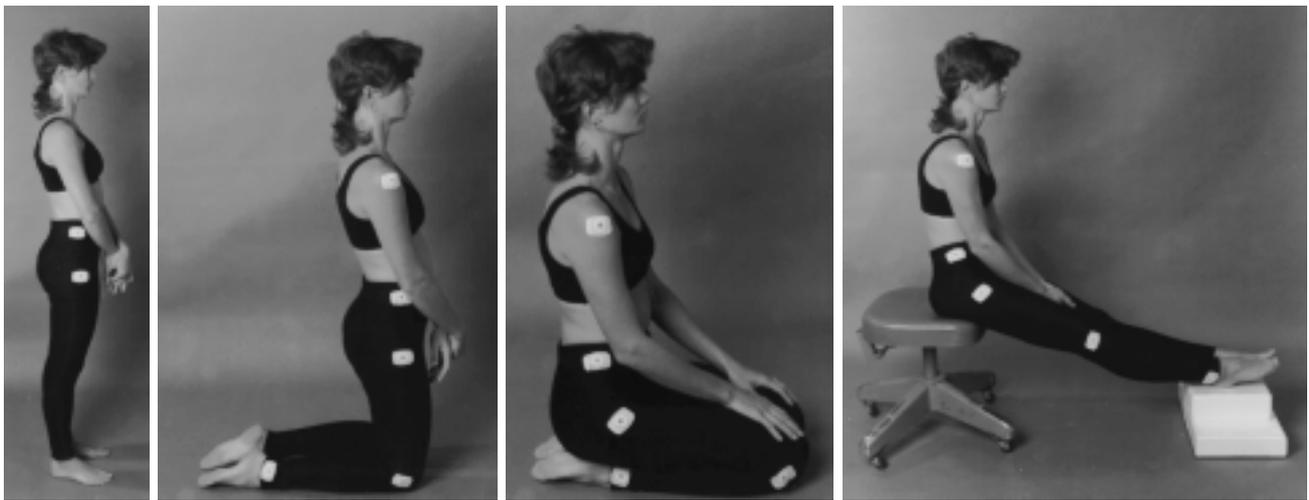
The position of the hands and arms also has a major influence on the posture of the body. It is strongly determined by the


Figure 2. Common postures according to lumbar position and constraint: 1, standing – lumbar spine extended, constrained posteriorly; 2, "praying" posture – lumbar spine highly extended; very constrained in posteriorly and anteriorly (due to lack of anterior base of support); 3, kneeling – lumbar spine in mid-range; unconstrained; 4, "long" sitting (stool) – lumbar spine flexed, constrained anteriorly; 5, "kneeling" chair – limbar spine in mid range (slightly extended); unconstrained; 6, supported kneeling – lumbar spine in mid-range; unconstrained; 7, "long" sitting (floor) – lumbar spine highly flexed; very constrained anteriorly; 8, "90 degree" sitting – lumbar spine unextended or slightly flexed and unstable due to tendency to slump forwards; 9, squatting – lumbar spine highly flexed; highly constrained.

location of work objects with respect to the user, and the forces required to carry out the task. The optimal location for work objects is ~40 cm in front of the worker, between the level of the shoulders and elbows. Objects should not be placed to the worker's side as this encourages axial rotations of the trunk which in turn increase stress on the facet joints and intervertebral discs. Objects should not be placed above shoulder height or so low as to demand stooping. The need to exert large forces may cause workers to adopt flexed or awkward postures in an attempt to close the postural chain by "locking" a limb against a part of the workstation. Seated workers should be able to work close to the front of the desk so that they can work while reclining against a backrest. Standing workers should be able to get their knees and feet underneath the worksurface and rest one foot on a footrail.

7.4 Temporal Factors

Temporarily constrained workers are particularly at risk and must be given the opportunity to alternate between sitting and standing wherever possible. Split-level worksurfaces should be considered so that some part of the job, even superficial or secondary tasks like the ordering of supplies or the sending of a fax, can be done in the alternate posture.

A detailed discussion of workstation design is beyond the present scope. Actual dimensions depend on the anthropometry of the user population, which is often unknown. A list of general recommendations given below will enable workers to adapt appropriately to the constraints of the task and workstation and to alternate between several comfortable working and resting postures.

8. RECOMMENDATIONS

1. Provide clearance under desks and benches so that foot and knee position are not constrained.

2. The feet must never be confined to a small area as this degrades balance and shifts the load of postural adaptation to vulnerable structures higher up the kinetic chain.
3. For every task, find an optimal visual and manual distance that will minimize forward flexion of the trunk and flexion of the neck.
4. Provide footrails for standing workers and footrests for seated workers.
5. Enrich or enlarge the job to increase postural variety. Differentiate new tasks by introducing configurations demanding alternate postures.
6. Activate the venous muscle pump. Require walking, wherever possible. A period of 5 min h^{-1} may be optimal.
7. Design sit–stand workstations.
8. If multi-user worksurfaces are of a fixed height, provide height-adjustable platforms for standing workers. For seated workers, choose a height that will fit taller workers and provide footrests for shorter workers. The height of floors is always adjustable in the upward direction.
9. Alternating between asymmetric postures is a strategy for minimizing static loading. Design workstations and jobs to encourage this strategy.

This article is concerned with the principles that describe the behavior in some of the human's simplest movements, discovered and refined over the past 50 years or so. Such actions might involve one-directional hand movements to a target, where the action is brief and usually rapidly done. The principles discussed here are those that define the relationships among various manipulable or measurable features in these actions, such as the movement's duration, the distance moved, the loads applied, the type of load (friction, mass, etc.), and the accuracy demands in achieving a target. Understanding these simple actions is probably fundamental for understanding more complex actions, assuming that more complex actions are in some sense "built" out of simpler ones. We can conceptualize these principles of simple movement as analogous to the laws of Newtonian physics (e.g. the relations among force, velocity, time, etc.) in movements of a mass, which form the cornerstone for understanding more complex mechanical devices (e.g. automobiles).

1. MOTOR PROGRAMMING PRINCIPLES

The rationale for the research in this area, and the basis for understanding many of the results, is based on the concept of motor programming discussed by us elsewhere (see Control of Rapid Actions). Briefly, the idea is that, in rapid movements, the central nervous system (CNS) sets up patterns of activity that control the musculature for several hundred milliseconds or more. In this sense, this activity is "pre-programmed" and, when run off, results in patterns of activity in the muscles that define the movement. In such brief actions there is not sufficient time for sensory information to be transduced, delivered to the CNS, translated and delivered back to the responding limb. In many cases, the actions are completed before any such sensory-based compensations can begin to have an effect. For this reason, primarily, the system organizes the actions in advance. Our most rapid actions are thus relatively immune to sensory information that would alter the movement in some way, and the action tends to be run off as planned.

One major hypothesis concerning how motor programs are thought to operate is by the control of two essential features of muscle activity: (1) the amount of force produced in a muscle and (2) the temporal features of the contraction (when it occurs, and for what duration). In this sense, the "language" of the motor program is thought to be *impulses*, i.e. the integral of force over time in physics (the area "under" the force–time curve of a muscle contraction). A fundamental assumption is that muscular impulses are timed by the CNS so that the muscles generate the desired pattern; hence, the term *impulse timing*.

2. DETERMINANTS OF MOVEMENT ACCURACY

One of the important questions for human factors and ergonomics concerns what features determine the movement's accuracy. Accuracy can be evaluated in many ways, but an important one in this regard concerns the *variability* of the movement, usually measured as the standard deviation of the trajectory about some target value to which the movement is aimed. Based on the notion that the CNS controls impulses, we turn next to the fundamental ways that movements can become inaccurate — variability in force and variability in time.

2.1. Force Variability Principles

It has been known for most of the twentieth century that when muscles contract to produce force on bones, they do so somewhat unreliably. This force variability tends to be distributed approximately normally about the mean target-force, unless the contractions are very small or are near the operator's maximum capabilities. This variability, usually measured as the standard deviation of the force produced about the subject's own mean force, increases with the amount of force produced. From very small contractions up to forces of ~65% of the subject's force capability, the positive relationship between force and force variability is essentially linear, or perhaps slightly concave downward. The slope of this function varies with the muscle tested, with larger muscles having steeper slopes. For the elbow flexor muscles, this variability is ~8% of the mean.

When the forces become larger, such as are found in many activities where violent, rapid actions are required (e.g. manual materials handling, sports, etc.), the relationship between force and force variability adopts an inverted-U shape. In some studies, the maximum force variability occurs at ~65% of the subject's maximum force capability, with the force variability actually becoming smaller as the maximum force is approached. In other studies, the curve merely becomes increasingly concave downward in this range. In any case, the linearity between force and force variability disappears at lower forces.

An important implication is that, when an action is to be produced more forcefully — by decreasing the duration of the movement (with distance constant), increasing the distance (with time constant), or increasing the inertial load — the necessary increases in muscular force brings a change (usually an increase) in the variability of the contractions (except for near-maximal contractions, as discussed above). This locus of this variability is almost certainly at the neuromuscular level related to the recruitment of motor neurons and/or the contraction of muscle itself. As discuss below, these sources of force variability influence variability of the movement's trajectory — especially so in a brief action that cannot be modified en-route.

2.2. Temporal Variability Principles

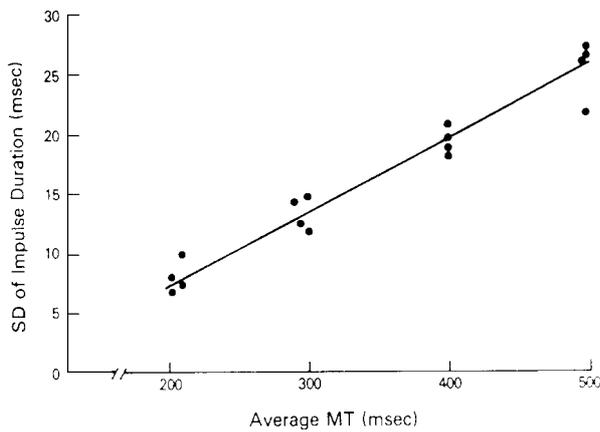
The second component of the impulse is its duration. It has been long known from studies of timing and time-estimation tasks (such as rhythmical tapping) that the variability of a temporal interval is directly and strongly related to the duration of that interval, even for intervals as long as several seconds. More recent work has shown that other intervals (such as the duration of an impulse in a rapid action) also follow this general rule. When the duration of impulses ranging from 200 to 500 ms have been examined in reciprocal (and other) movements, the variability of


Figure 1. Variability in impulse duration as a function of the movement time in reciprocal actions (from Schmidt and Lee 1999).

Figure 2. Effects of movement time and movement amplitude on variability in the movement's endpoint (effective target width, W_e) (redrawn from Schmidt *et al.* 1979).

the impulse duration is almost directly proportional to the duration of the impulse (Figure 1). The amount of temporal variability is ~5% of the mean duration under these conditions. Various studies have revealed that the source of this increased variability is in the central timing processes, and is not caused by increased variability at the muscle level (unlike force variability, see Section 2.1). It is as if these various intervals are produced by "noisy" central timing processes, with longer intervals having more of the variability included. This general trend holds for much longer intervals as well, although the relationship is not always linear.

These principles are important in several ways. For rapid movements, the variability in the duration of pre-programmed impulses provides another source of error that is related not only to the movement trajectory but also to its intended duration. As we will see, this provides a basis for understanding why increasing the action's duration increases the temporal variability of the action (Schmidt *et al.* 1979). In addition, in many tasks an operator must produce an action at a precise time with respect to some other event; if the action is programmed, then increased variability in the duration of that action (by, for example, increasing its movement time) increases the variability in the timing error.

3. SPEED–ACCURACY TRADE-OFFS

We have long recognized that when an action is to be produced more quickly, it is usually done with less accuracy. Furthermore, we seem to have the capability of "trading" speed for accuracy in many tasks, so that one can maximize accuracy by producing actions more slowly. Recent work on this so-called "speed–accuracy trade-off" has formalized this idea somewhat, and various statements about this kind of trade-off can now be made.

3.1. The Linear Speed–Accuracy Trade-off

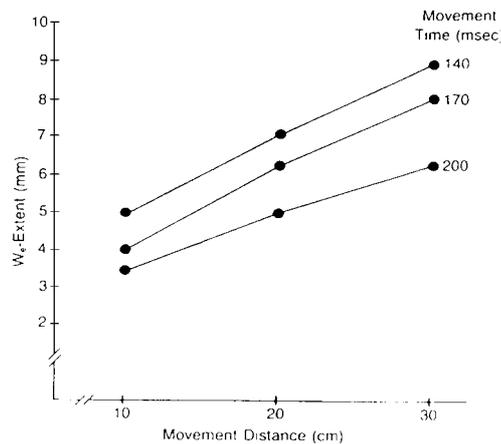
When actions are very brief, such as rapid aiming of a hand-held stylus to a target, a clear relationship emerges among the movement's amplitude, the movement's duration and the movement's accuracy (measured as the variability at the movement's endpoint). It is important to note that variability is measured in *spatial* units, and not in terms of time. As shown in


Figure 2, when the distance is varied (holding the time constant via instructions), the variability in the movement's endpoint (effective target width, W_e) increases almost linearly with distance. And, when the movement time is varied (changing the time instruction, with distance constant), W_e decreases almost linearly as the movement time increases.

Both of the manipulations in Figure 2 (movement distance and movement time) have the effect of altering the movement's mean velocity. In fact, when W_e is plotted against the movement's mean velocity (that is, movement amplitude divided by movement time, in cm/s), the relationship has been found to be linear; movement endpoint variability (W_e) is linearly related to average velocity as shown in equation 1:

$$W_e = a + b \ [A/MT], \tag{1}$$

where A is the movement amplitude, MT is the movement time, and a and b are arbitrary constants (Schmidt *et al.* 1979). The slope constant b varies with the particular limb used; smaller limbs with musculature that is more oriented toward precision (hands) have smaller slope constants than larger limbs (arms). With hand movements to targets, the slope is ~3.3 mm/100 ms. This general trade-off holds when the variability is measured in the direction parallel to the overall movement direction (errors in distance) as well as in the direction perpendicular to the movement (errors in direction); direction errors are about half the size of distance errors, at least in hand movements. This general finding has been produced in a variety of movement tasks, and even holds with saccadic eye movements.

3.2. The Temporal Speed–Accuracy Trade-off

Another type of trade-off emerges for rapid tasks in which the accuracy is evaluated in terms of *time* rather than space as it was above. In this trade-off, the operator makes a movement of a given distance, but the *time* of the action is measured. In other tasks, the operator moves a given distance, with a follow-through beyond the point of contact (e.g. batting a baseball), where the time from initiation until the target point is measured. With distance held constant, numerous studies have shown that shortening the movement time produces decreases in the

variability in movement timing, with the variability in timing being almost proportional to the movement time (Schmidt *et al.* 1979). While the major determinant of movement time variability is movement time itself, there is a small effect of movement velocity (when time is held constant and distance is varied), especially if the movement velocities are very low. Here, low-velocity movements are especially "noisy" in terms of temporal variability. Many rapid tasks (such as batting) require precise timing of the action to the movement of an external object (e.g. a ball). Here, shortening the movement time via instructions to move more quickly reduces not only the variability in the overall movement duration, but also the variability of both the movement initiation time (relative to the ball's flight) and the time of the limb's arrival at the target-point (where the ball is to be struck). This makes the entire action more temporally stable and increases the capability for accurate temporal anticipation.

This temporal effect seems related to the idea, presented above, that the central production of time intervals is a "noisy" process, and that shortening the interval reduces these processes to make the action more temporally stable. It seems to make little difference whether the intervals are brief (e.g. 50 ms) and are produced non-consciously via the output of a motor program (such as the duration of a muscle contraction), or are longer and consciously produced (as in estimating 5 s). Note also that this effect is quite different from the movement time effect found when spatial errors are measured. At the same time that decreases in movement time reduce temporal variability, the decreased movement time produces *increases* in spatial variability (see Section 3.1). In tasks like batting, where both temporal and spatial accuracy, and the speed of the bat and its effects on the baseball, are important, the trade-off of these two sources of variability can be quite complex. These various findings are described well by the so-called *impulse-variability* view of movement accuracy (Schmidt *et al.* 1979, Schmidt and Lee 1999).

3.3. Speed–Accuracy Trade-offs and Violent Actions

The principles of rapid actions presented above have an exception when the movements are very rapid and violent. When the level of force production is < 65% of the operator's maximum, decreased movement time results in an almost linear increase in spatial error (see above). However, as the movement is made more violent by reducing the movement time further (and/or by adding inertial load), a decrease in the spatial error is found, with a maximum spatial error at ~60% of the subject's maximum force. This value agrees rather well with the finding that force variability peaks at ~65% of the subject's force capabilities (see above). It appears that, in some of the most violent and forceful actions (e.g. a kick in football), performers seem to enjoy the benefits of larger forces and higher velocities, but without the detriment of increased movement variability as a result. Much more needs to be done in this area to determine, for example, whether such principles also work in actions with multiple joints and/or high levels of required precision (e.g. a golf swing), as well as the role of practice in these relationships.

3.4. Logarithmic Speed–Accuracy Trade-off: Fitts' Law

Certainly one of the most famous and well-established principles of rapid actions was developed by Fitts (1954). In what has been termed the Fitts Paradigm, the operator taps a hand-held stylus alternately between two target plates, attempting to maximize the number of taps in a trial of fixed duration without missing the target more than ~5% of the time. These targets are varied in width (*W*, along the direction of the movement) and amplitude (*A*, or the separation between target centers). A typical trial might be 20 s in duration, and the experimenter measures the number of successful taps in that period. These data are converted to number of seconds/tap, as an estimate of the average movement time. Note that this paradigm is somewhat different from that used with the linear speed–accuracy trade-off. The independent variables in the Fitts work are *A* and *W*, with the movement time being the dependent variable; with the linear trade-off, the independent variables are *A* and MT, and the dependent variable is the effective target width, or W_e.

The typical finding is that the movement time increases (i.e. slows) as the distance to be covered (*A*) increases or the size of the target (*W*) to be contacted decreases. This is not particularly surprising. But Fitts' main discovery was the finding that these variables relate to each other in a relatively simple way. In the expression of Fitts' Law:

$$MT = a + b \, [\log_2 (2A/W)], \tag{2}$$

where MT is the average movement time, *A* is the separation between targets, *W* is the width of the targets, and *a* and *b* are empirical constants. In this work, the expression $\log_2 (2A/W)$ has been termed the index of difficulty (ID), as "difficulty" seems to be expressed both in terms of the separation of the targets and their widths. Thus, Fitts' Law states that the average movement time is linearly related to the ID. The nature of this relationship is shown in Figure 3.

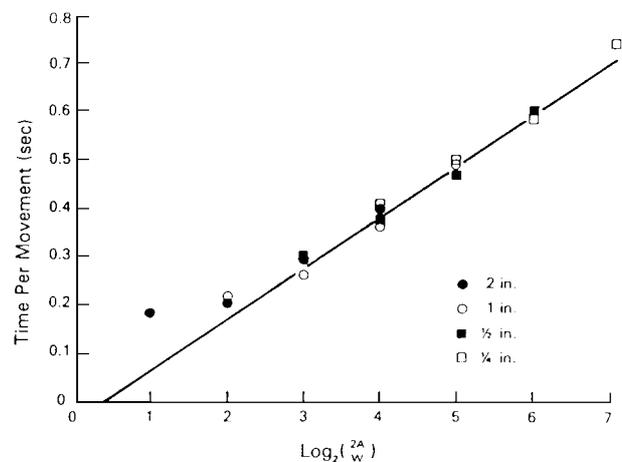
An important implication from the equation is that the movement time will be constant whenever the ratio of *A* and *W* are constant; that is, doubling both *A* and *W* together produce no effects on movement time. As well, the Fitts principle embodies


Figure 3. Average movement time as a function of the index of difficulty [(ID = log₂ (2A/W)], where *A* is movement distance and *W* is target width (adapted from Fitts 1954).

the general finding that the movement time is logarithmically related to movement distance; doubling movement distance (*W* constant) increases movement time by only a factor of 1.3. The Fitts principle also accounts well for discrete, single-aiming movements, in which the subject makes a single movement as quickly as possible from a starting location to a target, where the distance to the target (*A*) and the target's width (*W*) are varied.

The Fitts principle appears to hold in a remarkably wide variety of situations. It has been studied in a variety of subject populations, with different limbs and manipulanda, in various body orientations, with microscopic movements, and even under water. In fact, recent findings with movements of a computer "mouse" and joystick from a starting point to a target area on the screen followed very well the expectations of Fitts' Law. Target width has been operationalized in various ways, such as the "play" between a rod and a washer that was to be fit over it, and the results agree well with the general findings. There is a change in the slope constant (*b*) with different limbs, with slopes systematically increasing when the movements are done with the finger, wrist and arm. Various attempts have been made to refine the mathematical statement of Fitts' Law to account for greater variance in movement times, such as a power law presented by Kvalseth [$MT = a(A/W)^b$]; but little or no gains in precision have been produced, and the original statement seems to be preferred. It is certainly one of the most robust principles in the area of movement control. See Schmidt and Lee (1999), Meyer *et al.* (1990) and Plamondon et al. (1997) for a more complete discussion.

Besides the strong generality to many different kinds of movement situations, Fitts' Law has many implications for design issues in human factors. In human–computer interaction, the size of the target and the distance to which the cursor needs to be moved should be considerations in software design. In designing workstations or assembly lines, the time for an action is limited strongly by the target width or "fit" required at the endpoint. Also, the law allows auto engineers to compute the effect of design changes in the size of the brake pedal and/or the distance away from the accelerator on the resulting time to move the foot to the brake (Schmidt 1989).

3.5. Logarithmic versus Linear Trade–off

On the surface, the Fitts principle appears to contradict the linear speed–accuracy trade-off described earlier here (see above). Several features seem to distinguish them, though, and the current understanding is that these actions are descriptors of different phenomena. An important consideration seems to be that the linear trade off is especially relevant for very rapid actions, where the movements are almost certainly programmed; the movement times in this work are usually < 200 ms (Figure 1). The data which fit the Fitts equation most effectively are typically slower (Figure 3), where the movement times often range from 200 to ~1 s. However, it is probably not correct to say that the linear

model is for quick actions and the Fitts' model is for slow ones; one would expect that, even if the movement were slow, if it were programmed without corrections, it would follow the predictions from the linear model, just as if it were faster. In terms of mechanisms, the present view is that the linear trade-off is descriptive of programmed actions, whereas the logarithmic trade-off is descriptive of actions with programmed initial portions and feedback corrections later. One important modeling effort has used the linear trade-off principles to describe the programmed initial part of slower movements; in these views, visually based corrections may or may not later be used to bring the hand to the target depending on various external constraints on the action.

4. APPLICATIONS

The basic principles of human movement discussed here represent a component human performance that resides at the "lowest" level — the functioning of the effector system itself. Often, these components are ignored in analyses of human errors, as they seem to lie "downstream" from errors in perception, in decision-making and judgement, and other more cognitive aspects of performance that are so critical in some performances. Even so, these low-level processes are important for predicting human performance in tasks for which the perceptual and decision-making aspects are minimized, such as in free-throw shooting in basketball or striking a nail with a hammer. Often, in such cases, these lower-level processes are a primary determinant of success. As well, these processes are useful in the understanding of more complex actions, in which variability in components of actions "sum" to give an indication of the proficiency of the larger performance.

Psychophysiological Fitness for Work

A.Y. Burov
Centre of Ergonomics and Safety, ELAN Ltd, Kyiv, Ukraine

1. INTRODUCTION

The analysis of accidents in power plants shows that one of the main causes of increase of their number is a discrepancy in operators' psychophysiological possibilities and professional demands. The economic losses are stipulated not only for accidents, but also for the uneffient operation of equipment. Besides, the operators who do not have appropriate professional requirements become ill and experience industrial trauma more often. There is a necessity to monitor an operator's psychophysiological professional important qualities (PPIQ) during all stages of his professional life (initial professional selection, periodical and daily check). Such an approach allows not only a reduction of economic damage because of uneffient and mistaken human action, but also prevents the premature aggravation of his health and prematurely leaving the profession.

Ergonomic approaches to the evaluation of operator's fitness to work have typically assumed that the functional characteristics of the operator (e.g., knowledge about task, skill level, information processing capacity, etc.) are invariant. They are assumed to not be influenced by variables such as operator mood state, sleep history, time on task, etc. Research efforts aimed at enhancing the safety and reliability of complex process plant operations have, as a result, focused on the improvement of the technical skills of the operator, as well as by reducing operator requirements by automating processes. In complex technological systems, human involvement in the production of accidents is estimated at between 40 and 60% (power plants) and up to 80% (aircraft accidents). This testifies to the inadequate evaluation of operator efficiency by existing techniques. The monitoring of an operator's physiological parameters during his professional life known to be related to effective skill utilization can be used to enhance system performance. While the requirements for professional knowledge and skills may be defined for various kinds of physical and mental work, the evaluation of their functional state over time suffers from a failure to take into consideration not only levels of psychophysiological parameters, but also changes of state of the operator, especially those occurring over different periods of time (year to year, day to day variation, within work schedule variation, variation produced by changing shifts, etc.). The direct or indirect measurement of psychophysiological changes allows for the evaluation of the structure (or moment to moment state of the operator) of the functional state of the operator, allowing us to predict individual fitness and reliability of the operator for effective work.

The objective is the development of the methodology and applied systems of psychophysiological maintenance of operator's fitness to work during all stages of his professional life in order to reduce human errors and to raise his efficiency.

2. PSYCHOPHYSIOLOGICAL RESEARCH

To make psychophysiological research methods valid in industry it is necessary to convert scientific researches into industrial systems when using new developments in the field of psychophysiological initial professional selection, for example, of operators, and periodical and day-by-day checks of human fitness to work as applications for the industry.

To solve this problem a computer system was developed for psychophysiological researches which could be simply transformed to the industry systems for psychophysiological initial professional selection and periodical and day-by-day checks of operators' fitness to work (Burov 1996). The system is intended for psychophysiological researches and provides:

- the opportunity of running a sequence of the presentation, and dimensioned characteristics of test tasks;
- registration of characteristics of each test task performance;
- registration of physiological parameters;
- synchronization between test tasks and physiological parameters;
- database control; and
- time series analysis and statistical modeling.

To record physiological parameters, a hardware–software complex is used which consists of a set of sensors, multi-channel analog–digital converter, personal computer and software. The software realizes functions of control process of registration, processing and database control of physiological signals realization. In dependence on tasks, the analysis of data received during experimental researches can be conducted in different directions, for example

- assessment of the level of anindividual's psychophysiological parameters in relation to a surveyed group;
- dynamics of psychophysiological parameters during psychological tests performance;
- connection of physiological parameters and parameters of mental activity; and
- study of psychophysiological reaction of a human organism affected by external factors (industrial, household, medical).

The researcher has some flexibility to control the experiment.

The developed interactive display systems (IDS) of psychophysiological security allow the solving of research and assessment problems on the basis of the following principles:

- suitability of using tests to the functions which are investigated;
- ergonomic information display on the screen;
- minimal touch;
- taking into account the time factor;
- taking into account the dynamic of operator's work;
- specialized database management system (DBSM) as a heart of the system; and
- using of external criterion.

3. SYSTEMS FOR INDUSTRIAL USE

The observance of these principles allows the creation of psychodiagnostical systems on the basis of the system of psychophysiological researches as being a specialized variant for decision of concrete psychodiagnostical tasks – a system for initial professional selection, daily and periodic psychophysiological checks. Thus the architecture of the system allows for:

- exception of subsystem for registration of physiological parameters,
- transmission of test control from researcher to the DBSM; and
- storage in the database of only the resulting data and, as the consequence, a more economical use of computer resources.

Such a structure provides the availability of managing the program (monitor); subsystems, ensuring of functions of training, testing, data processing, construction of valuations and of predictive models. The carrying out of all these functions, as well as the functions of database control is executed by specialized DBSM which provides as the integrity of internal database an exchange by data of the system with the external program environment.

The IDS allow one to unify the effect on method and to retain information gained all control stages of functional state (FS) and operator fitness to work (OFW):

- psychophysiological professional selection (with recommendations on teaching individualization);
- periodic psychophysiological control FS and operator OFW including monitoring of professional aging;
- daily (preshift) check of professional OFW of operator in "regular" routines;
- daily (intra-shift) check of professional OFW of operator in extreme routines;
- means of functional rehabilitation (psychophysiological correction of functional operator's state);
- training process support included in teaching means; and
- PPIQ's training with specialized psychological playing simulators.

All IDS are intended to work in real-life conditions and can be combined with automated systems and do not need such as supplementary personnel specialists from medical and psychological services.

The systems of initial psychophysiological selection are aimed to estimate unspecific professionally important qualities which make possible (or prevent) good work in the profession. The means and estimation methods must be sufficient to make a decision concerned with potential professional fitness.

The periodical check systems must make possible the estimation of characteristics and personality, and are used periodically (once a year). Time of inspection can be considerable (> 1 h), but the inferences of status must be sufficient to make a decision concerning renewal options of the professional activity.

Systems for initial psychophysiological selection and periodic checks can use objective medical-biological and psychological information concerning the human state in psychophysiological parameters registered by special apparatus in laboratory conditions.

Daily pre-shift and intra-shift check. The pre-shift psychological check must be directed at revealing unfitness for professional activity affected by functional (inconstant) changes in the physiological or psychological status of individual.

An intra-shift psychophysiological check must be directed at the clearing up of any psychophysiological activity dysfunction. The means and methods of verification of this must be effected without reduced professional activity, but be sufficient for the possibility of its continuation on the right levels.

The means and methods of functional rehabilitation must restore the functional abilities which were decreased as result of profes-

sional activity. Such methods can include diverse exercises and measures on renewal of health, and also the full arsenal of physio- and psychotherapeutic means.

At present, to realize this approach were developed and used systems of industrial purpose:

- for a psychophysiological initial professional selection;
- for a periodical check; and
- for a daily check.

The systems permit the evaluation of the reliability and efficiency of the operator's work, as well as to construct the prognosis of changes of these parameters during his professional activity. The results of valuation and prognosis allow either an unreliable operator not to work or to increase his reliability and fitness to work and make preventive measures for accident precautions.

Psychophysiological initial professional selection (Burov 1995). The efficiency of an operator's work depends not only on his professional knowledge and working conditions, but also on the conformity of psychophysiological features of a person to the requirements of his profesion. As the results of preliminary researches have shown, the following structure of tests for determination of the professional fitness group of the operator is optimum: structure of personality, structure of intelligence, an individual's psychodynamic features, and his bent for either kinds of mental activity. The most informative parameters of efficiency of tests performance are included in the model of a "standard operator" enabling the psychophysiological prediction of the group of the professional fitness of a candidate.

Periodical check. The periodical check is intended for a valuation of changes of PPIQ which vary evaluation of slowly, that permits the moment when the operator needs to do some rehabilitation steps or when it is necessary for him to be prepared to leave his profession, if irreversible age-related changes occur. With this purpose the system of valuation of operators' professional aging rate is used (Burov and Chetvernya 1996a, b). The results of valuation of staff's professional age are presented as an integrated age value, which is calculated by the chosen model, as well as an "age profile", which is a vectorial diagram of main parameters determining biological and professional human age.

The daily check (Burov 1997). This is used by the system of valuation of an operator's functional state and for the prediction of professional fitness to work in the workplace which is a method of providing feedback to an operator, enabling him to make necessary changes in case of deviation from his individual "norm." The following tasks are solved in the system:

- development of objective methods of valuation of a human's psychophysiological condition in a relation to norm;
- individual approach to valuation of human's serviceability that is a construction of the individual psychophysiological norm, instead of the group's one; and
- development of organization-technical aspects of valuation's use.

The system allows:

- economical running of the technological object (power industry, aviation);
- economy of energy resources;
- to increase of operators' professional "longevity";
- to do the system as a self-adjustment. It forms automatically the individual "norm" of operator's working ability; and
- to achieve a high precision of prognosis (85–90%).

The use of the systems allows the monitoring of the operator's psychophysiological fitness to work on all stages of his professional life to secure the necessary level of the human–technical system's effectiveness.

Push and Pull Data

B. J. Daams

Delft University of Technology, Department of Industrial Design Engineering, Jaffalaan 9, 2628 BX Delft, The Netherlands

1. INTRODUCTION

The amount of force that must be exerted on or with a product is important to the perception of the consumer and to the product satisfaction (or especially to the dissatisfaction if the product does not fulfil its task properly). The importance of force exertion in product design is discussed here and in Chapter XX.

When designing for force exertion, a few steps must be taken to get a good result. First, the problem has to be defined the right way during the information stage. Second, an ergonomically sound concept should be developed in the concept stage with the help of global information (rules of thumb) on force exertion. Third, the actual size of maximal and/or minimal forces should be determined in the detailing stage.

Thus, the information needed for the design consists of two parts:
- general information (rules of thumb) for the early stage of design; and
- detailed information (exact forces) for the detailing stage of design.

These rules of thumb are important, because they force the designer to think about a good design concept. If no effort is put in at this first stage, it is no use detailing a basically bad ergonomical design. Rules of thumb can be found in Chapter XX, together with examples of product design. Also, some tips on measuring force exertion for design purposes are given.

After the concept phase of the design, the details should be looked into. How much force can the envisaged user group exert? Or better, how much force can the weakest users exert? This question must preferably be answered by research, but usually there is lack of time, money and/or interest to do so. Therefore, the question about the force that can be exerted can only be answered by literature. Adequate information on force exertion in literature is very scarce, because a situation in which force exertion is investigated seldom corresponds with the situation in which a product is expected to be used, and even less with the real situation. For an attempt to gather design-relevant information and to present it in a way that makes it useful for the designer, see Daams (1994). A choice from these tables are given in this article and in Chapter XX. This chapter comprises the pushing and pulling forces of adults, children, the elderly and the disabled.

2. OVERVIEW OF THE DATA

2.1. Maximal and Comfortable Force

Although the object was to gather a variety of data for this collection, only information on static force exertion could be found. Nearly all investigations concerned maximal force. Only Kanis (1989), Schoorlemmer and Kanis (1992) and Daams (1994) measured comfortable force exertion. Daams (1994) also measured maximal endurance times of submaximal forces.

2.2. Posture

Data on pushing and pulling in free posture can be obtained from Daams (1993) and Steenbekkers and van Beijsterveld (1998). The other investigations concern force exerted in standardized postures.

2.3. Support

Van de Kerk and Voorbij (1993) measured standing force exertion with feet support. Caldwell (1962) investigated the influence of back supports at various heights.

2.4. Fingers

Most push and pull forces are exerted using the whole hand. Kanis (1989) and Steenbekkers (1993) measured push force with the forefinger. Push force with the thumb was measured by Kanis (1989) and Schoorlemmer and Kanis (1992). Pull force with forefinger and thumb was measured by Fothergill *et al.* (1992) and Steenbekkers (1993). Maximal finger forces are in general smaller than maximal forces exerted with the whole hand.

2.5. Laterality

In most cases, the strength of one hand was measured. Force exertion with two hands was measured by Frank *et al.* (1985) in sitting position, and by van de Kerk and Voorbij (1993) in both standing and sitting position.

2.6. Sex

Information on women's force exertion is in Daams (1993 and 1994), Thompson *et al.* (1975), Fothergill *et al.* (1992), Kanis (1989), Schoorlemmer and Kanis (1992) and Steenbekkers and van Beijsterveld (1998), who measured both sexes. Frank *et al.* (1985), Steenbekkers (1993) and van de Kerk and Voorbij (1993) investigated both boys and girls.

2.7. Children

Frank *et al.* (1985) investigated push and pull forces exerted by two groups of children, at 5.5–8.5 and 10–13 years old respectively. Push and pull exerted with hand and with fingers by Dutch girls and boys aged from 4 to 13 years are measured by Steenbekkers (1993). Push and pull in sitting and standing posture by girls and boys aged 4–12 years was investigated by van de Kerk and Voorbij (1993). Bovend'eerdt *et al.* (1980) measured the pull force of children from 12 to 18 years old.

2.8. Healthy Adults

Forces exerted by healthy adults were measured by Daams (1993, 1994), Kroemer (1968), Rohmert (1988), Caldwell (1962), Fothergill *et al.* (1992) and Schoorlemmer and Kanis (1992). In these investigations, relatively young adults are used with an average age of 23–30 years. An exception is Schoorlemmer and Kanis (1992) whose subjects have an average age of 49 years.

2.9. Elderly

Forces in various directions exerted by the elderly aged 60–75 were measured by Thompson (1975). Steenbekkers and van Beijsterveld (1998) measured maximal grip force, push, pull and torque for various age groups from 50 to > 80 as well as for a group of young people.

2.10. Disabled

Kanis (1989) investigated forces exerted by arthritic persons and those suffering from muscle diseases. Schoorlemmer and Kanis

(1992) looked into push force with the thumb, exerted by healthy people and persons suffering from various diseases. They both measured female and male subjects.

2.11. Summary

The information gathered should preferably be summarized to facilitate comparison. However, this is not possible because all experiments describe and prescribe posture in different ways. This makes plotting of various results in one figure, or even a comparison of some of the values, virtually impossible.

For push and pull in standing posture, maximal forces exerted in free postures are higher than maximal forces exerted in standardized postures. Maximal forces exerted while standing with the feet close together are lower than those with one foot in front of the other. Maximal forces exerted with two hands are larger than those exerted with one hand, although usually less than twice as much.

3. PUSH AND PULL DATA

3.1. Bovend'eerdt (1980)

3.1.1. Subjects
- Number: 6000.
- Sex: girls and boys.
- Age: 12–18 years.
- Other characteristics: –

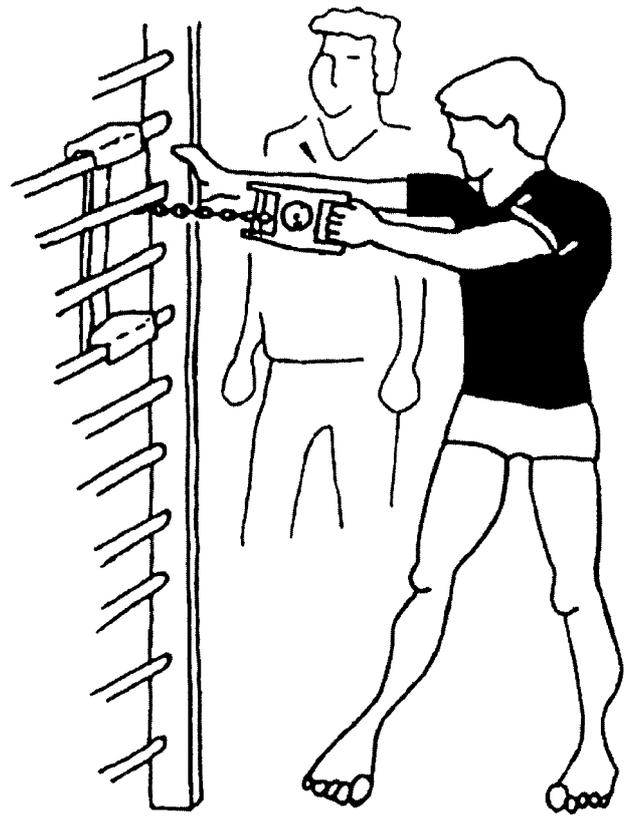
3.1.2. Method
- Direction of force: pull.
- Posture: standing. The instruction for the subject was the following: "stand with legs apart, with the shoulder of the strongest arm furthest removed from the wall bars. Lean with your 'weak' hand horizontally and with the arm stretched against the wall bars. Grasp the dynamometer with your strongest hand, thumb up. At my sign, start pulling. Do not use your weight. Your weak hand should stay on the bar during pulling".
- Sort of force: maximal static force.
- Laterality: the strongest arm.
- Measurement: on a given sign, subjects should pull as hard as possible. The score is the best of two trials.
- Sort of handle: a dynamometer, see figure.
- Size of handle: ?
- Position of handle: at shoulder height, see figure for orientation.
- Other characteristics: the measurements were carried out in a gymnasium with wall bars.


Figure 1. Posture during the experiment (Bovend'eerdt 1980).

For results; see Table 1.

Table 1. Pull (N), categories of percentiles of girls and boys of various ages (Bovend'eerdt 1980).

3.2. ⚡ Daams (1993)

3.2.1. Subjects

- Number: 20.
- Sex: 10 female, 10 male.
- Age: average 23 years (SD 4).
- Other characteristics: mainly healthy students of Delft University.

3.2.2. Method

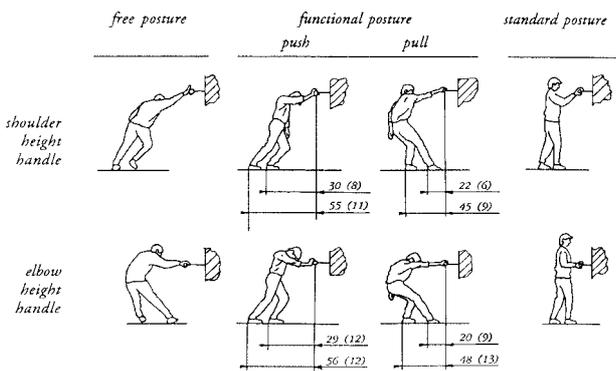
- Direction of force: push and pull (only horizontal components measured).
- Posture: see figure, standing in: free posture; functional posture: position of feet determined; standard posture: one foot 30 cm in front of the other, elbow in 90° flexion.
- Sort of force: maximal static force exertion.
- Laterality: the preferred hand.
- Measurement: duration 6 s, the score is the average of the last four, the average of two trials.
- Sort and size of handle: push: doorknob, round model, Ø 59 mm, slightly convex; pull: bar Ø 32 mm.
- Position of handle: at shoulder height, elbow height, 0.70, 1.30 and 1.70 m.
- Other characteristics: non-skid flooring was used.


Figure 2. Postures during the experiment, three types of posture and two handle heights (Daams 1993). Functional posture: horizontal distance from heel to vertically projected position of handle is expressed in percentage of body height.

For results; see Table 2.

Table 2. Push and pull (N), averages and SD of 10 women and 10 men (Daams 1993).

Results

3.3. ⚡ Kroemer (1968)

3.3.1. Subjects

- Number: 30–43, varying per condition.
- Sex: male.
- Age: adults.
- Other characteristics: –

3.3.2. Method

- Direction of force: push.
- Posture: see figures.
- Sort of force: maximal static force.
- Laterality: see figures and tables.
- Measurement: ?
- Sort of handle: force plate, 20 cm high _ 25 cm long.
- Size of handle: –
- Position of handle: vertically oriented, height of center of force plate: see tables.
- Other characteristics: all conditions include a structural support to 'push against'.

For results; see Table 3.

3.4. ⚡ Rohmert et al. (1988)

3.4.1. Subjects

- Number: 21.
- Sex: male.
- Age: average 23.6 (SD 3.1).
- Other characteristics: body height: average 180.2 cm (SD 8.1); body weight: average 70.6 kg (SD 9.6).

3.4.2. Method

- Direction of force: push, pull, lift, press, and forces in various other directions in the sagittal plane.
- Posture: standing, with the handle at shoulder height at a

Table 3. Push (N), average and SD of males. *Not indicated in literature. However, the sizes of the exerted forces indicate that both hands exert them (Kroemer 1968).

Results

posture		height of centre of force plate	horizontal distance between force plate and vertical support	exerted force

distance of 80% of arm reach, and the feet in a fixed position (see figures, a = 0 and 80%).

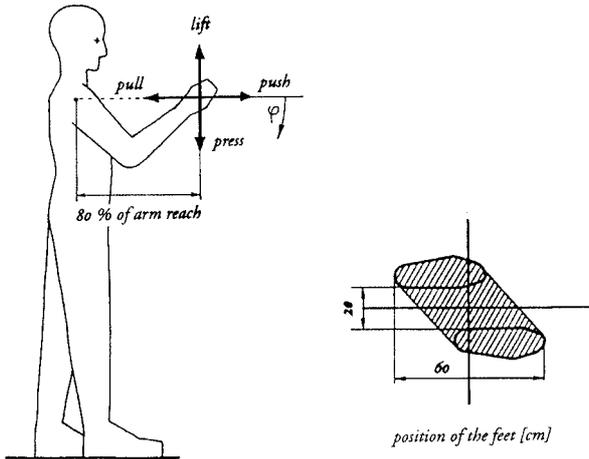
- Sort of force: maximal static force.
- Laterality: one or two hands? (the exerted forces are limited by the posture, so this may not affect the results).
- Measurement: ?
- Sort of handle: ?
- Size of handle: ?
- Position of handle: at shoulder height, at a distance of 80% of arm reach.
- Other characteristics: –


Figure 3. Posture during the experiment (Rohmert *et al.* 1988).

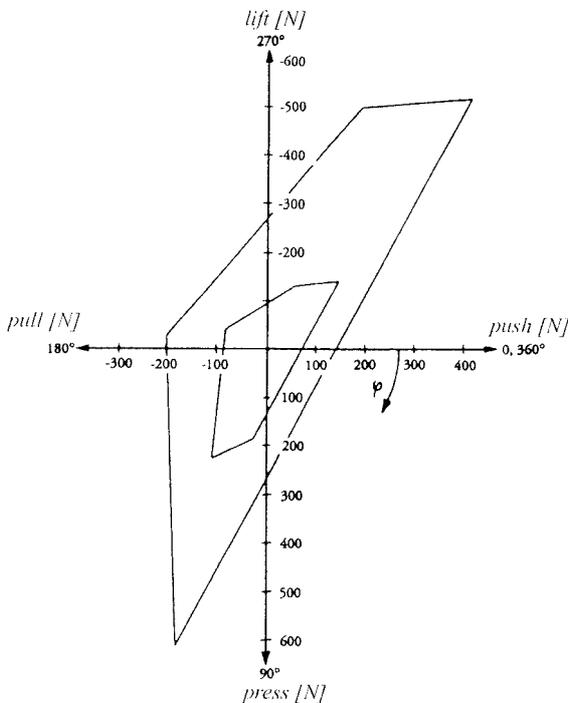
For results, see Figure 4.


Figure 4. Push, pull, lift, press and forces in various other directions in the sagittal plane (N). Range of 21 men. The inner contour represents the minimum maximal force, the outer contour represents the maximum maximal force (Rohmert *et al.* 1988).

3.5. Thompson (1975)

3.5.1. Subjects
- Number: 100.
- Sex: 62 female, 38 male.
- Age: 60–65 years: 22 female, 13 male; 66–70 years: 23 female, 14 male; 71–75 years: 17 female, 11 male.
- Other characteristics: subjects were selected locally at random from elderly persons within this age range who were living in unassisted occupation of a dwelling. However, preliminary screening eliminated from selection those with any indication of coronary disease.

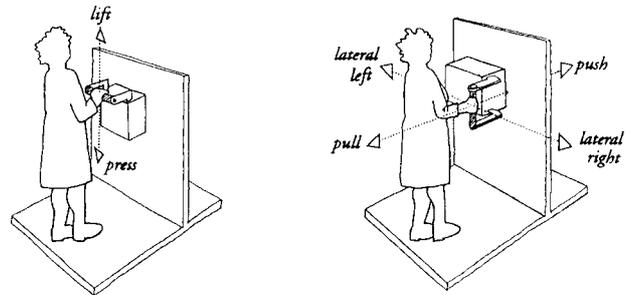
3.5.2. Method
- Direction of force: push, pull, to the left, to the right, lift and press.
- Posture: a line was drawn on the floor in line with, and vertically beneath, the handle of the apparatus. The subject's leading foot was positioned on this line to ensure maximum force application. Apart from this positioning, subjects were allowed to adopt whatever stance was natural to them.
- Sort of force: maximal static force.
- Laterality: the dominant hand.
- Measurement: subjects were told to exert force as hard as they could until they felt they had reached their maximum, and they were then to release the handle. The highest value of three trials is the value used for computation of the strength data.
- Sort of handle: for push, pull, to the left and to the right: handle in vertical position.
- for lift and press: handle in horizontal position.
- Size of handle: handle Ø 3.2 cm.
- Position of handle: 0.83, 1.0, 1.3 and 1.6 m above the floor.
- Other characteristics: –


Figure 5. Postures during the experiment (Thompson 1975).

For results; see Table 4

Table 4. Various forces (N) exerted on a handle at various heights. Averages, SD, ranges and 5th percentiles of 62 elderly women and 38 elderly men.

3.6. van de Kerk & Voorbij (1993)

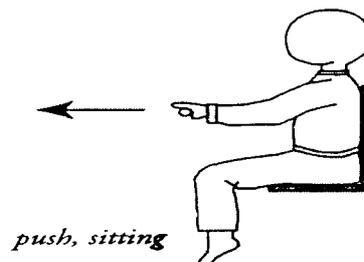
3.6.1. Subjects
- Number: total 203.
- Sex: 95 girls, 108 boys.
- Age: 4–12 years.
- Other characteristics: –

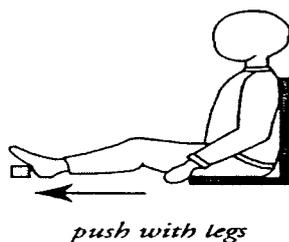
3.6.2. Method
- Direction of force: push and pull.
- Posture: standing and sitting, see figures.
- Sort of force: maximal static peak force.
- Laterality: two-handed.
- Measurement: sudden peak force was measured. The children were encouraged during the measurements.

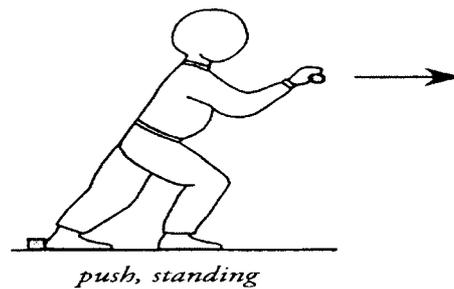
pull, standing

push, standing

push with legs

push, sitting






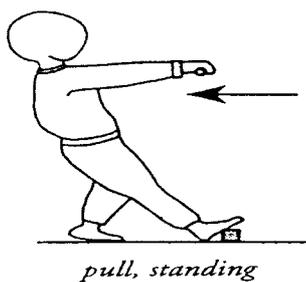


Figure 6. Postures during the experiment (van de Kerk and Voorbij 1993).

- Sort of handle: a cylindrical bar.
- Size of handle: Ø 3 cm.
- Position of handle: see figures.
- Other characteristics: –
  For results; see Table 5.

3.7. ⌐→ Caldwell (1962)

3.7.1. Subjects

- Number: 9.
- Sex: probably men.
- Age: average 24 years, range 22–26.
- Other characteristics: body height: average 174.6 cm, range 1647.6–188.6 cm; body weight: average 71.7 kg, range 57.6–88.4 kg.

3.7.2. Method

- Direction of force: push.
- Posture: sitting, knee angle 140°, with five different elbow angles: 60, 85, 110, 135 and 160°.
- Sort of force: maximal static force.
- Laterality: probably one (the right) hand.
- Measurement: each trial lasted 7 s. The subject was told to push as hard as he could on the handle and to reach maximum output in ~3 s.

- The subject was instructed to note his peak output on the meter and to do his best to exceed this on the next trial. The first trial of each pair was used as a 'motivator'. The results presented are based only on the second trials.
- Sort of handle: ? see figure.
- Size of handle: ?
- Position of handle: at shoulder height, at a horizontal distance changing with the elbow angle (see posture).
- Other characteristics: five backrest conditions were included:
1. No backrest.
2. Backrest height 20% of shoulder height.
3. Backrest height 40% of shoulder height.
4. Backrest height 60% of shoulder height.
5. Backrest height 80% of shoulder height.

A footrest was provided.

Table 5. Various forces (N), averages of girls and boys between 4 and 12 years old (van de Kerk and Voorbij 1993).

force and posture	age [years]	girls				boys

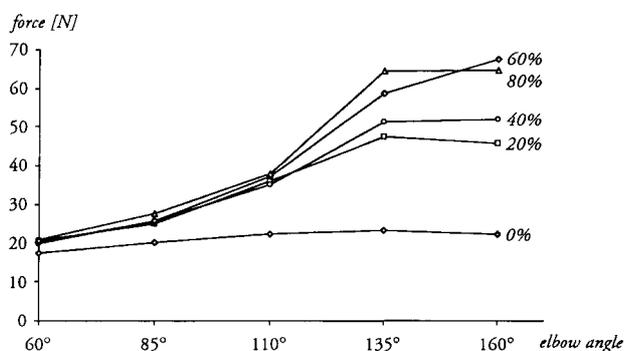
80%	20.9	27.5	37.9	64.4	64.8	43.1


Figure 8. Arm extension force (N) at five elbow angles with different backrest positions. Averages of nine subjects (Caldwell 1962).

3.8. Daams (1994)

3.8.1. Subjects
- Number: 24 for maximal force and endurance measurements, 17 for discomfort measurements.
- Sex: maximal force and endurance: 12 female, 12 male; discomfort: eight female, nine male.
- Age: average 28.2 years (SD 11.2).
- Other characteristics: university students and staff.

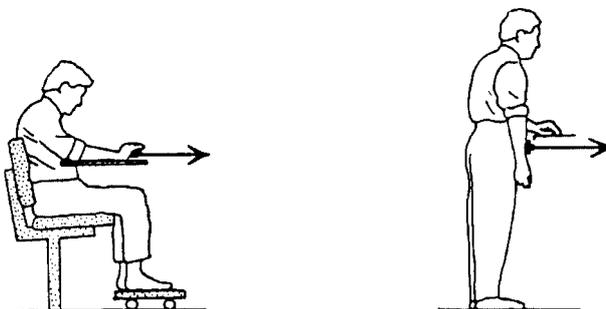
3.8.2. Method
- Direction of force: push.
- Posture: maximal force and endurance: sitting and standing, see figures;
- discomfort: sitting.
- Sort of force: maximal static force, endurance and discomfort of submaximal static force. 'discomfort' is measured as the time to the first change of hand when maintaining a submaximal push force with one hand.
- Laterality: maximal force and endurance: non-preferred hand sitting, preferred hand standing;
- discomfort: alternating, starting with the preferred hand.
- Measurement: duration of maximal force: 2 s build up, 4 s maximal force.
- Duration of endurance: measurement limit 30 min. Duration of discomfort measurements:
1. At 80% of maximal force 69 s.
2. At 60%: 144 s.
3. At 40%: 282 s.
4. At 30%: 474 s.
5. At 20%: 1170 s.
6. At 15%: 1800 s (30 min).
- Sort and size of handle: sitting: a slightly convex doorknob, round, Ø 59 mm. Force is exerted with the hand; standing: a metal plate covered with soft plastic, size 13.5 _ 4 cm. Force is exerted with the distal part of the lower arm.
- Position of handle: see figure.
- Other characteristics: –


Figure 9. Postures during the experiment (Daams 1994).

For results; see Tables 7–9 and Figure 10.

Table 7. Push (N), maximal forces exerted sitting and standing, averages and SD and numbers of measurements of 12 women and 12 men (Daams 1994).

	females			males			both

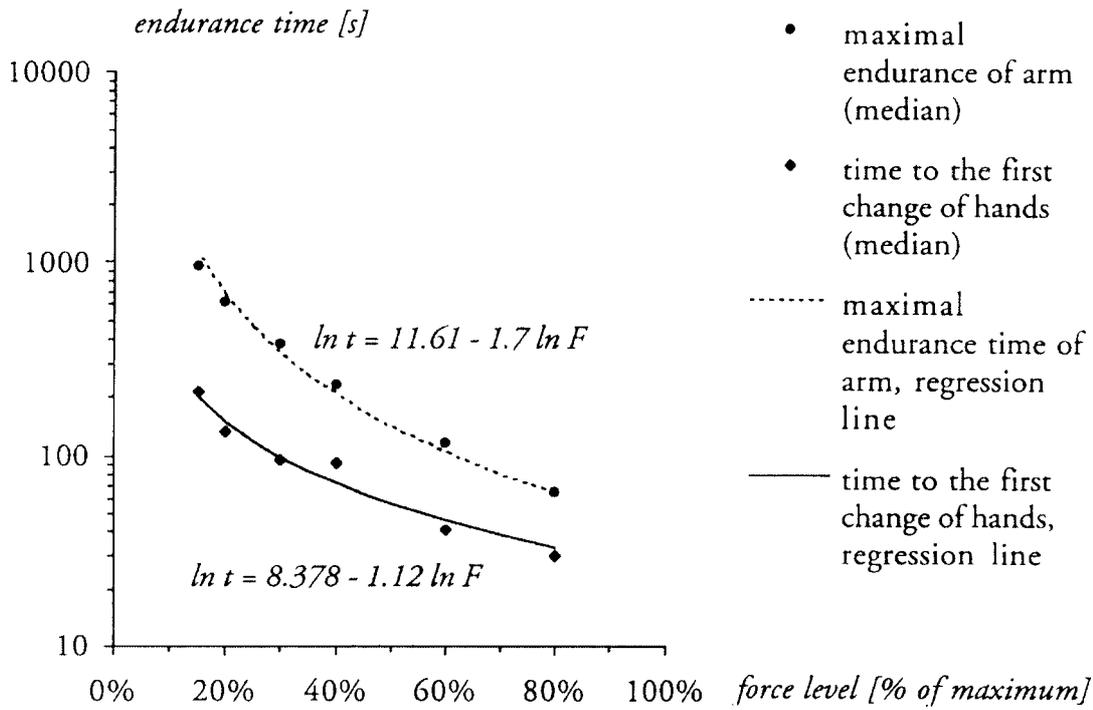

Figure 10. Medians and interpolations of maximal endurance time and time to the first change of hand (s), for arms only (Daams 1994).

3.9. 🏃↔ Frank et al. (1985)

3.9.1. Subjects

- Number: 59.
- Sex: youngest group: 13 girls, 18 boys; oldest group: 14 girls, 14 boys.
- Age: youngest group: 5.5–8.5 years; oldest group: 10–13 years.
- Other characteristics: length and length/weight ratio are sufficiently representative for Dutch children.
- Body height, youngest group: average 125.6 cm (SD 6.7); oldest group: average 149.1 cm (SD 8.5); body weight, youngest group: average 24.6 kg (SD 3.9); oldest group: average 39.1 kg (SD 8.1).
- Distance of back to feet when the knees are at an angle of 110°: youngest group: average 59.1 cm (SD 6.1); oldest group: average 76.9 cm (SD 7.4).

3.9.2. Method

- Direction of force: push and pull.
- Posture: sitting in an experimental situation similar to a 'Vliegende Hollander' (Flying Dutchman, children's vehicle propelled by pushing and pulling with arms and upper body), see figures.
- Two different postures: with knees at an angle of 110° and at an angle of 160°. Apart from this, the posture was free.
- Sort of force: maximal static force.
- Laterality: both hands.
- Measurement: ?
- Sort of handle: a cylindrical bar.
- Size of handle: ?
- Position of handle: see figure, height not known.

- Other characteristics: a foot support was provided, to push against.

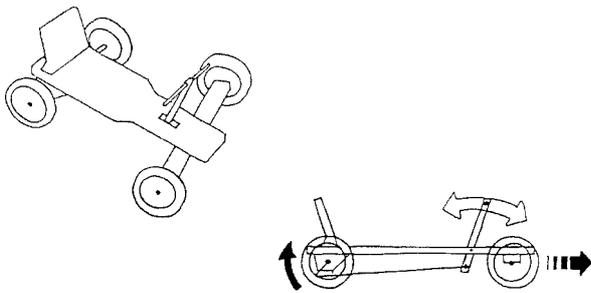
posture during push   *posture during pull*


Figure 11. Postures during the experiment (Frank *et al.* 1985).

For results; see Table 10.

Table 10. Push and pull (N), average, SD and percentiles of children (Frank *et al.* 1985).

Results

age	n	force	x	s	P5	P95
5.5–8.5 years	31	push	151.9	33.7	96.3	207.6
		pull (knee 110°)	333.9	103.3	163.4	504.4
		pull (knee 160°)	373.4	82.1	237.9	508.9
10–13 years	28	push	230.5	57.2	136.1	324.9
		pull (knee 110°)	573.9	159.1	311.3	836.4
		pull (knee 160°)	603.6	133.8	382.8	824.4

3.10. Steenbekkers (1993)

3.10.1. Subjects
- Number: 782.
- Sex: 392 girls, 390 boys.
- Age: 4–13 years.
- Other characteristics: Dutch children, selected to be representative for the Netherlands.

3.10.2. Method
- Direction of force: push and pull with hand and fingers.
- Posture: sitting before the measuring device, which is in front of the forearm. The forearm is horizontal and in a sagittal plane. Upper arm and forearm are at an angle of about 150°. The legs hang down freely or are positioned forward: (a) pulling with the hand: the bar is placed vertically, its axis between middle finger and ring finger; (b) pulling with thumb and forefinger: the finger is placed on top of a round knob, the thumb is on the bottom of the knob. The other fingers are flexed into a fist; (c) pushing with the hand: force is exerted with the palm of the hand; (d) pushing with the forefinger: the finger is placed in the middle of a round concave knob. The other fingers and the thumb are flexed into a fist.

- Sort of force: maximal static force.
- Laterality: preferred and non-preferred hand (they are not significantly different and therefore represented in one table).
- Measurement: duration 3 s.
- Sort and size of handle: (a) vertical bar, Ø 1.1 cm; (b) round concave knob, Ø 2 cm; (c) round convex knob, Ø 4 cm; (d) round concave knob, Ø 2 cm.
- Position of handle: mounted on a table.
- Other characteristics: –

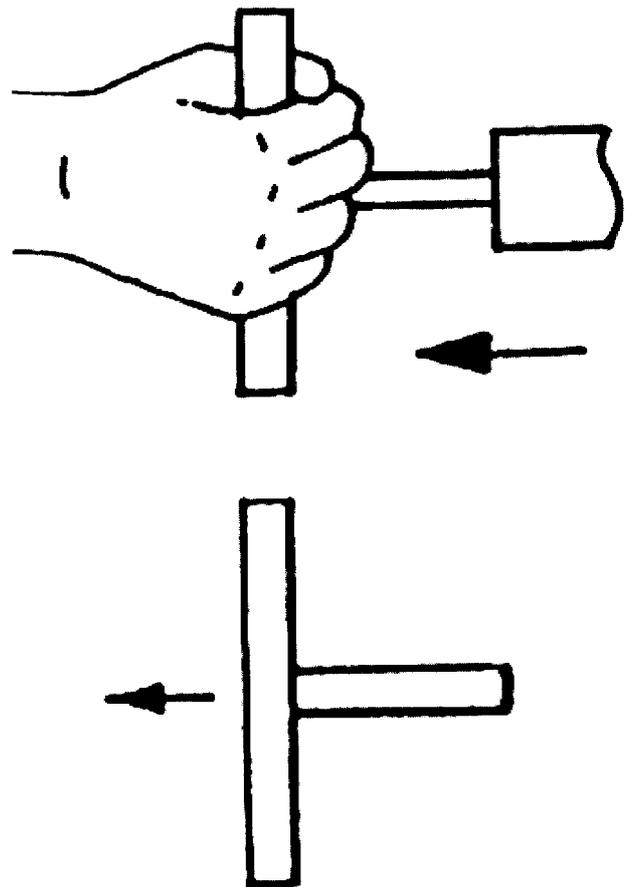
For results, see Figures 12–15 and Tables 11–14.


Figure 12. Posture during experiment A (Steenbekkers 1993).

3.11. ✏ ⫞ ert Icon K> Fothergill et al. (1992)

3.11.1. Subjects

- Number: 30.
- Sex: 16 female, 14 male.
- Age: average 30.0 (SD 8.2).
- Other characteristics: volunteer staff and students: body height: average 170.4 cm (SD 9.6); body weight: average 67.5 kg (SD 9.4).

3.11.2. Method

- Direction of force: pull.
- Posture: standing. The type of grip on each handle and the posture adopted were freely chosen, provided that (1) only the dominant hand was used on the handle/bar; (2) only the feet made contact with the floor; and (3) the leading foot was not placed in front of the handle.
- Sort of force: maximal static force.
- Laterality: the dominant hand.

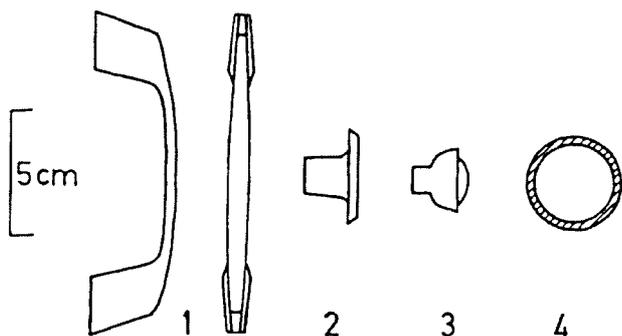
- Measurement: subjects were instructed to exert a steady maximal pull on each handle for 5 s, in a direction as close to the horizontal plane as possible. For each measurement, peak force was determined and steady pull strength was calculated from a 3-s average.
- Sort and size of handle: three handles and one bar were used (see figure).
- Position of handle: two handle heights: 1.0 and 1.75 m.
- Other characteristics: the floor was covered with a coarse emery paper to prevent slipping. Subjects wore their normal everyday footwear. The majority wore rubber soled shoes or trainers.


Figure 16. Side views of the four handles used in this study (the front view for handle 1 is also shown). Handles 1 and 2 were cast alloy, handle 3 was of Bakelite, and handle 4 was a mild steel bar (Fothergill *et al.* 1992).

For results; see Table 15.

3.12. Kanis (1989)

3.12.1. Subjects
- Number: 34.
- Sex: 28 female and six male.
- Age: average 54 years (SD 14.2).
- Other characteristics: 28 arthritic subjects (24 women, four men) and six subjects (four women, two men) with a muscle disease.

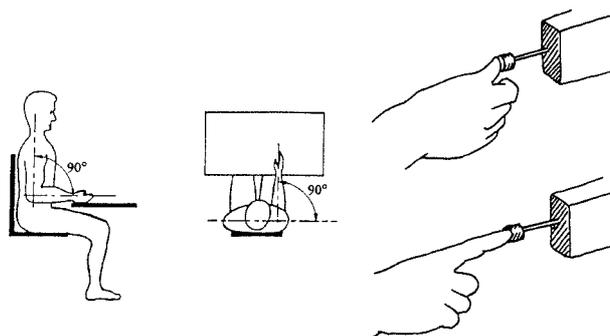
3.12.2. Method
- Direction of force: push with thumb and push with forefinger.
- Posture: sitting, with the elbow 90° flexed; see figures.
- Sort of force: maximal and comfortable static force. "Comfortable" refers to a level of pain or fatigue found acceptable by the subject.
- Laterality: preferred hand.
- Measurement: subjects were instructed to build up their force gradually and to hold the maximum force for at least a few seconds.
- Sort of handle: plastic cylinder.
- Size of handle: height 15 mm, Ø 20 mm.
- Position of handle: mounted on a table.
- Other characteristics: –


Figure 17. Posture during the experiment (Kanis 1989).

For results; see Table 16.

3.13. ☞ Schoorlemmer and Kanis (1992)

3.13.1. Subjects
- Number: 27.
- Sex: 21 female, six male.
- Age: average 49.4 years (SD 17.4)
- Other characteristics: average body height 165 cm (SD 12), average body weight 67 kg (SD 12). Twelve healthy subjects, five spastics, four visually impaired, three blind subjects, three subjects with Parkinson's disease.

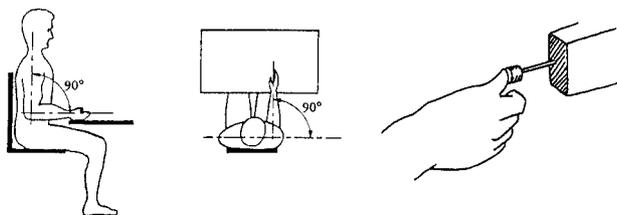
3.13.2. Method
- Direction of force: push with the thumb.
- Posture: sitting, with the elbow 90° flexed (see figures) and in free posture.
- Sort of force: maximal and comfortable static force. 'Comfortable' refers to a level of pain or fatigue found acceptable by the subject.
- Laterality: left and right hand (averaged in the table).
- Measurement: subjects were instructed to build up their force gradually and to hold the maximum for at least a few seconds.
- Sort of handle: plastic cylinder.
- Size of handle: height 15 mm, Ø 20 mm.
- Position of handle: mounted on a table.
- Other characteristics: –


Figure 18. Posture during the experiment (Schoorlemmer and Kanis 1992).

For results; see Table 17.

3.14. ⊢→ ⊢ Steenbekkers and van Beijsterveld (1998)

3.14.1. Subjects
- Number: several hundreds; see tables.
- Sex: women and men; see tables.
- Age: 20 to > 80, divided in nine different age groups; see tables.
- Other characteristics: Dutch adults and elderly, selected to be representative for the Netherlands.

3.14.2. Method
- Direction of force: push (with two hands); pull (with one hand).
- Posture: the subject stands before the measuring device and adopts a free posture, see figure.
- Sort of force: maximal static force.
- Laterality: pushing with both hands; pulling with one hand (own choice).
- Measurement: duration 3 s.
- Sort and size of handle: for pushing: a horizontal bar, Ø 3.0 cm; for pulling a horizontal bar, Ø 3.2 cm (see figure).
- Position of handle: at elbow height standing.
- Other characteristics: –

Table 17. Push (N) with the thumb. Averages and SD of 12 healthy and 15 impaired subjects (Schoorlemmer and Kanis 1992).

Pushing and Pulling Strengths

S. N. Imrhan

Industrial and Manufacturing Systems, Engineering Department, University of Texas, Arlington, TX 76019, USA

1. INTRODUCTION

Pushing is the act of applying a muscular force in a direction away from the body; pulling is the opposite. Directions oblique to the trunk may be regarded as push or pull depending on the direction of the resultant force. In some cases the distinction between a pull and a lift may not be clear, as when extending the arm in front the body and gripping and raising an object from below the shoulder. A pull is almost always characterized by grasping the object, except in rare cases as when using a hook grip. A push may be applied with or without a grasp, as when the palmar surface of the open hand and fingers makes contact with the wall of a large box. The hand-handle contacts during pushing or pulling vary considerably but, for convenience, they may be classified into three main types: (i) full-hand power grasping, (ii) finger pinch grasping, and (iii) flat hand contact.

Pushing and pulling are executed for either moving an object from a state of rest or accelerating it from a state of constant motion (dynamic exertion), or stabilizing it (static exertion). Push forces may be exerted by any part of the body but only hand pushing/pulling have been identified as workplace activities of enough frequency or importance for ergonomic investigation.

Depending on the workspace design and muscular strength requirements, pushing/pulling tasks in the workplace may be performed in a variety of postures, among the most common are standing erect, stooping, squatting, kneeling, sitting, and lying down, and they may be performed with one hand or both hands. Thus any discussion of push/pull strengths must specify the posture and hand-object coupling characteristics clearly.

Push/pull activities occur in a wide variety of tasks; they assume importance when push/pull muscular strengths may be inadequate for a task and may result in (i) failure to accomplish the task properly, (ii) impairment to health (such as cumulative strains), or (iii) unsafe work conditions. Push/pull strengths have been investigated to determine the strength capabilities of people while pushing or pulling under a variety of conditions. In some of these studies the variables were experimentally controlled whereas others have simulated in industrial tasks. The essence of their results is briefly discussed in this article. More details may be obtained from my literature review (Imrhan 1999) or from the individual studies listed there.

2. FACTORS INFLUENCING PUSH/PULL STRENGTHS

Push or pull strength may be defined as the maximum force that a person can generate at the interface of the body (usually the hand) and the object being pushed or pulled. It is usually measured at this interface as the peak or mean force from a maximal voluntary push/pull (MVC) exertion lasting about 4–6 s under specified conditions. (An MVC exertion implies the maximum effort a person is willing to produce without pain or significant discomfort.) The mean is usually taken as the average force within the middle 3 s. Push/pull strengths, like almost all types of muscular strength, are influenced significantly by a number of factors relating to (i) the type of task, (ii) the method of performing the task, (iii) work equipment, and (iv) personal characteristics (e.g., body size and weight).

The degree of influence has been investigated for many factors, including type of exertion (static or dynamic), number of hands performing the exertion, general body posture, handle characteristics, hand–handle interface characteristics, use of gloves, height of application of the forces by the hands, distance between the object or handle and the body (or reach distance), direction of force application, frequency of force application, endurance, body support characteristics, foot–floor or shoe–floor traction, speed of motion of the body or hands, environmental stressors, and characteristics of the person. An understanding of how these factors influence push/pull strength can help practitioners in reducing, minimizing, or eliminating strains; this may help to improve work and workplace design, or equipment design. These influences are discussed below. To clarify the conditions of pulling, "strength" in these discussions will refer to static push/pull exertions while standing, unless otherwise stated.

2.1. Body Posture

A comparison of all the major body postures in similar push/pull conditions has never been investigated. Hence comparisons are related only to conditions that have been tested (Table 1). These comparisons indicate significant differences among different working postures and in variations within each posture, such as standing and leaning backward, standing and leaning forward, and sitting. Results indicate that (i) in general, two-handed hor-

Table 1. Average push/pull force ranges from experimental studies

Type of strength	Posture	Male force (N)	Female force (N)
Two-handed static push	Standing	400–620	180–335
Two-handed static pull	Standing	310–370	180–70
Two-handed dynamic pull	Standing	200–290	170–430
Two-handed dynamic push	Standing	225–500	160–180
One-handed push/pull	Standing	70–327	70–327
One-handed push/pull	Sitting with restraints	350–540	335–673
One-handed pull	Lying down prone	270–283	270–283
One-handed push	Lying down prone	285–330	285–330

izontal push and pull strengths were slightly greater when standing, but kneeling strengths may be greater for some positions of the arm; and (ii) for one-handed pull strength, standing strength was 37% greater than sitting strength.

The postures associated with the greatest strength are those which allow the body (i) to capitalize on the leverages about various joints, (ii) to use the body weight for enhancing push/pull force, and (iii) to maintain stability. Spreading the legs, one in front of the other, will allow greater pull or push strength than keeping them together; and kneeling on one knee is also likely to produce greater strength than standing with the feet together. More specifically, research has shown that pushing is strongest when the person leans forward with the pivoting (rear) foot behind the body's center of mass, and pulling is strongest when the pivoting (front) foot is in front of the center of mass. Also, push strength seems to be as great as or greater than pull strength when the feet are spread one in front of the other but are about the same when the feet are together.

2.2. Height of Pushing and Pulling

The height of the hand above the feet that produces the greatest strength depends strongly on body posture and degree of leaning forward or backward. In general, however, the best height for two-handed pushing while standing is between the elbow and hip; this is true whether pushing horizontally or at an angle to the horizontal. The best height for pulling is between hip and knee. Pushing upward with the hand above the shoulder or pulling upward with the hand below the elbow generates greater forces than with the hand in other positions because these forces are enhanced by the reactive forces of the feet on the floor (while standing) or buttocks on a seat (while sitting). More specific information on these heights depends on other factors, such as type of exertion (static or dynamic), elbow angle, foot–floor traction, etc.

2.3. Foot and Hand Reach Distances

The degree of reaching forward to push or pull while maintaining good balance is influenced by the positions of the feet, and determines the body's overall posture. Reaching should therefore influence push/pull strengths. Again, the nature of the effect is complex because of the interplay of other task variables. Among other muscular actions, pushing involves elbow extension and pulling involves elbow flexion. For many postures, push/pull strengths should therefore be greatest in the reaching range where the elbow is strongest for extension or flexion — i.e., with the elbow angle at about 90 to 110° — and where the additional effect of body weight is significant. The strength–reach trend is therefore an increasing/decreasing trend for both static and dynamic exertions.

When standing, the foot distance is defined as the distance from the hand–handle contact to the ankle of the pivot foot; and when sitting or standing, the reach distance is defined as the distance from the hand–handle contact to the shoulder (acromion). It may be expressed as a percentage of a person's shoulder height. Reach distance is influenced by the amount of space available for the arms, the height of hand–handle or hand–object contact, the nature of foot–floor contact, shoe–floor contact, or buttocks–seat contact, and it is also influenced by other factors (Kroemer 1974). Experiments have shown that the strongest standing pushing strengths occur when foot distance is about 90–100% of shoulder height, behind the hand; and the strongest pulling strengths occur when reach distance is 10%, in front of the hand.

2.4. Direction of Force Exertion

The direction which produces the greatest strength is where the body's reaction force is maximized at the contact with the floor. Pulling with the hands below the horizontal and pushing with the hands above the horizontal are among the best directions for maximizing strength when standing. Also, the force is greatest when directed along the arm axis for the fully extended arm. But when sitting and pulling with a harness around the chest, the horizontal direction (in the sagittal plane) seems to be the strongest.

For one-handed or two-handed exertions, pull/push strengths in the horizontal direction are strongest when the hands are directly in front of the body at about chest to shoulder height; and when the exertion is only with the right hand, the forces are greater to the right of the body than to the left. Pulling toward the body is about 10% stronger than pulling across the body; and for finger pulling at least, strengths obliquely across the body are about the same as strengths horizontally.

2.5. Body Supports and Traction

There are body supports and mechanisms for enhancing traction at the shoe-floor interface when standing, and for enhancing the buttocks–seat interface when sitting. They enable greater push/pull strengths by enhancing the reaction to the applied manual forces. Body supports are most influential when the applied force is perpendicular to them. Suitable supports for standing exertions include panels, walls, and fixed footrests; and for sitting exertions, a stable chair backrest or footrest may be used for pushing and a harness may be used for pulling. Research suggests the enhancement may be as much as 50 N when the shoe-floor coefficient of friction increases from 0.3 (poor traction) to 0.6 (good traction). Postural effects seem to be more influential for lower traction than for higher traction.

2.6. Speed of Walking

Research by Resnick and Chaffin (1995) has shown that, regardless of their (MVC) muscular strengths, people push (dynamically) with greater forces at greater speeds of walking; and the maximum speed of walking while pushing or pulling a load depends on a number of factors, such as shoe–floor coefficient of friction, personal strength, load weight, handle type, and handle height. Within the shoulder to knee range, people also seem to push faster when the load is lighter. For one-handed pulls, peak static strength is achieved later in the range of pull for higher pull speeds, and earlier for lower pull speeds. In other words, greater space must be allowed for a person to achieve maximum pull strength at higher pull speeds.

2.7. Frequency of Pushing and Pulling

Dynamic strength decreases as the number of repetitions of a muscular exertion increases. Experimental data confirms that, in simulated work tasks, people choose lighter loads to push or pull as the frequency of task performance increases.

2.8. Personal Characteristics and Gender

The available empirical data indicates that females are 0.5–0.9 times as strong as males for pushing or pulling. Some of this variation is due to differences in the sample characteristics and test procedures among the various experimental studies. It seems also that

the greater ratios occur where the legs play a more important role in strength exertion, such as pulling at low to medium height, and in situations where it is difficult to exert one's maximal effort. Body weight is the most influential anthropometric variable on push/pull strength. It adds to strength when leaning forward during pushing or leaning backward during pulling. However, no single anthropometric variable or combination of anthropometric variables can predict push/pull strengths accurately enough for ergonomic applications. Practitioners should therefore consult tables (Snook and Ciriello 1991, Ayoub and Mital 1989) to determine push/pull strength capabilities under specific work conditions.

3. MAXIMAL (MVC) STRENGTH VALUES

Measured average MVC push/pull strength values can be found in the ergonomics literature for several different studies conducted by different researchers. These values vary widely because of the different conditions in which the tests were conducted and because of the different physical characteristics among subject samples in the different studies. In view of that, only generalized results will be given here. More details, including test conditions, can be found in the ergonomics literature. Be careful when applying any data to task design or evaluation.

- Two-handed standing static push   Male   400–620 N
                                     Female 180–335 N
- Two-handed standing static pull   Male   310–370 N
                                     Female 180–270 N
- Two-handed standing dynamic push   Male   225–500 N
                                     Female 160–180 N
- Two-handed standing dynamic pull   Male   310–370 N
                                     Female 180–270 N
- One-handed static push or pull,   Standing   70–327 N
  combined male and female sets   Sitting
                                     restrained 350–540 N
                                     Lying down 270–330N

4. AT WORK

The previous sections provide information on the various factors that affect maximal muscular efforts. They may be used for rough estimates of how stressful or helpful a change in work conditions would be. For example, we know that suitable shoe and floor material (kept clean and dry) can allow a person to push 12 times as hard as on poor shoe–floor contact, and having handles on carts at elbow to hip height minimizes muscular strain when push forces are applied horizontally but not when they are applied at a sharp angle to the horizontal, and so on. However,

another kind of application of push/pull strengths is in determining how much load a worker is expected to work with under various conditions of work. These loads or forces are actually submaximal values and should be called "maximal acceptable forces" instead of strengths.

There are no definite and extremely accurate values for maximal acceptable forces under all conditions, but useful practical guidelines exist for the industrial workplace. The best guidelines seem to be the tables of Snook and Ciriello (1991); they are based on simulated industrial tasks and each of their force values represents the "maximum initial or sustained push or pull force which a given percentage of the population can exert over a specified distance, at a specified frequency, and at a specified height without a significant chance of being injured or developing cumulative trauma disorders." Remember these forces are much less than the maximum forces people can exert voluntarily (MVC forces) in a single (maximal) effort, and sustained force is about 20% less than an initial force.

5. CONCLUSIONS

Push or pull strength depends on a variety of factors; among the most important are posture and factors associated with posture. The condition or level of each factor must be specified for any meaningful strength estimate. Push/pull forces that people are willing to exert for a typical industrial task are known as maximum acceptable forces, not strengths (MVC forces). Maximum acceptable forces are significantly less than MVC forces. There are no accurate quantitative models that can predict MVC forces or maximum acceptable forces for pushing or pulling, and the best estimate should be derived from published tables which typically include means, standard deviations, and sometimes percentiles.

Recumbents

B. J. Daams

Daams Ergonomie, Mauvezand 17, 1251 JC Laren, The Netherlands

1. INTRODUCTION

Recumbent bicycles are relatively popular in The Netherlands, but they are still few in number. There are > 15,000 recumbents to a population of 16 million. Recumbent cyclists are generally convinced of the advantages of their vehicle. Their opinion is investigated by Daams (1999a, b), who gives an overview of the ergonomic aspects of recumbents and compares them with upright bicycles.

2. ADVANTAGES

The results indicate that recumbents are generally more comfortable, more efficient and safer than upright bicycles. Advantages are more comfortable sitting and looking around, more efficient and thus faster cycling, and better safety (stability is at least equal, better overview, better brake properties because of bicycle geometry and the location of the center of gravity, and less damage when falling because it is not the head that hits the ground first). Disadvantages are the price, getting on and off takes

Figure 1. Typical recumbent for city use: the Basic from Flevobike (courtesy: Flevobike).

Figure 2. Typical recumbent for touring: a M$_5$, fully loaded (courtesy: Bram Moens, M$_5$).

slightly more time, looking over the shoulder may be more difficult and adjusting for leg length takes some effort.

3. SUITABLE FOR VARIOUS PURPOSES

The usefulness of a recumbent depends very much on the type of recumbent (Figures 1–4) and the purpose for which it is used.

Recumbents are most advantageous on long distance rides (for commuting and cycling tours), in races and as a post delivery bike for long distances. Furthermore, recumbents are ideal for cyclists with certain physical problems, like back pain, saddle pain, and pain in wrist and arm.

Recumbents are less suited than conventional bikes for city use (short distances shopping), for all terrain use and as post delivery bike in the city (short distance).

4. ERGONOMIC ASPECTS

Some ergonomic aspects of recumbents are discussed in the following.

4.1. Recumbent Seat

The seat supports three parts of the human body (Figure 5): shoulders, back and bottom. The right size is very important in a recumbent seat. An oversized bottom support interferes with the movement of the legs while cycling; an undersized bottom support makes the cyclist slide down the seat. If the back support is not the right size, the chair does not fit and is very uncomfortable. A lumbar support is important.

(a)

(b)

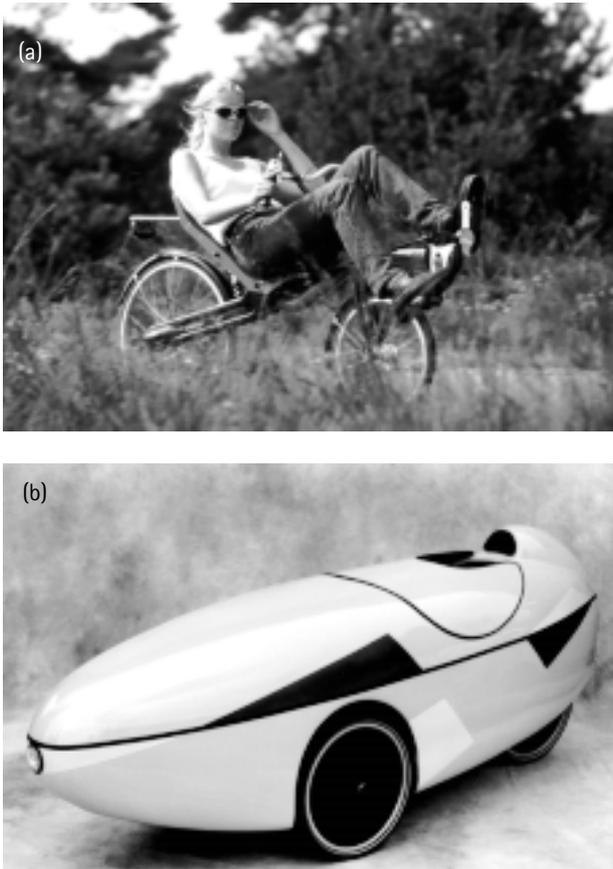
Figure 3. Two typical recumbents for racing: a carbon low racer with tail fairing (a) and a fully faired carbon racing recumbent (b) (both courtesy: Bram Moens, M$_5$).


Figure 4. Two typical commuting recumbents: in summer the Focus from Challenge (a; courtesy: Challenge) and in winter the faired C-Alleweder from Flevobike (b; courtesy: Flevobike).

Most seats are available only in one or two sizes. Ideally, a recumbent seat should be made to measure because no two backs are alike (Staarink 1995).

Women should be taken into account when designing recumbent seats. They tend to have more of a bottom, for which the seat should provide sufficient space. Until now no such recumbent seat could be found. Insufficient bottom space leads to insufficient lumbar support, and thus to discomfort during long cycling tours.

4.2. Speed

Recumbents are much faster than conventional bikes, especially when they are faired. The World Speed Record in 1999 was 110 km/h in a 200-m sprint with a flying start, the Hour Record is 81.158 km, both in a fully faired recumbent by amateur cyclists. The Hour Record on a conventional bike is 56.357 km — by Chris Boardman, a professional, though he used an "arms-forward" aerodynamic position that has now been banned by the world governing body for cycling, the UCI. For consumer use, the speed of recumbents is slightly higher than that of conventional bikes (depending on the types) due to better aerodynamics.

4.3. Posture

The posture of the rider on a recumbent bicycle should be such that the feet should not be located higher than the heart, to prevent circulation problems. Cold and "sleeping" feet will be the consequence of a bottom bracket that is too high relative to the heart. When the feet are too low, relative to the seat, the rider will push himself out of the seat when cycling.

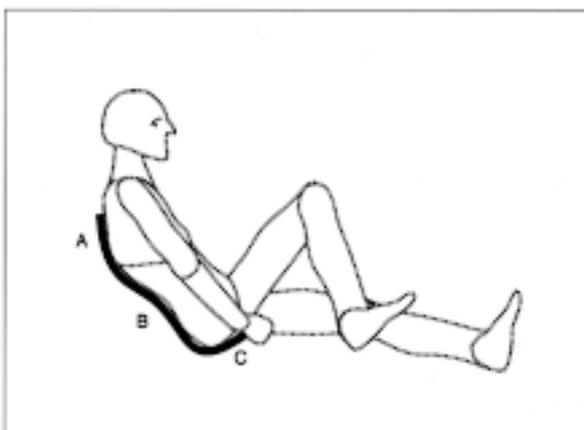
The posture of a recumbent rider is defined (Figure 6) by: χ, the shoulder angle; ψ, the back angle; θ, the pedaling angle. The resulting angle between body and upper leg (ω) determines to a large extent the maximal power output. An angle between 105


Figure 5. Recumbent seat consisting of three supports (Daams 1999a): support of the shoulders; support of the back; and support of the bottom.
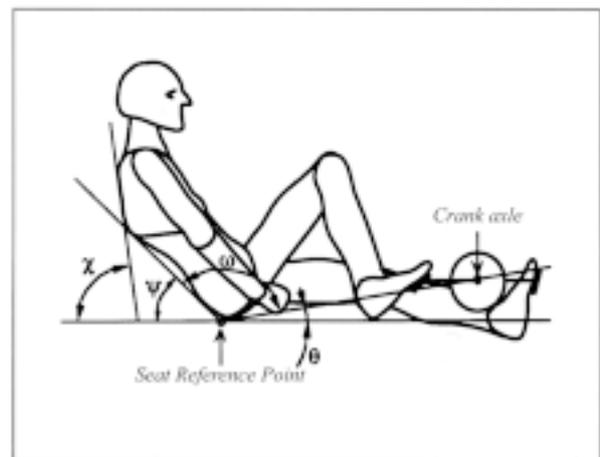

Figure 6. Posture of a recumbent rider is defined by: χ, the shoulder angle; ψ, the back angle; θ, the pedaling angle. The resulting angle between body and upper leg (ω) determines to a large extent the maximal power output (Daams 1999a).

and 130° is advised (Reiser and Peterson 1998). The posture also influences the aerodynamics of the recumbent (which influences the speed), the feelings of comfort and the view on the road. Investigation is needed into the relation between posture, power output, aerodynamics and endurance.

4.5. Muscle Use

There is some controversy whether the muscles used for recumbent cycling are the same as those used for conventional cycling. Received wisdom says the leg muscles need about as much as a year to adapt to recumbent cycling, imply that muscle use is different. However, no research on this subject could be found.

5. CONCLUSION

The conclusion is that recumbents are more ergonomic than conventional bicycles for commuting, for cycling tours, in races and for cyclists with certain physical problems. The popularity of recumbents is, however, not proportional to the ergonomical advantages. Why recumbents are not more popular may have a number of reasons, mainly concerning unfamiliarity with recumbents, the image of the bicycle, the attitude of other people, and the price. These factors are slowly changing in favor of the recumbent. In The Netherlands, recumbents are growing more popular and less expensive, and it is expected that this will continue over the coming years.

Sleeping Postures

B. Haex and T. Huymans

Biomechanics and Engineering Design, Celestijnenlaan 200 A, B-3001
Leuven, Belgium

1. INTRODUCTION

Both psychological factors and physical conditions during bed rest affect the quality of sleep. Concentrating on the latter component, most authors consider a resting place as being ergonomically justified when the entire musculoskeletal system can recuperate well: muscles have to relax while the unloaded intervertebral disks are rehydrating. Owing to an insufficiently adapted sleeping system or an incorrect sleeping posture the human body — especially the vertebral column — is often supported unsatisfactorily, leading to low back pain or sleep disorders in general. This text will concentrate mainly on the prevention of back pain and on pressure distribution since other components (e.g. moisture, heat transportation) are only affected marginally by sleeping posture.

During sleep a local ischemy will arise in body zones in contact with the sleeping system. This ischemy generates metabolic substances that stimulate the sensible nerve extremities, which will cause the person to change their posture before it gets painful. Posture changes are necessary to avoid a pressure overloading of soft tissues and to prevent muscle stiffness. Most people have a preferred sleeping posture and change posture ~20 times a night. These facts make it almost impossible to define an overall ideal sleeping posture. Section 2, therefore, discusses different sleeping postures and how they influence back support. Section 3 discusses how back support can be measured and modeled to evaluate correctly an individual's posture on a sleeping system.

2. POSTURES

Most people have a preferred posture to fall asleep in, it often being the fetal position. Furthermore, the sleep locomotion system starts working, resulting in 65% of people sleeping in lateral recumbency, 30% in posterior recumbency and the remaining 5% in a prone position. Sleeping postures are also age-related: older people mostly have a preferred side to sleep on (especially on the right side), they rarely sleep in a prone position, they sleep for a shorter time and change their position less frequently (De Koninck *et al.* 1992).

2.1. Prone Recumbency

In spite of a good distribution of body weight over a large contact surface, a prone sleeping position is the most unfavorable posture in relation to back support, even on a well-qualified sleeping system. Gravity causes the most heavy middle part of the human body to sink deeper into the mattress while the legs remain stretched. Consequently, the lumbar lordosis will increase significantly and will augment the pressure on the facet joints at the posterior side, while soft tissues (e.g. ligaments) will be under tension at the anterior side. This effect may result in a hyperlordosis on soft mattresses and some pressure-distributing sleeping systems due to an increased mattress indentation in the pelvic zone.

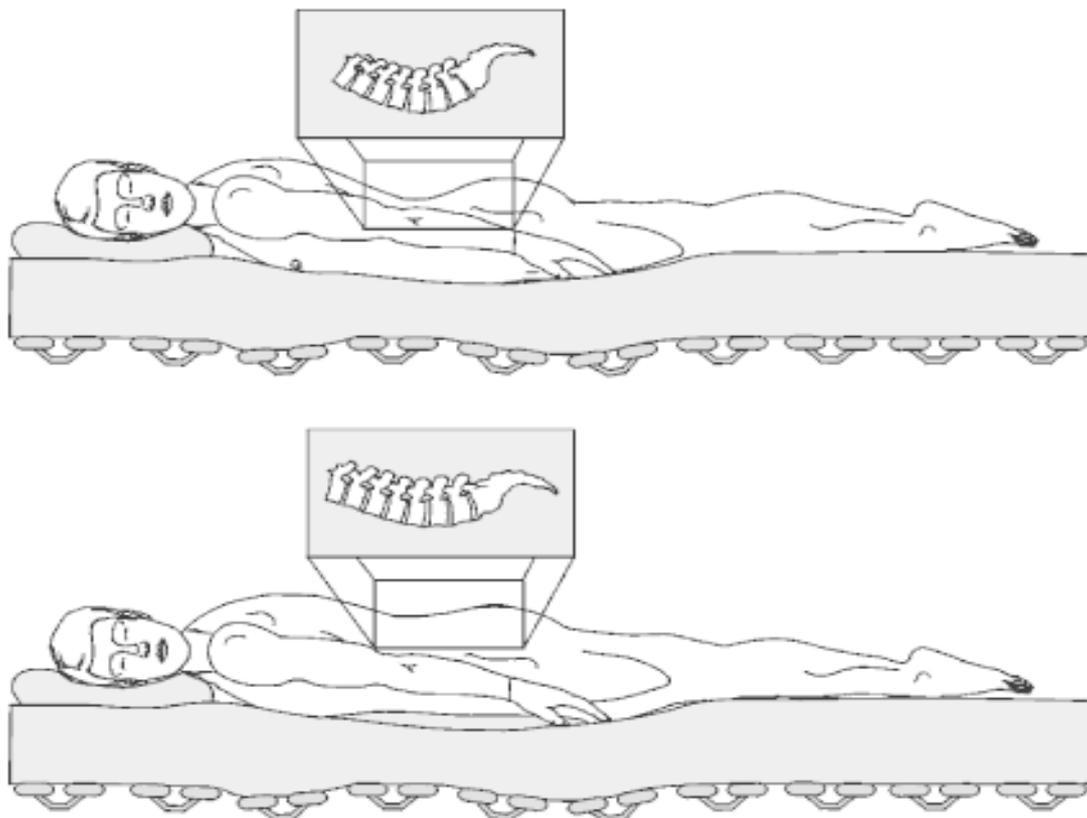
When sleeping in a prone position, the combined effect of (1) the body weight resting on the rib cage and (2) the intestines being


Figure 1. Increased lumbar lordosis when sleeping in a prone position (top) and improved the back support (bottom).
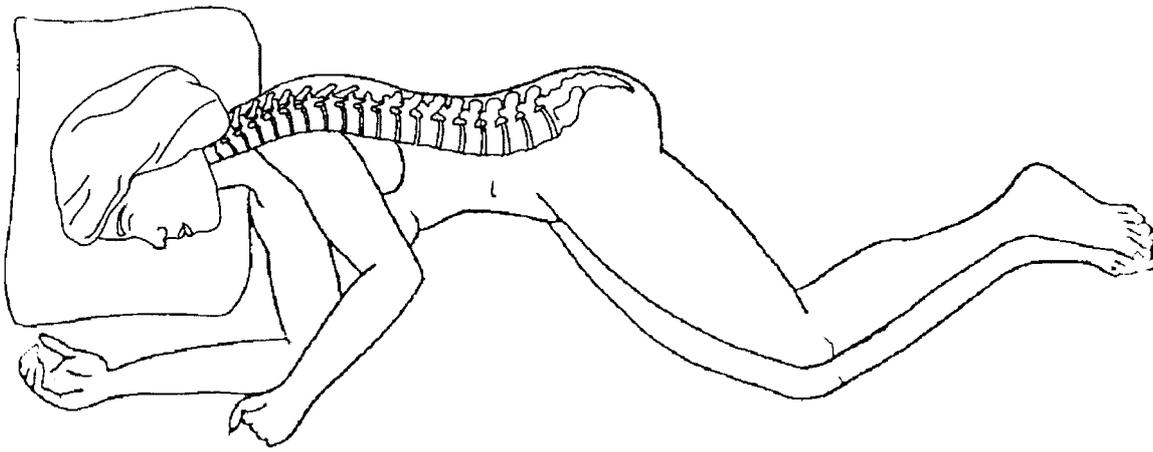

Figure 2. Correct lateral position.

pressed against the diaphragm enlarges the pressure on the lungs, which may cause respiratory problems. Further, the head is mostly turned sideward to improve breathing, which increases neck rotation. Consequently, an increased spinal loading occurs because several facet joints of most cranial vertebra are compressed at the side to which the head is turned, while ligaments at the other side are under tension. Also blood vessels may be compressed causing headaches, dizziness and other disorders.

In spite of all enumerated disadvantages — especially the increased lumbar and cervical spinal loading — many people prefer a prone position. It is, therefore, advisable to improve spine support by a simple means: sleeping without a head cushion will reduce neck rotation, which can even be improved by putting a pillow under the shoulder and the rib cage at the side to which the head is turned, or by lifting the arm at that side. Putting a pillow under the belly easily restores the natural lumbar lordosis. The same smoothening of an eventual hyperlordosis can be reached by elevating the knee and the hip at the side to which the head is turned, which can be enhanced by placing a pillow under the hip and the knee at this side. In fact, most presented corrections implement a slight position shift to lateral recumbency.

2.2. Lateral Recumbency

The lateral position is the most adopted sleeping posture, and it can support the human spine correctly in case both sleeping system and head cushion are well conceived: the spinal column is a straight line when projected in a frontal plane, while natural curves (cervical lordosis, thoracic kyfosis and lumbar lordosis) are maintained. There are no differences between sleeping on the left or on the right side, except from the weight of the liver working on the stomach and the lungs when sleeping on the left side.

Owing to the decreased contact surface and the center of gravity being more elevated, lateral recumbency is an unstable sleeping position, which can be altered by a correct position of the extremities. Bending arms and legs enlarges the support area and thus improves stability, but care should be taken not to apply torsion on the spine, to which intervertebral disks are especially vulnerable: when turned about a longitudinal axis, both pelvic and shoulder girdle should adopt the same angle.

Pillows can be an easy solution for the prevention of torsion of both pelvic and shoulder girdle: putting a head cushion or blanket between the knees will stabilize an elevated leg in a horizontal position. This position also avoids an asymmetric loading of the spine, which might induce a scoliosis. A similar effect can be reached by putting a pillow between the elbows. Because the human body will strive for minimal loading while sleeping, most people will automatically adjust their position and use a blanket to obtain the described minimal loading of the spine.

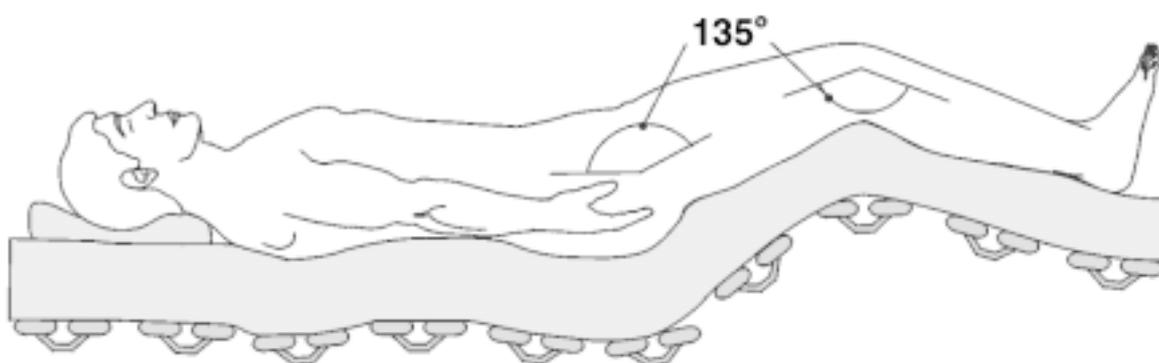
People — and muscles — are relaxed when sleeping in a fetal position; upper legs and trunk should form an angle of 135° to avoid a hyperlordosis (when stretching legs) or a smoothened lordosis (when elevating knees to close to the trunk). Further, it is clear that people with major spinal disorders (e.g. people with


Figure 3. Semi-Fowler's position on an adjustable bed.

a spinal injury) need a special treatment: a moderate spine torsion or flexion may yield a stress relief at the level of injury, implying only a temporary solution because the spinal column will suffer an increased loading at other places.

2.3. Posterior Recumbency

The main advantage of sleeping in posterior recumbency is the fact that body weight is distributed over a large surface, resulting in pressure distribution and stability being optimized. The lumbar part of the vertebral column will mostly be positioned between a smoothened lordosis and a slight kyphosis, depending on (1) the kind of sleeping system, (2) the natural curves of the spine and (3) muscle tension while sleeping. When a sleeping system is too soft, places where body weight is concentrated (e.g. the hip zone) will sink deeply into the mattress. Some muscles may be well relaxed in this position, but the spine certainly will not: the pelvis will cant backward resulting in a complete and unnatural lumbar kyphosis. At the anterior side intervertebral disks will be compressed while soft tissues (e.g. ligaments) will be under tension at the posterior side. To support the natural cervical lordosis it is best to use a head cushion, although it is less obligatory compared with lateral recumbency. Further, people with respiration problems had better avoid sleeping in posterior recumbency: apnea and snoring frequency are much higher in this posture.

To discuss how posture should be adjusted in case of low back pain, neck problems or muscle stiffness is out of the focus of this chapter. Only the semi-Fowler's position will be mentioned here, it being a common relaxing posture for many patients. It can be adopted in case of an adjustable bed: both hip and knee joints have an angle of 45°, resulting in a relaxed iliopsoas muscle and a slightly smoothened lumbar lordosis. It is remarkable that astronauts experience more or less the same posture (Drerup and Hierholzer 1994).

2.4. Posture Evaluation

A reliable sleeping posture diagnosis can be made based only on invariant shape properties of the spine, e.g. preservation of the lumbar lordosis. Mattresses and mattress supports with different stiffness and different comfort zones (softer shoulder zone, harder pelvic zone, etc.) can be evaluated by two different techniques

measuring spinal deformations during bed rest. First, a 2D camera system is suited for both posterior and lateral recumbency; second, 3D video-raster-stereography (VRS) is appropriate to measure 3D postures in case the back surface are visible, i.e. all postures are between lateral and prone recumbency.

3. EVALUATION

3.1. 2D Evaluation

A first experimental set-up designed to measure lumbar and thoracic spinous process positions during bed rest is a camera system. For lateral recumbency 17 reflecting markers are glued to the skin to cover the spinous processes and are detected by a Qualisys MAC-Reflex, camera system. A 2D approximation of the vertebral curvature is obtained by projecting the markers in a frontal plane and by calculating their position relative to two reference markers. For posterior recumbency a system with pins piercing the mattress measures the spinous process positions. A conducting strip glued to the spinous processes and an electrical circuit permit to ensure permanent contact between the pins and the spinous processes. Two reference markers allow the recalculation of the positions of the markers mounted on the lower side of the pins to the actual spinous process positions.

When concentrating on the optimal sleeping system for normal healthy people — as it is suggested by most ergonomic specialists — it has to support the human spine such that it adopts its natural position, which is assumed to be the same as it takes in the upright position. If this thesis is presupposed then an optimal body support for lateral recumbency gives rise to the spinal column being a straight line when projected in a frontal plane. For posterior recumbency an optimal support gives the spinal column the same thoracic kyfosis and lumbar lordosis as in the upright position, yet slightly smoothened by the loss of body weight working in longitudinal direction on the spinal column. Consequently a small prolongation of the spine occurs, as during weightlessness.

3.2. 3D Evaluation

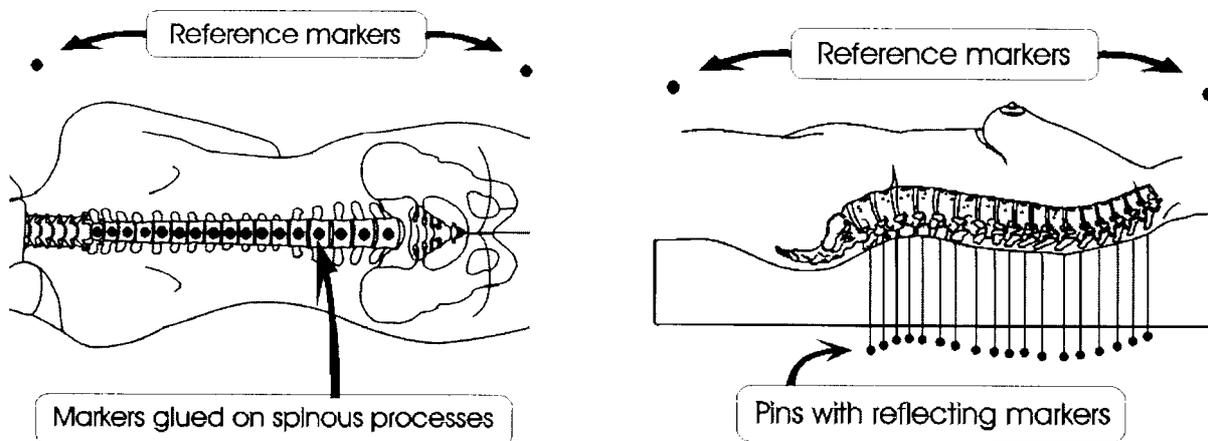
The fact that people do not limit themselves to 2D sleeping positions justifies the need for more reliable and realistic


Figure 4. Camera measurements for lateral (left) and posterior recumbency (right).

evaluations, by measuring both mattresses and supporting structures in 3D. As a result of comparing different measurement techniques, VRS is now used to locate the processi spinosi of a person on a sleeping system.

VRS is an objective analysis method for the assessment of 3D objects using a line raster diapositive and a camera. It is applied to measure the back shape of test persons and, therefore, acts as a powerful tool for the evaluation of different sleeping postures. The measurement technique can scan any 3D surface by projecting raster lines on the surface and captures these lines under a known and fixed angle. The measured surface can be reconstructed mathematically by fitting a dense point cloud, which is created based on triangulation algorithms (Krag *et al.* 1990).

Frobin and Hierholzer developed hardware and image processing techniques for the reconstruction of the 3D back surface to detect a lateral scoliosis. These techniques could be adapted to lateral recumbency applications. The camera and raster diapositive were optimally chosen: the image processing reconstructs the back surface with a mean error of 0.75 mm. A raster with more raster lines or a camera with a higher resolution is, therefore, not necessary.

As a result of the image processing a cloud of randomly distributed points, indicating the raster lines, describes the back surface. Using 1D linear interpolation the randomly distributed data points are transformed to a regular grid, which will simplify further calculations.

Owing to major differences between the upright and lying position, e.g. soft tissue influences, new dedicated software had to be developed starting from the regular point grid. We, therefore, developed Matlab, procedures (1) to model a back surface accurately and (2) to detect processi spinosi and other anatomical landmarks — sacrum point, vertebra prominens — based on asymmetry functions and convex/concave characteristics.

A reliable diagnosis only can be made based on invariant shape properties of the back. Frobin and Hierholzer proposed surface curvatures to analyze the shape of a human back. Owing to this, the landmark localization is independent of a patient's position and insensitive to moderate asymmetry and posture changes of the patient. The landmarks are, therefore, well suited for the objective definition of a body-fixed coordinate system.

In case of healthy people the medial sagittal plane is a symmetry plane that divides the back in a symmetrical left and right part. In case of lateral asymmetry of the back this is no longer true: a deformation of the spine — due to scoliosis or an incorrect mattress support — can cause lateral asymmetry. Software routines were developed to create a profile for these cases, dividing the back in a left and right part with minimal asymmetry. The entire profile of minimal asymmetry is found by connecting symmetry points, which are calculated in each horizontal cross-section. This line is called the symmetry line and is a rough approximation of the line through the processi spinosi. Drerup and Hierholzer (1994) described how the symmetry line is used to locate anatomical landmarks on the back, including the vertebra prominens C_7 (VP), the sacrum point (SP) and the left and right dimple of the spina iliaca posterior superior (DL en DR). All landmarks are determined from local surface curvature extrema. Further, the 3D line through the vertebral bodies is constructed out of (1) the symmetry line and (2) the positions of the anatomical landmarks, based on an empirical formula assuming that the vertebral rotation is equal to the surface rotation (Refshauge 1994).

4. RECOMMENDATIONS

- In a correct sleeping posture the human spine adopts its natural position, which is assumed to be the same as it takes in the upright position, yet slightly smoothened by the loss of weightlessness working in longitudinal direction.
- It is almost possible to obtain a correct back support in a prone sleeping position. In case a person has no complaints (as to respiratory or back problems), lateral and posterior positions are equivalent.
- Owing to the fact that the human body will strive for minimal loading while sleeping, most people will automatically adjust their posture to their sleeping system.
- When changing a sleeping system it usually takes 2 weeks to get used to it. A temporarily worse back support on a new and better sleeping system is possible due to these adaptation symptoms.

Static and Dynamic Strength

K. H. E. Kroemer

Industrial And Systems Engineering, Virginia Tech, Blacksburg, VA, and Eri, Inc., A Consulting Company, PO Box 3019, Radford, VA 24143-3019, USA

Generation of muscle strength is a complex procedure of nervous activation and control of myofilaments. It may involve substantial shortening or lengthening of muscle, i.e. a concentric or an eccentric effort, respectively; or there may be no perceptible change in length, i.e. the effort is isometric. Mechanically, the main distinction between muscle actions is whether they are "dynamic" or "static".

Static strength. Per definition, muscle length is constant during an isometric effort. Thus, involved body segments do not move; in physics terms, all forces acting within the system are in equilibrium, as Isaac Newton's First Law requires. Therefore, the physiological "isometric" case is equivalent to the 'static' condition in physics.

The static condition is theoretically simple and experimentally well controllable. It allows rather easy measurement of muscular effort. Therefore most of the information currently available on human strength describes outcomes of static (isometric) testing.

Measurements of isometric strength yield reasonable estimates of maximally possible exertion for most slow body link movements, if they are eccentric. However, the data do not estimate fast exertions well, especially if they are concentric and of the ballistic-impulse type, such as throwing or hammering.

Dynamic strength. Dynamic muscular efforts are more difficult to describe than static contractions. In dynamic activities, muscle length changes, and therefore involved body segments move. This results in displacement. The amount of travel is relatively small at the muscle but usually amplified along the links of the internal transmission path to the point of application to the outside, for example at the hand or foot.

Displacement and its time derivatives, velocity and acceleration, are of importance both for the muscular effort (as discussed earlier) and the external effect: for example, change in velocity determines impact and force, as per Newton's Second Law.

Definition and experimental control of dynamic muscle exertions are much more complex tasks than in static testing. Various new classification schemes for independent and dependent experimental variables can be developed. One such system for dynamic and static efforts includes the traditional tests as well as new ones (Marras *et al.* 1993). See the chapter on Muscle Terms — Glossary.

Setting the displacement (muscle length change) to zero — the *isometric* condition — one may either measure the magnitude of force (or torque) generated, its duration, or the number of repetitions that can be performed. Of course, since there is no displacement, its time derivatives are also zero.

Alternatively, one may choose to control velocity as an independent variable, i.e. the rate at which muscle length changes. Keeping velocity to a constant value, one generates an *isokinetic* muscle strength measurement. (Note that this *isovelocity* condition is often mislabeled "isokinetic".) Time derivatives of constant velocity, acceleration and jerk, are zero. Mass properties are usually controlled in isokinetic tests. The variables displacement, force (torque), time and repetition can either become dependent variables or they may be controlled independent variables. Most likely, force and/or repetition are chosen as the dependent test variables.

In some tests the amount of muscle tension (force) is set to a constant value. In such an *isoforce* test mass properties and displacement (and its time derivatives) are likely to become controlled independent variables, and time or repetition a dependent variable. This *isotonic* condition is, for practical reasons, often combined with an isometric condition, such as in holding a load motionless.

(Note that the term "isotonic" has often been applied falsely. Some older textbooks described the examples of lifting or lowering of a constant mass (weight) as typical for isotonics. This is false for two physical reasons. The first is that according to Newton's Laws the change from acceleration to deceleration of a mass requires application of changing (not: constant) forces. The second fault lies in overlooking the changes that occur in the mechanical conditions (length, pull angles and lever arms) at the muscle. Hence, even if there were a constant force to be applied to the external object (which is not the case), the changes in geometry would result in changes in muscle tonus.)

In the *iso-inertial* test, the external mass is set to a constant value. In this case, load (force, torque), time and repetition of moving the constant mass (as in lifting) and its displacement may be selected as independent or dependent variables.

The most common and general case of motor performance is "free dynamic": the person freely chooses all the independent variables of muscle use. Force, torque or some other performance measure serve as dependent output.

The complexity of dynamic testing explains why, in the past, dynamic measurements (other than isokinematic and iso-inertial) have been rarely performed in the laboratory. On the other hand, if one is free to perform as one pleases, such as in the "free dynamic" tests common in sports, very little experimental control can be executed.

Static Muscle Strength

J. L. Smith

Department of Industrial Engineering, Texas Tech University, Lubbock, TX 79409-3061, USA

Static, or isometric, muscle strength is defined as a muscle contraction that results in no movement of the object that the muscles are resisting. Common examples of static muscle exertions include pushing against a solid wall, or pushing your hands together. When relating muscular activity to work, many ergonomists are concerned with only the dynamic aspects of the work activity. However, there are many examples of static muscle activity in industry. One example involves the carrying of loads, while the legs are involved in the dynamic muscle activity of walking, the arms are often in a fixed (static) posture, holding an object as the worker walks. Other static activities are associated with postures and maintenance of postures for long periods of time without moving. Typically, such activities are referred to as static muscle loading. Upper extremity problems can occur when workers have to hold their arms up while working. The actual hand work may be very dynamic, but the shoulders and upper arms may be under a great deal of static load to maintain a required posture.

To "match the capabilities and limitations of workers to the demands of their jobs," static strength capabilities must be established. Generally, static strength is isolated to one (or a few) muscle groups performing a simple activity. Most commonly reported static strength measures are for arms, legs, shoulder and back.

Assessment of static strength is popular due to its relative simplicity to measure, low equipment costs, short testing time and test–re-test reliability. The basic equipment needed for static strength testing includes a load cell with a display unit, a platform or testing station, and a variety of handles, connectors and braces. A variety of load cells are commercially available ranging in cost from a few hundred to > $1000. A typical setup would involve a load cell connected to a handle on one end and anchored to a fixed point on the other end. A chain or cable that is easy to adjust in length is used as a connector.

Instructions to subjects typically ask them to build up to a maximal exertion (within 2–5 s), and then hold that maximal exertion for 3–5 s. The steady-state maximal exertion is then recorded. It should be noted that the data being collected are maximal voluntary exertions, which may vary under differing testing conditions. The ergonomist should attempt to minimize variability through: (1) standardized instructions, (2) isolation of testing from other subjects and/or observers and (3) not providing feedback to subjects regarding their strength performance. Adherence to these guidelines can help reduce competition among subjects, and reduce the chances of someone overexerting himself/herself. Adequate rest time (1–3 min) should be allowed between exertions. Some test protocols require repeated testing until three values are obtained that are within 15% of each other. A frequent problem encountered in isometric strength testing is a false reading due to the subject jerking on the load cell and adding an acceleration component to the reading. This problem is most prevalent in systems that have a maximum hold option for the display. Thus a momentary false reading could be "held in memory" and recorded as the maximum value for that trial. By watching, a continuously changing display, the test administrator can observe a "steady-state" value and record that data point.

Static strength data obtained from the ergonomics laboratory at Texas Tech University are summarized in Table 1. The data were obtained from a population of relatively young (mostly 18–25-year-old) male subjects who participated in a variety of research projects. Table 2 presents static strength data for 551 industrial workers (Chaffin *et al.* 1977) ranging in age from 18 to 62 years (average age 28.9 years). The two data sets agree closely for male arm strength, but differ on leg strength values. The difference in leg strength values is likely due to slight differences in the posture assumed for the strength tests, which points out the importance of documenting the strength test protocol, so that when it is replicated in the future, the values will be comparable. In general, average female strength values would be expected to be 40–70% of the average male values. The strength values presented in Tables 1 and 2 are provided for reference only and may not reflect the strength capabilities of specific industrial populations.

Table 1. Average static strengths for male subjects (n=129) in Texas Tech ergonomics studies.

Muscle group	Average static strength (N)
Arms	378
Legs	1410
Stoop back	905
Standing back	722
Composite	1162

Table 2. Average static strength values from Chaffin, *et. al.*(1977) for male and female industrial workers (n=443 males and n=108 females).

Muscle group	Average static strength (N)	
	Males	Females
Arms	381	200
Legs	941	417
Torso	544	266

There is a good deal of variability in static strength data, especially if male and female data are pooled and as wider age ranges of subjects are incorporated. The coefficients of variation (the ratio of standard deviation to the mean) for the data in tables 1 and 2 range from < 15% to > 50%.

Static strength testing has some appeal as a screening tool to match the capabilities and limitations of workers to the demands of their jobs. In such cases, job demands are often examined as a "worst case" or "most typical case" in which the appropriate posture of the worker is assumed for purposes of static strength testing. The worker's capabilities are then assessed as the worker performs a static exertion. The primary argument against using static strength testing is that dynamic activities can not be adequately represented as a series of static tasks.

However, if a screening test is desired, NIOSH (1981) recommends that following questions be asked before accepting the screening test:

- Is it safe to administer?
- Does it give reliable, quantitative values?
- Is it related to specific job requirements?
- Is it practical?
- Does it predict the risk of future injury or illness?

The ergonomist should carefully consider the above questions before recommending a screening test. If satisfactory answers are not available for the above questions, legal issues over job discrimination might arise.

Strength Testing

S. Gallagher

National Institute for Occupational Safety and Health, Pittsburgh Research Laboratory, PO Box 18070, Pittsburgh, PA 15236-0070, USA

1. INTRODUCTION

If we consider ergonomics to be an exercise in matching job demands to worker capabilities, one of the principal capabilities we must be concerned with is that of *human strength*. Our ability to evaluate different characteristics of muscular strength has increased dramatically over the past couple of decades with the development of new and increasingly sophisticated instrumentation. One would think that armed with such advanced techniques, we might be able to develop methods to conclusively identify workers at risk of injury in physically demanding jobs. Unfortunately, this has not yet proven to be the case. Instead, what these instruments have continued to point out is how intricate a function muscular strength really is, and how complicated and ambiguous its relationship is to musculoskeletal injury.

While we cannot just use isolated tests of strength to specify precisely who may be at risk of injury, studies have indicated that strength testing can be a useful tool for job design and, under certain circumstances, selection of workers for demanding jobs. However, because strength is such a complex phenomenon, there has often been some confusion regarding the proper application and interpretation of strength tests in ergonomics, especially among persons not thoroughly familiar with the limitations and caveats associated with the available procedures. The purpose of this chapter is to discuss some of the fundamental principles of strength assessment in ergonomics, so that these procedures can be better applied to control the risk of musculoskeletal disorders in the workplace.

1.1. What is Strength? (And what are we Measuring?)

Many of the complications associated with strength assessment arise from the simple fact that even our most sophisticated machinery *does not directly measure* the force or tension developed by a muscle in a living person. Instead, we can only observe the consequences of force development by a contracting muscle, or more likely, by a *combination* of muscles. There are many ways in which we can measure the effects of muscular contraction, and the techniques we use can have a dramatic impact on the strength readings we will obtain. Consider the situation illustrated in Figure 1. In this example, the muscle exerts a constant force of 1000 Newtons (N). However, the forces we measure can vary quite dramatically depending on where we place the force cuff — from 167 N if we place it near the wrist to 500 N if we place it near the elbow. Which value should we select as properly representing the muscular strength for this elbow flexion exertion?

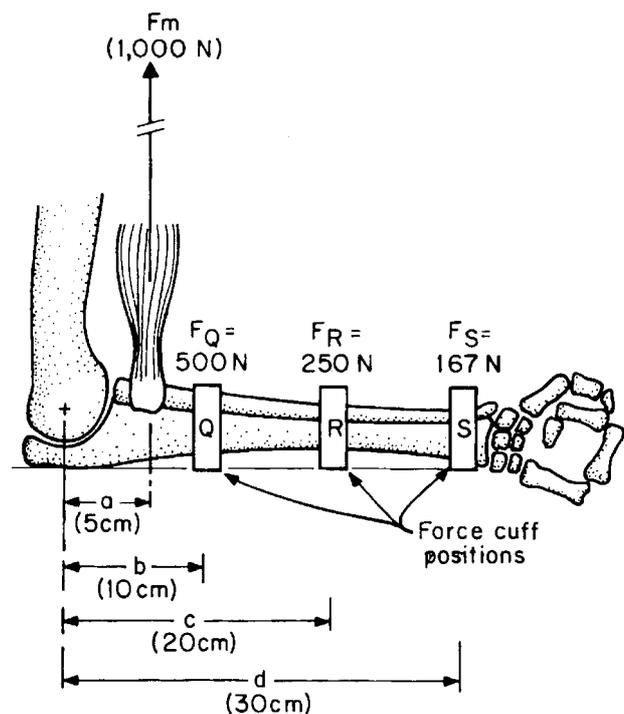
The preceding example illustrates some important points with regard to strength assessment. Perhaps the most important is that "muscular strength is what is measured by an instrument" (Kroemer *et al.* 1990). It should also be clear from this example


Figure 1. Given a constant muscle force (F_m), forces measured at various distances from the elbow will result in different force readings (F_Q, F_R or F_S).

that two researchers could perform an elbow flexion strength experiment on the same group of subjects, but if each selected different force cuff positions, they might end up with wildly differing estimates of strength. Differences in the strengths of various muscle groups in the published literature may be the results of differences in the procedures and measurement methods used by the experimenters. Thus, it is critical that any strength data presented be accompanied by a detailed account of the manner in which the data were obtained.

A few additional points need to be made with regard to the testing of human strength. We must be clear that what we are obtaining in such tests are not a person's maximal strength capability, but their maximal *voluntary* strength. The voluntary nature of the exertion introduces an unknown, but surely substantial, amount of variability in our measurements of strength. One can imagine two subjects with identical muscular strength capabilities, but with varying levels of motivation or discomfort tolerance, for example. We are likely to observe considerable differences in the voluntary force exerted by the two, but it should be understood that such results may be largely the result of psychological factors, and not differences in muscular strength *per se*. The important point to be made here is that not only are we unable to directly measure muscular force, what we *are* able to measure is modified by an invisible filter — a filter subject to a wide variety of influences and which will differ considerably for every person we test. To make matters worse, this filter would be expected to change even within a given individual on a given day. From the foregoing discussion, one can perhaps better appreciate some of the difficulties with establishing a definitive relationship between an individual's measured strength and that individual's risk of injury.

2. PURPOSES OF STRENGTH ASSESSMENT IN ERGONOMICS

There are a number of reasons people may want to collect human strength data. This article will discuss two of the most common uses of physical strength assessment in ergonomics: *job design* and *worker selection.*

2.1. Job Design

Probably the most effective use of worker strength evaluations is in the area of job design. Job design has been a primary focus of the psychophysical method of determining acceptable weights and forces. The psychophysical method attempts to determine workloads that are "acceptable" (a submaximal strength assessment) for populations of workers. Once the acceptable workloads for a population are determined, the job or task is designed to accommodate the vast majority of that population. It has been estimated that this approach to the design of lifting tasks might reduce the risk of back injuries by up to 33%.

2.2. Worker Selection

The purpose of worker selection and placement programs is to ensure that jobs which involve heavy physical demands are not performed by those lacking the necessary strength capabilities. It should be noted that this method is not the preferred strategy of the ergonomist, but is a provisional measure for the control of work-related musculoskeletal disorders (WMSD) where job design cannot be used to alleviate task demands. Nonetheless, this method can be effective in reducing the harmful physical effects caused by the mismatch of worker and job, given adherence to two fundamental principles. These principles are: (1) ensuring that the strength measures are related to the demands of the job, and (2) that strength assessment is performed only under circumstances where they can predict who may be at risk of WMSD. The literature has shown that worker selection is *only effective when a worker's strength capacity is equated with the demands of the job.* All too often, emphasis is placed on collecting data on the former attribute, while the latter receives little or no attention. The second issue that must be considered when worker selection is to be implemented is that of the test's *predictive value.* The predictive value of a test is a measure of its ability to determine who is at risk of future WMSD. In the case of job-related strength testing, the predictive value appears to hold only when testing individuals for jobs *where high risk is known.* Strength testing does not appear to predict the risk of injury or disease to an individual when job demands are low or moderate.

3. TYPES OF MUSCULAR STRENGTH ASSESSMENT AND THEIR USE IN ERGONOMICS

Muscular exertions can be divided into those which produce motion about a joint (dynamic exertions), and those which do not (isometric or static exertions). The vast majority of occupational tasks involve dynamic motions. Unfortunately, the complexity of such motion makes it more difficult to quantify. Static exertions, on the other hand, are easier to control and measure, but may be inappropriate to apply in situations where dynamic activity is present. Neither mode of strength testing is inherently better than the other — the key is to make sure that the test that is used relates to the application being studied. The following sections briefly describe the most common strength analysis techniques used in ergonomics. The first deals with isometric strength testing, the remaining sections describe various dynamic tests of strength. Greater detail on these strength assessment procedures can be found elsewhere (Gallagher *et al.* 1998).

3.1. Analysis of Isometric Strength

When a worker is called upon to perform a physically demanding lifting task, moments (or torques) are produced about various joints of the body by the external load. Often these moments are augmented by the force of gravity acting on the mass of various body segments. For example, in a biceps curl exercise, the moment produced by the forearm flexors must counteract the moment of the weight held in the hands, as well as the moment caused by gravity acting on the center of mass of the forearm. In order to successfully perform the task, the muscles responsible for moving the joint must develop a greater moment than that imposed by the combined moment of the external load and body segment. It should be clear that for each joint of the body, there exists a limit to the strength that can be produced by the muscle to move ever increasing external loads. This concept has formed the basis of isometric muscle strength prediction modeling.

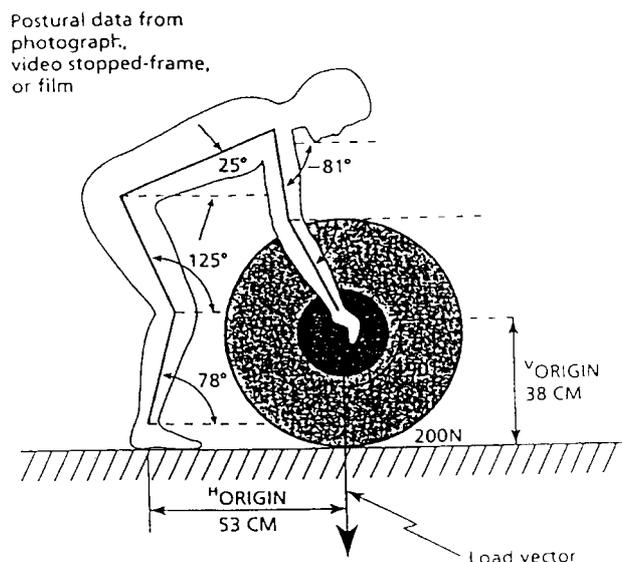
The following procedures are generally used in this biomechanical analysis technique. First, workers are observed (and usually photographed or videotaped) during the performance of physically demanding tasks. For each task, the posture of the torso and the extremities are documented at the time of peak exertion. The postures are then re-created using a computerized software package, which calculates the load moments produced at various joints of the body during the performance of the task. The values obtained during this analysis are then compared to population norms for isometric strength obtained from a population of industrial workers. In this manner,


Figure 2. Postural data required for analysis of joint moment strengths using the isometric technique.

the model can estimate the proportion of the population capable of performing the exertion, as well as the predicted compression forces acting on the lumbar discs resulting from the task (Chaffin and Andersson 1991).

3.2. Iso-inertial Methods

3.2.1. The strength aptitude test

The Strength Aptitude Test (SAT) is a classification tool for matching the physical strength abilities of individuals with the physical strength requirements of jobs in the Air Force (McDaniel *et al*. 1983). The SAT is given to all Air Force recruits as part of their pre-induction examinations. Results of the SAT are used to determine whether an individual possesses the minimum strength criterion which is a prerequisite for admission to various Air Force Specialties (AFS). The physical demands of each AFS are objectively computed from an average physical demand weighted by the frequency of performance and the percent of the AFS members performing the task. Objects weighing less than 10 pounds are not considered physically demanding and are not considered in the job analysis. Prior to averaging the physical demands of the AFS, the actual weights of objects handled are

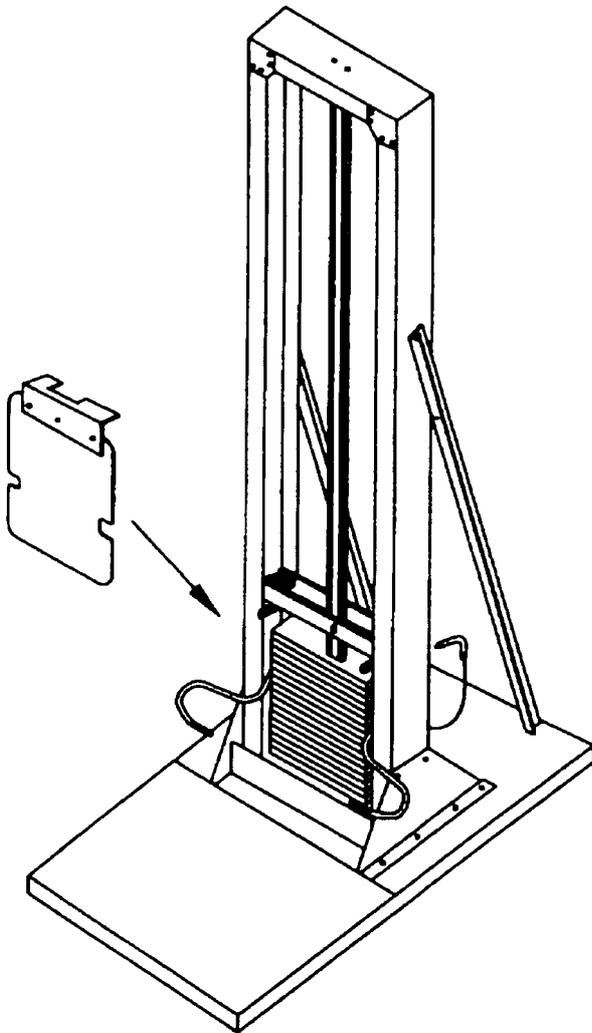
Figure 3. Incremental Weight Lift Machine. The barrier has been removed to expose the hidden stack of weights.

converted into equivalent performance on the incremental weight lift test using statistical procedures developed over years of testing. These relationships consider the type of task (lifting, carrying, pushing, etc.), the size and weight of the object handled, as well as the type and height of the lift. Thus, the physical job demands are related to, but are not identical to, the ability to lift an object to a certain height. Job demands for various AFS are re-analyzed periodically for purposes of updating the SAT.

In this technique, a preselected mass, constant in each test, is lifted by the subject using a device such as that shown in Figure 3. The amount of weight to be lifted is relatively light at first, but the amount of mass is continually increased in succeeding tests until it reaches the maximal amount that the subject voluntarily indicates s/he can handle. A unique aspect of this technique is that it is the only strength measurement procedure discussed in this document where results are based on the success or failure to perform a prescribed criterion task. The criterion tasks studied have typically included lifting to shoulder height, elbow height or knuckle height.

3.2.2. Psychophysical strength assessment

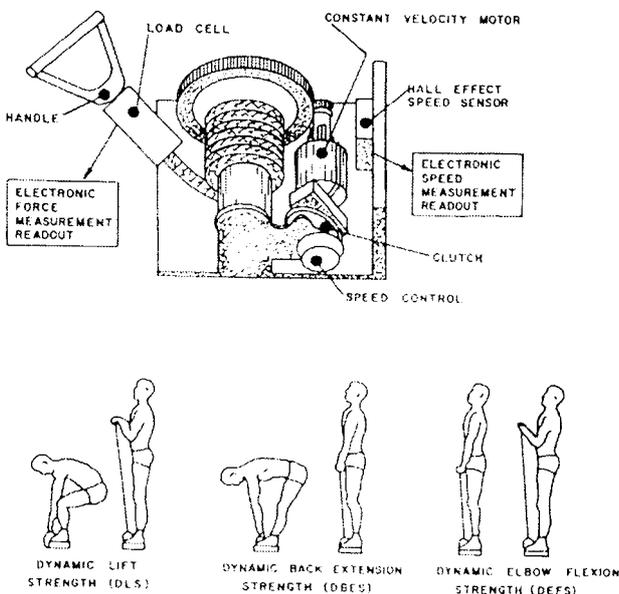
As mentioned previously, job design has been a primary focus of the psychophysical method of determining acceptable weights and forces. In this technique, subjects are typically asked to adjust the weight or force associated with a task in accordance with their own perception of what is an *acceptable workload* under specified test conditions. It can be seen from this description that this technique does not attempt to evaluate the maximum forces a subject is capable of producing. Instead, this procedure evaluates a type of "submaximal," endurance-based estimate of acceptable weights or forces.

In the context of lifting tasks, the following procedure is usually used in psychophysical strength assessments. The subject is given control of one variable, typically the amount of weight contained in a lifting box. There will usually be two 20-min periods of lifting for each specified task: one starting with a light box (to which the subject will add weight), the other starting with a heavy box (from which the subject will extract weight). The box will have a hidden compartment containing an unknown (to the subject) amount of weight, varied before each test, to prevent visual cues to the subject regarding how much weight is being lifted. The amount of weight selected during these two sessions is averaged and is taken as the maximum acceptable weight of lift for the specified conditions. In psychophysical assessments, the subject is instructed to work consistently according to the concept of "a fair day's pay for a fair day's work": working as hard as s/he can without straining himself, or becoming unusually tired, weakened, overheated, or out of breath. As psychophysical strength data is collected on large numbers of subjects, it becomes possible to design jobs so that they are well within the strength capabilities of the vast majority of workers. One criterion that is often used is to design the job so that 75% of workers rate the load as acceptable. Studies have indicated that if workers lift more than this amount, they may be three times more likely to experience a low back injury. On the other hand, designing jobs in accordance with this criterion has the potential to reduce the occurrence of low back injuries by up to 33% (Snook and Ciriello 1991).


3.3. Isokinetic Strength

A technique of dynamic testing that has been growing in popularity is that dealing with the measurement of isokinetic strength. As defined previously, this technique evaluates muscular strength throughout a range of motion and at a constant velocity. It is important to realize that people do not normally move at a constant velocity. Instead, human movement is usually associated with significant acceleration and deceleration of body segments. Thus, there is a perceptible difference between isokinetic strength and free dynamic lifting. In the latter instance, subjects may use rapid acceleration to gain a weight lifting advantage. Acceleration is not permitted in isokinetic tests of strength.

The majority of isokinetic devices available on the market focus on quantifying strength about isolated joints or body segments, for example, trunk extension and flexion. This may be useful for rehabilitation or clinical use, but isolated joint testing is generally not appropriate for evaluating an individual ability to perform occupational lifting tasks. One should not make the mistake of assuming, for instance, that isolated trunk extension strength is representative of an individuals ability to perform a lift. In fact, lifting strength for a task may be almost entirely unrelated to trunk muscle strength. Strength of the arms or legs (and not the trunk) may be the limiting factor in an individuals lifting strength. For this reason, machines that measure isokinetic strengths of isolated joints or body segments should not be used as a method of evaluating worker capabilities related to job demands in most instances.

Many investigators have used dynamic isokinetic lifting devices specifically designed to measure whole-body lifting strength. These devices typically have a handle connected by a rope to a winch, which rotates at a specified isokinetic velocity when the handle is pulled (Figure 4). Studies using this type of


device have demonstrated good correlations between isokinetic Dynamic Lift Strength (i.e. a lift from floor to chest height) and the maximum weights individuals were willing to lift for infrequent tasks using the psychophysical approach (Pytel and Kamon 1981). Thus, under certain circumstances, this device appears to possess some validity for assessment of job related dynamic lifting strength capabilities of individuals. Some investigators have attempted to modify this type of instrument by providing a means to mount it so that isokinetic strength can be measured in vertical, horizontal, and transverse planes. However, while advances have been made in the use of isokinetic devices for worker strength evaluation, this procedure cannot be thought to be fully developed in the context of worker selection procedures.

4. CONCLUSIONS

In spite of advances in measurement techniques and an explosive increase in the volume of research, our understanding of human strength remains in its introductory stages. It is clear that muscle strength is a highly complex and variable function dependent on a large number of factors. It is not surprising, therefore, that there are not only substantial differences in strength between individuals, or that strength measurements for a single individual can vary a great deal even during the course of a single day. Strength is not a fixed attribute — strength training regimens can increase an individual's capability by 30–40% or more. Disuse can lead to muscle atrophy.

The use of physical strength assessment in ergonomics has focused on both job design and worker selection techniques. Of these, the former has a much greater potential to significantly reduce WMSD. Worker selection techniques must be considered a method of last resort — where engineering changes or administrative controls cannot be used to reduce worker exposure to WMSD risk factors. This technique has only shown a moderate effect in truly high-risk environments, and only in short-term studies. It is not known whether worker selection procedures have a protective effect over the long-term.

Figure 4. An isokinetic device allowing assessment of various muscular strengths (such as those shown) at a constant velocity.

1. INTRODUCTION

The amount of force that must be exerted on or with a product is important to the perception of the consumer and to the product satisfaction (or especially to the dissatisfaction if the product does not fulfil its task properly). The importance of force exertion in product design is discussed in the article 'Force Exertion for (Consumer) Product Design: Problem Detinition'.

When designing for force exertion, a few steps must be taken to get a good result. First, the problem has to be defined the right way during the information stage. Second, an ergonomically sound concept should be developed in the concept stage with the help of global information (rules of thumb) on force exertion. Third, the actual size of maximal and/or minimal forces should be determined in the detailing stage.

Thus, the information needed for the design consists of two parts:

- general information (rules of thumb) for the early stage of design; and
- detailed information (exact forces) for the detailing stage of design.

These rules of thumb are important because they force the designer to think about a good design concept. If no effort is put in this first stage, it is no use detailing a basically bad ergonomical design. Rules of thumb are given in the article 'Force Exertion for (Consumer) Product Design: Information for the design Process', together with examples of product design. Also, some tips on measuring force exertion for design purposes are given.

After the concept phase of the design, the details should be looked into. How much force can the envisaged user group exert? Or better, how much force can the weakest users exert? This question must preferably be answered by research, but usually there is lack of time, money and/or interest to do so. Therefore, the question about the force that can be exerted can only be answered by literature. Adequate information on force exertion in literature is very scarce because a situation in which force exertion is investigated seldom corresponds with the situation in which a product is expected to be used and even less with the real situation. For an attempt to gather design relevant information and to present it in a way that makes it useful for the designer, see Daams (1994). A choice from these tables is given here. This chapter comprises the pushing and pulling forces of adults, children, the elderly and the disabled.

2. OVERVIEW OF THE DATA

2.1. Various Sorts of Torque

Torque can be exerted in various ways. Not only is the orientation of the lid/knob/handle is important, but also its shape. With a circular knob, the torque force cannot exceed the tangential force caused by the friction between hand and knob (which increases with increasing grip force). A small grip force thus limits the maximal exertion of torque. It is easier to operate a torque device that enables the hand to exert torque without the exertion of much grip force, like a T-bar or a lever with paddle. Torque knobs with levers or handles are recommended therefore for products that require much force and in designs for weak persons.

2.2. Products

Some investigators used "real products" to measure the torque exerted, and Daams (1994) used aluminum replicas of jam jars. Putto (1988) measured torque on light bulbs.

Not included in the data, but containing useful information on forces exerted on products: Berns (1981) investigated forces exerted on replicas of jam jars and bottles. Imrhan and Loo (1988) investigated glass jars with circular screw-type container lids. Bordett et al. (1988) used various faucet handles. Adams and Peterson (1988) used electrical connectors. Mital and Sanghavi (1986) and Mital (1986) used various hand tools, including wrenches and screwdrivers. Pheasant (1983) used screwdriver-like handles.

2.3. Maximal and Comfortable Torque

All measured torques are static. Most are maximal, but Kanis (1989) and Schoorlemmer and Kanis (1992) measured comfortable torque. Putto (1988) investigated the actual torque exerted when screwing in light bulbs, the maximal torque exerted when unscrewing bulbs and the maximal torque exerted on dummy bulbs.

2.4. Clockwise and Counter-clockwise

Kanis (1989), Schoorlemmer and Kanis (1992) and Steenbekkers (1993) investigated both torque directions and came to the conclusion that the exerted moments were not significantly different. They presented their results in one table. Mital (1986) measured clockwise torque only. Berns (1981), Daams (1993) and Imrhan and Loo (1988) measured counter-clockwise torque only. Bordett et al. (1988), Adams and Peterson (1988), Thompson (1975) and Rohmert and Hettinger (1963) give both values in a table. From the reports of Swain et al. (1977), Pheasant (1983) and Mital and Sanghavi (1986), it is not clear what the measured torque direction is.

2.5. Fingers

In general, torque is exerted with the whole hand, certainly when large lids or knobs are involved. With smaller knobs, either the whole hand can be used, or just the fingers. Adams and Peterson (1988) define and measure both fingertip grasp and full wraparound grasp. Kanis (1989) and Schoorlemmer and Kanis (1992) use a lateral grip. The subjects of Steenbekkers (1993) exert torque both with the whole hand and with forefinger and thumb only.

For laterality, nearly all forces are exerted with one hand, although in the case of the jam jar of Daams (1994), in free posture the subjects could use both hands. Probably the same applies to the jam jar of Berns (1981).

2.6. Sex

The torque exerted by women was investigated by Bordett et al.

(1988). The torque exerted by men was investigated by Swain *et al.* (1970). All other researchers measured both sexes.

2.7. Children

For children, Steenbekkers (1993) measured torque exerted by Dutch girls and boys between 4 and 13 years of age.

2.8. Elderly

The following investigators measured torque exerted by elderly subjects. Berns (1981) had subjects aged from 20 to > 71 years. Imrhan and Loo (1988) investigated elderly people aged between 60 and 97 years. Bordett *et al.* (1988) looked into the capacities of females aged between 60 and 90. The age of the subjects of Thompson (1975) ranged from 60 to 75 years.

2.9. Disabled

Berns (1981) and Schoorlemmer and Kanis (1992) measured torque of both healthy persons and various disabled subjects. Kanis (1989) investigated torque exerted by arthritic persons and persons with muscle diseases. All measured female and male subjects.

2.10. Summary

Part of the collected data is summarized, as far as possible, in the following tables. Torques around a horizontal axis and a vertical axis are summarized in different tables. Only torque on circular knobs or lids is included, because the moment arm of torque on handles cannot be determined exactly. Averages and SD are included. A selection is made of the values of some authors. Of Steenbekkers' values, for example, the results of three age groups were selected. For more detailed information, the relevant tables should be studied.

3. TORQUE DATA

3.1. 🖼 Daams (1994)

3.1.1. Subjects
- Number: 22
- Sex: 10 female, 12 male.
- Age: eight young women and nine young men, average 22 years. Two women and three men were older.
- Other characteristics: healthy students and staff of Delft University.

3.1.2. Method
- Direction of force: torque, counter-clockwise.
- Posture: standing in free posture (figure 1), (a) torque on a fixed jar; (b) torque on a freely movable jar.
- Sort of force: maximal static force.
- Laterality: one-handed on the fixed jar, two-handed on the freely movable jar.
- Measurement: duration 6 s, measure is the average of the last 4 s. The score is the average of two trials.
- Sort of handle: jam jar shaped with built-in force transducer, material aluminum, weight 650 g.
- Size of the handle: lid Ø 66 mm, jar Ø 75 mm, jar height 113.5 mm.
- Position of handle: fixed jar: lid fixed at 0.95 m from the floor.
- freely movable jar: not fixed.

Table 1. Torque (Nm) on a jam jar, exerted in two postures. Averages and SD of 10 women and 10 men (Daams 1994).

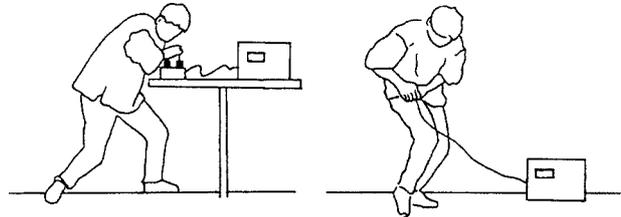
posture	females x	females s	males x	males s	both x	both s
free, jar fixed at 0.95m	6.36	1.61	11.70	3.45	9.27	3.84
free, jar not fixed	5.91	1.26	9.67	2.20	7.96	2.62


Figure 1. (a) Torque on a fixed jar; (b) torque on a freely movable jar (Daams 1994).

- Other characteristics: non-slip plastic material was placed between hand and jar if maximal torque could otherwise not be obtained.

3.2. 🖼 Steenbekkers and van Beijsterveld (1998)

3.2.1. Subjects
- Number: several hundreds; see tables.
- Sex: women and men; see tables.
- Age: 20–80+, divided in nine different age groups; see tables.
- Other characteristics: Dutch adults and elderly, selected to be representative for the Netherlands.

3.2.2. Method
- Direction of force: torque with two hands.
- Posture: the subject holds the measuring device (which resembles a jam jar) in his or her hands and adopts a free posture, whether holding the jar or leaving it on the table.
- Sort of force: maximal static force.
- Laterality: exerting torque with both hands.
- Measurement: duration 3 s.

Figure 2. Example of hand posture during the experiment (Steenbekkers and van Beijsterveldt 1998).

Table 2. Torque (Nm) with two hands. Averages, SD and number of subjects per age category (Steenbekkers and van Beijsterveldt 1998).

age	women					men					all

total		1.4		4.9			2.1		7.7				

- Sort and size of handle: a measuring device with the weight, shape and surface texture of a full jam jar.
- Position of handle: free.
- Other characteristics: –
  For results, see Figure 2 and Table 2.

3.3. Swain et al. (1970)

3.3.1. Subjects

- Number: 120.
- Sex: male.
- Age: civilians: average 31.4 range 22–40 years; military, army: average 27.2 range 21–38 years; military, navy: average 27.4 range 23–32 years.
- Other characteristics: 96 civilians, 12 army, 12 navy.

3.3.2. Method

- Direction of force: torque.
- Posture: standing. The steadying hand was always placed on top of the measuring apparatus. The subjects were required to stand approximately in front of the device, to keep both feet on the floor and not to move the device.
- Sort of force: maximal static force.
- Laterality: preferred hand.
- Measurement: the subjects were instructed to get a firm grip and give the knob a single, hard twist and then stop.
- Sort of handle: small knob.
- Size of handle: knob Ø 9.5 mm, 12.7 mm and Ø 19.1 mm.
- Position of handle: about 81 cm above the floor.
  Two orientations were used:
- control panel facing the subject; and
- the edge of the control panel toward the subject so that the knob was on his right.

Table 3. Torque (Nmm) exerted on knobs, with bare hand and gloves, averages and SD of males (Swain *et al.* 1970).

knob		mil. under 29		mil. over 29		civ. under 29		civ. over 29		all	
		n = 16		n = 8		n = 31		n = 65

Other characteristics: bare hands and gloves were used. To avoid the effects of sweaty hands, paper towels were provided and subjects were instructed to wipe their fingertips before each trial.

For results, see Table 3.

3.4. Thompson (1975)

3.4.1. Subjects
- Number: 38.
- Sex: 23 female, 15 male.
- Age: 60–75 years.
- Other characteristics: subjects were selected locally at random from elderly persons within this age range, who were living in unassisted occupation of a dwelling. However, preliminary screening eliminated from selection those with any indication of coronary disease.

3.4.2. Method
- Direction of force: (a) torque, clockwise and counter-clockwise; (b) torque on door/window handles.
- Posture: a line was drawn on the floor in line with and vertically beneath, the handle of the apparatus. The subject's leading foot was positioned on this line to ensure maximum force application. Apart from this positioning, subjects were allowed to adopt whatever stance was natural to them.
- Sort of force: maximal static force.
- Laterality: the dominant hand.
- Measurement: subjects were told to exert force as hard as they could until they felt they had reached their maximum and they were then to release the handle. The highest value of three trials is the value used for computation of the strength data.
- Sort and size of handle: (a1) circular knob, Ø 2.8 cm; (a2) square knob, 3.1 x 2.5 cm; (b1) handle, oval diameter; length 11 cm; (b2) handle, square diameter, length 12 cm.
- Position of handle: 1 m above the floor.
- Other characteristics: –

For results, see Table 4.

3.5. Kanis (1989)

3.5.1. Subjects
- Number: 34.

- Sex: 28 female; six male.
- Age: average 54 years (SD 14.2).
- Other characteristics: 28 arthritic subjects (24 women, four men) and six subjects (four women, two men) with a muscle disease.

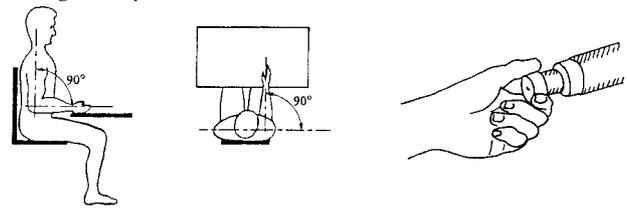
3.5.2. Method
- Direction of force: torque, averaged for clockwise and counter-clockwise together.
- Posture: sitting, with the elbow 90° flexed. Lateral grip. See figures.
- Sort of force: maximal and comfortable static force. 'Comfortable' refers to a level of pain or fatigue found acceptable by the subject.
- Laterality: left hand, right hand and preferred hand.
- Measurement: subjects were instructed to build up their force gradually and to hold the maximum for at least a few seconds.


Figure 3. Posture during the experiment (Kanis 1989).
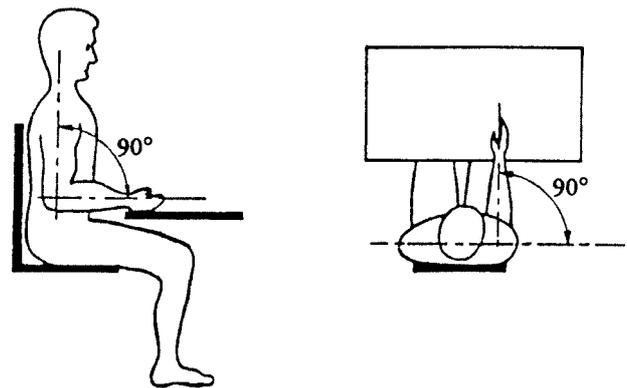

Figure 3a.

Table 4. Torque (Nm) exerted on two different knobs and two different handles. Averages, SD, ranges and 5th percentiles of 38 elderly people (Thompson 1975).

handle	force direction*	female x	s	range		P5	male x	s	range		P95

- Sort of handle: two aluminum cylinders with anti-slip texture.
- Size of handle: height 15 mm, Ø 13 mm and Ø 40 mm.
- Position of handle: mounted on a table.
- Other characteristics: –

For results, see Table 5.

3.6. ⌖ Schoorlemmer and Kanis (1992)

3.6.1. Subjects
- Number: 27.
- Sex: 21 female, six male.
- Age: average 49.4 years (SD 17.4).
- Other characteristics: average body height 165 cm (SD 12), average body weight 67 kg (SD 12).

- Twelve healthy subjects, five spastics, four visually impaired, three blind subjects, three subjects with Parkinson's disease.

3.6.2. Method
- Direction of force: torque, clockwise and counter-clockwise (they are not significantly different and thus represented in one table).
- Posture: sitting, with the elbow 90° flexed (see figures) and in a free posture. Lateral grip.
- Sort of force: maximal and comfortable static force. 'Comfortable' refers to a level of pain or fatigue found acceptable by the subject.
- Laterality: left hand and right hand (averaged in the table).
- Measurement: subjects were instructed to build up their force gradually and to hold the maximum for at least a few seconds.

- Sort of handle: three handles: two aluminum cylinders with anti-slip texture, one with a rim (see figure).
- Size of handle: height 15 mm for all, Ø 13 mm and Ø 40 mm (see figure)
- Position of handle: mounted on a table.
- Other characteristics: –

For results, see Table 6

3.7. Steenbekkers (1993)

3.7.1. Subjects
- Number: 782.
- Sex: 392 girls, 390 boys.
- Age: 4–13 years.
- Other characteristics: Dutch children, selected to be representative for the Netherlands.

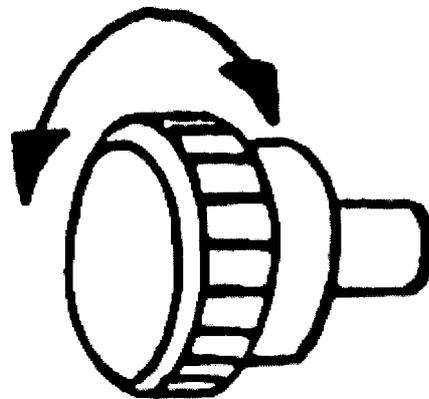
3.7.2. Method
- Direction of force: torque, clockwise and counter-clockwise (they are not significantly different and thus represented in one table).
- Posture: the child sits upright before the measuring device, which is in front of the forearm. The forearm is horizontal and in a sagittal plane. Upper arm and forearm are at ~150°. The legs hang down freely or are directed forward. (Torque of forefinger and thumb: the thumb and fingers are positioned on the knob opposite one another. The other fingers are flexed into a fist.
- Sort of force: maximal static force.


Figure 5. Posture during experiment (a) (Steenbekkers 1993).
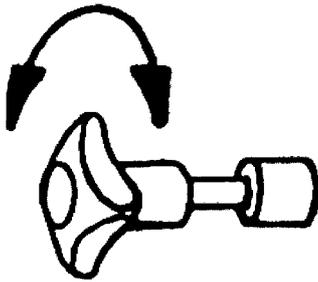

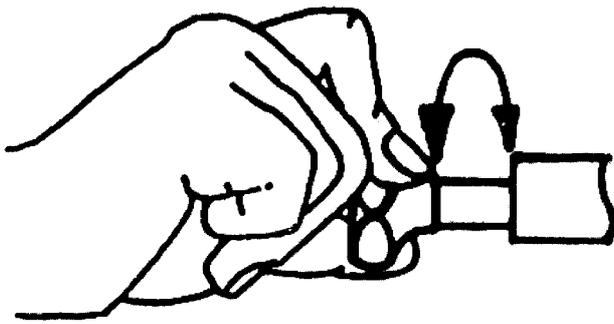

Figure 6. Posture during experiment (b) (Steenbekkers 1993).

• Laterality: preferred and non-preferred hand (they are not significantly different and thus represented in one table).
• Measurement: duration 3 s.
• Sort of handle: (a) cylindrical knob; (b) star knob (see figure).
• Size of handle: (a) Ø 4 cm; (b) maximum Ø 2.5 cm.
• Position of handle: mounted on a table.
• Other characteristics: –
For results, see Tables 7 and 8

3.8. Putto (1988)

3.8.1. Subjects
• Number: 16.
• Sex: two female, 14 male.
• Age: average 41.9 years (SD 10.2), range 23–59 years.
• Other characteristics: Philips staff. Some had more than average knowledge of light bulbs, but their results did not differ from the others.
• Body height average 1.79 m (SD 0.10); body weight average 77.1 kg (SD 1.3); hand length average 19.2 cm (SD 1.3).

3.8.2. Method
• Direction of force: torque, clockwise and counter-clockwise.
• Posture: free posture when screwing and unscrewing a light bulb.
• When exerting maximal force, the subject's own posture adopted when unscrewing a light bulb was reproduced (i.e. the grip, the orientation relative to the bulb and the arm posture were the same).

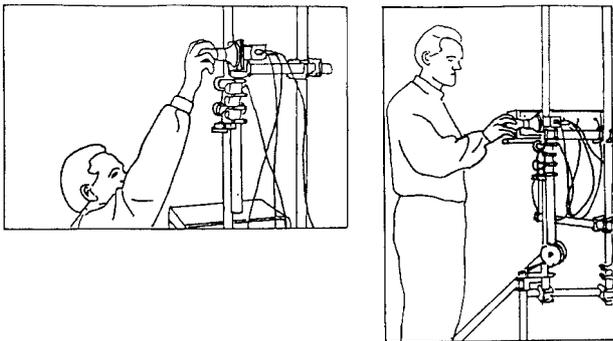
- Sort of force: (a) screwing in a light bulb (actual force, not maximal); (b) unscrewing a real (although fixed) bulb. The exerted force is static and as high as the subjects dare exert; (c) real maximal static torque, unscrewing a dummy bulb.
- Laterality: the preferred hand.
- Measurement: (a) and (b): exerted as in real bulb screwing; (c) for the maximal force, the subjects were instructed to slowly build up their force to a maximum and to maintain it for a few seconds.
- Sort and size of handle: five different types of bulbs and three different types of dummies were used (see figure):
- Bulbs (real): 1, small bulb, Ø 45 mm; 2, standard bulb, Ø 60 mm; 3, PLC-E small energy-saving bulb (square), diagonal cross section 45 mm; 4, fancy bulb (square), diagonal cross-section 55 mm; 5, SL large energy-saving bulb, Ø 70 mm.


Figure 7. Posture with bulb at reach height and at heart height (Putto 1993).

- Dummies, made of polished PC (Polycarbonate): similar to the small bulb, Ø 45 mm (no. 1); similar to the standard bulb, Ø 60 mm (no. 2); similar to the large energy-saving bulb, Ø 70 mm (no. 5).
- Position of handle: orientation of the bulbs: with the axis around which torque is exerted, horizontal.
- Two different heights: chest (heart) height and maximum reach height.
- Other characteristics: –

3.8.3. Results

Comparing the maximal forces exerted on real bulbs and dummy bulbs, it can be seen that the characteristics of the real bulb limit the maximal force that is exerted (table 9).

1. INTRODUCTION

Computerized biomechanical models to predict the trunk muscle forces have been developed for many years because there is no other way directly to measure spinal loading *in vivo*. Most biomechanical models aimed at reducing the risk of musculoskeletal injuries have focused on the activities of the trunk musculature, which is important because trunk muscles counteract external moments imposed upon the trunk during manual materials handling (MMH) activities. The forces generated by these muscles can easily become excessive given that their moment arms between the spine are at a much shorter distance compared with the distance between the spine and the object being handled. Since these internal forces are often the primary loading components of the spine, it is extremely important to understand how the trunk muscles collectively load the spine under occupational conditions. Therefore, a desirable feature of a biomechanical model is that it should predict both the synergistic actions of the various internal forces acting upon the spine as well as the loading due to external forces.

Unfortunately the problem of muscle force prediction is not easy, partially because a large number of muscles cross each joint in the body. In a situation where more muscles cross each joint than mechanical equilibrium conditions, the mechanical representation of the joint is statically indeterminate. In such a situation, there are an infinite number of possible muscle force combinations that can satisfy the mechanical equilibrium conditions. Thus, a biomechanical model that incorporates many muscles must adopt a strategy to resolve the issue of static indeterminacy together with obtaining the simultaneous solution of moment constraints about the joint axes.

2. ANATOMY AND FUNCTIONS OF TRUNK MUSCLES

It is generally accepted that activities of the erector spinae (ES), rectus abdominus (RA), internal oblique (IO) and external oblique (EO) muscles are critical during flexion, extension, rotation and lateral bending of the torso. The general locations of the EO, IO, RA, and ES muscles are illustrated in Figure 1.

The effect of non-symmetric and symmetric hand forces on a three-dimensional torso model requires an initial analysis of four factors:

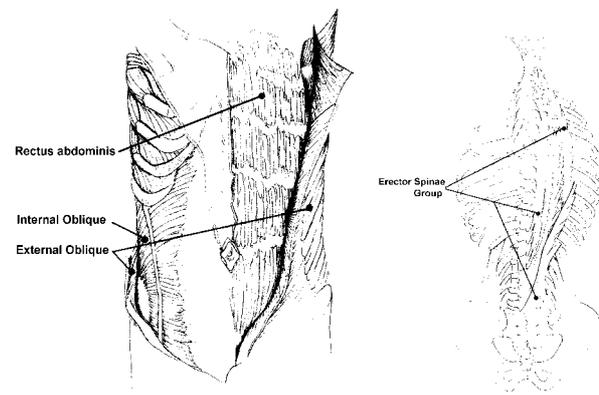
- Lines of action and level of activity of the IO and EO muscles as a function of body loading and position, and how these muscles relate to ES and RA activity.
- Effect of non-symmetric hand loading on ES and RA muscles.
- Significance of IO and EO muscle activity in relation to the ES and RA muscle groups presently included in the model.


Figure 1. General location of external oblique, internal oblique, rectus abdominis and erector spinae.

- Confirmation of the assumption that antagonist muscle activity is zero. This assumption is frequently made to make the system of equilibrium equations determinant.

2.1. Lines of Action and Activity Level of Oblique Muscles

2.1.1. Flexion versus extension

It is clear that activity of the EO will cause trunk flexion since activity in any part of the muscle will tend to pull the trunk down. The activity of the IO will also cause flexion. The line of action of the posterior part of the muscles may oppose this however. Farfan (1975), in fact, contends that the posterior two-thirds of the IO causes an extensor moment about the L5 vertebrae. This is supported in a model developed by Takashima *et al.* (1979) in which the lines of action of the EO would cause flexion while the lines of action of the posterior part of the IO would cause trunk extension about the L5 vertebrae. Through the analysis of multiple cross sections through a frozen cadaver trunk, Rab *et al.* (1977) found that the lines of action of both the EO and IO would tend to cause trunk flexion. Yettram and Jackman (1980) discuss a model in which the IO muscles are trunk flexors and are only active in the upright position and not in full forward flexion where they are at the short end of their range of motion (ROM).

It was initially hypothesized that, if the activity of the IO and EO could be consistently correlated with either the ES or RA, then (assuming synergistic activity) the flexor or extensor role of the IO and EO could be established. Such consistency was not found however. Eckholm *et al.* (1982) notes that when IO and EO EMG activity exists in a lifting task it usually occurs in conjunction with RA EMG activity (flexion) rather than ES activity (extension). Kumar and Davis (1978), however, found that during a stoop lift the EO EMG activity was related to ES EMG activity at the moment of maximum stress during extension. Ortengren and Andersson (1977) note that RA, IO, and EO EMG activity increased when these muscles were stretched during extension and that during flexion they were active only during the first few degrees of rotation. Schultz *et al.* (1980) found that during physical activity there was significant EMG activity in the IO and EO that occurred with activity in the ES. Schultz also found that the IO and EO muscles contract with the RA to develop trunk flexion. It may be that the IO and EO are trunk flexors but exhibit antagonistic activity during extension.. It is also possible that the

IO and EO must be active to stabilize the trunk during manual material handling activities and therefore must be active whether the torso muscle force is needed to flex or extend the trunk.

While the EO muscles are accepted to be trunk flexors, there does not appear to be a consensus as to the effect of the IO on trunk flexion or extension during sagittal plane lifting activities. One possible reason for the inconsistency of the results is that sagittal analysis is inadequate. Since IO and EO muscles also act to rotate and bend the body laterally, their activity during lifting activities may be to assist in maintaining overall body stability and coordination of body movement in all three directions and not just assist in the creation of moment about the L5/S1 disc or pelvis. There was also no consensus as to the contribution made by contractions of the IO and EO on the increase of abdominal pressure during lifting activities. Kumar and Davis (1978) and Gracovetsky *et al.* (1981) contend that the oblique muscles are instrumental in the increase of abdominal pressure, but in a review of relevant literature Eckholm *et al.* (1982) suggest that the role of the oblique muscles in creating abdominal pressure may have been overemphasized.

2.1.2. Lateral flexion and rotation about the vertical-axis

In the case of the EO muscle, when one side acts alone it tends to bend the vertebral column laterally and bring the shoulder of the same side forward. In the case of the IO, when one side acts alone it tends to bend the vertebral column laterally and bring the shoulder of the opposite side forward. When both sides of either the IO or EO act together they tend to cause trunk flexion. In a calculation of muscle power based on the previously noted cadaver analysis, Rab *et al.* found that lateral bending is primarily caused by IO and EO muscles, and that rotation is caused by activity in the ipsilateral IO muscles and activity in the contralateral EO muscles.

Yettram and Jackman (1980) predicted, using an LP model which summarizes the total force in 171 muscle forces in the human spinal column in lateral flexion, that the activity level of the IO on the convex side was 141.4 N versus an activity level of 24.3 N on the concave side, and 80.2 N on both sides in the upright position. Schultz *et al.* (1980) developed a model using LP (minimize F comp) and assuming a maximum contractile force of 100 N/cm². He predicted that in resisting lateral bending, extension and twisting, the maximum contralateral oblique force would be 420 N as opposed to 120 N ipsilateral forces. Ortengren and Andersson (1977) note that back muscles and abdominal muscles show higher EMG activity on the contralateral side than on the ipsilateral side during trunk lateral flexion (bending). They also note that the back muscles are active on both sides of the spine in trunk rotation but found no consensus in the literature as to the relative activity level on the two sides. They note only slight abdominal muscle activity during trunk rotation. The consensus appears to be that IO, EO and ES muscles have higher activity on the contralateral side during bending and twisting, but that ipsilateral activity is not zero. McNeill *et al.* (1980) assumed that in lateral bending, the A-P forces of the IO and EO cancel one another leaving only vertical forces in the same frontal plane as the L5 vertebrae. Schultz and Andersson (1981) also assume that the centroid of a cross section of the IO and EO muscles acts in the same frontal plane as the L5/S1 disc. But they do not assume the A-P forces of the IO and EO are zero. This facilitates the assumption that the IO and EO cause no sagittal flexion or extension moment about the L5 vertebrae. This assumption does not appear to be entirely valid in light of the previous discussion of IO and EO activity during trunk flexion or extension.

2.2. Non-symmetric Hand Loading versus ES and RA Muscles

It is found that for a seated operator holding a load in a hand extended to the side, the ES EMG activity on the side opposite the load was, in general, greater than the ES EMG activity on the same side as the load. For the standing operator, when weight was held in one hand, the contralateral side EMG in the lumbar region was higher than that of the ipsilateral side. This effect was more pronounced when combined with 20° lateral flexion and reduced when combined with trunk rotation. Ortengren and Andersson (1977) note that during lateral flexion, the EMG activity of the back muscles was higher on the contralateral side of the lumbar region. They also note that in trunk rotation the back muscles are active on both sides. They cite three studies that note that the activity is similar on both sides and four studies that note that the activity is different.

2.3. Significance of IO and EO versus ES and RA Muscles

Rab *et al.* used cross-sectional measurements from human cadavers as the basis for their contention that the RA, EO, and IO each contribute ~33% to flexion moment. Takashima *et al.* (1979) found that the cross-sectional area of the RA, EO, IO and transverse obliques are all ~3.5 cm² (approximately equal) and that the total of the erectors is ~48 cm².

In the previously noted LP model developed by Schultz *et al.* (1980) the maximum forces in resistance to lateral bending, rotation and twisting for the ES, RA, contralateral oblique, and ipsilateral oblique muscles were 890 N (on each side), 130 N (on each side), 420 N and 120 N respectively. It can be seen that the forces generated by the oblique muscles during some activities are not insignificant, especially when compared with the rectus abdominus.

2.4. Investigation of the "Zero Antagonist" Assumption

Many models of the lumbar region include the assumption that the antagonist muscle activity is zero. This assumption is required to reduce the number of unknowns in the equations of equilibrium and arrive at a determinant state. A review of some relevant literature suggests that this assumption may not be entirely valid. The model developed by Yettram and Jackman (1980) predicted an IO activity level of 80.2 N on both sides in the upright position as compared with 24.3 N on the concave side and 141.4 N on the convex side in lateral bending. The predicted antagonist concave muscle activity is lower but not zero.

Significant antagonist ES EMG activity was observed for a seated operator when holding a load in the outstretched hand. In fact, in the no-load case the right side activity (same side as load) was higher than the left side when the hand was held laterally out from the body. Kumar and Davis (1978) note that

the EO muscles are trunk flexors but found that the 'massive activity' of the EO coincides with the ES at the moment of maximum stress in the stoop lift task. They suggest that this EO activity may assist the deeper muscles in raising the abdominal pressure, although as noted earlier, the role of the EO and IO muscles in raising the abdominal pressure has been questioned. Schultz *et al.* (1980) found that during various types of physical activity there was significant antagonistic EMG activity. For example, both the EO and IO were sometimes active and antagonistic to the ES. Of course, as noted earlier, it is not certain whether the posterior two-thirds of the EO would cause a flexor moment (antagonistic to the ES) or an extensor moment (synergistic to the ES). Ortengren and Andersson (1977) note that the abdominal muscles (RA, IO, and EO) show increasing activity while being stretched in trunk extension. However, this does not agree with the work by Lee (1982) indicating no RA activity during the pull task.

It therefore appears that the requirement for stabilization and control during dynamic activity results in situations where the assumptions that antagonist muscle activity does not exist must receive careful analysis to prevent the underprediction of total system muscle forces.

3. BIOMECHANICAL TRUNK MUSCLE FORCE MODELS

3.1. Static versus Dynamic Models

Computerized biomechanical models for trunk muscle force prediction models have progressed from static, two-dimensional analysis, to more recent attempts at understanding dynamic, three-dimensional stresses on the spine. These models attempt to accurately and realistically represent the mechanical loading and behavior of the lower back, while refraining from as much unnecessary complexity as possible.

3.1.1. Static models

Most knowledge concerning the reaction of the trunk internal spine loading structures has been based on static exertions of the trunk. Chaffin and Baker (1970) were the first to create a model of loading on the lumbar spine under occupational conditions. Their model, which was two-dimensional and static, consisted of several links representing the major articulations of the body. They computed the torque imposed on each joint and the subsequent compression on the spine. The effects of internal trunk loadings were not considered other than from trunk extensor muscles represented by a single equivalent trunk muscle. Schultz and Andersson (1981) later created a lumbar spine model that could be used for workplace assessment. Their model considered the effects of the external moments on the activity of ten trunk muscles and on intra-abdominal pressure. This model computed the compression and shear forces on the spine primarily under static conditions, but it was not designed to calculate additional spine loading attributable to co-activation of the trunk muscles.

The most obvious criticism of the static models is that most MMH activities are dynamic, therefore static models tend to underestimate the forces and moments because the internal loads imposed by dynamic actions are ignored. Many of the dynamic models have estimated that loading of the lumbar spine under dynamic conditions is 22.5–60% greater than loading under static conditions.

3.1.2. Dynamic models

Most of the dynamic models are based on kinetic or kinematic body motion information. The researchers computed the spinal loads attributable to internal forces generated by the body segments during motion as well as spinal loading from static gravitational forces. McGill and Norman (1986) developed a model of spinal loading during sagittally symmetric trunk motion using EMG data as input. This model incorporated previously published relationships of internal structure responses to motion conditions in order to assess spinal loading while tracking body segment motions. However, limited empirical evidence of the model's validity was provided. Marras and Sommerich (1991) developed and validated a three-dimensional dynamic model for predicting sagittally symmetric and asymmetric lifting moments and associated spinal loading during lifting.

3.2. Optimization-based versus EMG-assisted Models

Two basic approaches to partitioning the moment-generating duties among the trunk musculature have been reported in the literature: optimization-based and EMG-assisted models.

3.2.1. Optimization-based models

The optimization approach attempts to satisfy the reaction moment requirement by recruiting the various muscular contributions based on an optimization criterion such as minimization of joint compression and shear load, or first minimization of muscle contraction intensity and then spine compression load. One of the major problems with this approach is selection of appropriate objective functions as well as constraints to solve a redundant problem. It does not fall within the deterministic realm of mechanics and requires physiological data that are yet unavailable.

The application of a linear optimization technique for the prediction of trunk muscle force was suggested first by Schultz and Andersson (1981). In this study, the objective function was to minimize the compressive force on the lumbar vertebra. This objective function allocates the most forces needed to resist the external load to the muscles with the largest moment arms. To prevent this situation, Bean and Chaffin (1988) suggested an alternative procedure that involves formulating and solving two linear programming models sequentially using maximum muscle intensity and the sum of muscle forces respectively as an objective function. Han *et al.* (1991) proposed a nonlinear optimization force model using a nonlinear objective function for predicting forces in the muscles, and force contributions of the disc at the L3/L4 level of spine subject to a combined flexion and left lateral bending load. In these models, a cost function minimizes the sum of the square of the difference between the actual muscle stress and the maximum permissible muscle stress for various muscles. Chung *et al.* (1999) also suggested an optimization model that was modified to take into account the muscle co-activity. The model used three types of linear and nonlinear objective functions (minimize maximum muscle intensity, minimize sum of magnitudes of the muscle forces raised to power 3, and minimize sum of the muscle intensities raised to power 3) in various asymmetric lifting conditions. According to their results, these models reflect the twisting effect of muscle force vectors for eight primary trunk muscles when trunk rotation is

involved, and give good predictions of the forces of contralateral erector spinae, latissimus dorsi and external oblique muscles when compared with the EMG signals obtained from experiments. Among the three objective functions, minimization of the maximum muscle intensity showed the best prediction capability.

A common feature among the diversity of the optimization model formulation is the tendency for many muscles to have zero predicted muscle forces. Researchers have shown that the assumption of a lack of co-activity is not justified under dynamic conditions. Optimization models usually cannot account for co-activity because the quantity of the model solutions is limited by the number of non-boundary solutions, or six of the muscle forces, since the functional constraints are usually driven from the force and moment equations. Optimization models that have managed to include co-activity have forced it to occur by imposing artificial model boundary constraints. Consequently, these models often cannot predict the same level of co-activity that is observed experimentally.

3.2.2. EMG-assisted models

The second modeling approach to determine the load sharing duties among the trunk musculature is based on EMG and knowledge of joint kinematics. The advantage of these models are (1) they are not limited by the constraints of optimization objective functions; (2) they account for muscle co-activation forces via measurement; and (3) they typically use predicted, physiological coefficients for instantaneous validity checking.

McGill and Norman (1986) proposed a dynamic model of the lumbar spine that attempted to determine the significant forces in both active tissues using an EMG-assisted strategy, and in passive structures from estimated strain. McGill (1992) utilized the same methodology in calculation and assessment of the loads in both passive and active lumbar tissues during dynamic lateral bending.

Marras and Sommerich (1991) developed an EMG-assisted model in which relative muscle forces are determined from EMG activities normalized to a maximum, however, maximal and submaximal EMG change significantly with trunk angle, isokinetic velocity, and acceleration. Granata and Marras (1993) resolved this problem by normalizing the EMG input as a function of both trunk angle and asymmetry, and modifying for length and velocity artifact.

However, the EMG-assisted models are not general-purpose models. Rather, they are intended for use under laboratory conditions, and to interface with heavy laboratory instruments (EMG, dynamometers, etc.) that can assess the influence of motion-related biomechanical factors. It is often impractical to collect EMG activity in industrial locations due to the hostility (such as presence of magnetic field) of work environments. In this respect, Mirka *et al.* (1996) developed a simulation-based model that can generate EMG signals given a set of environmental conditions such as weight, moment, trunk posture and trunk dynamics. The shapes of best fit distributions were developed with multiple runs of the simulation and then the estimated EMG values were generated for bending and lifting activities by the multivariate Johnson distribution method.

Lee (1998) proposed another way for predicting the trunk muscle activities, named the fuzzy logic-based human expert EMG prediction model (FLHEPM), which utilizes two physical variables (trunk moment and trunk velocity) as inputs and ten trunk muscle activities as output. In this model, human expert knowledge obtained from task observations is utilized as model inputs in terms of linguistic values in order to predict the EMG signals.

The basic idea of the above two approaches is to develop an EMG prediction model for generating EMG data under given task conditions, which will be utilized as input to any EMG-assisted model, without direct measurement.

4. SUMMARY AND CONCLUSION

The assets and liabilities of state-of-the-art biomechanical models for predicting spinal loadings during MMH tasks have been discussed. Many of the biomechanical models that are currently available are still in their evolutionary stages and many researchers are trying to enhance the accuracy of models by removing several unrealistic conditions from them. In recent years, most research efforts have focused on investigating the dynamic conditions relative to static conditions, the effects of asymmetric conditions relative to symmetric conditions, and the interaction effect of dynamic and asymmetric conditions on the amount of stresses imposed on the spine. This raises a problem concerned with the trade-off between accuracy and applicability. Like any modeling approach, biomechanical models attempt to represent the workload accurately and realistically while refraining from as much unnecessary complexity as possible. The more input parameters are incorporated in the model, the more valid estimates for the workload might be obtained. As the models become more complex, however, their suitability for application in the occupational field declines considerably.

1. INTRODUCTION

It is widely held that vision provides 90% of driving-relevant information to the driver, though this has not been quantified. Over the past 25 years, there have been many studies which have investigated the relationship between specific visual attributes and driving performance in order to determine the visual requirements of the driving task or develop more effective driver vision tests. Many of these were correlational studies in which the visual attributes of drivers were measured and related to traffic convictions and accident experience (Burg 1968, 1971, 1975). Although these studies only produced weak correlations, researchers were able to speculate about the relative importance of various visual attributes to different driving behaviors (Henderson and Burg 1974). Shinar (1977) evaluated a battery of vision tests (including static visual acuity under normal illumination, dynamic visual acuity, detection-acquisition-interpretation, movement-in-depth in the central visual field, central and peripheral angular movement thresholds, field of view in the horizontal meridian and static acuity in presence of glare), and found that all of the attributes significantly correlated with accident rates in at least one of the subsets (based on age and time of accident), but none correlated in all the subsets. The results indicated that many of these tests had less than desired repeatability and none, including the SVA (static visual acuity), could reliably predict driving performance. For a review of the literature in this area, readers should consult Bailey and Sheedy (1988) and Shinar (1977).

Other researchers have found stronger correlations. For example, Hofstetter (1976) provided some evidence that poor visual acuity discriminated between drivers with multiple accidents and those with one or no accidents. Johnson and Keltner (1983) reported that drivers with binocular field loss had traffic violations and accident rates twice that of drivers with normal visual field. Interestingly, the acuity and visual field tests employed in these studies used conventional clinical tests rather than the more exotic tests favored by vision scientists.

In summary, however, correlational studies have generally failed to provide consistent evidence for a strong relationship between measures of visual capacity and driving. There are a multitude of good reasons for the weak statistical relationships found between visual measures and driving performance (such as citations and accidents). These include driver compensation for poor visibility, high individual differences in driving ability, diversity of driving situations and effects of other visibility factors such as windshield dirt, solar glare, fog and rain, obstructed signs, worn lanes, and driver compensation. Furthermore, most drivers with severe visual deficits have been denied licenses so that they are not represented in aggregate road safety statistics. Another important factor is that it is difficult to separate purely visual limitations from cognitive processes involved in areas such as attention, perception, recognition, and decision-making.

2. VISION SCREENING FOR ELDERLY DRIVERS

2.1. Current State of Driver Licensing

Driver visual screening is based primarily upon measures of acuity (e.g. using Snellen charts). A survey of Canadian provincial and US state licensing requirements reveals that the most common standard is 6/12 (20/40), with a range of 6/6 (20/20) to 6/21 (20/70). In addition, some jurisdictions have a standard for monocular and binocular horizontal visual field, color vision, and diploplia.

Briggs (1983) asserts that traditional acuity testing by itself or supplemented with simple color, peripheral vision, or other tests may be inadequate as a basis for visual standards because:

- the test is irrelevant to many real-world tasks such as driving
- there is little correlation between acuity and task performance
- acuity testing is often a clinical first step in discovering anomalies in visual function; this is irrelevant to performance screening
- there is no consistency in applying a standard for acuity
- criterion levels are often based upon the consensus of a panel
- experts from different jurisdictions do not agree upon any acuity standard or test procedure
- there is disagreement on the use of corrective lenses to meet visual acuity standards

2.2. Effects of Age on Visual Capacity

The visual characteristics of the elderly and the effects of aging on visual capacity is well documented. Nearly every aspects of visual function decreases with age, including:

- loss of accommodation
- decrease in color discrimination due to loss of transparency of lens
- decreased sensitivity to light
- decreased static and dynamic visual acuity (to the point where corrective lenses cannot completely overcome refraction losses)
- decreased visual field
- decrease contrast sensitivity
- increased susceptibility to disability glare due to increased intraocular light scatter
- decreased ability of pupil to dilate resulting in decreased scotopic vision
- retinal disorders include degeneration of macular retina, development of cataracts, retinal detachments, retinitis pigmentosa, degenerative myopia, diabetic retinopathy, hypertensive retinopathy, arteriosclerotic retinopathies and glaucoma.

In addition, higher-order functions have also been shown to decline with age. These include:

- visual spatial judgments (e.g. depth and speed) and organization skills
- psychomotor ability
- focused and divided attention
- short-term memory
- complex problem-solving abilities

2.3. Prospects for Improving Driver Vision Testing

There are seven useful criteria described for establishing visual standards: (1) visual attribute must be linked to safe driving; (2) pass/fail criterion should allow individual consideration; (3) vision

screening test should be reliable and valid; (4) the imposition of standard should aim to identify those whose vision can be significantly improved through proper refractive correction and eliminate those that cannot achieve minimum standards even with the best of correction; (5) the safety benefits must justify the costs of administrating the standard; (6) there should not be engineering or other interventions which are more cost-beneficial than the imposition of the standard; (7) the standard should permit imposition of restrictions, where appropriate (Bailey and Sheedy 1989).

Most, if not all, of suggested alternative standards fail to meet these criteria. A major difficulty has been the inability to identify the visual attributes most important for safe driving and determine criterion levels of performance. Moreover, most of the alternate tests of vision that have been suggested have serious shortcomings (e.g. low inherent repeatability of measures, high cost of equipment, high administrative burden associated with implementing new standards such as the need to provide space and trained personnel and the need to deal with a greater number of failed drivers).

Notwithstanding, the lack of success of past efforts in this area, researchers continue to seek improved techniques for screening drivers (young and old). Readers should refer to contrast sensitivity and effective visual field.

2.4. Accommodating age effect in the design of highways and vehicles

Since, for the foreseeable future, the prospects for improving driver vision testing are not high, it may be more appropriate to concentrate efforts on interventions which are likely to reduce the visual requirements of drivers in an attempt to achieve a better match between the demands of the driving task with the capabilities and limitations of elderly drivers. The most critical problems associated with advancing age are (1) declining visual acuity and contrast sensitivity, (2) glare sensitivity, and (3) decreasing ability to accommodate. Many of these problems can be alleviated by improved designs for highway signs, in-vehicle displays, and improved headlight systems. It is recognized that these interventions are not trivial or inexpensive, but they may offer more effective solutions for accommodating the growing population of elderly drivers.

3. USEFUL FIELD OF VIEW

Driving is a skill that requires processes beyond just visual input. Other central functions such as attention also play a key role in driving performance. Some of the most promising work relating vision and aging to driving safety has emerged from research on the Useful Field of View (UFOV). The UFOV is a measure of visual function, which takes into account the cognitive and the perceptual aspects of the driver's performance. The UFOV measure integrates both visual and attentional processes by investigating localization, detection, and identification performance of visual information obtained from the external environment.

Research on the UFOV has consistently shown that driving performance declines for the elderly when faced with additional task demands beyond driving (i.e. steering and button pressing versus just steering) (Schieber 1999). Older adults appear to experience difficulties in absorbing all the aspects of divided attention. In addition, the area of the visual field over which attention may operate decreases with age. It has been suggested that perhaps the elderly have a difficult time coordinating two or more different motor processes required to execute dual task responses into one effective motor scheme. For instance, it has been found that under divided attention conditions, steering accuracy improved significantly when a vocal response (as opposed to a manual response) was required on the secondary task. The size of the age-related differences due to dual task responses decreased when the several tasks performed required the use of different attentional resources. It appears that the functional field of view is narrowed in older adults due to the attentional demands imposed by driving (Schieber 1999).

Workload and Electro-encephalography Dynamics

G. Sammer

Center of Psychobiology and Behavioral Medicine, University of Giessen, D-35394 Giessen, Germany

1. WORKLOAD

Workload is a rather ambiguous concept. Subconcepts like cognitive load, informational load, attentional load and emotional load are not based on uniformly used theoretical considerations. The distinction between stress, strain and workload is difficult to make, especially in real work settings. Within these concepts psychophysiological measurements are influenced by a number of psychological and physiological factors due to intrasubject and task parameters in the interaction of subject with task. The importance of motivational processes, emotional processes and the total workload, resulting from both paid and unpaid work in its entirety, has been discussed within cognitive–affective–physiological frameworks. Moreover, there is evidence that time-related factors, individual differences, cognitive styles and coping strategies have effects on the psychophysiological measurements and cause changes in the dynamic properties of the physiological systems.

The term "workload" frequently describes concepts that focus on the costs necessary for a subject to perform a task. Within selective and divided attention theories the costs are seen as a problem of the limited capacity of cognitive resources. Therefore, load means costs as a function of available resources. The experimental manipulation of the resources during the performance of tasks by variations of modality, physical properties of the stimuli, the required reaction, variation of speed-features of a task, dual tasks and consequences from the quality of performance are standard factors in the investigation workload.

Mental workload describes the amount of cognitive resources involved in performing a task. The concept refers to a dynamic equilibrium between requirements of the task and available cognitive resources that are necessary for the task performance. Mental load is higher if the task requirements are larger than the available resources and vice versa. Mental load cannot be measured only by investigating one of both task requirements and the outcome of performance but also has to take into account the relationship between requirement and costs.

An alternative approach for the investigation of workload is to investigate single subprocesses of human information processing under workload conditions. Assuming independent resources, modality specific subsystems are postulated, which can be described by different cognitive operations. Such cognitive operations, which are included in practically all relevant theoretical frameworks, are stimulus encoding, stimulus analysis, semantic processing, recovering of information, decision-making and response selection. In a review on mental load Gopher (1994) suggested including automatic versus controlled performance,

implicit versus explicit processes, influence of capacity and interference processes, conscious attention control and others. In addition, Gopher also distinguishes between short-time load and vigilance, such as are of importance in different kinds of monitoring tasks in industrial production or traffic professions. It is of interest that these terms represent different kinds of cognitive processing which do not necessarily affect the outcome of a task.

2. PSYCHOPHYSIOLOGICAL APPROACH

As stated, workload research concentrates on the costs necessary for a subject to maintain its task performance. According to Gopher (1994) there are two classes of physiological cost functions: (1) general arousal and energy modulation measures and (2) correlates of specific brain activity involved mental load processes. The underlying assumption in point 1 is that task demands activate body systems to service the increased requirements for efficient task processing.

Although the psychophysiological approach seems to have satisfactory validity, serious theoretical problems still remain. Psychophysiological measurement requires the relationship between the underlying construct of workload and the physiological indicator-system to be defined. Usually this cannot be achieved by a single model or hypothesis that integrates all psychological and psychophysiological results. More often psychological models try to explain cognitive or behavioral relationships, and physiological and biophysical models try to explain the relationship between the activity of a physiological system and their measurements. Explicit psychophysiological hypotheses only exist for a few psychological constructs, such as stress. However, one difficulty with these psychophysiological hypotheses lies in the fact that different patterns of psychophysiological measurements for the same psychological construct are found between individuals.

Further, it is difficult to integrate concepts, which have their roots in different disciplines. For instance, from the neuropsychological point of view it is necessary to understand *where* and *how* information is processed in the brain. Cognitive modeling is based on empirical evidence without being mainly interested in the issue of localization; for neuropsychological modeling neurobiological evidence has to be added. It follows (1) that the concepts concerned are quite different and (2) that psychological constructs can not easily be mapped neither on neuronal structures nor on neurophysiological activity. Instead of mapping "workload" on cerebral structures or on, for example, electrophysiological patterns it appears to be useful to extract basic functions in order to gain concepts of lower complexity.

2.1. Electro-encephalography, Information Processing and Workload

Electro-encephalography (EEG) is a multivariate method (e.g. different recording leads, different frequency bands). Both tonic and phasic components can be recorded with high-time resolution. Recording is non-invasive and may be implemented in the laboratory as well as in field studies. The reactivity is considered to be very low.

EEG represents macropatterns of cortical cell-assembly activity. This activity is strongly influenced by subcortical structures. For example, a pacemaker-function of some specific

thalamic nuclei for the EEG a-activity is discussed frequently. However, empirical and theoretical evidence is not sufficient to explain the "secrets" of the brain rhythmic activity. Different from attempting to identify some cortical or subcortical generators it might be useful to relate the macroscopic EEG spatio-temporal dynamics to well defined brain states.

The toolbox for the analysis of EEG dynamics includes spectral analysis and auto-regressive methods, non-linear methods (dimensional complexity measures, entropy measures), coherence-analysis, the computation of the event-related de-synchronization and even more methods.

In many studies, mental workload assessment was investigated with event related potentials (ERP) of the EEG. From the literature, there is a good evidence that different components of the ERP are workload sensitive. In fewer workload studies the ongoing EEG was investigated. This fact might be due to two disadvantages of ongoing EEG analysis.(1) Spectral analysis requires the data to be stationary. This prerequisite condition does not meet psychological assumptions about human information processing. Brain states are discussed to be stationary in the range between 10 and a few hundreds of milliseconds. (2) The relatively short duration of stationary brain states reduces both the time precision and the correlation to any brain state. That makes it difficult to relate EEG measures to time-structured models of human information processing (as often done with ERP parameters).

3. WORKLOAD ASSESSMENT BY EEG

For EEG studies workload can be understand as changes in both quality and quantity of cognitive and cerebral processes caused by an increased task-demand under the premise of keeping task-performance constant. This definition makes possible (1) multivariate designs for the investigation of cognitive workload by variations of both quality and quantity features of task-demands, (2) relating psychological or psychophysiological indicators to concepts of human information processing and workload in neuropsychology, cognitive psychology and ergonomics, and (3) the inclusion of results from EEG studies on subsystems of human information processing (not on workload in general).

3.1. Spectral Analysis

Spectral analysis was the most frequently used method in studies of workload and ongoing EEG. The spectral power is computed for the usually inspected EEG frequency bands d (0.5–3.5 Hz), q (4–7 Hz), a (8–13 Hz) and b (14–30 Hz). Sometimes the a band is subdivided into a lower a_1-band (8–10.5 Hz) and an upper a_2-band (11–13 Hz). Similarly the b frequency range is split into several sub-bands. The meaning of the bands is well documented for arousal, relating slower waves, which usually have larger amplitudes, to low arousal states and sleep. However, activity in all of the frequency bands can be observed even during task-performance, where the relationship to functional states of the brain is manifold and presently is under intense discussion.

3.1.1. Alpha- and Theta-EEG

Studies gave evidence for a decrease of activity in the a-band during cognitive task performance. This was especially true for the a_2 frequency range in tasks such as concept learning, memory scanning, mental arithmetic, aviation (flight performance) or

playing computer games. Moreover, there is good agreement that an increase of q activity occurs during cognitive task performance. This applies especially for anterior electrode locations. Similar results on both frequency ranges were gained from computations of the event-related de-synchronization (ERD). However, there are as well reports about increased a-activity with workload. Increased a-power was shown to come up with mental arithmetic, imagery, mental rotation and others. There is some evidence that the faster a_2 frequency band is rather load-sensitive, while a_1-power is in correlation with changes of the attentional demand of both external and mental tasks. Owing to the highly complex structure of attention, the topographical distribution depends on the specific characteristics of the task. For instance, selective attention and controlled processing were shown to be in correlation with frontal activity, whereas the transition from controlled toward automatic processing is accompanied by an activity shift towards parieto-temporal regions. Another reason for conflicting results may be found in different implementations of the baseline recordings. It makes an important difference if eyes are open or closed, if subjects are instructed to just relax or if they are asked to perform a reference task. It is also strongly recommended that multiple baselines are implemented to monitor time-related changes. Various frequency band definitions contribute to a reduced comparability of results. If appropriate, this could be faced computing individual frequency peaks for each subject.

Topographical mapping of EEG parameters give information about any subsystem-configuration which is specific for a certain task-induced workload. Mostly, hemispherical lateralization, lobe specific distributions and coherence between various cortical areas are evaluated. Beside the rather coarse-grained topographical findings mentioned above, which were replicated many times, topographical distributions show a strong dependency from specific characteristics of a task. The investigation of hemispherical asymmetries did not reveal significance as an indicator for cognitive workload. Mostly, hemispherical asymmetries can be explained with well-known material-specific (verbal, figurative) effects.

Not always the appearance of slow EEG frequencies (e.g. q-EEG) is an indicator of increased workload. Long-distance train drivers also elicited increased power in slow EEG frequency bands during low-workload stages (Cabon *et al*. 1993). This effect was explained with low vigilance that is well known from monotone sustained attention tasks with a very low target probability. Similarly, if human limits are overtaxed, not only is a high cognitive workload stage is induced, but also there may emerge serious changes in emotion, motivation or arousal. Dependent on these factors it was shown that EEG parameters can shift toward the baseline values or return to the baseline. Therefore, it is important to collect behavioral data to discriminate high workload from overtaxing stages.

3.2. DC–EEG

The investigation of EEG dynamics is not limited to the conventional frequency range of the EEG. DC-EEG (often the term steady potential is used) is defined within a frequency range below d. For recording DC-EEG it is necessary to use adequate DC-amplifiers. Phasic changes of the DC-potential (DC-potential shifts) represent processes of cortical neuronal excitability and changes of arousal. DC-potential shifts appear spontaneously as

well as event-related. Negative DC-shifts were found in various workload conditions, e.g. traffic-noise exposure, tracking- and reaction-time tasks, mental arithmetic.

3.3. Non-linear Analysis

Recently, methods of the non-linear systems theory have been applied to the ongoing EEG. The same time series fed into the spectral analysis can be used for the computation of the so-called correlation dimension. This method is used to evaluate the geometrical representation of the reconstructed system dynamics. The correlation dimension is an estimation of the lower threshold of the number of degrees of freedom for the underlying system. Therefore, the correlation dimension is a measure for the overall complexity of the brain system dynamics estimated from the (EEG) time series. Following Pritchard and Duke (1995) the term dimensional complexity is now used for estimations of the correlation dimension.

There are few studies on workload and non-linear EEG dynamics. Sammer (1996) carried out studies on working memory-induced load and the dimensional complexity of the EEG. The main results showed an increased dimensional complexity with higher workload over frontal areas. Often, dimensional complexity was in negative correlation to the q-activity, which varies with task induced load. Results from a few studies on dimensional complexity and task-induced workload are very similar.

No differences were found between mental, physical or emotional workload indicating cognitive task involvement even under conditions of physical and emotional load. As for spectral parameters of the EEG, hemispherical asymmetries were dependent on characteristics of the stimuli.

4. SUMMARY

Both the theoretical framework and the practical measurement of mental workload are far from being standardized rules for the measurement or fundamental general theoretical modeling of mental workload. There is a remarkable overlap of concepts. Moreover, the theoretical gap between psychological concepts of mental workload and (psycho-)physiological measurement is far from being closed. Given the rich and elaborate psychological hypotheses that exist for some aspects of mental workload, priority should now be assigned to developing hypotheses to link these with psychophysiological phenomena to enhance the reliability and validity of psychophysiological measurement in the investigation of mental workload.

EEG dynamics were shown to vary with workload. Results from the application of different methods are in good agreement. Other than heart rate variability measures, which are load-sensitive but do not allow the discrimination of different amounts of workload (with the exception of memory load), there are several findings indicating that EEG dynamics as well allow a discrimination of hard and less hard workload stages. Moreover, topographical analysis in connection with a focus on cognitive subprocesses of workload may reveal both a better diagnosis of actual workload and may raise new questions of interest. From these results ongoing-EEG analysis can be especially recommended for investigations in which interest centers on different levels of task-induced cognitive workload, the discrimination of cognitive load related to different stimulus-types or differences between cognitive workload and attentional processes.

However, the relationship between EEG dynamics and workload is manifold and complex depending on specific characteristics of the workload setting. Attention must be paid to a number of factors that have an uncertain impact on the EEG dynamics. Such factors are for instance monotonous low-load work, overtaxing of individual abilities, interindividual differences (e.g. personality, individual physiological responses) as well as effects of cardiovascular activity on brain activity (e.g. baroceptor activity influences thalamocortical pathways, e.g. in connection with the transition of the body into orthostasis), where further research still is needed.

To conclude, there are many studies suggesting that EEG dynamic analysis may essentially contribute to powerful strategies of workload assessment. Nevertheless, a lot of both basic research and applied studies must be carried out to close the gap between theoretical frameworks and applied ergonomics.

Part 3

Performance Related Factors

Activity

J. Leplat

Ecole Pratique des Hautes Etudes, Laboratoire d'Ergonomie Physiologique et Cognitive, F-75005 Paris, France

1. INTRODUCTION

The notion of activity tends to be more and more central in ergonomics. One of its origins can be found in Russian psychological research (Bedny and Miller 1997). It became very important in European ergonomics, first in the French-speaking countries, then in the Scandinavian countries. American research, influenced by the trend called "situated action" accords it a growing interest. In France, a well-known ergonomist, Wisner (1995), wrote that "the central and original part of the ergonomic analysis of work is the analysis of activities." This ergonomics of activity is well illustrated into a French manual of ergonomics (Guérin *et al.* 1997). In a recent "Vocabulary of Ergonomics," de Montmollin (1997) distinguishes this ergonomics of activity from the ergonomics of human factors. Schematizing the difference a little, it can be said that the latter views ergonomics as the application of general knowledge to human functioning, which knowledge is, for the most part, acquired outside of the work situation. Emphasis is placed on the acquisition of this general knowledge: its application is not considered as a preferred object of research. Ergonomics of activity is centered on the activity of the person in his/her work situation, on what s/he really does. This activity is viewed as a complex process, which comprises essential dynamic and temporal aspects and which integrates the effect of multiple conditions. Activity must be distinguished from behavior that only constitutes the observable facet of activity: activity includes behavior and its regulating mechanisms.

Activity is often associated with the notion of task, which is defined as a goal to be achieved under determined conditions. Activity answers task goals and demands, but it answers them in a non-passive way. An operator receives the task and answers it according to his own purposes which can lead him to re-define the task, its goals and conditions. Operator, task and activity form a triad in which the terms are in a relationship of co-determination. Let one take the simple (?) example of using a video cassette recorder. The user's task is to obtain a correct recording, with the technical conditions defined by the properties of the instrument and various constraints. The user has a certain level of competence with regard to the instrument, as well as a more or less great desire to succeed alone, etc., which will influence his activity. The activity will express itself by observable trials and errors, by comments concerning the task, satisfaction (or annoyance!), etc. All of this cannot be straightforwardly and completely inferred from previous knowledge about the task and the user. Interaction between the three terms can be easily imagined. The situation can be made more complicated by introducing a collective component into the triad, with a person who comes to give advice.

To study activity is to study the organization of the terms of the triad. To do this, one can take the task or operator point of view, it being clear that the one involves the other as shown by the discussion below.

2. ACTIVITY FROM TASK POINT OF VIEW

In adopting this point of view, it should not be forgotten that the task is always for a given operator, in other words, the relationship between activity and task is conditioned by the operator who carries out the task.

2.1. Prescribed Task

The definition of "task" is often taken from Leontiev (1972) who considers a task as a goal to be achieved under determined conditions. "Conditions" are to be understood as everything that must be taken into account for the activity to be carried out. When these conditions are deemed to have negative effects, they are called "constraints." The task is called "prescribed" when the goal and conditions are fixed by hierarchical, thus external, authority (business, administration, etc.). They can be fixed with variable degrees of precision. In complex work, such as the nuclear field, goals and conditions are minutely defined by a procedure. At the other extreme, the task is only made more explicit by its goal or goals. In this case, one often speaks of a *mission* and the operator must define his own task himself, which task will guide his activity: this is the case, for example, with design activities.

A prescribed task is itself the result of an activity, designer's or organizer's activity. It depends on both what the designer or organizer wants to achieve and on the model he has build of the operator's activity. The designer or organizer more or less explain the task according to the competence the operator is deemed to have, more if the operator is judged less competent. The operator must be provided with the information he his lacking by means of external conditions for realization (instructions, diverse aids).

There are various nature of task conditions: physical (i.e. thermic, luminous ambiance, etc.), technical (i.e. type of tool, machine, etc. Rabardel, 1995), organizational (i.e. isolated work, type of management, span of discretion, etc.), social (belonging to an occupational or labor group, social protection, etc), etc.

2.2. From Prescribed Task to Activity

A certain number of steps can be distinguished in the activity which leads from the prescribed task to the final activity: prescribed task → task deemed prescribed by the operator → task re-defined by the operator → task truly realized (corresponding to the final activity). Final activity can be characterized by the analyst (realized task for the analyst) or by the operator himself (realized task for the operator).

Deviations between these tasks reveal activity characteristics and can be used as guidelines for analysis. For example, a deviation between the prescribed task and the task deemed prescribed can come from a poorly formulated task or from a lack of operator's competence.

2.3. Prescribed Task Analysis and Activity Analysis

Several authors talk about and use the essential distinction "task"/"activity," but employ terms other than those presented. For example, Hollnagel (1993) calls prescribed task analysis "task analysis" and activity analysis "task description or performance analysis."

Activity analysis is oriented by task analysis, but must be carefully distinguished from it. A pitfall to be avoided is that of

considering prescribed task as a reference by assimilating the deviations between the real and prescribed task to error. Deviations are very important for activity analysis, but they must be interpreted: the mechanisms which produce deviations as well as how they are involved in the activity must be discovered. Deviation raises a question, but does not constitute a response.

3. ACTIVITY FROM THE OPERATOR'S POINT OF VIEW

Activity is always the activity of a person often called "operator" in ergonomics. In addition, a good understanding of the activity depends on the operator's knowledge relative to the tasks to be realized. Two means by which the operator intervenes in the activity can be distinguished: as a task treatment system and as a generator of activity purposes.

3.1. The Operator as a Task Treatment System

To carry out his task and achieve his own objectives, the operator disposes of means, instruments and resources linked to his human quality and to acquisitions obtained during his life. Thus, he possesses a number of characteristics, in particular physiological and cognitive, which condition his activity and are present in the handbooks and manuals of ergonomics and human factors. For example, properties of perceptive, motor and cognitive systems, chronobiological and chronopsychological factors, modifications connected with age, postural factors, etc. will be looked at. Ergonomics studies (or should study!) these traits in relationship to work. For example, visual discrimination will be linked to instrument panel reading, nycthemeral variations with shiftwork, etc.

Cognitive ergonomics has lead to the giving of much importance to competence or the system of knowledge which enables the generation of activity in response to the demands of a class of tasks. Knowledge of this cognitive architecture underlying activity is essential for the fitting out and design of numerous types of work.

A growing interest is given to meta-knowledge, in other words, to knowledge the operator has of his own competence, knowledge which is essential for the management of his activity. It is actually necessary that he knows what he is able to do, what he can do under such and such conditions, and the limits beyond which it is no longer possible to respond to task demands correctly.

Among operator traits that condition the activity, personality must not be forgotten, even if ergonomics has only attached little importance to it up to now, perhaps because its study involves methods not familiar to ergonomics and its role is difficult to bring to the foreground and to take into account.

3.1.1. Activity cost and resources

Activity represents a cost (effort, constraint, load) to the organism and requires resources: here, the matter is the energetic or intensive component of the activity. The evolution of activity lead to an interest in mental load. Evaluation of this load and its nature has been the subject of much research. Regulation mechanisms of load are important in the work situation and were particularly brought to the foreground in the context of task allocation in collective work.

3.2. Operator as Generator of Activity Purposes

Activity has not as its only function to respond to task demands, and an operator has not as his only role to exploit his possibilities to respond to task demands. Through his activity, the operator aims at achieving his own purposes: to build his identity, to improve his self-image, to be recognized by his peers, to express certain values, etc. Therefore, activity responds to a double rationality, instrumental and subjective, and finds its meaning in relation to external demands (the task) and in relation to the author's own purposes. Work psychologists and sociologists emphasize the importance of the second type of rationality by noting, for example, "the commitment of the subject's values in his activity" (Clot 1995) and that "technical activity interferes with moral concerns" (Dodier 1995). Until recently, this facet of the activity takes little importance in ergonomics. The first traces of it can be found through the notion of motivation, understood as the value or interest the operator attaches to his activity. The agent's purposes were also approached from the point of view of physical and mental health protection. Thus, it could be shown that the risks incurred in activity arouse defense mechanisms which, paradoxically, can be expressed by an increase in risk (Dejours 1993).

4. ACTIVITY AS A PROCESS

Activity has a manifest, therefore observable, component and an internal, therefore hidden and unobservable component. The observable component corresponds to behavior while the second concerns the mechanisms that direct and regulate this behavior: cognitive, affective and cognitive mechanisms. This component, inferred from the first one, always maintains a hypothetical character. The difficulty lies in the fact that some mechanisms can only and very indirectly be expressed into observable activity. As a result, inference of activity mechanisms is a basic goal of the analysis of the same. Thus, the importance of the methods of activity analysis can be understood. These methods are, in general, derived from classical methods, but adapted to work situations. Let us take, as example, methods of aided observation (with event counters, videotapes), of aided consecutive verbalization (self-confrontation), of simulation, of errors, incidents, accidents analysis and of analysis of long term effects of activity (fatigue, psychological troubles), exploratory sequential data analysis, etc. Models also convey and favor certain types of methods.

The importance of *collective activity* is growing in ergonomics. This is the activity of a group of persons, often called team, who interact in order to realize the same task: what one does depends, in part, on what the other does. In relation to individual activity, this activity raises new problems: nature of the work group (composition, organization, competence, etc.), link between group structure and task structure, mode of task allocation within the group. It gives prominence to the main role of coordination and communication. It leads to interest in the common system of reference or shared mental model which is worked on to make communication easier (for example, language and gestural work systems).

Activities can also be characterized over diverse dimensions and the models proposed for them are themselves diverse and often non-exclusive. These models can be seen as revealing the

variety of activity properties: some types of these properties are mentioned below by emphasizing the activity characteristics they favor.

4.1. Models of Activity Structure

Several principles have been put forward to structure activity. First, one encounters the methods proposed for task analysis, such as the hierarchical analysis (Patrick 1992) and the goals-means task analysis (Hollnagel 1993). Russian psychology is the origin of an often exploited model which distinguishes three phases or functionings in activity: an *orientation phase*, preparatory to execution and aiming at establishing a model of the situation likely to serve as a base for the activity which follows; an *executory phase*, which allows the passage from the initial state to the final state to be obtained; and a *control phase*, which monitors the progress of the previous phases and evaluates the conformity of the result with the targeted goal.

Another framework of analysis, often cited, is from Rasmussen (*et al.* 1994) called the "*decision ladder.*" In the production of activity, a certain number of steps are distinguished: activation, observation, identification, interpretation, evaluation, task definition, procedure definition, execution. All these steps are not necessarily found in a particular activity, and typical short cuts enable activity levels to be characterized (see below).

4.2. Models of Organizational Level of Activity

An often-used model from Rasmussen (*et al.* 1994) distinguishes three modes of activity control: knowledge-, rule- and skill-based. The distinction "controlled activities/automated activities," which comes from experimental psychology, is also very popular. The operator often has the possibility to regulate his activity at one or the other of these different levels, which is what gives him a large capacity to adapt and, therefore, to be flexible in carrying out tasks.

4.3. Model of Regulation: Emphasis on Goal and Evaluation

This model, popularized by cybernetics, emphasizes the role of goal and of the interpretation of deviations from this goal, in other words the process that leads from deviations to the actions to be taken in order to reduce them. Activity can implement several regulatory loops, which can be fitted into each other or not. Some loops enable mental simulation of the controlled system and make anticipation of phases of functioning of this system easier, thus, the operator can prevent dysfunctions.

4.4. Systemic Models: Widening of the Field taken into Account by the Activity

Activity can be considered in relation to a more or less wide set of conditions and one can go more or less far back in the analysis of these conditions. Systemic perspective of activity analysis aims at articulating these different conditions. In particular, it has developed through the introduction of collective and organizational components: for example, let us look at the processes of intervention described and illustrated by Guérin *et al.* (1997) and Rasmussen's (*et al.* 1994) model with its "nested loops of social control." The systemic point of view leads to a modification of the methodologies which is less oriented toward an analysis into elements than to the overall functioning within various contexts.

5. CONCLUSION

To place activity in the center of ergonomics leads ergonomics to focus on its essential object: anthropocentered improvement of work conditions. Individual or collective activity expresses the quality of this improvement, and it is through a better knowledge of activity that technical and organizational improvements, in particular, can be made more adapted to the operators.

Activity Theory

G. Bedny

Essex County College, Newark, NJ07079, USA

1. INTRODUCTION

It becomes apparent that overcoming the traditional separation between studies of cognition, external behavior and motivation is essential for increasing the efficiency of ergonomics. A general approach that attempts to integrate cognitive, behavioral and motivational components of behavior into a holistic system is called the theory of activity. The conceptual apparatus in this approach differs significantly from those applied in behavioral or cognitive psychology. The term "activity" here derives from this conceptual apparatus and is exclusively restricted to human behavior and cognition. Psychologists who take part in the development of this approach emphasize that there is a big difference between human and non-human psychic processes and behavior. Humans, because of their ability to use language, can acquire knowledge of events that they have not actually experienced. Language allows an individual to consciously evaluate potential consequences of a specific behavior. The psychic processes of humans are developed not only according to the biological laws but also according to the laws of social–historical evolution (Vygotsky 1956). Through evolution, work activity and social interaction shaped human consciousness (Rubinshtein 1959, Leont'ev 1977). Tools made by people determine the specificity of their actions. One generation can transfer its experiences to another through actions and operations, which are to be carried out by means of specific tools. The theory of activity uses mental and motor actions performed by the person as the major units of analysis in the study of human behavior.

2. MOTIVES AND GOALS AS COMPONENTS OF ACTIVITY

An important aspect of the theory of activity is its analysis of the relationship between motive and goal as component of activity. Motives and motivation in general are considered a source of energy that drives the activity. Goal is the conscious and desired result of activity and it represents information that includes imaginative and logical components of the future results of a person's own actions. Not all mental reflections of future results are goals. Goals are future results that are connected to motives and can be attained as a result of person's activity. This brings us to a different understanding of goal from the one that exists in Western psychology (Bedny and Meister 1997). For example, according to Lee *et al*. (1989) goal has the attribute of intensity. The more intense the goal the more an individual will strive to reach it. Hence, goals "pull" activity. In the theory of activity the goal does not have such an attribute as intensity. A goal is only cognitive and informational in nature and can be precise, clear, and totally or partially conscious. The motive, on the other hand, is an energetic component, and may be more or less intense. The more intense the motivational process, the more desirable the goal, the more efforts a person will expend to achieve that goal. The goal is connected with the motives and creates the vector "Motive → Goal" that lends activity a goal-directed character. Psychological differences between the desired goal and current

situation are evaluated from the viewpoint of personal significance. The more significant the difference, the more the individual is motivated to act to attain the desired goal. The level of motivation depends not only upon the psychological distance between the goal and the current state of the situation, but also on the significance of the goal, consequences of failing to attain the desired goal, and obstacles between the current situation and the desired goal (Bedny and Meister 1999).

The analysis of the above material allows us to distinguish two forms of behavior. The more basic form has a reactive character. It occurs only in response to presented stimuli. Activity is a more complicated form of behavior that has goal-directed character. There are various approaches to understanding the concept of goal. For the behaviorist approach the goal is not a scientific notion. A person's behavior is described in terms of stimulus, reaction and reinforcement. In the field of cybernetics goal is a final situation, which can be achieved during the functioning of technical or biological systems. For psychologists who study purposeful behavior the goal is the end state toward which motivated behavior is directed. In the study of activity however, the goal is always a conscious mental representation of the future result of a person's own action and is connected with motive.

3. GENERAL CHARACTERISTICS OF SYSTEMIC–STRUCTURAL ANALYSIS OF ACTIVITY

One important aspect of the systemic approach is that the object of study is considered as a system that consists of elements and their connections. This allows us to describe the structure of the object under study. Representation of the object as a system depends not only on the specificity of the object, but also on what method of study is used to analyze this object. According to the systemic approach the same object can be described from different points of view, using different models that represent distinct aspects of the object or phenomena. Systemic analysis of a real object or phenomena with a description of its structure is called systemic–structural analysis.

Activity is not an aggregation of responses to diverse stimuli. Rather it is an organized system of distinct units with specific relationships among these units. This is why systemic–structural analysis constitutes a basic paradigm for approaching the study of activity. A system is goal directed if it continues to pursue the same goal through different strategies of behavior while environment conditions change. This system can also change its goal while functioning. Activity is a goal-directed system. Here we use the systemic–structural approach to study human behavior rather than the man–machine system.

We can outline the following methods in the study of activity: (1) cognitive analysis of performed activity, where human information processing is focused on the decomposition of activity into sensation, perception, memory, thinking and so forth; and (2) the activity approach, which is based on the systemic–structural analysis, and includes the parametric, functional and morphological methods of describing, and studying activity. The parametric method has received wide recognition in practice. It is the study of the aspects or elements of human behavior most important to the given research. These elements can include time of task performance, speed of separate reactions, duration of visual fixations, etc. This method of study is useful but very often not sufficient in the theory of activity. Other methods of study of

human behavior that allow scientists to describe activity as a system were developed. The concept of self-regulation of activity allows the integration of separate elements of activity into a system and makes possible a functional and morphological analysis of activity.

The basis of the functional description of activity is the analysis of the mechanisms of self-regulation. The concept of self-regulation is widely used in contemporary psychology. This term has been made synonymous with such notions as willpower, ego strength, and volition (Kuhl 1992). Kanfer (1996) considered self-regulation as a motivational mechanism that sustains attention and effort over time in the face of difficulty and failures. This understanding of self-regulation is not accurate. Self-regulation is a process related not only to living beings but to inanimate objects as well although they lack consciousness, will and motivation. We can give the following definition of self-regulation. Self-regulation is an influence on the system that derives from the system to correct its behavior or activity. In humans there are two types of self-regulation processes: physiological and psychological. The physiological self-regulation system is based on homeostasis. The psychological self-regulation system is directed to achieving an established goal. Self-regulation enables the person to change the strategies and goals of activity. For example, it was discovered that even in strictly predetermined stimulus–response situations, the strategies developed by the subjects varied with the conditions and instructions presented to subjects. This suggests that complicated self-regulative processes take place even in the simplest reaction tasks.

More complicated processes of self-regulation have been observed during the performance of more elaborate tasks. For example, we studied the interaction of complex choice reactions performed sequentially (Bedny 1987). The left-hand reaction was performed first in response to a sound stimulus. It followed immediately the right-hand reaction performed in response to visual stimulus. The auditory stimulus varied from one to four. The visual stimulus varied from one to eight. By changing the amount of stimuli possibilities for acoustical and visual tasks, performed sequentially, the researcher can determine how the subject allocates attention between these two tasks, depending on their complexity and on what strategies the subjects are using in general. The study showed that in spite of the fact that the two reactions were performed sequentially they could not be considered as independent of each other. The time necessary to perform the second reaction depends not only on its own complexity but also on the complexity of the previous reaction. The more complicated the first reactions the more time is necessary to perform the second reaction. This experiment demonstrates that subjects develop complicated strategies of activity that can be explained in terms of self-regulation mechanisms. Independent reactions when performed in sequence are integrated into a holistic system and influence each other. Hence, the study of activity as a system with a particular structure through systemic–structural methods is essential for ergonomics.

4. FUNCTIONAL DESCRIPTION OF ACTIVITY

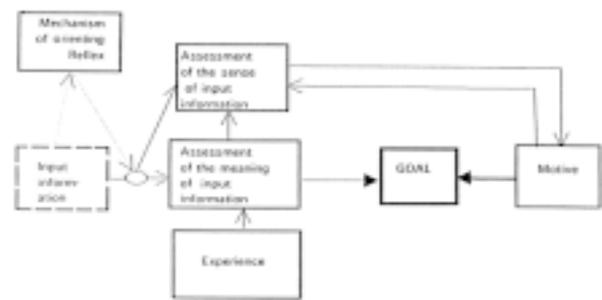
Activity can be described as a functional system that consists of functional mechanisms. These mechanisms are integrated with the help of the feedforward and feedback interconnections to achieve the accepted goal. Graphical representations of such a


Figure 1. Functional model of goal formation process.

system are functional models of activity. Figure 1 presents an example of a model of the functional system that describes the goal-formation process according to Bedny and Meister (1997). This model is a dynamic system that consists of different function blocks, which are the major units of the activity analysis. The concept of a function block is very important in functional analysis and will be examined further in more detail. Here we just want to specify that the model of goal-formation processing consists of the following function blocks: mechanisms of the orienting reflex; assessment of the meaning of the input information; the assessment of the sense of input information; motive; goal and experience.

Let us briefly consider the above listed function blocks. The orientating reflex alters the sensitivity of different sense organs, changes blood pressure, the electrophysiological activity of the brain etc. The orienting reflex plays an important role in the functional mechanism of involuntary attention.

The function block "assessment of the meaning of the input of information" refers to a functional mechanism that represents reality in our consciousness. "Meaning" is the person's interpretation of the situation. It must be noted that meaning provides not only orientation in a situation, but also regulates the executive actions of the operator. The meaningful interpretation of information is possible if the operator has adequate past experience and the ability to use the required skills and knowledge in the present situation. Depending on the operator's past experience and abilities s/he can infer different meanings and understandings of the same situation. To account for this the function block "experience" is presented in Figure 1.

The function block "assessment of the sense of the input information" refers to objective meaning being translated into internal subjective sense. "Sense" is an evaluation of the significance of information for the operator, and represents the emotionally evaluative components of activity. The "meaning" defines the position and function of an object among other objects. The "sense" determines the relationship between external objects and the needs of the person.

The function block "motivation" is distinct from the function block "sense" because of its essential link with goal directness. The presence of the motivational function block allows emotionally evaluative components of activity to be transformed into inducing components. This gives the human self-regulative system its goal-directed quality, which can be represented as the vector "motive–goal" (designated by a bold arrow on Figure 1).

The model in Figure 1 explains how a person accepts or internally formulates a goal. The system described in this model is an entity, which consists of a combination of functional mechanisms directed to achieving the established goal. Each functional mechanism is designated as a function block, the contents and importance of which depends on the specific task.

The functional structure of activity can be defined as a system of interconnected and interrelated mechanisms or components. Functional mechanisms and function blocks are fundamental concepts in functional analysis. Studies in cognitive psychology as well as in theory of activity demonstrate that processing of information, which appears instantaneous to the individual, actually occurs as a series of subprocesses or stages of information processing that are short but measurable in time. In the theory of activity these stages are called functional mechanisms. These mechanisms are not something physical or directly observable, but rather constructs that are inferred as a result of certain chronometrical experiments and qualitative analysis. Examples of such mechanisms are sensory memory, iconic memory, scanning, recognition buffer, etc. (Sperling 1970, Zinchenko 1972). When functional mechanisms are presented as components of the functional model of activity with their feedforward and feedback interconnections, they are defined as function blocks. In functional models of activity such as the one presented in Figure 1, the function block has a much more complex architecture and takes much more time than in a microstructural analysis of the cognitive processes. In the functional model function blocks represent a coordinated system of subfunctions, which has a specific purpose in the structure of activity. For example, a function block can represent the creation of a goal, dynamic image of the situation, or program of execution, or complex functions of control and corrections. Any function block, which is introduced in a functional analysis, is the product of elaborate experimental and theoretical studies. Functional models composed of such blocks should be distinguished from multiple figures and schemes that also consist of boxes and are informally introduced by researchers to describe their results. To introduce a new block into a functional model one has to prove experimentally and theoretically that a certain functional mechanism does exist and then determine its interconnections with the other functional mechanisms of the developed model.

The functional analysis of activity describes the phenomena of cognition more comprehensively than existing theories. For example, the concept of situation awareness (SA) in ergonomics can be understood more precisely as a function block in the activity structure (Bedny and Meister 1999). This function block is responsible for developing a dynamic picture of the world. Functional models of activity allow a more detailed analysis of the strategies of and the prediction of an operator's behavior. The explanatory and predictive features of these models are facilitated by the approach that considers motive, goal, meaning, sense, etc. as parts of a system of interconnected mechanisms, that have certain functions in the structure of activity and influence each other. Further while many theorists assume the existence of a fixed goals, the functional model on the other hand emphasizes the process of goal acceptance or formation and its specific functions in the performance of a particular task. The functional analysis of activity allows comprehensive evaluation of the operator's performance. For instance it explains why an operator can neglect the safety requirements when he has high aspirations to reach the goal. Here is another example. The accuracy with which a pilot can read aviation instruments often depends more on the significance of the instrument than on its visual features. Another illustration would be that a subjective standard of success can influence the precision of performance.

5. MORPHOLOGICAL DESCRIPTION OF ACTIVITY

The morphological description of activity entails the description of the structure of activity in which the major units of analysis are actions and their components are called operations. We can give the following definition of the structure of activity in conducting a morphological analysis. The structure of activity is a logical and spatio-temporal organization of actions and operations performed to achieve a given goal. To describe the structure of activity it is necessary to subdivide it into tasks, which must then be individually described in terms of mental and motor actions. Each action has a separate, intermediate goal, which must be reached to attain the final and overarching goal of the entire task. An action is a relatively bounded element of activity that fulfills an intermediate conscious goal. In light of the fact that actions and operations are the fundamental units of the morphological description of activity, it is necessary to briefly describe them from the perspective of the theory of activity. Actions that can change the states of objects in the external world are called object actions, or motor actions. These actions include different motions, which are called motor operations. For example, action "move arm and grasp lever" is composed of two operations "move arm" and "grasp." Mental actions are classified according to mental processes dominating at the present time. Such actions can be complex and simple. If they are complex they are composed of several mental operations. A mental operation is a relatively homogeneous mental act that has no conscious goal. We can outline the following mental actions. Sensory actions allow us to obtain information about separate qualities of external objects such as color, temperature, or sound pitch. Perceptual actions allow us to perceive whole qualities of objects or events. Recognition of a picture is an example of perceptual action. Mnemonic (memory) actions are composed of memory processes such as memorization of units of information, recollection of names and events etc. We can also isolate imaginative actions. For example, one can mentally turn the visual image of an object from one position to the next according to the goal of one's action. Verbal actions are tied to verbal expression of different statements. Finally we can outline thinking actions and decision-making actions. A simple example is making a decision according to "if–then" rules. Other methods of classifying actions exist; an example of another classification is object–practical actions, which are performed with real objects, object–mental actions that are performed mentally with images of objects. Sign–practical actions are performed mentally with images of objects. Sign–practical actions are performed with real signs like receiving symbolic information from different devices and transforming this information. Sign–mental actions are performed mentally by manipulating symbols. Each action is completed when the person reaches the intermittent conscious goal. Internal actions are formed on the basis of external actions. There are two theoretical concepts of this process. One conception is based on the theory of internalization, and the other on the theory of self-regulation of activity (Bedny and Meister 1997).

The criteria by which actions are isolated can be technological or psychological. The classification of actions by technological criteria entails the subdivision of the task into specific elementary parts or subtasks that allow attaining intermediate technological result. For example, "move the lever," "read the meter" are actions isolated according to the technological principle. However, this description of action is often insufficient. As a result, in the second stage it is necessary to apply the psychological method of description. In this stage psychological criteria are used (Bedny 1987). For example, the action "move the lever" can be very different depending on the necessity to move the lever to an exact location at a distance of 10 inches with the control resistance of 7 lb; we can characterize this movement according to MTM-1 rules as M10C7. Any specialist familiar with MTM-1 knows what kind of movement the operator will perform. The similar principle is used in describing mental actions. For example, the action "read the meter" in technological terms in normal visual conditions according to MTM-1 is called "eye focus time" in psychological terms. In more complicated situations we can use verbal terminology applied in cognitive psychology. For example, "recognition of a familiar visual signal in normal conditions" can be considered as a standard perceptual action, if one knows the specificity of the signal, the viewing distance, and the illumination. It also has to be determined when the action begins and when it ends. Actions are usually first described in technological terms and only after that in psychological terms because often in the beginning there is no data necessary for the psychological analysis of actions.

6. FOUR STAGES OF SYSTEMIC–STRUCTURAL ANALYSIS OF ACTIVITY

Systemic–structural analysis of work activity entails four stages to the loop structure principle (Figure 2). The later stages sometimes require reconsidering the preliminary stages and at any stage activity can be described in different levels of detail. Each stage involves a cognitive, functional and morphological analysis.

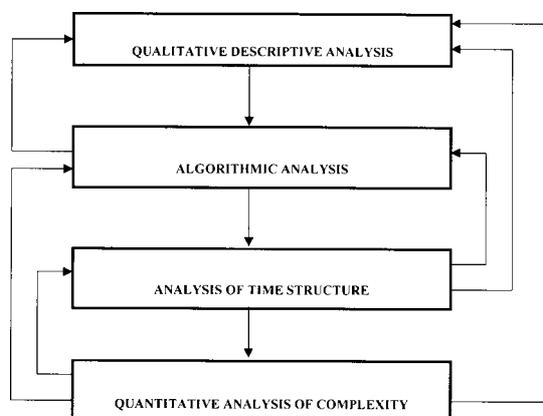
The initial qualitative stage of description includes a general description of the task. In this stage the researcher characterizes the task in general terms, gives its verbal description, and attempts


Figure 2. Four stages of systemic-structural analysis of work activity

to find out the most preferable performance strategies. The verbal description can be combined with the symbolic description of the task and can be done in different levels of detail. At the first stage of activity analysis the functional description plays the leading role. Here we study acceptance or formation of the goal, the significance of the task and its separate components and actions, subjective criteria of success etc. particular to the situation.

The second stage is the algorithmic description of activity. An algorithm of activity is a logically structured system of actions and operations, the order of which is determined by the set of rules defined by this algorithm. The human algorithms are significantly different from non-human algorithms. The algorithmic description of human activity derives from non-human algorithms. The algorithmic description of human activity divides the task into elementary actions that are called "operators" and "logical conditions." The latter determines the sequence of actions. At the same time several tightly interconnected actions can be described as one "operator." For example, the "operator" "move the organ of control to the specifically set position" is composed of two motor actions "move the hand and grasp the handle" and "move the lever to the specifically set position." The level of details of the algorithmic analysis often cannot be specified in advance and may have to be subsequently modified.

It is important to differentiate between prescribed and performed algorithms of activity. Prescribed algorithms are standardized while performed algorithms are those that are actually used by the operator. In the process of design the ergonomists develop prescribed algorithms. It is important that these prescribed algorithms of activity correlate as closely as possible probabilistic as well as deterministic (Bedny 1987). Deterministic algorithms have logical conditions with only two outputs, 0 and 1. Probabilistic algorithms can have more then two possible outputs each of which can vary in their probabilities.

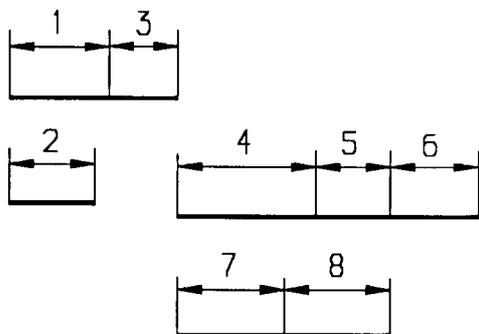
The third stage of activity design is the description of the temporal structure of activity. It is possible to build a temporal structure of activity only after determining the duration of the actions involved in the task performance. The temporal structure of activity consists of the logical sequence of activity elements, their duration, and the possibility of them being performed simultaneously or sequentially (Bedny 1987, Bedny and Meister 1997). Before developing a temporal structure of activity it is necessary to describe the structure of activity algorithmically. Temporal structure of activity can not be developed until it is determined what elements of activity can be performed simultaneously, and what elements can be performed only sequentially.

The last stage of analysis is an evaluation of task complexity. The more complex the task itself the higher the probability that it will be difficult for the performer. The intervals of time devoted to standard elements of activity should be used as the units of measurement of complexity (Bedny 1987, Bedny and Meister 1997).

A quantitative evaluation of the complexity of task performance is possible only after developing a temporal structure of activity. A systemic–structural description of activity makes it possible to represent the structure of activity as a system of logically organized actions and operations. The goal of the design process is to create a system of interdependent models of the operator's activity. These models describe the structure of the operator's activity and can be used to design equipment and

develop efficient methods of performance. The main idea is that changes in equipment configuration probabilistically change the structure of activity. Suppose we wish to develop the time structure of activity during the performance of a particular subtask such as the following: An operator is simultaneously presented with a weak acoustic signal and a well-defined red light. The operator must detect the acoustical signal and perceive a red light at the same time. In response to this information he must grasp a lever on his right with his right hand, and move it straight forward to a specified position. The movement of the lever is complicated because he has to press a pedal with his right foot at the same time. On the other hand, if the acoustical signal is accompanied by a green light, the operator must move the same lever backwards, similarly accompanied by the same pedal movement with the right leg. We can determine the motor components of activity using system MTM-1. Based on an engineering psychology handbook or through chronometrical studies developed in cognitive psychology we may determine the duration of the cognitive components of activity. Based on this, the temporal structure of the activity may be developed (Figure 3). In our case we can extract the following actions in described subtask:

- Sensory action – detection of acoustic stimulus in threshold area;
- Perceptual action – recognition of visual stimulus in optimal visual conditions;
- Mental action – decision-making having two alternatives;
- Motor action – reach for lever and grasp it (method RA + G1A); and
- Motor action – move lever to exact location without releasing it (method MC);

The same rules that are used in MTM-1 representing particular motions apply. Symbol RA represents reaching the object in fixed location. G1A is to grasp the object when it can be easily done. MC means "move object to an exact position." FM means "press and release pedal with the foot." If we know the time structure of the activity we can calculate the complexity of task performance, including complexity of motor regulation of activity that has a cognitive nature (Bedny and Meister 1997). If one introduces some changes in equipment configuration, the time structure of the activity may change. Hence, one should evaluate the complexity of the task again. Comparing the complexity of task performance in both cases one can conclude which version is more difficult and demanding. Based on this, one can decide which physical configuration is superior.


7. CONCLUSION

Activity places a great deal of emphasis on studying units of analysis of human behavior. It calls for the use of systemic–structural method of analysis of the operator's activity. As a result it has become possible to combine methods of study of cognitive psychology with methods developed in the theory of activity where the major concept is an action. The information processing stage of analysis of cognition should be integrated with activity analysis.

The description of the relationship between the actions of an operator and the physical configuration of equipment offers new opportunities in ergonomic design. Given the same equipment, this approach also allows the development of more efficient and safer methods of performance. It also allows one to study how the time-structure of activity changes during training, and based on it to develop more efficient skill acquisition. Owing to the orientation of the study of behavior as a system in activity theory, it enables the integration of cognitive, behavioral and motivational aspects of human activity, and as a result increases the efficiency of applied research.

Allocation of Functions: Past, Present and Future Perspectives

E.F. Fallon

National University of Ireland Galway, Ireland

1. INTRODUCTION

Allocation of functions is concerned with decisions regarding what agent, human or machine, or combination of agents will carry out individual functions in a system. It is regarded by ergonomics/human factors academics as a core activity in the ergonomics design process and university programs in human factors/ergonomics that do not encompass the topic would quite rightly be regarded as less than ideal. However, the importance attached to the topic in the classroom is not always reflected in the workplace. Reported experience tells us that that allocation of functions is not addressed as often as theory would suggest except in situations where regulatory requirements must be met and safety is paramount.

2. FROM PAST TO PRESENT

Historically, allocation of functions has primarily been explicitly considered in the context of large systems development. The first reference to the topic was by Fitts (1951) with respect to air traffic control systems. The approach to the problem proposed then was to assign functions to either men or machines based on their relative capabilities and limitations with respect to predefined performance criteria. The ensuing Men Are Better At/Machines Are Better At (MABA/MABA) tools were generally applied within the context of a rational, mechanistic, systems development model. Their application was extended to military and nuclear power systems, and also to decisions regarding allocation of functions between robots and people in manufacturing systems. The latter application resulted in the formulation of Men Are Better At/Robots Are Better At (MABA/RABA) lists. Typically

Table 1. Typical MABA/MABA and MABA/RABA list entries

Men (people) are Better At (MABA)	Machines Are Better At (MABA)
Detecting masked signals	Detecting signals from many sources
Pattern recognition in light and sound	Detecting signals at speed
Creative and inductive reasoning	Deductive reasoning
Responding to unexpected events	Processing large amounts of data quickly
Improvising using small – medium forces	Storing large amounts of data

Men (people) Are Better At (MABA)	Robots Are Better At (RABA)
Require less detail in job descriptions	Energy efficient
Flexible (reprogramming not required)	Operate continuously
Require less space	Can apply large forces
Require less capital investment	Have no social or personal needs
Are easily transported	Repeat operations accurately

MABA/MABA and MABA/RABA lists would consist of the following types of items:

In the intervening years there has been recognition that the comparative approach based on Fitts' Lists or derivatives of them are not particularly useful for a number of reasons:

i. Humans and machines are not alike and are therefore not comparable.
ii. A number of important criteria are not explicitly addressed as part of the allocation process, e.g. cost, reliability, job design, and organizational considerations.
iii. There is no consideration of changes in the relative capabilities of humans and machines, e.g. pattern recognition and advances in artificial intelligence advances in the case of machines.
iv. Allocations are static and do not take account of the changing nature of task scenarios or conditions, e.g. increases in human workload during disturbances.
v. The final allocation never seems to resemble that suggested by the MABA/MABA lists.
vi. Experience of addressing the issue in practice reveals that at the very least allocation of functions is an iterative process.
vii. The requirement for a formalized proscriptive approach to allocation of functions is not been justified.
viii. There is no explicitly agreed definition of the term function and how it differs from a task, i.e. is it functions or tasks that are being allocated?
ix. The emphasis in their application has tended to be on single operator machine systems or groups of operators and machines treated as several single operator–machine systems.
x. There is a growing realization that the nature of work to be carried out in human–machine systems can only be determined through doing that work and not by a priori specification.

Jordan (1963) viewed humans and machines as complementary to each other. In effect the decision to allocate to human or machine was not viewed as an either/or situation. While this concept has intuitive appeal, it has been difficult to operationalize in the context of system design and development.

There is little recorded evidence of the successful application of allocation of functions methods. Typically, the final allocation never looks like that envisaged by "Fitts' Lists" or indeed any other structured design method. It is generally acknowledged that in safety-related and large human–machine systems, some element of allocation of functions is carried out, however the process of allocation is regarded as much of an art as a science.

It has been argued that allocation of functions as a discrete design activity does not exist. At best allocations are outcomes of design and are regarded as implicit in the activity of designing. A concomitant view is that successful allocation of functions will evolve, partly by chance and partly to conform to our fancies of the moment.

More recently the requirement for iteration in the allocation process has been recognized. In practice this essentially means that following the activities of initial function allocation, task synthesis, task description and task evaluation — reallocation is carried out through resynthesis of tasks without necessarily referring back to the original functional specification. This has tended to draw attention to the lack of clarity in distinguishing between functions and tasks.

Those involved in the rapidly developing field of Computer

Supported Cooperative Work (CSCW) have begun to consider the allocation of functions concept in the context of group and teamwork and its social requirements. For this community, the key issue is whether allocation of functions as currently expounded is a useful construct as it is argued that many functions are, and can only be, allocated during the course of use of a system rather than during the design process. Consequently, the optimum or a satisfying human–machine mix cannot be achieved at the design stage. The argument is that the act of placing technology in a work environment changes work practices and that these changes only become apparent as problems or conflicts are revealed.

On the positive side there is a significant cohort of researchers and practitioners who hold the view that allocation of functions is a real design activity and that resources should be employed to try to achieve a fuller understanding of how it is carried out and to develop better methods for its implementation. Within this context, there is recognition of the need to understand the relationship between allocation of functions and the design process employed and to facilitate communication between other actors in the design process. There is also recognition of the need to widen the focus of allocation efforts from individual interactions with machines to team-based and organizational considerations such as job design, work organization, operator roles, and manpower planning.

3. THE CONTEXT OF ALLOCATION OF FUNCTIONS

3.1. Systems Development

The simplest and most primitive human–machine system can be analyzed in terms of its functions. However, in such cases, the allocation of these functions between human and machine is implicit in the design process, e.g. a spade or a hammer. Moreover, the choice of allocations is invariably restricted and often one which reduces human physical workload and extends or compensates for human capabilities or their deficiencies respectively. It is only when significant levels of automation are introduced that allocation of function issues have merited explicit consideration. Traditionally this was done within the framework of a systems development model at the earlier planning and conceptual design stages. The structure of such models was such that a single allocation was envisaged and the decision was normally an either/or decision — either to the human or to the machine. In theory, no iterations of the stages of the model were envisaged, though in practice the final allocation was rarely the initial one. The system development model initially employed by the US military industrial complex during the cold war period largely reinforced this rational, mechanistic approach to function allocation. In this model, detailed design of machine subsystem components was considered in parallel with detailed design of human subsystems. Such an approach requires a priori the allocation of functions to one or the other and implies subsequent independent consideration of each. In more recent years an understanding has developed that an iterative approach within the basic systems development framework is required.

3.2. Manufacturing

In the immediate post-World War II period, the approach adopted to allocation of functions in the context of discrete parts manufacturing systems was to automate those functions it was possible to automate and leave the remainder to the operator. Broadly speaking, the advent of Numerically Controlled (NC) machine tools resulted in the automation of machine tool control functions. The skill in determining cutter paths for tools was reallocated to programmers. The operator was left with responsibility for loading and unloading machines, turning them on and off, and intervening when required in order to avert or mitigate undesirable events. The initial development of Computer Numerically Controlled (CNC) machine tools, robotics, Flexible Manufacturing Systems (FMS) and Computer Integrated Manufacturing (CIM) saw little change in this approach. Ergonomists did make some attempts to consider function allocation in the context of work with robots, leading to Men Are Better At (MABA) Robots Are Better At (RABA) lists as outlined earlier. Despite this, there was little consideration of the broader manufacturing context in which manufacturing systems would operate.

The failure to achieve the anticipated benefits due to the application of technocentered CIM precipitated a rethink with regard to the role of humans in such systems. Efforts were focused on addressing the function allocation issue in the context of Human-Centered Computer Integrated Manufacturing (Human-Centered CIM). Human-Centered CIM advocates a work- or labor-oriented model of advanced manufacturing based on a strategy of group manufacturing in which operators are allocated the function of system control. The design approach employed involves the design of the technology, the social system, the interaction between the two, and the design process itself. System design is viewed as an evolutionary process involving user participation, prototyping, and continuous change. The approach includes as one of its main objectives a concern for the quality of working life. Consequently, in a human-centered system, human operators are regarded as an essential component of manufacturing systems and are given due consideration during the design process.

3.3. Supervisory Control

Supervisory control is a term used to describe the way in which operators and computers interact in controlling vehicles, continuous processes, robots, and also FMSs. Supervisory control activity is concentrated mainly at the human–machine interaction level and makes no pretences to explicit consideration of the quality of working life. The human operator normally sets the system goal by initiating set points, the computer effects some action to achieve the goal, measures its own performance relative to the goal, and subsequently adjusts its actions accordingly. The emphasis is on providing operators with the appropriate resources to carry out the following functions: planning, teaching, monitoring, intervening, and learning. In some respects, supervisory control is not an alternative to the earlier technocentric approach to human–machine systems. It recognizes that functions which can be automated will ultimately be allocated to machines, and that humans will carry out the remaining functions. However, within supervisory control, the human roles

required to carry out these remaining functions are identified and considered within a cognitive human factors framework.

3.4. Software Systems Design

Despite the fact that allocation of functions is viewed within the human factors/ergonomics community as a critical component in the design of human machine systems, it has not received similar consideration in the area of software systems design and HCI. This is surprising given that a significant number of Human Computer Interaction (HCI) textbooks contain sections on the topic. The predominant tendency in software systems design is to embody as many functions as possible in the software. However, unlike traditional systems development approaches, there is no explicit consideration of functions as mutually exclusive human or machine sets. This activity is implicit in the design process. There are a number of critical differences between the outputs and the context of each design process that may account for this. Some of the more important ones are illustrated below in table 2.

4. IMPLEMENTATION PHILOSOPHIES

In its initial inception allocation of functions was considered at the level of individual work activities at the immediate interface between human and machine. The main allocation criteria used were performance related, e.g. speed of operation, accuracy, and strength requirements. As outlined above, allocation decisions were made on the basis of comparative performance of human and machine with respect to these criteria. The process was viewed as a definite step within a sequential systems development framework. Given the rapid development in the capabilities and performance of machines, the logical consequence of this approach was that the majority of functions that machines could

carry out were allocated to machines and those functions that they were unable to carry out were allocated to humans.

Subsequent developments in the area were influenced by the realization that humans and machines were not comparable and should be viewed as complementary components within systems. They were also influenced by the recognition of the need to extend the allocation criteria to include, cost, reliability, maintainability, personnel requirements and safety.

Socio-technical theory provided the impetus for further developments. The locus of application of allocation of function decisions was extended from the immediate human machine interface to considerations of job design and organizational issues. The provision of meaningful work was endorsed as an acceptable allocation criterion.

Dynamic allocations in which functions are allocated to humans or a machine based on situation assessment has emerged as a possible approach to the issue. Successful application of this concept depends on the ability to identify situational factors that impact on allocation criteria and also to identify appropriate alternative human machine allocations. Typically, workload and predictions of human behavior are used to dynamically select the human–machine mix. The forms of dynamic allocation are varied and range from situations in which the machine is only used when the human requests help, to situations where the machine monitors the state of the human and intervenes when specified state variable thresholds are exceeded. As Older *et al.* (1997) point out, "Ironically it can be seen that dynamic allocation involves an allocation decision in itself, when deciding who/what should be responsible for initiating the change in allocation."

Some within the human factors community hold the view that allocation of functions is neither a useful nor pragmatic concept (Sheridan 1999; Fuld 1997). Sheridan argues that our

Table 2: Context and output differences between the human—machine design process and the software design process with respect to allocation of functions

Factors	Human machine system Design outputs and context	Software system Design outputs and context
Category	Bespoke and Specific	Generic
Operating Enviroment	Hazardous, can be safety-related or safety-critical	Less specific, rarely hazardous, hardly ever safety-related
Application areas	Aviation, Aerospace, Manufacturing (FMS), Medical systems, Process control — nuclear, power generation, petrochemical, pharmaceutical	Office enviroment. Home, Education establishments Manufacturing, e.g. MRP, Product database, Computer-Aided Design (CAD)
Configuration	Human as system components; Specialised software with relatively long time frame for replacement; Complex equipment operated and controlled through and by software	Human as user; Generic hardware platform; Software developed using generic programming languages or development enviroments; Replacement/re-release envisaged every 6–18 months
Quality standards	Comprehensive quality standards applied by outside bodies and client	Limited quality standards applied by outside bodies; Other standards selected by developer
Legislative contstraints	Possibly stringent legislative requirements imposed by local, national and international governments	Minimum health and safety standards imposed by national and international governments; Standards imposed by best practice and market demands
Consequences of error	Can be catastrophic; Significant loss of life; Significant loss of equipment; Reduced or no revenue.	Unlikely to be – catastrphic, loss of life. significant equipment losses. Short-term loss of revenue.
Design process	Tightly controlled, stage model or derivative; Possibly seperate contracts for individual stages; Multidisciplinary – hardware and software engineers; human factors engineers; Possibly significant human factors/ergonomics effort; Specified deliverables at decision points	Flexible stage model or derivative; Developer normally completes entire contract, largely software & hardware engineers; Minimum human factors/ergonomics effort; Specified deliverables at decision points; however the outcome is very flexible

ability to think through the human—machine mix in advance of trying it out is limited. McCarthy *et al.* (1999) paraphrase Sheridan's view as follows, "It is also unhelpful insofar as it attempts to limit the requisite variety which enables us to muddle through making sense of our experiences and learning from our mistakes, and in the longer term limits our understanding of both ourselves, the machines we make, and interactions between the two." Fuld, writing in the context of nuclear power, concludes that allocations are always implicit in design, but formal allocation models are not prescriptive models for design behavior. Moreover, he contends that function allocation provides a post hoc rationale for situated, pragmatic decision-making. For Fuld, human factors in design is concerned with building on acceptable solutions and weeding out the misfits between automation decisions and human capacities.

The CSCW perspective on allocation of functions is a much more radical departure from those previously described. It views formal system specification and design as no more than the commencement of a process of technology and practice in situ, which occurs mainly through developing and maintaining working divisions of labor. Essentially this acknowledges that work involves more than just transforming specified inputs to outputs and that operators are often engaged in workarounds and tailoring of technology to the working situation.

By definition working divisions of labor cannot be prespecified. They emerge through a process of work, negotiating, persuading, and coercing. The implications for design are that systems should have a high degree of tailorability and in addition to those functions assigned from without, should support mutual awareness and information sharing and self-organization. This view also has significant implications for the design process and procedures for quality and safety assurance.

5. METHODS AND CRITERIA

Though he has been predominantly associated with comparative performance of humans and machines, Fitts (1951) also gave other criteria due consideration in his paper, e.g. economic, manpower, and personnel issues. Despite this, they were largely ignored in subsequent proselytizing of his work. A short description of the main methods of allocation of functions that followed Fitts' pioneering work is included below: (Older *et al.* 1997; Fallon *et al.* 1997; Sharit 1997).

1. A quantitative evaluation of all reasonable function allocation arrangements with respect to selected criteria. It was envisaged that the criteria would be broader that those advocated in Fitts' lists and that relative weightings would be assigned to them for each arrangement. The weightings could then be summed or multiplied and the final decision on the human machine mix based on the outcome of the calculations.

2. An approach with four identifiable allocation strategies:
   - Mandatory allocations as dictated by legislative requirements or specific system requirements
   - A balance of value strategy in which allocations are made based on a relative goodness of fit of human or machine with respect to performance. The allocation assignment is not assumed to be an either or issue and the final outcome is dependent on the resources available to both human and machine:
   - Utilitarian and cost based approach — this is the opposite

of the technological imperative, however, initial selection of operators to carry out tasks must be subjected to relative cost considerations.
   - Allocations based on cognitive processing requirements and the quality of working life of the personnel involved.

3. A methodology with a sociotechnical perspective. This methodology encompasses many aspects of the strategies above, however it differs in that it includes organizational considerations and develops scenarios of prospective implementations. It also places less emphasis on performance criteria and comparability of humans and machines.

4. A computerized method that supports interdisciplinary design teams in developing complementary allocation of functions in Advanced Manufacturing Technology (AMT) systems. The emphasis is on ensuring that human flexibility is maintained in the final system through opportunities for the development and maintenance of both practical production skills and theoretical system knowledge. AMT system designers are provided with tools that enable them to analyze existing and envisaged tasks and provide support for human–automation interactions during the system design process. The method operates at three different levels: immediate human–machine interaction level, job level, and the work system level. The main criteria considered as part of the method include process transparency, dynamic coupling, decision authority and flexibility.

5. A team-based approach involving several stakeholders including designers, manpower-planning experts, operations staff, and human factors experts. The method involves capturing information requirements, allocation criteria, and operator and equipment requirements for each function in the system, and their subsequent consideration and allocation by the stakeholders. Significant state-of-the art knowledge of both hardware and software is required to successfully implement the approach.

6. An approach based on the configuration of knowledge required to carry out manufacturing functions. The basis of the approach is that organizations can be construed as a configuration of knowledge embodied in humans and machines that utilizes data to create information (e.g. the product data model) and its physical manifestations (products for sale). The problem is to optimize the configuration of knowledge and its allocation to humans and machines. The resulting output includes an allocation of functions, the definition of human roles and the distribution of management functions to these roles.

7. A method based on guidelines for allocating tasks within a manufacturing system. The method provides a series of detailed flowcharts for carrying out the allocations; however, it is recognized that much of this information is situation specific. There is also an acknowledgement that allocation of functions takes place within a multilevel environment and those initial allocations may be changed in the light of job design and work organization.

8. A language-based system for allocating cognitive and decision functions within a team supported by intelligent automation. It consists of three types of tools: a language for describing cognitive processes at the team level, a set of general principles for allocating cognitive functions to individual team members

and/or automation, and a set of measures relating the former to the later. The system develops a number of candidate solutions that are tested for their adherence to the general allocation principles. Iteration is implicit in this process.

9. A method that assesses the implications of human–machine allocation decisions on manning, recruitment and training policies. This method uses a socio-technical systems methodology to determine roles and responsibilities within a planned socio-technical system, and a scenario-based workshop approach to establish the implications of these.

10. A formal analysis method utilizing scenarios and a cost-benefit analysis of the impact of automation decisions on the performance of the primary role of operators and the relative demands placed on them within the generated scenario. The primary application area is aviation, however it could be extended to other areas.

11. A method that utilizes a joint cognitive system model of human and machine for specified target domains. Simple models of function allocation are rejected in favor of an emphasis on what is termed "function congruence" over a range of situations. Humans and machines are viewed as collaborators in achieving stated goals. The emphasis is on the shifting conditions of work, and the need to maintain the total equilibrium of the work situation. The *dynamic* aspects of allocation decisions are considered within a framework that includes human, technological, and (to some extent) organizational factors.

6. FUNCTIONS OR TASKS

One of the difficulties experienced in the application of allocation of functions is the question of what constitutes a function and how is it distinguished from a task? This question is similar to that often asked in formalized approaches to engineering component design, i.e. where does the artifact currently being considered fit in the hierarchy of assembly, sub-assembly, and component? Similar issues apply to decomposition of systems and sub-systems.

In the rational view of design, functions are viewed as activities that a system must carry out to achieve its goals. Such functions are considered to be independent of any implementation technology. In contrast, tasks are regarded as activities that people carry out in order to achieve a goal, subject to defined constraints and the availability of specified resources. This approach to functions depends for its validity on the assumption that systems can be formally and fully described in advance of building, testing or commissioning. It is largely supported and reinforced by stage models of the design process and sequential models of system development.

There are a number of difficulties with the approach. A number of researchers have used task descriptions as the unit of task allocation thus dispensing with the concept of a function as being independent of its implementation. More recent models of the design process such as the Spiral and Star models, and the user-centered design approach reject the sequential stage model view of design. While there is a recognition that the various stages exist in some form or other, there is emphasis on iteration, prototyping and user involvement throughout the design cycle. In other words, tasks are often considered before some functions are revealed through a process of testing prototype implementations in the workplace.

Different disciplines have different understandings of the term function. This lack of a common appreciation of the concept causes problems in communication between disciplines particularly in the context of the systems development process. For example, systems engineers tend to model functions using dataflow representations, while in contrast, human factors/ergonomics practitioners tend to model functions using task analysis techniques. It has been argued that the differences in representation account for the lack of consideration of inputs by human factors/ergonomics practitioners to the design process. A scheme to improve this situation has been proposed. In this scheme it is envisaged that logical functions (e.g. dataflow representations) would form inputs to the allocation of functions process and that tasks would be the output. Allocation of functions would be viewed as a linking activity between two competing requirements gathering methodologies in the design process, one used by engineers and the other by ergonomics/human factors practitioners.

The notion that design does not proceed in a rational formalized manner is a viable one. In particular, it can be argued that the concept of a function plays no worthwhile role in it. Design can be regarded as an evolutionary process in which failures are weeded out through a process of design and test. New designs are built on other previously successful designs. There can be little room for functional decomposition as part of this process, except as a component of a post hoc evaluation.

Researchers from the CSCW field question the notion that the essence of work can be described using functional decompositions. While recognizing that there are work allocations that can be made from without (during the design process), there is also an acceptance that a significant number of allocations can only be made from within (during system use). This latter concept has been referred to as "working divisions of labor" or the "work to make it work" and has been described earlier in section 4. At best, prespecified functions and allocations are regarded as one of many resources for situated decision-making.

7. STANDARDS AND REQUIREMENTS

Standards dealing with allocation of functions generally apply to large human–machine systems in the military and nuclear power domains. Typically, they provide a framework for carrying out allocation of functions, but do not necessarily require the use of specific allocation methods. Meister (1991) outlines a systematic and prescriptive method for carrying out allocation of functions in the context of military/naval systems design. The method concentrates on human–machine interactions and is summarized in section 5 above. The same method is recommended in UK Human Factors Defence Standards, though in more recently published defense guidelines greater emphasis is placed on human jobs and roles within the overall organization of the system. A similar emphasis is adopted within the Manpower and Personnel Integration (MANPRINT) military program. The MANPRINT framework recognizes that allocation of functions (tasks) takes place throughout the development cycle and is not necessarily a single identifiable event. In contrast to Fitts' Lists, MANPRINT considers the economics of tasks, the coherence of jobs and the flexibility in decision-making of human operators. It also evaluates operator workload and takes cognizance of the fact that military systems can be used in a wide range of scenarios and by a variety of personnel.

In contrast nuclear power standards have tended to be more prescriptive. Fuld (1997) provides a useful discussion of standards on allocation of functions to the design of new nuclear reactors. While lauding the descriptive evolutionary approach of the US Nuclear Regulatory Commission (USNRC), he criticizes the allocation process approach of the International Atomic Energy Authority (IAEA). He states, "This document still plainly suffers from FA's dichotomies; and though different sections of the document show conflicting philosophical perspectives, this at least adds some balance to the overall product. Its struggle for practicality, it is hoped, will go further in future revisions."

Allocation of functions is at the heart of recent draft European standards on work tasks with machines and human-centered design for interactive systems. In the former case it is part of a formal, systematic procedure for work task design. In the latter appropriate allocation of functions is described as one of four key principles of user-centered design. The standard emphasizes making sure human skill is used properly and that systems are effective, efficient and satisfying for their users.

8. SURVEYS OF USE

In the introduction to this paper, the bona fides of allocation of functions as part of human factors/ergonomics courses was alluded to; however, the extent to which it is practiced is not well documented. Older et al. (1997) reported on a survey of 32 practitioners in the systems development field. The methods reported as used for allocation of functions were not allocation of functions methods per se. They were components of larger systems development methodologies that did not cater explicitly for allocation of functions. They concluded that while the relevance of the allocation of functions process was obvious, it was rarely explicitly addressed in practice. Specific weaknesses in how to allocate tasks between humans, the consideration of social and organizational issues and the timing of allocation decisions were identified.

Bevis et al. (1996) reported on a NATO Workshop on "Improving Function Allocation for Integrated Systems Design" in a military context. They concluded that there was a real need for allocation of functions in systems development and that the most important outcome of doing so was the subsequent reduction in human cost and risk factors. The practical approaches reported at the workshop indicated that there was a departure in practice from the methods recommended in the humans factors literature. They also contradicted the popular view that organizational and social issues were neglected. The authors identified requirements for increased support of the creative design process through the provision of successful complete or partial solutions. They also identified the need for a comprehensive description of human factors criteria and their interrelationships including a trade-off matrix that helps with weighting of the relative contributions of the criteria.

Kearney and Fallon (1977) report on a survey of the role of the user in software systems design. Designers were asked what they understood by allocation of functions and at what stage in the design cycle it was carried out? They were also asked to identify the methods they use during this stage of design. The results revealed that the developers understanding of the allocation of function concept was limited. They were unable to identify any specific methods or tools they used for this activity

and where it fitted into the design cycle. The most favored approach was a "common sense" or "suck it and see" one.

Jenkinson (1997), in a paper on allocation of functions in industrial alarm systems, comments that, "in the majority of alarm systems studied by the author, alarm functions are not allocated according to any established ergonomics principles." The main reasons offered for this are that many of those who design industrial information systems are not aware of such principles or are insufficiently persuaded of their benefits. He also comments on the need for the availability of resources to implement available human factors/ergonomics techniques.

9. CONCLUSIONS

The study and understanding of allocation of functions has progressed from the early days of Fitts' Lists. There is widespread acceptance that a simple comparison between the respective capabilities and limitations of humans and machines at a functional level is an inappropriate basis for allocation decisions. The criteria for decision making have expanded to include economic, safety, job design and organizational criteria. The allocation of functions decision does not require assignment to either machine or human, rather it is a question of the selection of an appropriate human/machine mix. Allocation options are not regarded as exclusively static as technological developments have increased the possibility of practical realization of dynamic allocation. In theory the application domains of allocation of functions have broadened in scope due to developments in computing technology, nevertheless the practice does not reflect this. Allocation of functions can never be a single step in a sequential prescriptive design process. At worst it requires several iterations of allocate, test and reallocate. The nature of the human—machine system design process itself has changed and can involve extensive user participation and scenario modeling.

Despite the progress described above, the methods used by practitioners to implement allocation of functions have not advanced at the same rate or to the same degree as our understanding of the concept. It is clear from the literature that designers often completely ignore this phase of system development. Where it is explicitly addressed ad hoc methods or other vaguely related methods from extensive systems development methodologies are sometimes used. In other instances, designers rely on previous experience or what some have termed "common sense".

The relevance and usefulness of allocation of functions as proffered by the general ergonomics/human factors community has been questioned. One view disputes whether it exists as a separate stage in design. The main argument is that allocations that take place during design are implicit and that any attempt to impose a prescriptive design method on designers will impede them. The best one can do with allocation of functions is to use it as a means of identifying acceptable solutions and weeding out misfits between automation decisions and human capacities. A second view contends that it is futile to attempt to specify the human/machine mix in advance of trying it out. Allocation of functions limits the requisite variety needed to enable learning and to facilitate the emergence of satisfying solutions.

A less pessimistic but more radical perspective is the one that contends that complete allocation of functions cannot by definition take place prior to use of a system. Allocation of

functions during design is but the commencement of a process of technology and practice in situ which occurs mainly through developing and maintaining working divisions of labor. Allocations, it is argued, emerge through a process of work, negotiating, persuading, and coercing. Acceptance of this approach has implications for the nature of the design process and its outputs. For example, it would be reasonable to assume that once a system has been commissioned and is in use, the underlying user model utilized during the design process would no longer apply. Consequently, any a priori analysis relating to for example, human operator actions or safety analysis of human–machine interaction would no longer be necessarily valid. Ideally human–machine system designs should have a high degree of tailorability and in addition to those functions assigned from without, should support mutual awareness and information sharing and self-organization.

What is the outlook for the future of allocation of function? Older *et al.* (1997) have identified future directions for research and development in this area. They include:

i.   Development of methods for allocating tasks within teams.
ii. Integration of task allocation work from the ergonomics/ human factors and organizational psychology domains.
iii. Development of tools for generating viable alternative allocations.
iv. Integration of allocation of functions methods with existing system development methods.
v.   Evaluation of the effectiveness of explicit allocation of functions methods.
vi. Development of further decision criteria and identification of rationale for trade-offs between criteria.
vii. Involvement of users in all aspects of the development of methods and criteria.
viii. A contingency based method for dynamically allocating tasks.

If one were to accept that allocation of functions is not relevant to design, then it is recommended that no further development should be carried out. However, given its proposed usefulness for weeding out misfits, it would seem worthwhile expending some energy developing a design support tool containing details of design solutions containing acceptable allocations.

For those espousing technological determinism, it would be helpful if it could be established what role if any is envisaged for ergonomics/human factors in the machine–machine design process.

The CSCW perspective of the allocation of functions concept demands serious consideration. We need to explore the practical implications for design of adopting this view. In particular, issues pertaining to the scope and duration of design and the involvement of users should be addressed. It seems reasonable to suggest that any products of design should cater for and

facilitate as many permutations as possible for working divisions of labor. Alternatively, we should be able to bound the problem through the identification of viable candidate solutions.

Arousal States and Human Performance

G. Matthews

Department of Psychology, University of Cincinnati, OH 45221, USA

1. INTRODUCTION

Arousal may be defined as a continuum of states of mental activity, ranging from deep sleep to drowsiness, alert wakefulness and agitation. "Activation" is sometimes used as a synonym or related construct. The psychological theory of arousal originated in studies using the electroencephalograph (EEG) to assess central nervous system (CNS) function, pioneered by H. Berger in the 1920s. Researchers of the 1940s and 1950s, such as D. Lindsley, noticed a correspondence between the pattern of electrical activity recorded from scalp electrodes and the person's state of wakefulness (for a review of early studies, see Duffy 1962). Alert, mentally active subjects showed predominantly low amplitude waveforms, with a frequency of 13–30 Hz (b waves). As arousal decreased, amplitude tended to increase and frequency decreased, generating a waves (relaxed state 8–12 Hz) or q waves (drowsy state 4–7.5 Hz). At the same time, animal studies showed that stimulation of the reticular formation provoked both behavioral activation and concomitant changes in the EEG. Studies suggested that arousal may also be indexed by measures of autonomic nervous system (ANS) activity. Measures such as heart rate, electrical conductance of the skin and constriction of vascular muscles are linked to arousal associated with the "fight-or-flight" reaction, and the sympathetic branch of the ANS.

Hence, traditional arousal theory makes two key assumptions. First, physiological reactions can be described in terms of a single dimension of brain activity or excitement influencing both CNS and ANS measures. Second, this physiological dimension is psychologically meaningful: brain states correspond to mental states and to characteristic styles of behavior. It is often supposed that moderate levels of arousal promote effective action and optimal performance. There may be human factors problems deriving from the impaired performance of both tired, under-aroused operators, and excited, over-aroused operators.

2. MEASUREMENT OF AROUSAL

The physiological definition of arousal implies that a person's arousal level should be measurable from several alternative psychophysiological indices. A basic psychometric assumption is that alternative indices of the same underlying construct should be positively correlated. A person whose EEG shows b activity should also show an elevated heart rate, high skin conductance (due to perspiration), and other signs of CNS and ANS arousal. Unfortunately, alternative indices of arousal often fail to correlate with another, so that the construct resists reliable psychophysiological measurement. This finding is a serious problem that calls into question the validity of arousal theory. It has inspired three alternative research strategies: dealing with methodological difficulties in measurement, discriminating multiple dimensions of arousal and measuring arousal through self-report.

2.1. Psychophysiological Measurement

One possibility is that arousal is a valid construct, but it is difficult to measure. Psychophysiological indices may reflect factors other than brain state. For example, heart rate is influenced by muscle tension and activity, so an apparently aroused person may merely be fidgeting. Also, psychophysiological responses to increasing external stimulation may be non-linear. It is sometimes claimed that a process of "transmarginal inhibition" operates to decrease CNS arousal when the person is in danger of over-stimulation. Another problem is individual differences in the expression of arousal in psychophysiological measures. Some people might show arousal primarily as increased blood pressure, others as elevated skin conductance ("response stereotypy"). Improvements in psychophysiological methods may yet provide a reliable measure of overall brain activity. However, the complexity of psychophysiological responses demonstrated in existing research suggests this outcome is unlikely.

2.2. Multiple Dimensions of Arousal

One explanation for the observed dissociations between different psychophysiological indices is that they index different brain systems. The brain may have separate circuits controlling reactions to reward and punishment signals, for example, which may be independently aroused or de-aroused. There have been various attempts to develop multiple arousal theories, discriminating different systems, often on the basis of neurotransmitters. For example, it has been suggested that arousal associated with noradrenergic systems relates to selective attention, whereas dopaminergic arousal relates to motor activity. However, the impact of these theories on human performance studies has, so far, been limited.

2.3. Measurement of Subjective Arousal

Arousal may also be defined and measured psychologically rather than physiologically, through self-report measures of mental state. Thayer (1989) proposed that there are two dimensions of subjective arousal. A dimension of energetic arousal contrasts vigor with tiredness, whereas tense arousal contrasts nervousness with relaxation. Self-report arousal is reliably measured by questionnaire or adjective checklist. The disadvantage of such assessments is that respondents may deliberately or unconsciously distort their responses, but there is considerable evidence for the validity of self-report. Self-report scales are sensitive to external manipulations of stress and arousal, and predict performance in some paradigms. Self-report arousal correlates to a moderate degree with psychophysiological indices, although the neural basis for subjective arousal remains uncertain.

3. INFLUENCES ON AROUSAL

Arousal theory assumes that, at any given moment, the person's arousal level reflects both environmental factors such as sources of stress, and personality or dispositional factors. Indices of arousal are generally more sensitive to environmental stress factors than to personality. Environmental factors may be subdivided into those associated with external stimulation, and those related to the internal physiological environment. In contemporary research, environmental agents are conceptualized as "stressors" that influence a variety of aspects of state (Hockey 1984). Most researchers favor a multiple dimension conception of arousal,

within which different stressors may affect different physiological or subjective dimensions.

3.1. External Environmental Influences

Environmental stressors may influence arousal through both their physical and psychological properties. Loud noise, heat and cold all tend to increase arousal primarily because they are physically aversive. However, threat stimuli such as failure on a task or criticism from other people may raise arousal because of the way the stimulus is evaluated or appraised. The positive motivations and cognitions evoked by incentives for good performance may also be arousing. The distinction between physical and psychological stressors is not clear-cut, because response to physical stimuli is modified by the person's appraisals. Noise stimuli may be more "stressful" and arousing when they are appraised as uncontrollable and disruptive to ongoing activities.

3.2. Internal Influences

Various arousing or de-arousing agents influence the internal environment. The simplest example is psychoactive drugs. Stimulants such as amphetamine, caffeine and nicotine affect neurotransmitter action directly and tend to increase CNS and ANS arousal. Tranquilizers and sedatives decrease arousal. Another source of arousal variation is biological rhythms. There is pronounced variation in arousal with time of day, although the time at which arousal is highest depends on the arousal index used. Body temperature and indices of ANS arousal are maximal in the early evening, whereas subjective alertness and energy are highest at midday. Several distinct aspects of arousal may be controlled by internal "clocks" or oscillators driven in forced oscillation by external time-cues ("zeitgebers"). The phase of the menstrual cycle may also influence arousal, with women tending to experience higher tense arousal and lower energetic arousal premenstrually. A further type of "internal" influence is abnormal physiological states, such as disease. Sleep deprivation normally lowers physiological arousal, although arousal indices continue to show the normal circadian rhythm in the sleep-deprived person. Fatigue induced by prolonged or demanding task performance may also lead to loss of arousal. In these instances, low arousal is likely to be experienced as decreased energy; tension may even increase in some circumstances.

The mediating role of brain arousal systems in controlling the effects of stress factors is controversial. Some researchers believe that the person's cognitions and appraisals of physiological activity may be equally important. For example, placebos have been shown to influence arousal when the person is expecting a drug effect. Arousal is sensitive to suggestive techniques, such as the Velten technique which affect the person's mood and self-cognitions. It seems likely that arousal responses are determined by an interaction of physiological and cognitive factors but the nature of the interaction is not well understood. Some stress factors (e.g. circadian rhythms, sedative drugs) may be more strongly determined by physiology, whereas others (e.g. premenstrual tension, task-induced fatigue) may be more sensitive to cognitive factors.

3.3. Personality and Arousal

Arousal may be influenced by the interaction of environmental stressors with personality factors. Some individuals may be more prone to states of high or low arousal than others. The two personality factors most often implicated in arousal response are extraversion–introversion and anxiety. According to Eysenck and Eysenck (1985), introverts are more easily aroused than introverts, due to greater sensitivity of a reticulo-cortical circuit in the brain. In fact, the psychophysiological evidence for higher tonic cortical arousal in introverts is inconclusive. There is stronger evidence that extraversion–introversion influences transient, phasic arousal responses, but the behavioral implications of these effects remains unclear. The further personality dimension of trait anxiety is also said to relate to high arousal. In this case, the psychophysiological evidence fails to support the arousal hypothesis, and the behavioral consequences of trait anxiety are usually attributed to the worries, or interfering cognitions, that typically accompany anxiety. It remains likely that people differ in their arousability, but current personality theory has not been very successful in predicting which individuals will be most aroused in given circumstances.

4. AROUSAL AND PERFORMANCE

4.1. The Yerkes–Dodson Law

It is useful to distinguish traditional and contemporary perspectives on the relationship between arousal and performance. The traditional view is expressed by the "Yerkes–Dodson Law", which makes two statements. First, the relationship between cortical arousal and performance efficiency is described by an inverted-U function, so that moderate levels of arousal are optimal for performance, and states of low or high arousal are detrimental. Second, the precise optimal level of arousal is inversely related to task difficulty. Easier tasks are performed best when arousal is relatively high (alert, mentally active state), whereas a relatively low level of arousal is preferable for more difficult tasks (relaxed state). The law refers to a 1908 study conducted by R.M. Yerkes and J. D. Dodson that showed curvilinear relationships between strength of electric shock and learning of underwater mazes in the mouse, although the study was concerned with motivation rather than arousal. The relevance of this study to human performance has been questioned.

Testing of the Yerkes–Dodson Law has been impeded by the lack of a reliable psychophysiological index of arousal. Many researchers have followed a behavioral approach, advocated by D. E. Broadbent in the 1960s, that manipulates arousal through various stress factors such as noise, anxiety or time of day. Often, the aim is test to whether stress factors interact as predicted by arousal theory. For example, the combined effect of two arousing stressors, such as noise and anxiety, should be especially detrimental to performance. In general, such studies provide only patchy support for the Yerkes–Dodson Law (Matthews and Amelang 1993). Some pairs of stressors conform to the law, but others do not. The behavioral approach also has other weaknesses. A serious methodological difficulty for performance studies is that the interaction method does not test the Yerkes–Dodson Law stringently. With typical designs, it is possible to fit various patterns of data to the law *post hoc* (Hockey 1984). It is also difficult to distinguish multiple dimensions of arousal using this approach, although additive-factors methods have been used in attempts to do so. A further weakness of traditional studies is that they often fail to distinguish different components of performance. Cognitive psychological critiques of arousal studies

emphasize that arousing agents may have quite different effects on different processing functions.

4.2. Arousal and Cognitive Patterning

Contemporary studies typically acknowledge the multidimensionality of both arousal and performance. Hockey (1984) advocates a "cognitive patterning" approach in which the effects of stressors are evaluated across performance indices of various processing components, such as selective attention, speeded response and short-term memory. Different stressors tend to provoke different patterns of change in processing, which are only partially attributable to arousal change. Other mechanisms such as distraction, and motivational and cognitive change also contribute to stressor effects on performance. For example, fatigue states are de-arousing, but the detrimental effects of fatigue primarily reflect loss of task motivation and effort. Stressor effects may reflect both changes in basic information-processing functions, such as changes in attentional capacity, and changes in strategy, such as willingness to exert effort to maintain effective performance. The challenge for arousal theorists is to discriminate the subset of performance changes that directly reflect change in one or more dimensions of arousal, and to develop cognitive–psychological explanations. Hockey (1984) suggests that one of the principal effects of arousal is to increase attentional selectivity, so that primary tasks are prioritized at the expense of secondary tasks. Most arousing stressors provoke changes of this kind. Revelle (1993) proposes that arousal increases availability of resources for "sustained information throughput", required for attentionally demanding tasks, but decreases resources for short-term memory. The evidence that arousal improves attentional efficiency is stronger than evidence for detrimental effects of arousal on short-term memory. For example, many, though not all, arousing agents reduce vigilance decrement.

4.3. Individual Differences in Arousal and Performance

Contemporary studies also focus on individual differences in arousal, often using self-report assessment of arousal. Higher energetic arousal is associated with superior performance on a variety of demanding attentional tasks, including high event rate vigilance tasks and controlled search for various stimuli. High energy seems to become increasingly facilitative as task demands increase (Matthews and Davies 1998). These findings are consistent with Thayer's (1989) view that energy is a marker for a general psychological and physical mobilization for vigorous action. In contrast, the second major dimension of subjective arousal, tense arousal, does not relate consistently to performance. Personality effects on performance may sometimes be mediated by individual differences in arousal. Extraverts often perform better than introverts in stimulating or arousing conditions, which may reflect lower cortical arousability in extraverts. However, this explanation is challenged by the weakness of the association between extraversion and arousal, and by studies showing that extraversion effects vary with the information-processing demands of the task.

5. CONCLUSIONS

Arousal theory was at one time seen as the best explanation for stressor effects on human performance, and it still has value as a unifying principle. However, its application to performance studies has declined. The construct originated in psychophysiological studies, but it has proved to difficult to measure from CNS or ANS indices. It is also difficult to link psychophysiological indices to the multiple brain systems influencing performance. Furthermore, effects of arousing agents on performance vary with the precise information-processing demands of the task, indicating the need for a more differentiated, cognitive–psychological account of performance change, and a psychological rather than a physiological definition of arousal. Contemporary work generally focuses on specific stressors, and the multiple mechanisms that may contribute to the "cognitive patterning" of their effects on performance. Only some of these mechanisms reflect arousal processes. One such mechanism is the increased attentional selectivity often observed in states of high arousal. A second mechanism is the enhancement of attentional function associated with high subjective energy, and with agents which boost energy, such as stimulant drugs. Within this narrower view of arousal effects, research is exploring both the precise information-processing functions sensitive to arousal, and their neural underpinnings.

Traditional arousal theory is of very limited practical utility. It points to both under-and over-arousal as potential problems in operational settings, but it does not allow accurate prediction of performance failure. Contemporary research indicates the importance of fine-grained assessment of performance and state in operational environments: arousal change is embedded within often complex stress reactions. A detailed understanding of the operator's cognitions of the environment and its demands is required for designing systems for stress-tolerance, and for training operators to cope with stressors. In some settings, arousal may be much less significant than faulty cognitions, unwillingness to exert effort and distraction from worries and bodily sensations. Nevertheless, arousal effects such as neglect of secondary information sources (high arousal) and lack of attentional resources (low arousal) may sometimes be a focus for intervention. Good design of displays can mitigate against over-selectivity of attention, and attentional demands can be reduced to counter under-arousal. Future technology may provide 'neuroergonomic' interventions such as continuous psychophysiological monitoring for potentially maladaptive arousal changes.

Attention and Human Performance: A Cognitive Neuroscience Approach

A. Berger and M. I. Posner

University of Oregon, Eugene Oregon and Sackler Institute for Human Brain Development, Cornell Medical College, New York, NY, USA

1. A HISTORICAL REVIEW: MAIN QUESTIONS AND PARADIGMS

While human capacity is impressive in many areas, there are basic limitations to human performance. Eyes cannot be moved to two different locations at the same time and one cannot pronounce two different phonemes simultaneously. Human limitations go far beyond these physical constraints. Even if two activities are not physically impossible, performance does deteriorate when two different operations must occur at the same time even when input and responses are quite separate such as in reading a book while listening to TV. It seems as if the mind is constantly selecting a subset of stimuli, and this selection affects mental processes and behavior. This basic feature of performance gives rise to one of the most widely used metaphors regarding attention, the metaphor of the light beam that selectively illuminates stimuli sources, spatial locations and mental structures.

The modern era of attention research began during World War II in England. Pioneers like Broadbent, Cherry and Welford began the information-processing approach. Human performance was analyzed according to different processing stages and the main question of attention was at which stage was selection done.

1.1. Selective Attention

At the perceptual level, a person can, for example, selectively attend to one specific voice, enhancing it from the noise background. In the 1950s the basic experimental paradigms concerning selective attention was dichotic listening and shadowing. The subject repeated back information from one ear, while additional information was presented to the other ear. The question was to what extent subjects process information on the *unattended* ear. The first modern theory of attention was Broadbent's Filter theory (1958) that arose from an analysis of selective listening. The main idea was that selection occurs early in the processing stages. All stimuli are analyzed at the level of physical attributes, then the attentional *filter* selects stimuli for further processing. Stimuli that are filtered out do not reach semantic identification. According to *early selection* theories the bottleneck is localized at an early stage of the perceptual process, whether it is in the auditory, visual or other modality.

Consistent with the notion of early selection was evidence that subjects are unable to report almost anything about properties and content of the ignored stimulus. Subjects could report some physical features of the unattended message. For example, whether it was a male or a female voice and if they noticed if the feature changed while they were shadowing the attended message. However, they did not notice if the message started, for example, in English and then switched to German.

Filter theory was an example of an extreme early selection theory. At the other extreme were late selection theories. According to this view the bottleneck is localized after the semantic identification stage. There are no capacity limitations on the recognition of objects, only on memory processes, awareness and responses. Classic examples that seemed to refute early selection theories were breaking through ignored and unattended stimuli, like noticing one's own name in an unattended channel (Moray 1959). Another example in favor of the late selection account was that while subjects attended and shadowed a message in one ear, non-attended words presented to the other ear elicited galvanic skin responses (GSR) if they were previously associated with electric shocks (Corteen and Wood 1972).

Forty years of intensive research has supported elements of both early *and* late selection. When the overall processing load is very light, late selection theories do well, but with high processing load little unattended information survives. Some of the theories that were clearly "early" or "late" have been updated to support elements of both. One example is Treisman's Feature Integration Theory (FIT) (Treisman and Gelade 1985, Treisman and Gormican 1988). This theory dealt with search for a target in a complex field. According to this theory only simple visual attributes are registered and stored in parallel. These features are combined and integrated to form an object representation. This integration requires attentional focus to the object's location. Thus, attention is the glue required for object perception. In this framework the selective focusing of attention is early and precedes object recognition since it is considered a prerequisite for the object's representation. However, more recent descriptions of FIT (Treisman 1993) include ideas of late selection based on object files and the top-down selection of objects to control responses.

In the context of neuroscience there is clear evidence that selective attention influences visual system processes perhaps as early as the primary visual cortex. In this sense there is clear evidence for early selection. However, behavioral studies show that information not selected by attention may reach high levels of analysis including semantic levels. Thus, in appropriate conditions late selection can also occur.

1.2 Divided Attention

As mentioned above, there are some tasks that people seem able to carry out at the same time, while for other tasks this seems very difficult to do.

In the 1960s dual-task studies took a somewhat different direction than the dichotic-listening studies. In dual-task studies of human performance subjects were asked to perform two independent tasks in close temporal proximity. A leading theory at that time was that the source of interference between tasks was access to a limited capacity central processor. This single processor must be engaged to complete certain mental operations as memory retrieval, mental transformation and response selection.

In response to the finding that interference between tasks depended on their capacity demands, *Resource Theories* were developed. The main idea of these theories was that resources can be flexibly allocated to different tasks. For each task, two different stages were defined: (1) as long as performance of the task improves as a function of resource investment, the task is called *resource limited.* (2) However, there is a point at which more resource investment will no longer improve performance. At this point the

task is said to be *data limited* (Norman and Borrow 1975). Under dual-tasks conditions one can plot a *Performance Operating Characteristic* (POC) that specifies quantitatively the possible tradeoff in allocating resources between the tasks.

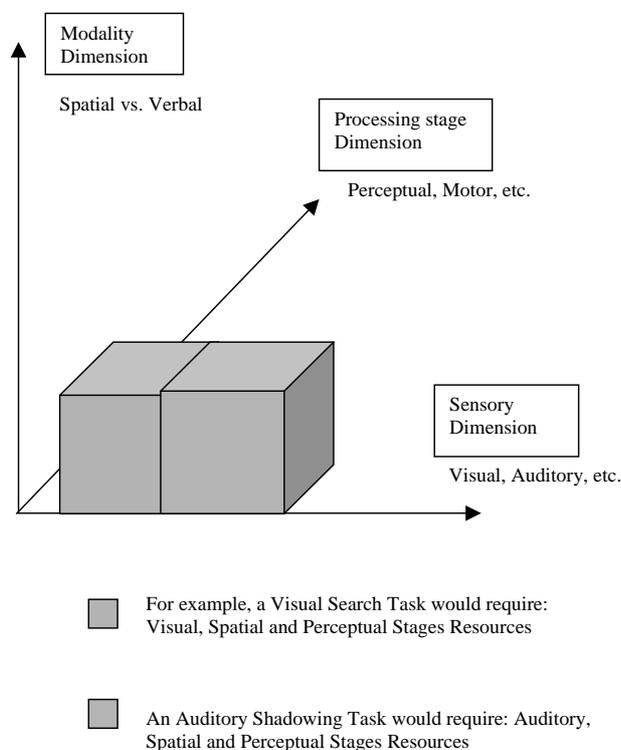
An alternative view to the unified resource pool suggests that there are *Multiple Resources.* One such view suggested a three-dimensional matrix of separate resources for the different processing stages (encoding, processing, responding) and for the different modalities (visual versus auditory, verbal versus spatial) (Wickens 1980). The initial conceptualization of this theory suggested a set of non-overlapping pools, each defined by a combination of levels on the three orthogonal dimensions. Literally, it predicted that task demanding non-overlapping resources would time-share perfectly (e.g. walking while listening to music through Walkman earphones). Evidence was found that, tasks within the same cell in the matrix interfere more with each other than tasks in adjacent cells. However, the data did not support the idea that tasks in adjacent cells are perfectly time-shared. For example, monitoring simultaneously to visual and auditory channels for detecting a target is impaired in comparison with single-channel monitoring. This is found both when targets are defined semantically, and when targets are defined physically within each modality of input (Treisman and Davies 1973). Moreover, it was found that when subjects monitor many channels for a target, whenever a target is detected, the processing of targets of any other channel drops dramatically (Duncan 1980). This finding leads to the idea of hierarchical resources. This is a kind of compromise conceptualization, between resource and central capacity views. While different modalities may have basic separate resources, there is still a central resource that could be defined as executive attention. This central supervisory


Figure 1. The idea of multiple resources, following Wickens (1980).

resource would be involved in the strategic allocation of other resources, monitoring, target detection, etc.

2. ATTENTION IN COGNITIVE NEUROSCIENCE

2.1. New Methodologies

The introduction of neuroscience methodologies to the study of attention have included the use of micro electrodes with alert primates, anatomical methods like computer tomography (CT) and magnetic resonance imaging (MRI), and functional methods like positron emission tomography (PET) and functional MRI (fMRI). These methods have permitted more meaningful investigation of the localization of cognitive functions in the brain. Recording from scalp electrodes can be used to provide clues regarding the temporal dynamics of anatomical areas involved in tasks. Although knowledge of the precise neural mechanisms responsible for attentional operations is still incomplete, many of the brain areas and networks involved have been identified.

2.2. Discovering the Neuro–anatomy of Attention

Based on behavioral data, neuropsychological data and the addition of the new imaging techniques data, Posner and Raichle (1996) summarized the three attentional networks and their localization in the brain. The anatomy of these three networks is presented in Figure 2.

2.2.1. Orienting network

The orienting network deals with shifting and focusing of visual attention. Orienting responses are usually made by movements of the eyes and head causing foveation of the stimulus. These are called *overt* shifts of attention. However, it is also possible to orient attention without eye movements. These are called *covert* shifts of attention. A second important discrimination; the one between *reflexive* orienting (meaning that a cue pulls attention to orient to the stimulus, e.g. a cursor blinking on PC screen) versus *voluntary* orienting of attention (meaning that the subject is given an instruction to attend to a location in the visual field, or that he has a internal motivation for doing so, e.g. a basketball player facing a player from the opposite team, would focus attention in order to pass him the ball accurately. This would probably be done covertly, otherwise his opponent would guess where the pass might go).

Neuropsychological evidence (including split-brain evidence) suggests that these attentional operations involve a brain network including the posterior parietal lobes, the pulvinar nucleus of the thalamus and the superior colliculus. PET studies have supported the importance of this functional network and have shown striking similarity between the anatomy of eye movements and of covert attention (Corbetta 1998).

2.2.2. Executive-control network

This network has been related to control of goal directed behavior, target detection, error detection, conflict resolution and inhibition of automatic responses. The executive control network seems to include the midline frontal areas including the anterior cingulate gyrus, supplementary motor area and portions of the basal ganglia. Neuro-imaging studies have shown activity in this area during tasks that require mental effort such as in dealing with conflict, handling novelty, developing anticipation and detecting errors.

Recently it has been shown that tasks involving both cognitive and emotional controls produce activation in the cingulate (Bush *et al.* 1998). There is some evidence that pathologies related to deficits in exercising executive control and monitor goal directed behavior, might be related to dysfunction and abnormalities of the executive network brain areas (Posner and DiGirolamo 1998, Berger and Posner 1999).

2.2.3. Alerting network

This network is involved in establishing a vigilant state and maintaining readiness to react to sensory events. Early attentional studies used long boring tasks to study the maintenance of the alert state. These tasks are important in tonic alertness (Parasuraman 1998). A second task used to study phasic alertness is readiness following a warning signal. Although these tasks are quite different they both seem to involve a strong right lateralized parietal and right frontal cortical network. The alerting network also involves the locus coruleus, which is the source of neurotransmitter norepinephrine in the brain. Norepinephrine is involved in alerting and may work by boosting the signal-to-noise ratio of the brain area where it is released.

It is important to mention that there are connections between these three networks and they interact with each other in their operations. These connections are both at the anatomical, and functional levels.

2.3. Discovering the Mechanisms of Attention

The progress in the field, and the introduction of new neuroscience techniques allow re-examination of some of the issues debated in the study of attention.

2.3.1. Early versus late selection – revised

The networks of attention that were briefly presented in the previous section, represent the *source* of the attentional selection. These are areas of the brain specifically activated during attentional processes. However, the *site of action* of the selection process, is the actual area of the brain where the computation is performed. For example, if the organism is monitoring a screen for detecting a specific target, one would expect that the site of the attentional effect would be an area related to visual processing.

How is this selection implemented? A basic finding from studies using microelectrode recording in alert animals is that attention modulation is observed at the level of individual neurons cells (Colby 1991). Motter (1998) presents an interesting example of attentional modulation of an individual cell's activity. A relevant and an irrelevant stimulus were both presented within the receptive field of a neuron recorded in a secondary visual cortex (V4). Subjects (alert monkeys) where attending the relevant stimulus in order to perform a "match to sample" task. This focal attention suppressed cells response to the irrelevant stimulus. Moreover, cells response to the relevant stimulus was unaffected by the presence or absence of the irrelevant stimulus appearing within the same receptive field. It is important to notice that when subjects were not focusing their attention on the relevant stimulus, the irrelevant stimulus did affect the cell response, since it was appearing within this cell receptive field.

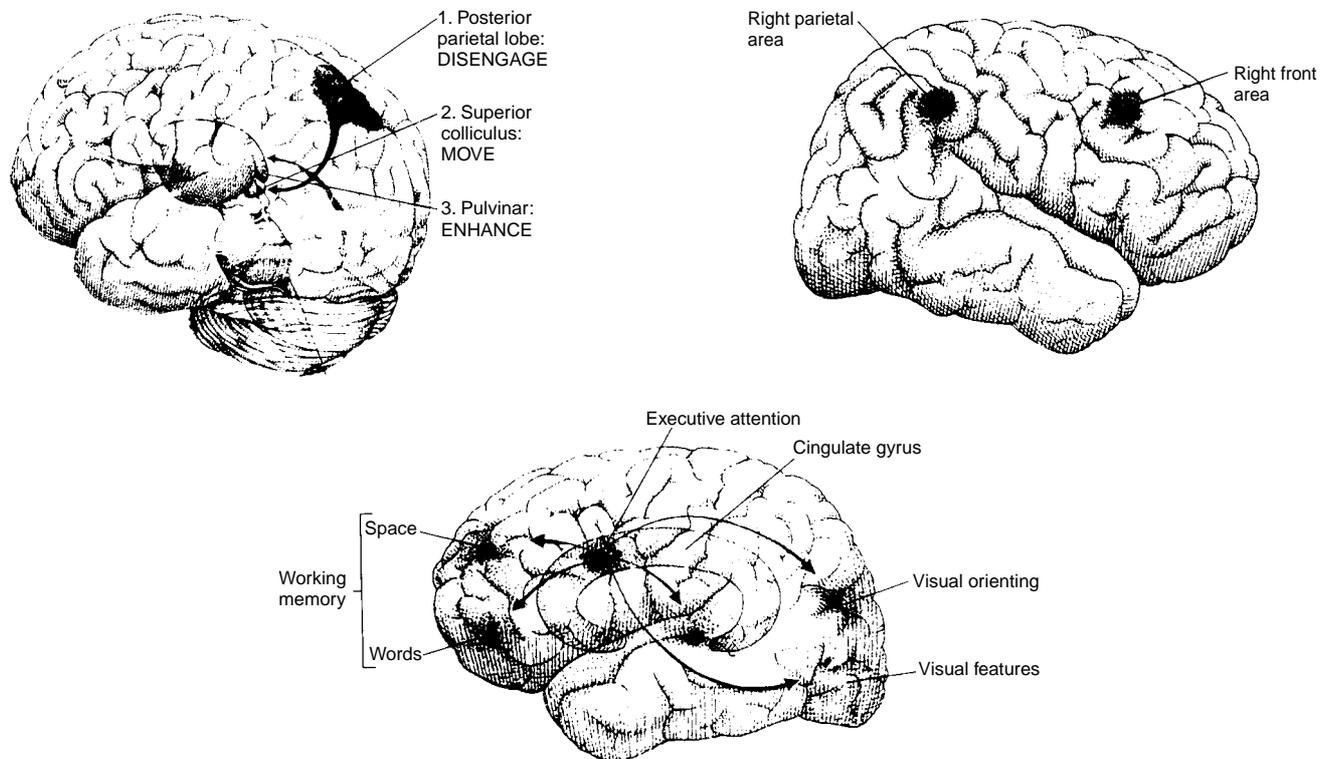
The old *early versus late* question, is now rephrased to how early in the processing of stimuli, is it possible to observe attention modulation of cells activity? Continuing within the example of the visual modality, PET studies show that attention can influence the


Figure 2. **Neuro-anatomy of the attentional networks. Start at 12 o'clock and moving clockwise: the orienting, executive and alerting networks. Adapted from Posner and Raichle (1996).**

activation of the secondary visual (extrastriate) cortex. Moreover, single cell recording suggests that under some conditions, the attentional modulation of cell activity can be observed as early as in the primary visual (striate) cortex Moran and Desimone (1985), which is the first cortical stage of stimuli analysis in the visual modality. These findings support the idea that attention *can* affect perceptual input at a very early stage of analysis.

2.3.2. Dual tasks – revised

As mentioned in the network description, there seem to be specific areas of the brain that show activity while dealing with monitoring of goal directed behavior. Interestingly, imaging studies show that these same areas are active during dual-task situations. This activation was observed in situations where the tasks did not share input nor response modalities, supporting the hypothesis that the interference between the tasks occurred at the level of a central resource (D'Esposito *et al*. 1995, Passingham 1996). These imaging findings seem to support the idea that during dual-tasks, the bottleneck occurs in the area of the brain related to the pragmatic allocation of attentional resources and the control of goal directed behavior. As mentioned in Section 1.2, subjects show impressive ability to allocate differentially their resources to the tasks and adjust their performance to the situation requirements (i.e. the experimenter's instructions).

According to the discrimination between *source* and *site of action* that was presented in Section 2.3.1, the cingulate gyrus and dorsolateral frontal areas would be the source of the attentional influence, while the site of this influence would be widely dispersed in the areas of the brain where the actual computations for the different tasks are made (i.e. working memory, memory retrieval, motor response planning, etc.) depending on the requirements of the involved tasks.

3. CONCLUSION

The study of attention is constantly making progress. Important advances include aspects of the neuroanatomy, neurochemistry, and temporal parametrics of attention. In this chapter we restricted ourselves to human ability to perform more that one task at the same time and to selectively attend to relevant information. We focused on these issues since they have had a major impact and implication within the ergonomics and human factors literature, especially in relation to questions about mental workload and humans capacity limitations. Although our understanding of the attention system is still far from being complete, it is important that human factor theories take into account the state-of-the-art, most updated knowledge in the cognitive neuroscience field, regarding this basic function of human cognition.

Body Postures

K. H. E. Kroemer

Industrial And Systems Engineering, Virginia Tech, Blacksburg, VA, and Eri, Inc., A Consulting Company, PO Box 3019, Radford, VA 24143-3019, USA

To standardize anthropometric measurements (see the chapter on Anthropometry), the body is put into defined static postures:

- *Standing*: the instruction is "stand erect; heels together; rears of heels, buttock and shoulders touching a vertical wall; head at erect; look straight ahead; arms hang straight down (or upper arms hang, forearms are horizontal and extended forward); fingers extended."
- *Sitting*: on a plane, horizontal, hard surface adjusted so in height that the thighs are horizontal; "sit with lower legs vertical, feet flat on the floor; trunk and head erect; look straight ahead; arms hang straight down (or upper arms hang, forearms horizontal and extended forward); fingers extended."
- The *head* (including the neck) is held erect (or "upright")

when, *in the front view*, the pupils are aligned horizontally, and, *in the side view*; the ear–eye line is angled ~15° above the horizon (Figure 1).

People do not stand or sit naturally in these standard measurement postures. Thus, the dimensions taken on the body in the standardized positions must be converted to reflect real postures and motions at work, or leisure, which vary greatly. The designer has to estimate the corrections that reflect the anticipated movements.

For more information see Kroemer (1999) and Kroemer *et al.* (2000).

Brain and Muscle Signal-based Control

G. R. McMillan

Air Force Research Laboratory, AFRL/HECP, 2255 H Street, Bd. 33, WPAFB, OH 45433, USA

1. INTRODUCTION

The activity of muscles and nerves can often be measured as electrical potentials at the surface of the skin. These potentials can, in turn, be used to control external devices. This chapter focuses on the use of two types of signals: the electromyographic (EMG) signals associated with the contraction of skeletal muscle and the electroencephalographic (EEG) signals associated with brain activity (Farry *et al.* 1996).

Control system designers in many fields have attempted to tap our natural physiological systems to achieve intuitive, non-fatiguing control of external devices. The notion of operating a device simply by thinking about it represents the ultimate in intuitive control. Although current technology limits our ability to achieve such natural control systems, several practical devices have been commercialized and other promising technologies are being evaluated in the research community. For example, prosthetic hands and wrists, controlled by electrical muscle signals, are of significant value to those with lower-arm amputations. Thousands of units have been fitted worldwide (Figure 1). This area represents the most significant current application of human physiological signals for control (McFarland *et al.* 1997).

2. CONTROL USING MUSCLE SIGNALS

2.1. Control Technology Description

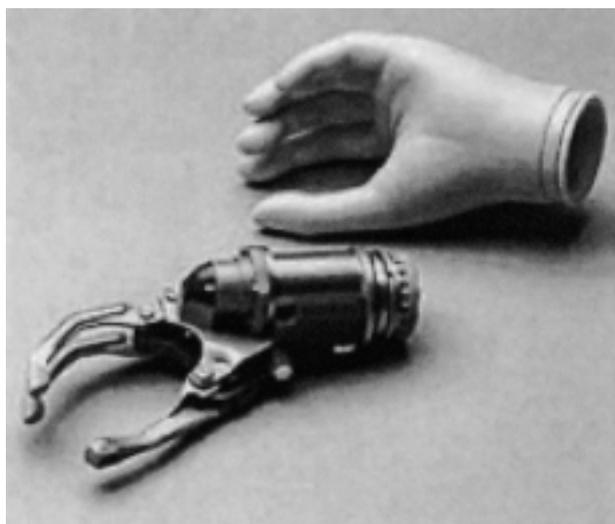
The EMG signal measured at the skin surface resembles random noise that is modulated in amplitude by changes in muscle activity. It results from the asynchronous firing of hundreds of groups of muscle fibers. The number of groups and their firing frequency


Figure 1. Prosthetic hand system. Photo: courtesy Otto Bock USA, Minneapolis.

controls the amplitude of this signal and the force produced by the muscle contraction. The EMG signals of interest range in amplitude from several hundred microvolts to a few millivolts. The EMG frequency spectrum has a peak at ~60 Hz and significant power from ~20 to 500 Hz. The small size of the EMG, and the fact that its frequency spectrum falls within the range of many common electrical devices, leads to signal acquisition challenges. However, these challenges have been successfully addressed in the laboratory and for numerous applications in the real world.

2.1.1. Signal acquisition

Prosthetic systems typically use stainless steel electrodes that are molded into the prosthesis and contact the skin surface. Because the EMG signal is most often measured at points on hairless skin, gel electrodes also represent a convenient option. Differential recording, with two active electrodes and one reference, is typically employed to minimize interference from external noise sources. Commercial biological signal amplifiers are well suited to the amplification and filtering of the EMG signal.

2.1.2. Signal processing

The raw EMG signal has an average value equal to zero; therefore this parameter cannot be used for control purposes. Mathematically, the mean absolute value of the signal is related to the strength of the muscle contraction, but the precise form of this relationship varies across muscles and individuals. In practice, rectification and low-pass filtering of the EMG signal can be used to estimate the strength of a muscle contraction. The most common prosthetic control algorithms employ on–off control based on the level or rate of change of this measure of EMG activity. If muscle activity at one electrode site exceeds some threshold, the prosthetic hand opens. Above-threshold activity at another site causes the hand to close. Hand movement stops when the EMG at both sites is below threshold. To permit control of functions such as grip force, some on–off algorithms employ "time proportional" techniques, i.e. grip force increases as long as the operator holds the closing signal above threshold. For multifunction prosthetic devices (e.g. simultaneous elbow, wrist and hand control), systems are being developed that use patterns of activity across multiple muscle groups or patterns extracted from the responses of individual muscles to control specific functions. In some cases these systems employ neural networks to recognize natural contraction patterns and produce a similar response in the prosthetic device.

2.1.3. Feedback requirements

EMG-based control provides muscle contraction feedback for operators with intact sensory systems. However, many other feedback channels are absent. Attempts to provide grip force feedback in prosthetic devices have most often employed vibratory or electrical cues. One study showed that pressure cues provided by an inflatable cuff permitted better grip force control than vibratory cues. However, visual cues alone appeared to be sufficient. To some extent this finding reflects limitations in the performance of current prosthetic devices, and it is generally believed that enhanced feedback will be required as the performance of prosthetic devices improves.

2.2. Other Applications and Evaluations

Numerous other applications of EMG signals have been

investigated, in addition to prosthetic devices. Early work by the US Air Force investigated the idea of assisting pilot arm movements during periods of high acceleration flight. An EMG-controlled, powered splint was developed and evaluated. Although the EMG signals provided an effective means of control, the system did not go into production.

Several studies by the National Aeronautics and Space Agency (NASA) have evaluated the feasibility of using EMG signals from an operator's arm to intuitively control a remote robot arm. If feasible, a low-cost EMG system might be used to replace or augment joysticks and exoskeletal instrumentation. Initial studies suggested that raw EMG time histories from normal hand and arm motion were not sufficient for controlling the complex movements of a robot arm. However, more recent work has found that a time–frequency analysis of the EMG patterns from forearm musculature can discriminate several different hand grasp types and thumb motions with a high degree of accuracy.

More recent work sponsored by the US Air Force has shown that subjects can use facial EMG signals, measured with electrodes on the forehead, to control a cursor and track computer-generated targets. For discrete responses, very rapid control inputs were achieved with little operator training. Early studies of an automotive application found that reaction time can be enhanced using an EMG trigger. A substantial reduction in operator reaction time was observed when an electronic braking system, triggered by EMG from the frontalis muscle, was used to augment a normal foot-activated automobile brake.

The EMG signal has additional potential to augment more traditional control methodologies, such as automatic speech recognition. For example, recent work has shown that certain facial EMG activity is highly correlated with speech. Follow-on studies at the University of New Brunswick in Canada demonstrated that a neural network could achieve up to 95% accuracy in recognizing the spoken words "zero" through "nine" based on EMG signals recorded from electrodes mounted in a flight oxygen mask.

3. CONTROL USING BRAIN SIGNALS

3.1. Control Technology Description

EEG recorded from the surface of the scalp represents a summation of the electrical activity of the brain. Although much of the EEG appears to be noise-like, it does contain specific rhythms and patterns that represent the synchronized activity of large groups of neurons. A large body of research has shown that these patterns are meaningful indicators of human sensory processing, cognitive activity and movement control. In addition, EEG patterns can be brought under conscious voluntary control with appropriate training and feedback. Although current EEG-based systems represent fledgling steps toward a "thought-based interface," significant long-term development is required to reach that goal. EEG-based control research is primarily confined to laboratory systems and is based on two general approaches:

- Learned control (self-regulation) of specific EEG characteristics. For example, voluntarily increasing the EEG activity in a specific frequency band might be used to turn a switch on.
- The use of involuntary EEG patterns, normally associated with sensory or motor activity, to produce an appropriate

response in an external device. For example, an operator might imagine moving their right hand to push a button. The computer system would recognize the EEG pattern associated with this movement preparation and operate the right-hand button without further operator action.

3.1.1. Signal acquisition

The most commonly used scalp electrodes are small (~1 cm diameter) gold or silver/silver chloride disks developed for EEG recording. Electrical contact is maintained with a conductive paste and the electrodes are affixed with adhesive rings, elastic caps and bands, or the conductive paste alone. Real-world applications will benefit from convenient dry electrode systems, but these are not yet commercially available. The EEG signals of interest are in the 1–40-Hz frequency range with amplitudes ranging from 1 to 50 mV. Although these signals are very small, appropriate biological signal amplifiers are commercially available. Despite a variety of signal acquisition challenges, EEG signals can be recorded from active operators, such as pilots.

3.1.2. Signal processing

After amplification and filtering to isolate the frequency range of interest, the first step in most systems is analog-to-digital signal conversion. The next step usually involves estimation of the EEG power in specific frequency bands using fast Fourier transforms, digital band-pass filters or some proprietary approach. Personal computer systems of the Pentium class are sufficient to support these computations, although digital signal processing boards are sometimes used. In several systems, the power in a specific frequency band is used as the control signal. For example, high power might move a computer cursor upward, while low power would move it downward. Some systems employ neural networks or other pattern discrimination techniques to determine the relationship between the processed EEG signals and specific body movements, joystick movements or simple utterances. Upon recognition of the required pattern the system performs the appropriate control action.

3.1.3. Feedback requirements

Biofeedback is one of the key technologies that enabled the development of systems based on learned control of EEG patterns. Operator feedback has been implemented in two ways: (1) as an inherent part of the task, e.g. movement of the computer cursor being controlled by EEG, or (2) as a separate display element when movement of the controlled element does not provide timely feedback. Biofeedback is not required in systems that use involuntary EEG responses. However, such feedback can be motivating to operators and informal observations suggest that it may useful in improving the quality and timeliness of the involuntary responses.

3.2. Applications and Evaluations

Several basic computer operations have been demonstrated with EEG-based control systems. Scientists at the Wadsworth Center, New York, have developed a system for computer cursor control that is based on self-regulation of mu (8–12 Hz) or beta (18–25 Hz) rhythms. In their two-axis control system, high mu or beta rhythm amplitude in both brain hemispheres produces upward

motion while low amplitude causes the cursor to move downward. Left and right motion is controlled by the difference in mu or beta rhythm amplitude between the two brain hemispheres. This represents a promising form of control for physically challenged individuals, despite the fact that speed and accuracy are limited. Scientists at Emory University, USA, are investigating cursor control using electrodes implanted in certain motor control areas of the brain. Simple word and message selection has been demonstrated in severely disabled patients.

Several researchers have also demonstrated alphanumeric input systems. Most approaches involve modulating (flickering) the individual elements of a simulated keyboard presented on a computer monitor. The resulting sensory-evoked responses are used to determine which character or word the operator wishes to select. Communication rates of up to 10–12 words per minute have been achieved. Scientists at the University of Tubingen, Germany, and the University of Alabama, USA, have employed the self-regulation of slow cortical potentials for alphanumeric input. By making these potentials negative, operators select one-half of the alphabet, while making them positive selects the other half. This halving process is repeated until the desired character is selected.

Scientists at Graz University, Austria, are developing the technology to "automate" simple control actions normally performed with the hands or feet. Neural networks are employed to recognize EEG patterns that precede specific body movements, such as finger, toe or tongue activity. No operator training is required, but the movements must be repeated 100–200 times for neural network training. After training, movement prediction is possible with only one second of EEG data. They have achieved > 90% accuracy in predicting button pushes with the left or right hand, for example. In addition, the neural networks can be trained with imagined rather than actual movements.

The US Air Force has investigated a variety of EEG-based control systems that involve the detection and use of evoked responses to flickering lights incorporated in a task display. One study addressed the control of a simple flight simulator. The simulator display included flickering lights at each side and presented a random series of commands requiring the operator to roll right or left to specific target angles. Operators controlled the simulator by raising their visual evoked response above a high threshold to roll right and suppressing the response below a low threshold to roll left. Typically, they were able to acquire 70–85% of the roll-angle targets after 5–6 h of training. A related study addressed the operation of a neuromuscular stimulator designed to exercise paralyzed limbs. Raising the evoked response above a high threshold turned the stimulator on and suppressing the response below a low threshold turned it off. This, in turn, caused the operator's knee to extend or flex in response to changes in stimulator current. The most recent Air Force work involves modulating selectable functions on a computer monitor. The

operator selects the desired function simply by looking at it. Over 90% accuracy with 2-s selection times was demonstrated for a two-choice task.

4. FUTURE DEVELOPMENT

With creative interface design, almost any discrete response task can be performed with EMG- or EEG-based systems. In certain cases, response time advantages have been demonstrated using EMG signals to replace the physical movement of a conventional control. The ability to perform other tasks is limited, and generally poorer than what can be achieved with conventional input devices. Simple EMG and EEG responses can be identified rapidly, but the recognition of complex patterns is more time consuming and constrains the speed of human–system interaction. Nevertheless, the pattern recognition approaches offer the greatest potential for discriminating signal from noise and for controlling multiple degree-of-freedom systems.

As discussed by McMillan *et al.* (1997) EMG and EEG signals may be most useful when applied in a manner that combines aspects of system control and operator state monitoring. Referred to as an intelligent controller paradigm, this approach employs an intelligent interpreter that monitors a range of human outputs (eye and head movements, gestures, behavior patterns, EMG and EEG signals). The interpreter combines this information to infer intent, and assists the operator, based upon this inference. While such a system has not yet been demonstrated, it may well represent the path to optimal utilization of human physiological signals for control (Sutter 1992).

Burnout

W.B. Schaufeli

Department of Psychology, Utrecht University, The Netherlands

1. INTRODUCTION

Burnout is a metaphor that describes a state of mental exhaustion or occupational fatigue. Literally it means to fail, to wear out or to become exhausted by making excessive demands on energy, strength or resources. In the mid-1970s, the colloquial term "burnout" was introduced as a scholarly construct to denote a negative psychological condition mainly characterized by lack of energy, detachment, decreased motivation, distress and a sense of reduced professional efficacy. The New York psychiatrist Herbert Freudenberger and the Californian social psychological researcher Christina Maslach were the first to use "burnout" as a psychological notion. Burnout was particularly observed among those who worked with other people, i.e. human services professionals such as teachers, nurses and social workers, and correctional officers, poverty lawyers and pastors. Soon after its introduction, burnout became a very popular topic, not only in work organisations and in the mass media, but also in academic psychology. By the end of the twentieth century, over 5500 scholarly publications had appeared and the number increases by some 300 each year. Single occupational groups most often studied are teachers (22%), followed by nurses (17%) and social workers (7%). Despite the impressive quantity of the empirical publications, their methodological quality is often questionable: typically, studies on burnout are surveys that almost exclusively rely on self-reports, use non-random samples and one-shot research designs. However, particularly in recent years, the quality of burnout research increased.

2. SYMPTOMS

A wide range of *individual* burnout symptoms has been identified that can grouped into five main categories: (1) affective (e.g. depressed mood, emotional exhaustion, anxiety); (2) cognitive (e.g. sense of failure, forgetfulness, inability to concentrate); (3) physical (e.g. headaches, muscle pains, chronic fatigue); (4) behavioral (e.g. procrastination, hyperactivity, impulsiveness); and (5) motivational (e.g. loss of zeal, disillusionment, demoralization). In addition, *interpersonal* symptoms have been described: (1) affective (e.g. irritability, lessened emotional empathy with recipients, increased anger); (2) cognitive (e.g. cynical and dehumanizing perception of recipients, stereotyping, blaming the victim); (3) behavioral (e.g. social isolation and withdrawal, aggressiveness towards recipients, expressing sick humor); and (4) motivational (e.g. loss of interest in others, discouragement, indifference with respect to recipients). Finally, symptoms in relation to the *organisation* have been observed: (1) affective (e.g. job dissatisfaction); (2) cognitive (e.g. cynicism about work role, distrust in management, peers and supervisors); (3) behavioral (e.g. reduced effectiveness, poor work performance, tardiness); and (4) motivational (e.g. loss of work motivation, low morale, dampening of work initiative). Most symptoms stem from uncontrolled clinical observations or from interview studies rather then from rigorously designed and thoroughly conducted quantitative studies. Despite the over-inclusiveness of this list, it appears that burnout symptoms are typically at three levels (individual, interpersonal, organizational) and that they include motivational symptoms, in addition to affective, cognitive, physical and behavioral symptoms which are also found in job stress. Most important, however, is that virtually all authors agree that exhaustion, energy depletion or chronic work related fatigue is the core symptom of burnout.

3. DEFINITIONS

Traditionally, state and process definitions of burnout are distinguished. The former describes burnout as a negative psychological condition, whereas the latter emphasizes its development. The most popular state definition is by Maslach and Jackson (1986: 1): "Burnout is a syndrome of emotional exhaustion, depersonalization, and reduced personal accomplishment that can occur among individuals who do 'people work' of some kind." This definition lies at the core of the most widely used self-report burnout questionnaire; the Maslach Burnout Inventory (MBI). *Emotional exhaustion* refers to the depletion or draining of emotional resources: professionals feel that they are no longer able to give themselves at a psychological level. *Depersonalization* points to the development of negative, callous and cynical attitudes towards the recipients of one's services. Contrary to its use in psychiatry, depersonalization does not refer to the extreme alienation from the self, but to an impersonal or dehumanizing perception of others. *Lack of personal accomplishment* is the tendency to evaluate one's work with recipients negatively, which is accompanied by feelings of insufficiency and poor professional self-esteem. Initially, Maslach and Jackson (1986) claimed that burnout exclusively occurred among those who dealt with recipients, like students, clients and patients. However, recently, the burnout concept was expanded beyond the human services and was redefined as a crisis in one's relationship with work, not necessarily as a crisis in one's relationship with people at work. Accordingly, it includes three more general aspects: exhaustion, cynicism and professional efficacy.

Cherniss (1980: 5) proposed an influential process definition: 'Burnout refers to a process in which the professional's attitudes and behavior change in negative ways in response to job strain.' More specifically, he describes burnout as a three-stage process: (1) an imbalance between resources and demands (stress); (2) the development of emotional tension, fatigue, and exhaustion (strain); and (3) changes in attitudes and behaviors, such as a tendency to treat clients in a detached and mechanical fashion (defensive coping). Consequently, for Cherniss, burnout is a wrong way of coping with chronic job-related strain.

Despite obvious inconsistencies among burnout definitions Schaufeli and Enzmann (1998: 36) formulated a synthetic definition:

> Burnout is a persistent, negative, work-related state of mind in "normal" individuals that is primarily characterized by exhaustion, which is accompanied by distress, a sense of reduced effectiveness, decreased motivation, and the development of dysfunctional attitudes and behaviors at work. This psychological condition develops gradually but may remain unnoticed for a long time for the individual involved. It results from a misfit between intentions and reality at the job. Often burnout is self-perpetuating because

of inadequate coping strategies that are associated with the syndrome.

4. BURNOUT AND RELATED PSYCHOLOGICAL CONDITIONS

From the outset, the distinction between burnout and related psychological phenomena (e.g. job stress and depression) has been debated. Burnout is as a *particular kind* of prolonged job stress. An individual experiences job stress when job demands tax or exceed adaptive resources. That is, job stress refers to a temporary adaptation process accompanied by mental and physical symptoms, whereas burnout refers to a breakdown in adaptation that manifests itself in profound and chronic malfunctioning at work. Furthermore, the stress responses includes physical, psychological (affective, cognitive, motivational) and behavioral symptoms, whereas burnout is defined as a multidimensional syndrome that includes — in addition to such symptoms — the development of negative, dysfunctional attitudes and behaviors at work. Finally, everybody can experience stress, while burnout can only be experienced by those who entered their careers enthusiastically with high goals and expectations and who restlessly pursued success in their jobs. Empirically speaking, burnout — as measured with the MBI — is related with job stress, but can nevertheless be differentiated from it.

Despite clear similarities such as dysphoric mood, fatigue, and loss of motivation burnout and depressive illness (i.e. mood disorder) can be distinguished. First, the former is usually accompanied by guilt (leading to suicidal ideation), whereas burnout generally occurs in the context of anger and resentment. Moreover, burnout symptoms, at least initially, tend to be job-related and situation-specific rather than pervasive. In contrast, depressive illness is characterized by a generalization of the person's symptoms across all situations and spheres of life. Finally, typical symptoms of depression such as significant weight gain or weight loss and mood swings during the day are virtually absent in burnout. Not only the clinical picture of burnout and depressive illness differs, but also empirical research corroborates the discriminant validity of the two most used self-report indicators of both constructs (i.e. the MBI and Beck's Depression Inventory).

5. ASSESSMENT

Burnout is almost exclusively assessed by means of self-report questionnaires; no standardized observation or interview procedures exist. The MBI (Maslach *et al.* 1986) is almost universally used: > 90% of the empirical studies on burnout include this instrument. The second most widely used self-report scale is the Burnout Measure (BM), which exclusively assesses the employees' level of exhaustion. Three versions of the MBI exist: the Human Services Survey (HSS), the Educator's Survey (ES) and the General Survey (GS). All versions include three scales that correspond with the dimensions of the state definition of burnout. Instead of one total composite score, the MBI yields three scale scores. The MBI has been thoroughly investigated psychometrically and appears to be a reliable and valid indicator of burnout.

"Burnout" is not a formal, officially known diagnostic label. It comes most close to the diagnostic criteria of an Unspecified Adjustment Disorder (Diagnostic and Statistical Manual of Mental Disorders — DSM-IVr) or of Neurasthenia (International Classification of Mental and Behavioral Disorders — ICD10) that is work related. Principally, the MBI can be used to assess the individual's level of clinical burnout. However, the current classification of burnout levels is based on arbitrary statistical norms that have not been clinically validated in a sample that consists of burned out patients. Therefore, the MBI categorization of burnout into "high", "average" and "low" levels is not (yet) suited for individual assessment.

6. PREVALENCE

Since no clinically validated cut-off score is available to distinguish "burnout cases" from "non-cases", the absolute prevalence of burnout among the working population cannot be determined reliably. However, the relative prevalence in particular occupational groups in the USA shows the following pattern: levels of emotional exhaustion are clearly highest among teachers; intermediate levels are found in the social services and in medicine, whereas workers in mental health services experience the lowest levels. For depersonalization the picture is slightly different: social workers and teachers report the highest levels, whereas levels in the mental health services are lowest. Physicians and police officers exhibit particularly high levels of depersonalization, which might reflect their occupational socialization characterized by objectiveness and distance. Finally, reduced personal accomplishment is especially found in the social services and among nurses, police officers, and probation and correction officers. Not surprisingly, the most highly trained professionals (i.e. physicians and psychologists) experience the strongest sense of accomplishment in their jobs. There is some evidence that these specific occupational burnout profiles are consistent across countries.

7. CORRELATES OF BURNOUT

Tables 1 and 2 present an overview of the correlates of burnout. Since the vast majority of studies used a one-shot design, only very few cause–effect relationships could be established so far.

As can be seen in table 1, burnout is observed more often among younger employees than among those aged > 30–40 years. This is in line with the observation that burnout is negatively related to work experience. On balance, women tend to score slightly higher on emotional exhaustion, whereas males score significantly higher on depersonalization. Most likely this reflects differences in sex roles, i.e. women are more emotionally responsive, whereas men hold more instrumental attitudes. Singles seem to be more prone to burnout than those who are married (or divorced) persons. Persons with high burnout levels are characterized by: (1) low involvement in daily activities, poor control over events, and little openness to change ("hardiness"); (2) attributing events to powerful others or to change ("external locus of control"); (3) avoiding problems instead of tackling them ("avoiding coping style"); (4) low self-esteem; (5) emotional instability ("neuroticism"); and (6) low intensity of interpersonal interaction ("extroversion"). Furthermore, burnout is positively related to high or unrealistic expectations about one's job and to various job characteristics. Generally speaking relationships with job characteristics are stronger than with personality characteristics.

It appears from table 2 that burnout is particularly associated

Table 1: Correlates of burnout: possible causes*

biographic characteristics			
age	−	−	
gender			+
work experience		−	
marital status			−
personality characteristics			
hardiness	−	−	−
external control orientation		+	+
avoiding coping style		+	+
self-esteem		−	−
neuroticism	+	+	+
extroversion			−
job related attitudes			
high (unrealistic) expectations			+
job characteristics			
workload	+	+	+
time pressure	+	+	+
role conflict and ambiguity		+	+
direct client contact		+	+
social support from colleagues or superiors		−	−
lack of feedback		+	+
participation in decision making		−	−
autonomy			−

Notes: * Adapted from Schaufeli & Enzmann, 1998; p. 75; The number of minus or plus signs denotes the strength and the direction of the relationship based on: (1) the number of studies involved; (2) their methodological quality; (3) the consistency of results across studies.

Table 2: Correlates of burnout: possible consequences*

individual level			
depression	+	+	+
psychosomatic complaints	+	+	+
health problems			+
substance use			+
spillover to private life			+
work orientation and attitudes			
job satisfaction	–	–	–
organisational commitment		–	–
intention to quit		+	+
organisational level			
absenteeism and sick-leave			+
job turnover			+
performance and quality of services			–

Notes: * Adapted from Schaufeli & Enzmann, 1998; p. 86. The number of minus or plus signs denotes the strength and the direction of the relationship based on: (1) the number of studies involved; (2) their methodological quality; (3) the consistency of results across studies.

with depression, psychosomatic complaints and job dissatisfaction, whereas it is less strongly related with subjective health problems, substance use, spill-over, poor organizational commitment, intention to quit, absenteeism, job turnover and poor job performance.

As far as the three dimensions of the MBI are concerned, emotional exhaustion is strongest related to possible causes, and consequences of burnout. This applies especially to job characteristics, neuroticism, depression and psychosomatic symptoms. Generally, correlations with depersonalization are weaker. On balance, personal accomplishment is least strongly related to potential correlates of burnout with the exception of some personality characteristics.

8. THEORETICAL EXPLANATIONS

There is no general psychological theory to explain burnout. Rather, three different sets of approaches can be distinguished that are supplementary instead of mutually exclusive (Schaufeli *et al.* 1993, Schaufeli and Enzmann 1998). First, *individual approaches* emphasize the role of factors and processes within the person. For instance, burnout can be seen as the result of a pattern of wrong (i.e. high or unrealistic) expectations, or as a failure to retain one's idealized self-image, or as a narcissistic disorder, or as a failed quest for existential meaning, or as a disturbed action pattern. Second, *interpersonal approaches* focus on demanding relations with others at work (i.e. recipients and/ or colleagues). For instance, from this perspective burnout is considered to be the result of emotional overload due to the demanding interactions with difficult recipients, or of a lack of reciprocity between investments put into recipients and the outcomes received, or of the dissonance between the displayed and the experienced emotions, or of emotional contagion (i.e. being 'infected' by others with burnout). Third, *organizational approaches* stress the importance of the organizational context.

For instance, from this perspective burnout is seen as the result of a mismatch between person and job, or as 'reality shock' (the clash of personal ideals with harsh organizational reality). Generally speaking, most theoretical approaches are rather speculative and have no firm empirical bases, perhaps with the exception of some interpersonal explanations.

9. INTERVENTIONS

Basically, interventions to reduce burnout may be focus on: (1) the individual; (2) the individual/organisation interface (i.e. the interplay between individual and organisation); and (3) the organisation. Although numerous interventions have been proposed (Schaufeli and Enzmann 1998), few are specific for burnout. That is, most interventions are general approaches to reduce stress at the workplace. Examples of *individual level* interventions are: didactic stress management (i.e. providing information about burnout to increase awareness and improve self-care), promoting a healthy life style (i.e. physical exercise, weight control, smoking cessation), relaxation, and cognitive-behavioral techniques (e.g. redirection the individual's irrational thinking). Examples at the *individual/organisation interface level* include: time management, interpersonal skills training (e.g. assertiveness), balancing work and private life, coaching and consultation by peers and supervisors, career planning, and specialized counseling and psychotherapy. Finally, interventions at the *organizational level* include: improving the job content by job redesign, management development, introducing corporate fitness and wellness programs, organizational development, and the institutionalization of occupational health and safety services. Many interventions at this level are mere 'Band-Aids' primarily designed for increasing productivity, improving quality or reducing costs. Empirical studies have shown that particularly cognitive and behavioral approaches such as relaxation training, time-management, didactic stress management and cognitive restructuring are effective in reducing levels of exhaustion. Effects on depersonalization and reduced personal accomplishment are far less strong or even absent.

Some of these interventions — most notably at the individual or interface level — are combined in so-called *burnout workshops* in which small groups of workers participate. Typically, such preventive workshops rest on two pillars: increasing the participants' awareness of work-related problems and augmenting their coping resources by cognitive and behavioral skills training and by establishing support networks. More specifically, such workshops include self-assessment, didactic stress-management, relaxation, cognitive and behavioral techniques, time-management, peer support, and the promotion of a more realistic image of the job. Taking together the few studies on the effectiveness of such multi-faceted workshops, it seems that they are effective in reducing levels of emotional exhaustion, even across relatively long periods of time (up to a year). Other burnout dimensions are usually not affected, though. The fact that depersonalization and reduced personal accomplishment do not change is not very surprising because most techniques focus on reducing arousal and not on changing attitudes (depersonalization) or on enhancing specific professional skills or resources (personal accomplishment).

Cognitive Modeling in Human–Computer Interaction

W. D. Gray and E. M. Altmann

Human Factors and Applied Cognition, Department of Psychology, George Mason University, Fairfax, VA 22030, USA

"There is nothing so useful as a good theory" (Lewin 1951).
"Nothing drives basic science better than a good applied problem" (Newell and Card 1985).

1. INTRODUCTION

The quotations from Lewin and from Newell and Card capture what motivates those who apply cognitive modeling to human–computer interaction (HCI). Cognitive modeling springs from cognitive science. It is both a research tool for theory building and an engineering tool for applying theory. To the extent that the theories are sound and powerful, cognitive modeling can aid HCI in the design and evaluation of interface alternatives. To the extent that the problems posed by HCI are difficult to model or cannot be modeled, HCI has served to pinpoint gaps or inconsistencies in cognitive theory. In common with design, science is an iterative process. The symbiotic relationship between modeling and HCI furthers the scientific enterprise of cognitive science and the engineering enterprise of human factors.

Cognitive modeling is a form of task analysis and, as such, is congenial to many areas and aspects of human factors. However, the control provided by the computer environment, in which most dimensions of behavior can be easily and accurately measured, has made HCI the modeler's primary target. As modeling techniques become more powerful and as computers become more ubiquitous, cognitive modeling will spread into other areas of human factors.

We begin this article by discussing three cognitive models of HCI tasks, focusing on what the models tell us about the tasks rather than on the details of the models themselves. We next examine how these models, as well as cognitive models in general, integrate constraints from the cognitive system, from the artifact that the operator uses to do the task, and from the task itself. We then explore what sets cognitive modeling apart from other types of cognitive task analysis and examine dimensions on which cognitive models differ. We conclude with a brief summary.

2. THREE EXAMPLES OF COGNITIVE MODELING APPLIED TO HCI

The three examples span the gamut of how models are used in HCI. We discuss them in the order of most applied to most theoretical. However, it would be a mistake to think of these as application versus research as each has contributed strongly to theory and each has clear applications to HCI issues.

2.1 Project Ernestine: CPM–GOMS

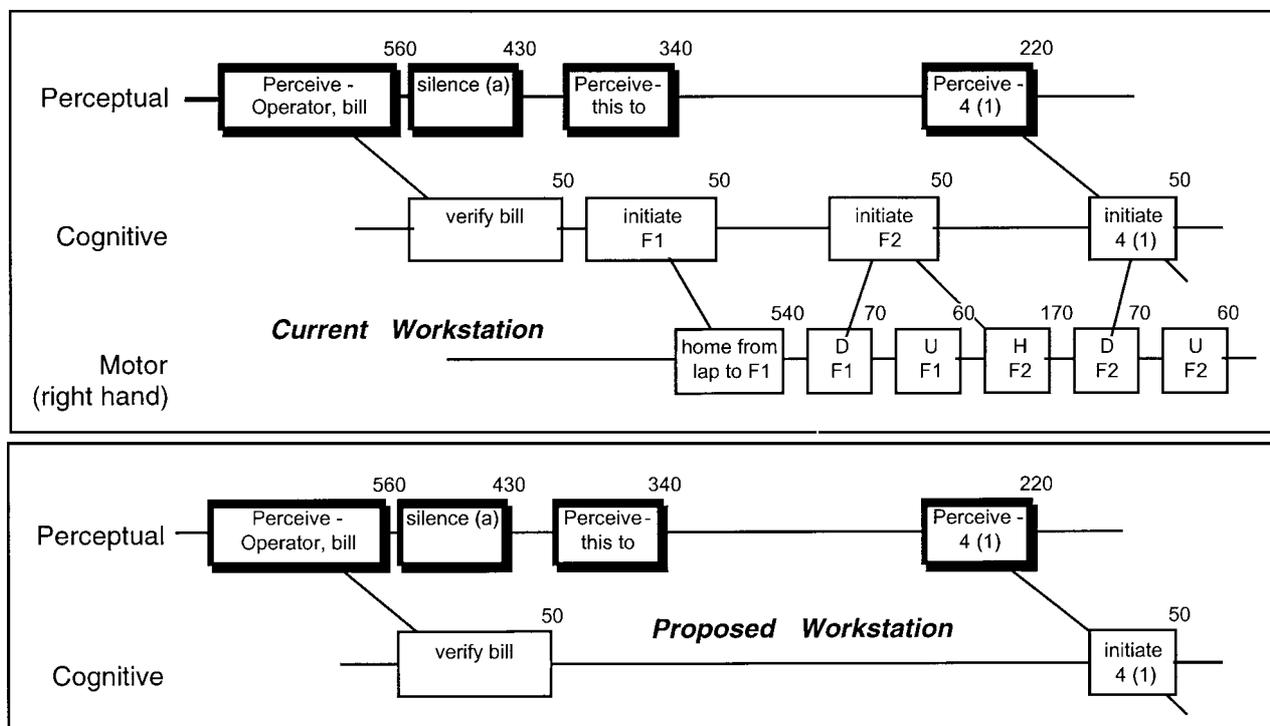
In the world of the telephone company, time is literally money. In the late 1980s, NYNEX calculated that if the length of each operator-assisted call decreased by 1 sec. the company's operating costs would be reduced by $3 million per year. Potential savings


Figure 1. Section of CPM-GOMS analysis for an operator-assisted call. The proposed workstation (bottom) has two fewer keystrokes totaling 6 motor and 2 cognitive steps. However, deleting these steps did not alter the critical path (shown in bold).

on this scale provided an incentive to shave seconds from the time that toll and assistance operators (TAOs) spent on operator-assisted calls.

A major telecommunications equipment manufacturer promised to do just that. For an equipment investment of $60 to $80 million, the old TAO workstations could be replaced by new, ergonomically engineered workstations. The manufacturer's back-of-the-envelope style calculations predicted that the new workstations would shave about 4 sec. from the average call for an estimated savings of $12 million annually.

Project Ernestine involved a combination of cognitive modeling and field trial to compare the new workstations with the old (Gray, John, and Atwood 1993; Gray, John, Stuart, Lawrence, and Atwood 1995). The cognitive models created in Project Ernestine used the GOMS task analysis technique developed by Card, Moran, and Newell (1983). GOMS analyzes a task in terms of Goals, simple Operators used by the person performing the task, and sequences of operators that form Methods for accomplishing a goal. If alternative methods exist for accomplishing a goal, then a Selection rule is required to choose among them. GOMS is best suited to the analysis of routine, skilled performance, as opposed to problem-solving. The power of GOMS derives in part from the fine-grain level of detail at which it specifies the operators involved in such performance. (For a fuller exposition on GOMS, see John and Kieras, 1996a, 1996b).

Project Ernestine employed a GOMS variant, CPM-GOMS, to analyze the TAO's task. CPM-GOMS specifies the parallelism and timing of elementary cognitive, perceptual, and motor operators, using a schedule chart format that enables use of the critical path method to analyze dependencies between these operators.

Contrary to expectations, the cognitive models predicted that the new workstations would add about 1 sec. to the average call. Rather than reducing costs as predicted by the manufacturer, this increased time would result in $3 million in additional operating costs. This prediction was borne out empirically by a four-month field study using live telephone traffic. A sample of the CPM-GOMS model for the beginning part of one call type is shown in Figure 1.

Beyond its prediction, CPM-GOMS was able to provide explanation. The manufacturer had shown that the proposed workstation reduced the number of keystrokes required to process a typical call and from this inferred that the new workstation would be faster. However, their analysis ignored the context of the call, namely the interaction of customer, workstation, and TAO. CPM-GOMS captured this context in the form of a critical path of cognitive, perceptual, and motor actions required for a typical call. By filling in the missing context, CPM-GOMS showed that the proposed workstation *added* more steps to the critical path than it eliminated. This qualitative explanation made the model's prediction credible to telephone company executives.

2.2 Postcompletion Error

An adequate theory of error "is one that enables us to forecast both the conditions under which an error will occur, and the particular form that it will take" (Reason 1990, p. 4). Such a theory was developed by Byrne and Bovair (1997) for a phenomenon that they named *postcompletion error*.

The tasks that people want to accomplish are usually distinct from the devices used to accomplish them. For example, the task might be to withdraw cash from a bank account and the device might be an automated teller machine (ATM). From the perspective that task and device are distinct, any action that the device (the ATM) requires us to perform after we complete our task (withdrawing cash) is a postcompletion action. An omitted postcompletion action is thus a postcompletion error. Postcompletion errors include leaving the card in the ATM after taking the money; leaving the originals on the photocopier after taking the copies; and forgetting to set the video cassette recorder (VCR) to *record* after programming it to videotape a show.

The striking characteristic of postcompletion errors is that, although they occur, they do not occur often. Most people, most of the time, take both the money and the card from the ATM (else, we suspect many fewer of us would use ATMs). What, if anything, predicts the occurrence of a postcompletion error?

Byrne and Bovair's postcompletion error model is based on the notion of *activation* of memory elements. Activation is a hypothetical construct that quantifies the strength or salience of information stored in memory. The postcompletion error model was constructed using CAPS, a programmable model of the human cognitive architecture (Just, Carpenter, and Keller 1996). CAPS assumes that a memory element is accessible only if it has enough activation. It also assumes that total activation is limited. Activation flows from one memory element to another if the two are related and if one is the focus of attention. This spreading activation accounts for standard psychological effects like semantic priming, in which, for example, focusing on the notion of "doctor" might spread activation to related concepts like "nurse."

In Byrne and Bovair's error model, as long as the focus is on a task goal like getting money, related device actions like *take the card* continue to receive activation. However, when a task goal is accomplished, attention shifts away from it. When this shift occurs, the device actions associated with the task begin to lose activation. This is fine for actions like *take the money*, which are necessarily complete, but problematic for postcompletion actions like *take the card*. If these postcompletion actions lose enough activation, they will simply be forgotten.

Beyond its explanation, the postcompletion error model offered a prediction. Like most memory theories, CAPS assumes that unused memory elements decay and over time; that is, their activation decreases. Because activation in CAPS is a common resource, decay of one memory element makes more activation available for other elements. Commensurately, Byrne and Bovair found fewer postcompletion errors in a condition that included a prolonged tracking task. Apparently the tracking task, which involved no memory load itself, allowed completed actions of the main task to decay. Postcompletion actions continued to receive activation because the task goal was not yet accomplished. In addition, they received the activation lost by the actions that decayed. This additional activation reduced postcompletion error.

As an example of applied theory, the postcompletion error model is important for several reasons. First, its explanations and predictions flow from existing cognitive theory, not from ad hoc assumptions made by the analysts. The model functioned primarily as a means of instantiating a theory on a particular problem. Second, the prediction comes from the model not the modeler. Any analyst could run the postcompletion error model with the same outcome. The debate over this outcome is then

limited to and focused by the representational assumptions and parameter settings reified in a running computer program.

2.3 Information Access

Information in the world is useful only if we can find it when we need it. For example, an illustration in a book is helpful only if we know it exists, if we recall its existence when it is needed, and if we can find it. This view of information adds a cognitive dimension to research into information access (e.g, the HCI sub-areas of information retrieval and interface design). How do we recall the existence of the helpful illustration? What was stored in memory about the illustration, and exactly what is being recalled? What were the cues that prompted the recollection? From the cognitive perspective, the process of information access is complex. However, with a better understanding of the role of memory, we can engineer memory aids that support this process.

Altmann and John (in press) studied the behavior of a programmer making changes to code that had been written over a series of years by a team of which the programmer was a member. Verbal and action protocols (keypresses and scrolling) were recorded throughout an 80-min. session. During this session, the programmer would trace the program for several steps, stop it, interrogate the current value of relevant variables, and so on. Over the course of the session 2,482 lines of code were generated and displayed on the programmer's screen. On 26 occasions, she scrolled back to view information that had appeared earlier but had scrolled off the screen.

Of interest was the role of memory in these scrolling episodes. The volume of potential scrolling *targets* was huge and the programmer's need for any particular target was small. However, the protocol data revealed that scrolling was purposeful rather than random, implying a specific memory triggered by a specific cue. These constraints meant that the programmer's memory-encoding strategy must have been both sweeping in its coverage of potential targets and economical in terms of cognitive effort.

Altmann and John developed a computational cognitive model of *episodic indexing* that simulated the programmer's behavior. The model was developed using Soar, which, like CAPS, is a cognitive theory with a computational implementation (Newell 1990). Based on the *chunking* theory of learning, Soar encodes sweeping amounts of information economically in memory, but retrieval of this information depends on having the right cue. When the episodic-indexing model attends to a displayed item (e.g. a program variable), Soar creates an episodic chunk in memory that maps semantic information about the item to episodic information indicating that the item was attended. A second encounter with the item triggers recall of the episodic chunk, which in turn triggers an inference that the item exists in the environment. Based on this inference, the model decides whether or not to pursue the target by scrolling to it.

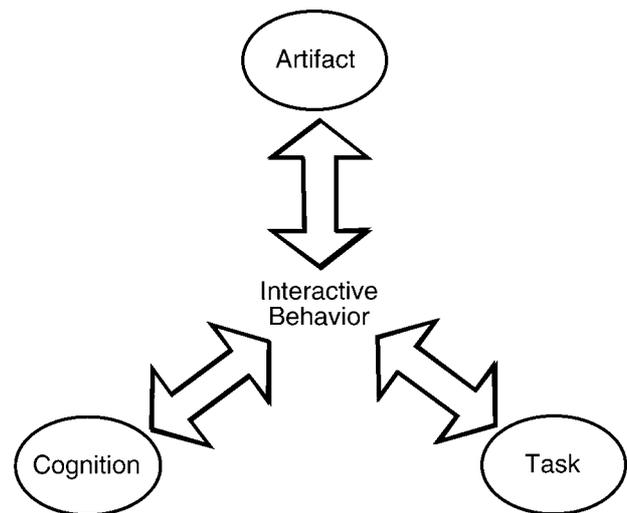
The episodic indexing model suggests that memory depends on attention, not intent. That is, episodic chunks are stored in memory as a by-product of attending to an object, with no need for any specific intent to revisit that object later. The implication is that people store vast amounts of information about their environment that they would recall given the right cues. This, in turn, suggests that activities like browsing are potentially much better investments than we might have thought. The key to unlocking this potential is to analyze the semantic structure of


Figure 2. The cognition–artifact–task triad. The behavior of an operator using an artifact to perform a task arises from the limits, mutual constraints, and interactions between and among each member of the cognition–artifact–task triad.

the knowledge being browsed and to ask how artifacts might help produce good cues later when the browsed information would be relevant.

3. THE COGNITION–ARTIFACT–TASK TRIAD

Almost everything we do requires using some sort of artifact to accomplish some sort of task. As Figure 2 illustrates, the interactive behavior for any given artifact–task combination arises from the limits, mutual constraints, and interactions between and among each member of the cognition–artifact–task triad. Cognitive modeling requires that each of these three factors be incorporated into each model.

Traditional methodologies generally consider cognition, artifact, and task *pairwise* rather than altogether. For example, psychological research typically seeks experimental control by using simple tasks that require little external support, thereby focussing on cognition and task but minimizing the role of artifact. Industrial human-factors research often takes the artifact itself to be the task, largely ignoring the artifact's purpose. For example, the proposed TAO workstation had an ergonomically designed keyboard and display but ignored the TAO's task of interacting with the customer to complete a call. Finally, engineering and computer science focus on developing artifacts, often in response to tasks, but generally not in response to cognitive concerns. The price of ignoring any one of cognition, artifact, and task is that the resulting interactive behavior may be effortful, error-prone, or even impossible.

In contrast, cognitive modeling as a methodology is bound to consider cognition, artifact, and task as inter-related components. The primary measure of cognition is behavior, so analysis of cognition always occurs in the context of a task. Moreover, analyzing knowledge in enough detail to represent it in a model requires attention to where this knowledge resides — in the head or in artifacts in the world — and how its transmission between head and world is constrained by human perceptual/

motor capabilities. Indeed, computational theories of cognition are now committed to realistic interaction with realistic artifacts (see, for example, Anderson, Matessa, and Lebiére, 1997; Howes and Young, 1997; Kieras and Meyer, 1997). Thus, given that human factors must consider cognition, artifact, and task together, cognitive modeling is an appropriate methodology.

4. COGNITIVE MODELING VERSUS COGNITIVE TASK ANALYSIS

Cognitive task analysis, broadly defined, specifies the cognitive steps (at some grain size) required to perform a task using an artifact. Cognitive modeling goes beyond cognitive task analysis per se in that each step is grounded in cognitive theory. In terms of the triad of Figure 2, this theory fills in the details of the cognition component at a level appropriate to the task and the artifact.

In Project Ernestine, for example, the manufacturer's predictions about the proposed workstation came from a cognitive task analysis. However, this analysis specified the cognitive steps involved in using the workstation as the manufacturer saw them. The CPM-GOMS models, in contrast, took into account theoretical constraints on cognitive parallelism and made predictions that were dramatically more accurate. In the other two models the influence of theory is strong as well. Most any cognitive analysis would identify memory failure as the cause of postcompletion error. However, the model based on CAPS went further, linking decay of completed goals to improved memory for pending goals. Similarly, memory is clearly a factor in information access, but the model based on Soar detailed the underlying memory processes to highlight the potential of browsing and the importance of effective cues.

Our discussions of cognitive theory have focused on GOMS (John and Kieras 1996a, 1996b), ACT-R (Anderson and Lebiére 1998), CAPS (Just *et al.* 1996), EPIC (Kieras and Meyer 1997), and Soar (Newell 1990). These are broad and integrated theories that deal with cognitive control (GOMS, ACT-R, and Soar), learning and memory (ACT-R, CAPS, and Soar), and perception and action (ACT-R and EPIC). There is also the class of connectionist or neural network models that offers learning and memory functions that have been highly successful in accounting for lower-level cognitive phenomena like visual attention (e.g. Mozer and Sitton 1998). In sum, a broad range of theory is now available to elaborate the steps of a cognitive task analysis and thus produce cognitively plausible models of interactive behavior.

5. DIMENSIONS OF COGNITIVE MODELS

The models we have described are points in a much larger space. In general, a model simply represents or stands for a natural system that for some reason we are unable to study directly. Many psychological models, for example, are mathematical functions, like memory-retention functions or regression equations. These make accurate, quantitative predictions but are opaque qualitatively in that they provide no analysis of what lies behind the behavior they describe.

We have focused on models that characterize the cognitive processes involved in interactive behavior. Process models can make quantitative predictions, like those of the TAO model, but go beyond such predictions to specify with considerable precision the cognitive steps involved in the behavior being analyzed. To give a sense of the space of possibilities, we compare and contrast process models on two dimensions: generative vs. descriptive, and generality vs. realism.

5.1 Generative versus Descriptive

Two of our sample models are generative and one is descriptive. The postcompletion error and episodic indexing models actually generate behavior simulating that of human subjects. Generative models are implemented as executable computer programs (hence are often referred to as computational cognitive models) that take the same inputs and generate the same outputs that people do. The TAO model, in contrast, simply describes sequences of actions rather than actually carrying them out.

Generative models have several advantages. These include, first, proof of sufficiency. Running the model proves that the mechanisms and knowledge it represents are sufficient to generate the target behavior. Given sufficiency, evaluation can shift, for example, to whether the model's knowledge and mechanisms are cognitively plausible. A second benefit is the ability to inspect intermediate states. To the extent that a model is cognitively plausible, its internal states represent snapshots of what a human operator may be thinking. A third benefit is reduced opportunity for human (analyst) error. Generative models run on a computer, whereas descriptive models must be hand-simulated, increasing the chance of error.

5.2 Generality versus Realism

Models vary in their concern with *generality* versus *realism*. Generality is the extent to which a model offers theoretical implications that extend beyond the model's domain. Realism, in contrast, is the extent to which the modeled behavior corresponds to the actual interactive behavior of a particular operator performing a given task.

Project Ernestine showed high realism in that each model accounted for the behavior for an entire unit task; that is, one phone call of a particular call category for a particular workstation. These models were not general in that it would be difficult to apply them to any task other than the one modeled. For example, they could not be applied to model ATM performance or VCR programming. Indeed, the existing models apply only to a particular set of call categories. If another call category were to be modeled, another model would have to be built.

In contrast, the models of postcompletion error and episodic indexing lack realism in that their accounts of behavior are incomplete. Byrne and Bovair's model cannot perform the entire task, and Altmann and John's model cannot debug the code. However, the implications of these models extend far beyond the tasks in which they are based. Situations involving postcompletion actions are susceptible to postcompletion error. If postcompletion actions cannot be designed out of an interface then special safeguards against postcompletion error must be designed in. Likewise, episodic indexing suggests that human cognition reliably encodes a little information about whatever it attends to. With the right cue, this information can be retrieved. These hypotheses bear on any artifact–task combination in which memory is an issue.

6. SUMMARY

The space of cognitive process models, even within the space of

models in general, is quite large (see Gray, Young, and Kirschenbaum 1997 for an alternative cross-section). It used to be that developing process models required access to specialized hardware and software that was available only at certain locations. Fortunately, the technology of programmable cognitive theories has improved to the point where computational models can be run and inspected over the Web (e.g. most of the models discussed in Anderson and Lebiére 1998 are available on the web). Access to such models enables the analyst to study working copies of validated models and potentially to build on, rather than duplicate, the work of others.

Cognitive modeling is the application of cognitive theory to applied problems. Those problems serve to drive the development of cognitive theory. Some applications of cognitive modeling are relatively pure application with little return to theory. Of the three models we considered, the model of the TAO in Project Ernestine (Gray *et al.* 1993) best fits this characterization.

In contrast, the episodic indexing model (Altmann and John, in press) was driven by an applied question — how a programmer works on her system — but produced no new tool or concrete evaluation. Instead, it proposed a theory of how people maintain effective access to large amounts of information. This theory suggests a class of design proposals in which the artifact plays the role of memory aid.

In the middle, the model of postcompletion error (Byrne and Bovair 1997) used existing theory to predict when an applied problem (error) was most likely to occur. On this middle ground, where theory meets problem, is where cognitive modeling will have its greatest effect — first on HCI, then on human factors.

1. INTRODUCTION

This paper will focus on recent applications of techniques and methods from Cognitive Psychophysiology to Human Factors and Ergonomics. It will begin by providing a definition of Cognitive Psychophysiology followed by a brief historical discussion of the use of psychophysiological techniques in Human Factors. It will then discuss the types of Human Factors questions and issues that might be addressed with Cognitive Psychophysiology and will provide illustrative examples of applications of psychophysiological measures to Human Factors issues. Finally, it will discuss potential future applications of Cognitive Psychophysiology to Human Factors.

Cognitive Psychophysiology entails the use of physiological measures that can be noninvasively recorded from humans in the study of mental processes including perception, cognition, memory and action. Over the past several decades a number of physiological measures have subserved this function. These measures can be subdivided into those that primarily index activity in the central nervous system (CNS) and those that are primarily sensitive to peripheral nervous system (PNS) activity. It is important to point out, however, that the CNS and PNS distinction is only a shorthand for the organization of the nervous system, since these two systems interact in the control of many physiological functions. The CNS contains all cells within the bony structures of the skull and the spinal column, including the brain, brain stem and spinal cord. The CNS measures that have been used in Cognitive Psychophysiology research and applications include the recording of electroencephalographic (EEG) activity, event-related brain potentials (ERP), magnetic activity of the brain (MEG), neuro-imaging measures including positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), and optical and electro-oculographic (EOG) measurements of eye movements. Measures of PNS activity have, for the most part, concentrated on activity of a particular branch of the PNS system, the autonomic nervous system (ANS). The ANS controls the internal organs of the body by inneverating involuntary (smooth) musculature and serves multiple functions, such as the mobilization of the body to meet emergencies and the conservation and maintenance of bodily resources, through its subdivisions the sympathetic (SNS) and parasympathetic (PNS) nervous systems. The PNS, largely ANS, measures which have been used in Cognitive Psychophysiological research include cardiovascular (e.g. heart rate and heart rate variability measures), respiratory, pupil diameter and electrodermal measures. The detailed description and discussion of the individual measures is beyond the scope here but can be found in Cacioppo *et al.* (in press).

2. COGNITIVE PSYCHOPHYSIOLOGY AND HUMAN FACTORS: A BRIEF HISTORY

Psychophysiological measures, principally measures of gaze direction, played an important role in the examination of human performance in complex systems during the early years of Human Factors. In the 1950s Fitts *et al.* (1950) at Wright-Patterson Air Force Base used measures of gaze direction, gaze duration and the sequence of eye movements to examine the information extraction strategies employed by novice and experienced aircraft pilots during instrument flight. The information acquired from these studies was used to reconfigure instrument panels to optimize the speed and accuracy with which pilots could locate and extract flight relevant information.

The use of other psychophysiological measures to examine issues of interest to the Human Factors community soon followed the pioneering research of Fitts *et al.* For example, EEG activity was recorded from pilots as they flew missions of varying difficulty in simulated and actual flight in an effort to examine the utility of this psychophysiological measure for the assessment of the deleterious effects of high-G environments and mental and emotional workload. Measures of heart rate and heart rate variability have long been used to provide a continuous record of the cardiorespiratory function and mental workload of operators in complex simulated and real-world systems. Heart rate measures have been recorded as aircraft pilots execute a number of maneuvers in simulated and actual aircraft such as landing, refueling during long haul flights, performing steep descents and flying combat missions. Such measures continue to be used today, often in the context of other psychophysiological measures and along with a more sophisticated appreciation for the underlying physiology and the relevant cognitive psychology.

In summary, although the application of psychophysiological techniques to Human Factors issues has a relatively recent history these measures have provided and continue to provide useful insights into human performance and cognition in laboratory and extra-laboratory (i.e. simulator and operational contexts) environments. One can now turn to a discussion of recent applications of psychophysiological measures to topics of interest to the Human factors community.

3. APPLICATIONS OF COGNITIVE PSYCHOPHYSIOLOGY TO HUMAN FACTORS ISSUES AND PROBLEMS

Given that there are a multitude of techniques available to address Human Factors problems and issues one must ask what role psychophysiology might play in Human Factors research and application. Certainly if the information that is gained through psychophysiological measurement is redundant with that obtained from other measures employed by the Human Factors community it is unlikely that psychophysiological measures will gain wide acceptance. This is likely to be the case for the foreseeable future given the relatively high cost and substantial amount of expertise required for the collection, analysis and interpretation of psychophysiological measures relative to the more traditional subjective rating and performance-based measurement

techniques employed by Human Factors practitioners and researchers.

Thus, for psychophysiological measurement techniques to gain acceptance in the Human Factors community these measures must (1) prove to be more valid or reliable indices of relevant psychological (or in some cases physiological) constructs than traditional behavioral and subjective measures, or (2) enable the measurement of constructs that are difficult or impossible to measure with traditional performance-based or subjective measures, or (3) enable the measurement of relevant constructs in situations in which other types of measures are unavailable. Indeed, there is evidence that each of these three criteria has been or can be met within a subset of Human Factors contexts and with subsets of psychophysiological measures.

One additional issue that merits some discussion is the applicability of psychophysiological measurement techniques to high fidelity simulation and operational environments. Certainly, the great majority of psychophysiological research has focused on explicating the functional significance of different measures and components with relatively simple tasks in well controlled laboratory environments. Even in such well controlled environments, a great deal of effort has been expended on the elimination of potential artifacts (e.g. from ambient electrical fields, contamination from other physiological signals that may mask the signal of interest, individual differences in baselines or a measure's morphology or topography, etc.). Given the diversity and magnitude of the artifacts that are encountered in such well controlled settings, is it a reasonable expectation to collect valid and reliable psychophysiological data in less well controlled environments such as high fidelity simulators or operational environments? Although the collection of psychophysiological data in such environments clearly still provides a considerable technical challenge, there have been a number of promising developments in the design of miniaturized recording equipment that can withstand the rigors of operational environments. There have also been developments of pattern recognition and signal analysis techniques that enhance the detection of some physiological signals in noise, and the development of automated artifact rejection procedures. Barring technological roadblocks, such developments should continue to increase the potential for recording psychophysiological signals in a number of complex environments.

One major area in which Cognitive Psychophysiology has made a substantial contribution to Human Factors is in the understanding and measurement of mental workload. Mental workload has been conceptualized as the interaction between the structure of systems and tasks on one hand, and the capabilities, motivation and state of the human operator on the other (Kramer 1991). More specifically, mental workload has been defined as the "costs" a human incurs as tasks are performed. Early views of the human side mental workload suggested that the "costs" of performing tasks could be conceptualized in terms of an undifferentiated capacity or resource. The performance of a difficult task (e.g. driving an automobile in heavy traffic) would leave fewer resources for performing additional tasks (e.g. talking to a passenger) than the performance of an easy task (e.g. driving an automobile on a deserted highway). More current views have argued that multiple resources and mechanisms are required to perform most complex tasks and the extent to which performance

suffers depends on the overlap between resources required for concurrently performed tasks.

Psychophysiological measures have been instrumental in defining the nature of the resources and mechanisms which underlie complex task performance while also enabling the measurement of dynamic changes in mental workload. For example, a number of components of the ERP have been useful in both characterizing resource tradeoffs between concurrently performed tasks and also distinguishing between different types of resources and processes required for complex task performance. The ERP is a transient series of voltage oscillations in the brain which can be recorded from the in response to discrete stimuli and responses. Specific ERP components, usually defined in terms of polarity and minimum latency with respect to a discrete stimulus or response, have been found to reflect a number of distinct perceptual, cognitive and motor processes thereby proving useful in decomposing the processing requirements of complex tasks.

For example, the P300 component of the ERP, a positive going deflection in the ERP which occurs anywhere from 300 to 1000 ms following the occurrence of a discrete stimulus (e.g. the appearance of an aircraft in a pilots field of view), has been found to provide a reliable index of the perceptual/cognitive resources required to perform a set of tasks. Sirevaag *et al.* (1987) found that P300s elicited by changes in the position of a target in a tracking task increased in amplitude with increases in the difficulty of the task. Correspondingly, the amplitude of P300's elicited by events in a task of lesser importance, an auditory discrimination task, decreased with increases in the difficulty of the tracking task. Thus, it would appear that changes in P300 amplitude in dual-task studies mimic the resource reciprocity effects predicted by resource models of mental workload, that is, when more resources are required to perform one task fewer resources are available for the performance of other tasks. The P300 reciprocity effects are important for several reasons. First, they provide converging support for the notion of resource trade-offs among tasks, support that is independent of the performance effects that have traditionally been used to define resource allocation policies. Second, the P300 data can be obtained in the absence of overt responses, thus enabling the assessment of resource allocation policies in situations where behavior occurs infrequently (e.g. a quality control inspector monitoring a visual display, a pilot monitoring the status of the aircraft while flying on autopilot, etc.). Third, the P300 appears to index a specific variety of resources, that is, resources required for perceptual and cognitive processes but not response selection and execution processes.

Other ERP components as well as aspects of heart rate variability have also shown to be sensitive to specific aspects of mental workload. For example, the P100 and N100 components of the ERP appear to reflect early selective attention processes and more specifically the distribution of attentional resources in visual space. The 10 Hz component of heart rate variability appears to be sensitive to working memory demands but insensitive to response or motor demands.

Interestingly, while some psychophysiological measures appear to be diagnostic of particular varieties of processing resources, other measures are less diagnostic and instead appear to reflect general or undifferentiated processing demands imposed upon the human. Psychophysiological measures that fall into this latter category include respiration, heart rate, eye blinks,

electrodermal activity and some components of EEG activity. The sensitivity of these measures to general or undifferentiated processing demands can have both advantages and disadvantages. On the positive side such measures can potentially be utilized in a wide variety of settings and across a number of different systems to provide a general indication of the mental workload experienced by the human operator. In many cases, such information can be extremely valuable to system designers who are interested in the overall magnitude of processing demands imposed upon the human operator. However, if more specific information concerning the type of processing demands is needed, for example to discern whether the response demands of a new control system or the perceptual demands of a new display configuration, are responsible for increased mental workload, then more diagnostic measures are necessary.

Recently there have been attempts to examine the extent to which psychophysiological measures can be used to track dynamic changes in mental load and operator alterness in an effort to enhance overall system effectiveness. For example, Makeig and Jung (1996) investigated the efficacy of EEG-based alertness detection systems for the prediction of missed responses during simulated sonar tasks using US Navy Sonar operators. In their studies, sonar operators attempted to detect 300 ms noise burst targets embedded in a white noise background. In some of the studies, particularly those in which ERP were of interest, brief task-irrelevant tones were also occasionally presented. Operator specific EEG algorithms were derived by employing several different frequencies in the d, q and a bands to predict vigilance decrements. These multiple regression-based algorithms were quite successful. The algorithms developed on data from one experimental session were capable of accounting for between 75 and 85% of the variance in error rates (i.e. response omissions or lapses) obtained in a second experimental session. Other results suggested that on-line algorithms, which detected changes in q and g (> 35 Hz) activity, were capable of predicting missed target detection responses up to 10 s in advance of the occurrence of a target. Finally, ERP components and, more specifically, N200 amplitude and latency and P100/N100 amplitude difference, elicited by task-irrelevant auditory probes did a reasonable job of predicting changes in error rates within a 32-s moving window.

The results from the Makeig and Jung and other recent studies suggest that it is now possible, in simulated real-world tasks, to detect and predict changes in alertness or task engagement that have important implications for system performance. One wonders, however, whether physiologically based alertness detection and prediction systems could be further improved by incorporating a number of psychophysiological measures. Indeed, a number of recent studies suggest that this may be the case. For example, studies have reported that changes in the a and q bands of the EEG along with slow eye movements detected in the EOG can reliably predict that a target would be missed a minute in the future. Thus, it would appear that a promising area of future research is the incorporation of a number of different physiological measures into alertness detection and mental workload assessment systems. Clearly, another important direction is the transition of psychophysiologicaly based alertness detection systems out of the laboratory and into operational environments. This is a particularly important step since many of the vigilance decrements that have been observed in laboratory research have not been reported in the field, which is likely due to the differential incentives to maintain adequate performance in these two settings.

Combination Manual Handling Tasks

L. M. Straker

Curtin University of Technology, Shenton Park, WA 6008, Australia

1. INTRODUCTION

Manual handling is thought by many to be an important contributor to musculoskeletal disorders such as work-related back disorder. The ergonomics profession has expended considerable resources, both in research and practice, attempting to both: understand the role of manual handling in the etiology of work-related musculoskeletal disorders and determine what ergonomic interventions can lessen the negative consequences of manual handling.

Combination manual handling tasks (CMHT) probably form the majority of manual handling tasks. Therefore, to be successful in preventing musculoskeletal disorders, effective assessment and reduction of the risk associated with CMHT must be achieved.

Combination manual handling tasks are composed of some sequence of single manual handling tasks such as lifting, lowering, pushing, pulling, holding or carrying. For example, a worker in a paint warehouse may be required to move 20-liter containers of paint from a shoulder-height shelf on one side of an aisle to a shoulder-height shelf on the other side of the aisle during stock taking. To achieve this the worker would commonly pull the container to the edge of the shelf, lower it to waist height, carry it to the new location, lift it to shoulder height and finally push the container into place on the shelf.

This chapter reviews the current state of knowledge on risk assessment for CMHT, presents recommendations for the assessment of risk in CMHT and suggests how to prevent musculoskeletal disorders associated with CMHT.

2. RISK ASSESSMENT FOR COMBINATION MANUAL HANDLING TASKS

The approaches available for the assessment of risk from CMHT are the same as those for single manual handling tasks: psychophysical, physiological, biomechanical, psychological, performance and combined approaches (Straker 1995). Within most of these approaches there are commonly four methods used: direct measurement, direct estimation from single-task values, estimation using models based on single-task values, and estimation using models based on worker and work factors. Although there has been considerable investigation and use of these approaches for single manual handling tasks, there is a scarcity of information concerning their use with CMHT. The current state of knowledge is summarized under the approach headings below.

2.1. Psychophysical Approach

Gallagher (1991), Rodrigues *et al.* (1989) and Straker *et al.* (1996) measured maximum acceptable weights (MAW) from people performing CMHT thus demonstrating that direct measurement using psychophysical measures can be used to assess the risk in CMHT.

Jiang and Smith (1985) stated that the only way to analyze CMHT was to analyze each component of the combination and use the most critical (strenuous) component task as the limiting factor. Thus, for a CMHT involving a lift, carry and lower, single-task MAW tables for lift, carry and lower could be viewed and the lowest single-task component MAW, say lift, could be used as an estimate, or substitute, of the CMHT MAW. A number of researchers have compared single and combination-task MAW to evaluate use of estimates of CMHT risk from component single-task risks. Taboun and Dutta (1984), Jiang and Smith (1985), Ciriello *et al.* (1993) and Straker *et al.* (1996) reported results that provide evidence that substituting single-task MAW for CMHT MAW may result in significant errors in risk estimation.

In response to this problem, Taboun and Dutta (1984) recommended that data bases be generated on CMHT capacities and presented one such table in their 1986 paper (Taboun and Dutta 1986). Jiang and Smith (1985) also present a table of MAW for various CMHT that could form part of a database. A number of problems could be anticipated with tables generated specifically for CMHT, the most obvious one being that there are so many potential combinations of tasks, when task type, height, frequency etc. are considered, that it may be impractical to develop and use tables for specific CMHT.

Besides the use of tables, modeling CMHT MAW has also been investigated. Jiang *et al.* (1986) concluded that if the limiting (most strenuous) single-task MAW is known, the CMHT MAW can be accurately predicted. However, modeling CMHT MAW from single-task MAW assumes a stable relationship between the single tasks and CMHT. The veracity of this assumption is questionable given the variety of CMHT and the evidence from the Straker *et al.* (1996) study.

Jiang *et al.* (1986), Taboun and Dutta (1986), Fredericks *et al.* (1992) and Rodrigues *et al.* (1992) have reported attempts at modeling CMHT MAW from work, worker and worker–work interaction characteristics. Although the models had reasonable coefficients of determination, they were unique to each task and again assumed a consistent relationship between CMHT MAW and work, worker and worker–work interaction characteristics across combinations of tasks. Without evidence of a stable relationship the generalizability of these models is questionable.

2.2. Physiological Approach

In the studies by Gallagher (1991) and Straker *et al.* (1997) direct measurement of physiological costs involved in performing CMHT was shown to be possible using measures like heart rate, oxygen consumption and ventilation.

Studies by Jiang and Smith (1985), Ciriello *et al.* (1990, 1993), Taboun and Dutta (1984) and Straker *et al.* (1997) have fairly consistently reported increases in physiological risk measures for CMHT compared with component single-tasks in the order of 15%.

Garg *et al.* (1978) developed models of energy expenditure for manual handling based on the assumption that a job can be divided into simple tasks. Taboun and Dutta (1989) tested the additivity assumption by calculating the extra cost of performing a CMHT over the sum of its components. The extra oxygen cost varied from –40 to +60%. Therefore, the additivity assumption appears not to be a valid assumption for every type of CMHT.

Taboun and Dutta (1984, 1989) report the development and

testing of models for estimating physiological cost during CMHT based on worker and work characteristics. The models had reasonable coefficients of determination (~0.8); however, each model was for a specific CMHT, limiting their utility. Also, the reports of modeling of MAW from worker and work characteristics showed that this method was often not as accurate as modeling from single-task MAW.

2.3. Biomechanical Approach

Despite the importance of the biomechanical approach, and its common usage for assessing manual handling tasks risk, little information on assessing CMHT risk using this approach could be found.

Of the commonly used biomechanical methods only the Force Limits method (Davis 1980) mentions CMHT, suggesting they can be divided and analyzed as separate single tasks. However, the relationship between IAP (intra-abdominal pressure) and lumbar stress is probably even more complex for CMHT than for single tasks. Therefore, this method is probably of limited utility given the validity concerns.

The two widely used biomechanical methods based on kinematic and kinetic data, SSPP (Center for Ergonomics 1990) and WATBAK (Norman and McGill 1989) models, do not mention assessing CMHT. Presumably a CMHT could be segmented into a number of single tasks and a static analysis performed on each component. However, Straker et al. (1997) compared estimates of peak lumbar stresses (compression force, shear force and torque) for a range of single tasks (lift, lower, push, pull, carry) and combinations of these single tasks and showed mean absolute differences between single and CMHT of ~22%.

2.4. Psychological Approach

2.4.1. Discomfort

Studies by Rodrigues (1990) and Straker et al. (1997) both illustrate the potential for direct measurement of discomfort to provide useful information for risk assessment. Straker (1995) suggests that although the use of tables and modeling is possible, given the difficulties in using potentially less labile dependent variables like heart rate and energy cost, it seems unlikely that these would be useful options.

2.5. Ratings of Perceived Exertion

Exertion ratings have been used in studies on CMHT risks by Taboun and Dutta (1984) and Straker et al. (1997), showing that the direct measurement option is possible. The study by Straker also explored the option of substituting single-task measures for CMHT measures. The results paralleled those for discomfort, with mean absolute errors for exertion rating of 19%. No reports of modeling in CMHT could be found.

2.6. Work Satisfaction

No reports could be found of the use of ratings of satisfaction for CMHT risk assessment. However, ratings of satisfaction with work tasks have the potential to provide useful information for risk assessment.

2.7. Performance Approach

Similarly, no reports could be found of the use of performance measures to assess the change in risk of CMHT following intervention to control risk.

2.8. Combined Approaches

Many combined approaches (National Institute for Occupational Safety and Health equation 1983, the tables produced by Asfour et al. 1985, and the modeling of Kim and Ayoub 1991) are only suitable for lifting. The tables prepared by Mital et al. (1993) do cover a range of single tasks, but not CMHT. Mital et al.'s tables could therefore be used to substitute single-task values for CMHT values. Checklists such as that of Worksafe Australia (1990) could be used for combination though are probably not sensitive enough.

3. RECOMMENDATIONS FOR ASSESSMENT OF COMBINATION MANUAL HANDLING TASKS

Direct measurement, using the psychophysical approach, is expensive, provides results which are probably not generalizable and is vulnerable to extraneous influences such as industrial relations issues. However, direct measurement of MAW for CMHT does not require the assumptions that the other methods do. It may therefore be useful for specialized tasks where unique characteristics make the extrapolation of other methods precarious.

The estimation of CMHT MAW from single-task tables or modeled on single-task values, assumes a consistent relationship between single-task MAW and CMHT MAW. This has been shown to be not the case (Jiang and Smith 1985, Taboun and Dutta 1984, Straker et al. 1997) with a mean error of estimation around ±20%. Modeling using linear models appears to be not sufficiently more accurate than substitution to warrant the extra complication. Thus, the best option for the assessment of risk in CMHT, when resources are not adequate to do direct measurement, may be to use substitution of MAW for critical component tasks (commonly lift or carry). However, this should only be used with the knowledge of an error margin of ±20%.

Physiological direct measurement appears a viable risk assessment option for CMHT. Its main disadvantage is the resource cost if used to evaluate every CMHT. As for MAW, this method is likely to be the most accurate. Estimation from single-task tables appears to be hazardous as there is consistent evidence for CMHT having different physiological costs to component tasks. Estimation from modeling from worker and work characteristics is likely to be less successful than modeling from single-task values. However, these conclusions are drawn from a small number of studies with limitations. Until more definitive research is available, the best option for assessment of CMHT using the physiological approach, when direct measurement is not practicable, may be to use substitution of single-task measures. However, considerable error margins need to be acknowledged if this method is used: ~60% when absolute loads are compared and ~20% when MAW loads are compared.

Biomechanical modeling based on kinematic and kinetic data appears the only viable biomechanical method available for assessing the risk in a CMHT. The literature suggests the most accurate method is by dynamic modeling from CMHT data. However, where this is not practicable, static analysis of critical parts of the CMHT may be of some use, although as for other approaches the errors are likely to be significant.

The use of discomfort, exertion, satisfaction or performance measures as risk indicators would probably be most accurate if done using the direct measurement method. Further developmental work is required to produce a reliable measures. However, when used in conjunction with other measures, it would provide a more holistic appraisal of risk.

No methods that combine approaches appear to be available for assessing the risk of CMHT. It is therefore probably important that measures from a number of approaches are gained as no one approach seems to adequately describe the risk.

Current methods for the assessment of risk in CMHT tend to suffer from limited validity or utility. Effective risk assessment is important to the ergonomics profession, both to evaluate the success of interventions and to defend the decisions of ergonomist in litigation. Practitioners and researchers therefore need to improve the current methods.

4. PREVENTION OF MUSCULOSKELETAL DISORDERS FROM COMBINATION MANUAL HANDLING TASKS

In view of the limited knowledge on risk assessment of CMHT, ergonomists should be tentative in their recommendations for preventing musculoskeletal disorders associated with CMHT. However, the following principles are likely to assist prevention:

- No component of a CMHT should exceed single-task recommendations.
- Loads for CMHT should err on the conservative side to allow for cumulative effects.

Principles of risk reduction for single tasks should be applied to CMHT (for example eliminate manual handling were possible, eliminate handling below knee and above shoulder level were possible, facilitate minimal load–worker distance, facilitate secure grips, facilitate secure footings, encourage smooth steady movements).

Comfort–Discomfort Phase Change

R. S. Goonetilleke

Department of Industrial Engineering and Engineering Management, Hong Kong University of Science and Technology, Clear Water Bay, Kowloon, Hong Kong

1. INTRODUCTION

Pressure at the human interface is generally considered to be an important parameter in comfort evaluation. However, the ideal pressure distribution between the human body and any surface of a given application has yet to be defined. A hard-core materials perspective to loading would be to distribute the force over an area as large as possible to minimize stress concentration. However, products such as a bed of nails or a bed of springs, "health sandals," steering wheel covers with semi-spherical protrusions are very popular in some cultures. So, why is it that people tend to like products with localized force? Researchers have pointed out that poor biomechanics may turn comfort into discomfort. Why does such a transition take place over time? The objective of this article is to explain why some design strategies work for human–product interfaces and why some others "slip" from their desirable state or change phase.

2. INTERFACE PRESSURE

Pressure at the human–product interface is unavoidable, and it has received considerable attention over the years because it can cause injury, pain, and discomfort. Pressure is defined as follows:

Pressure (Pascal) = force/area (Newton/m^2).(1)

Alternatively, stress has a similar formulation and is generally in the form of compression, tension or shear:

Stress (Pascal) = force/area (Newton/m^2).   (2)

Interface pressure can play an important role in the development of products and devices such as seat cushions (Figure 1), shoe insoles, handles and beds. An understanding of the pressure patterns that are appropriate for the human body (that is, the patterns that reduce discomfort or improve what is called comfort) can make product design and usage very satisfying and fulfilling. One primary problem related to this aspect stems from the fact that the word *comfort* has many definitions. For example, comfort has been defined as the lack of discomfort. More recently, it has been associated with feelings of *relaxation* and well-being (Zhang *et al.* 1996). A good example is the use of a beanbag. Generally, a sense of comfort is associated with a beanbag comprising macrospheres of rigifoam or the like. Are beanbags really comfortable because of their pressure distribution or are they comfortable because we use them in environments where we are already in a relaxed state?

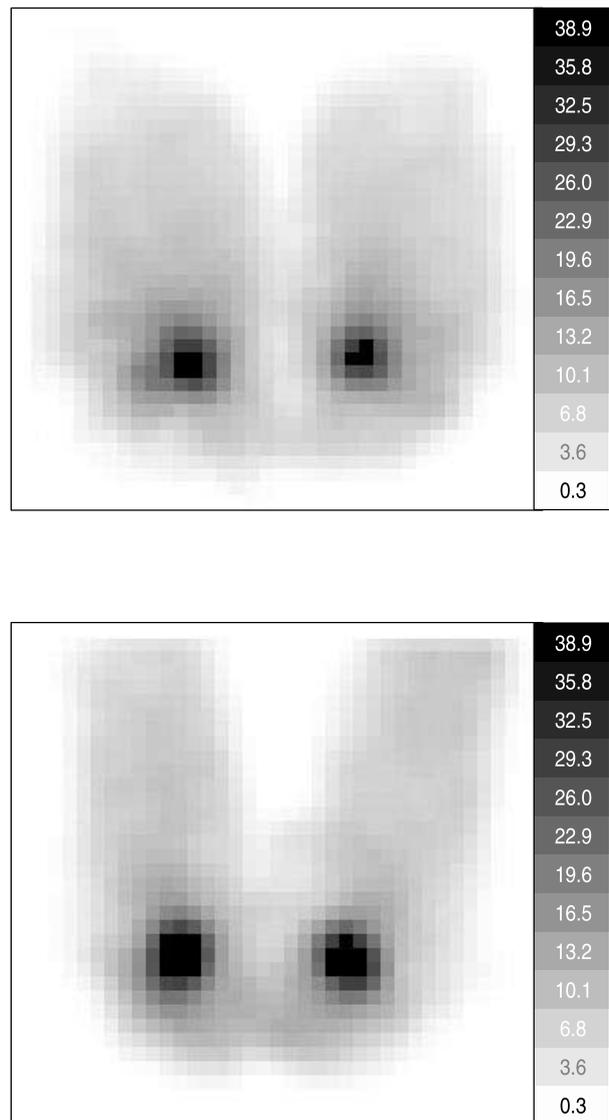
As shown in Figure 1, the pressure pattern between the two supporting surfaces is somewhat different. Researchers have shown that this pressure pattern is related to the level of comfort and discomfort (Lueder and Noro 1992). Generally, discomfort may be quantified using a combination of the following:


Figure 1. Pressure on buttock during sitting. (a) Pressure pattern on a laboratory chair; (b) pressure pattern on a hard surface (in kPa).

- Peak pressure.
- Pressure gradients.
- Contact area.

It is quite unfortunate that the most appropriate pressure pattern for each individual or individual–product interface is still unknown. If it were known, product design for the human body would be so much easier. Part of the problem stems from the fact that contact area has been neglected in the past.

In general, forces can be supported in two ways:

- distribute "Uniformly," or
- concentrate (i.e. load the "stronger" parts of the structure) to reduce "breakage."

Which one of the two strategies is best to maximize comfort or even minimize discomfort on the human body and why? Could it be that both strategies are applicable depending on the loading scenario? The most common and sometimes naive approach is to distribute force, as much as possible, to achieve the uniform condition. However, some consumer products and existing

research suggest a concentrated strategy. For example, Krouskop *et al.* (1985) has shown that mattresses with a uniform pressure distribution make people restless thereby opposing the distributed theory of force. In addition, products such as a bed of nails or a bed of springs, "health sandals," shoe insoles or steering wheel covers with semi-spherical protrusions, "massage" mats made of wooden slats and cane chairs are very popular in some cultures. All such devices induce localized force, rather than "distributed" force, supposedly creating desired sensations. Active cushions, which operate on the basis of periodic pressure relief in the form of a pressure wave, are also popular among paraplegic individuals. In some sense, these active cushions may be viewed as units that impose "concentrated" loading of a certain level with reduced duration of exposure. In other words, they create a concentrated strategy of short duration. Hence, it appears that concentrated force also has certain advantages and possibly a sensation of comfort or relaxation. If uniform pressure is the ideal pressure distribution for optimal comfort, interface design should be relatively easy, especially since pneumatic or hydrostatic balloons or bladders can be used to give this "constant" or uniform pressure at the interface. What could be affecting the pressure–comfort or pressure–discomfort relationship?

3. PHYSICAL SENSATION

Discomfort or pain originates when special nerve endings, called nociceptors, detect an unpleasant stimulus. There are millions of nociceptors in the skin, bones, joints, muscles, and internal organs. These nociceptors use nerve impulses to relay pain messages to networks of nearby nerve cells (peripheral nervous system). Each cell-to-cell relay is almost instantaneous and is facilitated by neurotransmitters. Messages then travel along nerve pathways to the spinal cord and brain (central nervous system). Scientists believe that pain signals must reach a *threshold* before they are relayed. *Gate control theory* explains how specialized nerve cells in the spinal cord act as gates that open to allow messages to pass, depending on the intensity and nature of the pain signal.

4. SPATIAL SUMMATION THEORY

The *spatial summation theory* (SST) states that simultaneous stimulation of many sensory receptors is required to arouse stimulation (Hardy and Oppel 1937). In simple terms, it means that the larger the area stimulated, the greater the sensory response experienced. For example, the sensation induced by a hand would generally be greater than that induced by a finger alone. The spatial summation theory has important implications for force distribution. Consider the case of a pleasant sensation gradually moving towards discomfort when the applied pressure is increased. At the limit, when sensations tend toward the so-called discomfort experience, a force distributed over a large area may induce greater discomfort than the same force over a small area. Thus, the extension of the spatial summation theory may be used to explain the discomfort experience as well. In this article, the validity of the SST extension is shown using maximum pressure tolerance (MPT). In addition, I would use an example of footwear to show why "comfort" changes phase to discomfort in the long-term.

Researchers have shown that the skin blood flow changes are influenced by three factors: the ratios of bone depth, the ratios of indentor diameter to bone diameter, and percentage compression of the tissue overlying the bone. "Indentor" or loading area is a factor neglected by many and its effect on discomfort can explain perceived sensations of interface designs having concentrated loading.

5. MAXIMUM PRESSURE TOLERANCE

Goonetilleke and Eng (1994) showed that the maximum pressure tolerance (MPT = applied force/probe area) is strongly related to the probe or indentor size or the contact area of the stimulus. The mean MPT with a probe of 5 mm diameter (831 kPa) was 3.3 times that with a probe of 13 mm diameter (249 kPa). The results for two locations on the dorsum (top) side of the foot are shown in Figure 2.

The measurement procedure is described in Goonetilleke and Eng (1994). There were no statistically significant ($p < 0.05$) differences between locations or between genders. In general, it was found that the values of pressure tolerance with the two probes were related by:

$$MPT_{5\text{ mm diameter}} = 3.3 * MPT_{13\text{ mm diameter}}. \qquad (3)$$

It is logical to look at the maximum *force* (or maximum force tolerance, MFT = MPT* area) that can be supported rather than the pressure. The force relation between the two indentors would be:

$$MFT_{5\text{ mm diameter}} = 3.3 * (5/13)^2 * MFT_{13\text{ mm diameter}} \qquad (4)$$

or

$$MFT_{5\text{ mm diameter}} = 0.5 * MFT_{13\text{ mm diameter}}. \qquad (5)$$

In other words, at the maximum tolerable value, the force that a probe with a 5 mm diameter can exert is half of what a probe with a 13 mm diameter can exert. This suggests that even though the MPT is lower with a 13 mm diameter probe, the force that the 13 mm probe can support at the tolerable threshold is twice the force that can be supported by a 5 mm probe. This is a surprising result when the MPT is compared to a "dead" material. For any material other than the human tissue, the equivalent "MPT" at breaking point (or breaking strength) should be independent of area since it is *constant* for a given ("dead") material.

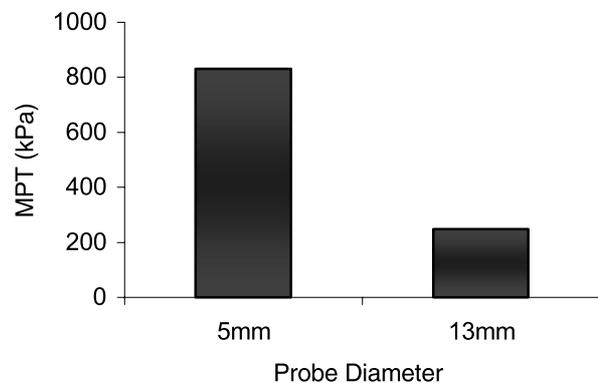
If the maximum force is such that even though only half of


Figure 2. Effect of probe size on the mean value of maximum pressure tolerance.

the force can be supported with a 5 mm probe, the probe area results in 3.3 times the tolerance of the 13 mm probe area, then it implies a counter-intuitive suggestion for loading on the human body. Consider the force supported at the tolerance level (249 kPa) of the 13 mm probe. The maximum force corresponding to the MPT with the 13 mm probe (249 kPa) is 33 Newtons and the corresponding area of support is 132.7 mm². The area of the 5 mm probe is 19.6 mm² (that is 6.8 times smaller). If six (for convenience, rather than 6.8) load bearing areas of 5 mm diameter are chosen to carry the load corresponding to the MPT of the 13 mm probe, the load on each 5 mm probe will be 5.5 Newtons or a pressure of 281 kPa (will be 249 kPa if 6.8 was used instead of 6), which is far below the MPT with one 5 mm probe. In other words, the load, which may have caused someone to indicate that it is the maximum tolerable force over an area of 132.7 mm², could now be shared among a number of smaller areas (localized) without experiencing any such maximum tolerable value. The advantage of smaller areas to support loads is clear when the loads are high.

6. THE PHASE CHANGE

Since the maximum pressure tolerance is dependent on the contact area, it may be concluded that, at high forces, a larger area may cause a higher level of discomfort than a smaller area when stimulated with the same magnitude of pressure. The aforementioned results suggest that localized pressure regions may in fact prove to be less discomforting when compared to "distributed-moderate" pressures. However, we do not know whether distributing force over a larger area increases comfort at low force values even though spatial summation theory indicates that the sensation will be higher. We may thus conclude that perceived sensation and contact area appear to have a relationship similar to that shown in Figure 3. The term sensation is used since it is unclear whether comfort can be equated to positive sensations. However, a negative sensation may be viewed as discomfort. The traditional thinking of distributing forces may be successful only in the upper half of Figure 3, when forces are very low or below a critical value, F_{crit}. The bottom half of Figure 3 will not be seen at very low forces or forces below F_{crit}. Hence, the decision to distribute or concentrate forces really depends on the magnitude of the pressure that exceeds a critical or threshold pressure (P_{crit}) for a given surface area.

7. EXAMPLES

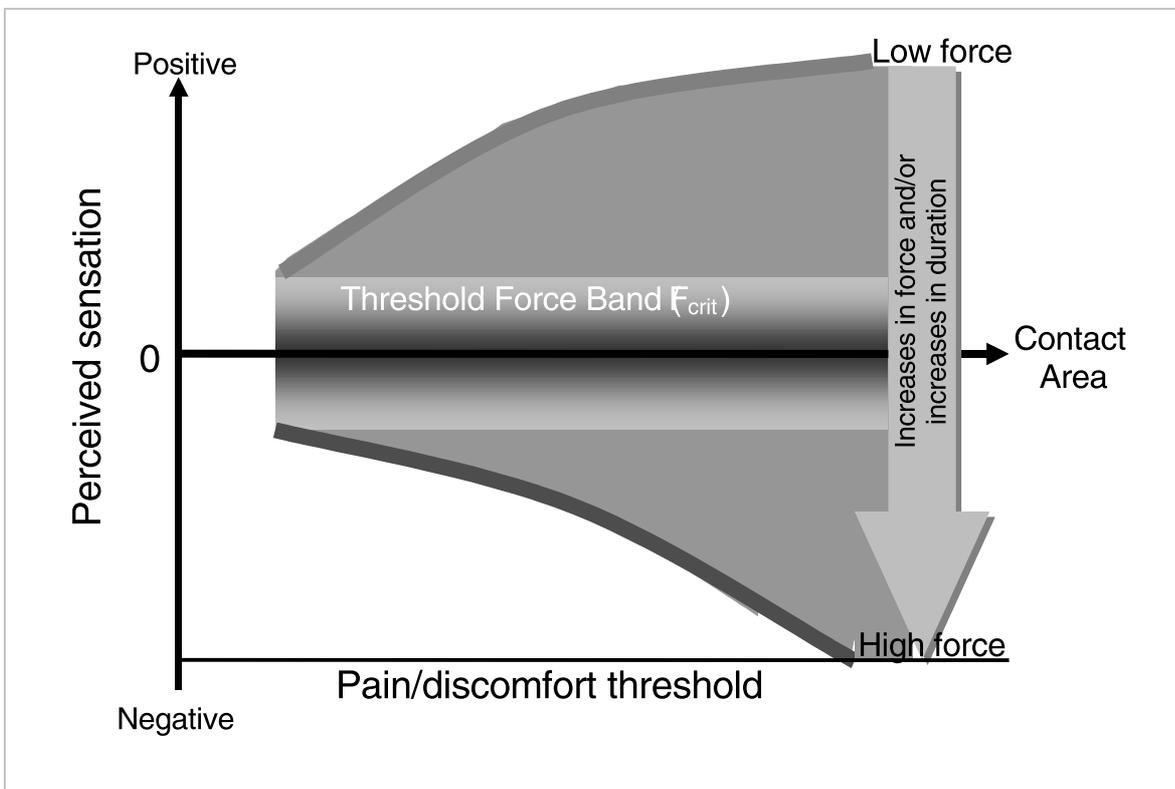
The extension of the spatial summation theory, the *discomfort hypothesis*, will now be illustrated using two examples. Some "high-end" commercial footwear have adopted "dynamic fit sleeves" made of an elastic material, which may convince consumers that such footwear conform to the foot resulting in a better "fit" and a uniform pressure, and thereby high sensation. In the short-term or at the point of purchase, these shoes are very comfortable. However, with prolonged use, due to foot swelling and foot deformations, shoes using a dynamic fit sleeve can be extremely uncomfortable. So how does the *discomfort hypothesis* explain such a change in sensation? At the point of purchase, the foot covering conforms to the foot giving a stronger sensation as predicted by the spatial summation theory since there are more sensory receptors being stimulated at one time (upper half of Figure 3). However, with activity, the foot swells and deforms, and then the pressure induced is greater at each of the


Figure 3. Hypothetical relationship between perceived sensation and contact area.

receptors. At this point, the wearer is at the other end of the sensory experience. More receptors are stimulated over a greater area, giving the wearer greater discomfort than if he/she wears shoes that do not have dynamic fit sleeves (bottom half of Figure 3). In other words, over time, the perceived sensation changes phase (or "slips") from the top half to the bottom half, transforming the "high" intensity pleasant sensations (at $t = 0$), to a "high" intensity unpleasant (or discomfort) experience.

A different type of example is a pilot headset. A conventional headset has cushioned material against the ears. It is generally comfortable in the short-term. As the flying time increases, however, such a headset causes a high level of discomfort as a result of a phase change from positive sensations to negative sensations. The discomfort on the ears can be relieved even in the long-term with the use of slow recovery (or open cell) foam such as Confor™ foam. With this type of foam, the force acting on the ears is significantly reduced so that even with increases in time, no phase change occurs.

8. RECOMMENDATIONS

Based on the above discussion, the following suggestions are made to designers of human–product interfaces:

- Identify the threshold force or pressure (F_{crit} or P_{crit}) to delineate between the experience of a positive sensation and discomfort.
- If the pressure is below P_{crit}, then it would be best to distribute the forces.
- When the pressures are 'high' and close to the MPT, the designer needs to consider a more localized or concentrated force (preferably of short duration) to relieve discomfort caused by simultaneous neuron firings over larger areas.

No doubt, it is sometimes impossible to concentrate pressures over small regions if there is a high risk of damage in terms of pressure sores or ulcerations (Webster 1991), especially for paraplegics who have no sensation or reduced sensation. The ideal pressure profile generally comes from a combination of distribution and concentration, which gives a showroom or point-of-purchase feel with a distributed force but a less discomforting support with concentrated force. Successful examples include mattress overlays and shoe insoles.

Constraints in Design Decision-making

D.L. Day

Computer and Information Sciences Department, Towson University, Towson, MD 21252, USA

1. INTRODUCTION

Since the day in the 1960s when Stanley Kubrick's film *2001* was first screened in the United States, the role and impact of tools has been a central feature of popular American technology. Of course, tools had played a major role in the development of industrial society since long before the Industrial Revolution in England. As demonstrated by the popular BBC television series "Connections" and its sequel "The Day the Universe Changed", there has been a long-standing fascination with tools as an extension of man's inherent capabilities.

Beyond this fascination, however, lies a very real and very key fact for civilization, whether it be European, South American, or Asian: tools improve man's understanding of the natural world around him, and leverage his capabilities. They exaggerate man's command of his environment, taking advantage of his unique capability of storing, processing and applying information. Man's ability to shape useful artifacts in his environment to his purposes has been a central facet of life since Kubrick's proto-humans metaphorically grasped a jaw bone, thrust it into the air, and created a space station.

Tools are extensions of mankind. However, tools are a double-edged sword. The key benefit to tools is their capacity to be customized to a task at hand. The more appropriate a tool is for its intended task, the better it is deemed to be. However, the "appropriateness" of a tool always involves an estimate of its utility, its cost, and its alternatives within the natural environment. More, assessment of whether to use a tool inevitably rests on whether the tool benefits or harms the purpose at hand. If the learning necessary to use tools is taken into account, often the disadvantages outweigh promised benefits.

In the current century, the ultimate tool of mankind may be the computer workstation. It has become for many citizens the ultimate tool: a device that can be acquired cheaply, operated with minimum inconvenience and cost, and used to magnify individual skills to an extent that few could anticipate when Kubrick sent his modern apes to Jupiter.

2. CONSTRAINT OBJECTIVES AND IMPACTS

The benefit and bane of computerized systems is that, based upon the assessment of "professionals" in a particular domain (to which the systems are to be applied), they restrict the user to particular behaviors. These behaviors include only those actions that professionals in the field believe are rational within the context of the application. Irrational behaviors are held to be counter-productive, and are therefore discouraged (if not prohibited outright). The imposition of controls to prevent irrational behaviors within a specific application context is known as "constraint".

Constraint is a tricky concept. It has been defined variously as a principle that should be followed to control the selection and ordering of actions during design, and as a rule that defines the range of options available in performance of a task. In any case, constraints guide tool users in creation of quality outcomes by delimiting the problem space and recommending (with various degrees of force) preferred procedures.

In the Western cultures, concerned as they are with individual freedoms, the term "constraint" has a negative connotation. It implies an inappropriate control of the individual to further the undefined purposes of someone or something else. However, in other cultures, the idea of constraint is positive. It is the mechanism by which informed society communicates appropriate and necessary guidance to its members.

Regardless of context, however, the preferred behaviors encouraged or dictated by computerized systems are an important part of modern life. The question that remains, however, is how well the constraints imposed by computerized systems match the needs of people to use such systems as effective tools in their everyday lives. Unlike use of the jaw bone in Kubrick's film, the application of computers to domain tasks is very much dictated by the many highly technical individuals who created the tool — not by the user, who merely tries to operate an appropriate device to accomplish the tasks at hand.

Constraints are intended to make users more productive. Constraints limit wasted effort: they define the problem solution space within which the individual should work, based on the perceptions of people who developed their computerized tools. The problem, of course, is that many users do not agree with the perspectives of tool developers.

This chapter addresses the potential mismatch between computerized tools and their users. It examines the lack of understanding between highly skilled artisans of sophisticated systems and the perhaps less sophisticated but numerous users who must apply computerized systems for economically productive work. The key feature of this mismatch is the insensitive implementation of constraints for whatever it is that the user does with the system.

3. CONSTRAINTS IN DESIGN ENGINEERING

The examination of constraints as part of tool-assisted problem solving is relatively new. Relevant theory has been developed in several areas, including decision support, cognitive psychology, software engineering, and human–computer interaction.

Although the intent, implementation, and effects of constraints in computerized tools can be of interest in any activity, the context of interest here is design. Design engineering is fertile ground for the examination of constraints because design inherently involves individual creativity, typically affords and even requires independent decision-making, and has strong secondary effects. (The constraints applied to design activities directly impact work product quality and utility, as well as costs of product generation.)

Computerized design tools form a common medium through which the design preferences of tool developers are communicated to tool users. Communication takes place via constraints that developers feel are important in the application domain. Constraints impact design not only because of the types of controls developers chose to include in tools, and the strength with which such controls are enforced, but also because of the styles of implementation chosen. In practice, tools that apply constraints

to design tasks act as decision support systems. The decisions being supported are those intrinsic to the task at hand, to the domain environment, and to design engineering.

3.1. Modeling Constraints

One view holds that constraints naturally express the many dependencies, restrictions, and high-order characteristics that are intrinsic to design. The basic interdependence of decisions made during design can be represented as a semantic network. In this model, each node represents a significant decision, linked to others by arcs representing the potential sequence of decisions. Nodes in the network are viewed as frames, with slots composed of various attributes. Some of these are related to general decision-making style, while others reflect concerns in the specific task domain. Constraints and their characteristics form an important slot within the node frames. As decisions are taken, the links between nodes are fired, causing related further decisions to be considered in the context of decisions already made and of slot contents at the new node. A completed design is the sum of all decisions, including the extent to which standards and procedural best practice were followed (i.e. constraints adhered to) in creating the work product.

3.2. Constraint Characteristics

In order to be of practical use, concepts and approaches in any field must be operationalized. Only then can key elements and their impacts be assessed consistently and reliably. Mere definition, no matter how precise, is insufficient. In one respect, operationalization clarifies definition by providing examples.

If the domain of interest were computer-aided systems engineering, the following examples might be used to clarify the concept of constraint:

- Every process in a data flow model must have at least one input data flow and at least one output data flow.
- A parent process must be specified before its child processes.

Another way operationalization can clarify definition is by identifying descriptors that characterize instances of a concept in the given domain. The set of descriptors so identified are arrayed in a taxonomy, allowing the categorization (and subsequent measurement) of the phenomena of interest. In the case of constraints, such a taxonomy has been developed. It includes the following descriptors.

1. *Source of authority*. The justification for a constraint, usually stemming from the role, position, or recognized expertise of the authority that decided a constraint should exist.
2. *Weight*. The importance of a constraint, judged either as the extent to which appropriate process is considered vital or as the anticipated effects of constraint violation upon work product quality.
3. *Balance of control*. The degree to which a tool rules the design process, allows user intervention, and provides notice to users of decisions taken by the tool. This affects the kind of options given to users who encounter constraints, and the tool's response when constraints are violated.
4. *Constraint type and target*. The aspect of design activity (process or product) affected by a constraint, and the types of objects impacted. A constraint may affect the structure of the design artifact (product) or the way in which the artifact is produced (process).

5. *Means of implementation*. The style chosen by a tool builder to implement a constraint. Style is important because the same constraints implemented with different styles may result in different user responses, and therefore have different impacts on product and/or process.

Each of these descriptors is an architectural feature of decision node constraint slots, using the semantic network model of design decision making. A descriptor serves as a classification that may be used to group or separate constraints, based on whether they share significant common values. A profile of each constraint may be created, by assessing the values for all descriptors.

3.3. Constraint Negotiation Behaviors

Examination of the role that constraints play in design engineering stems from concerns about how constraints impact the behavior of tool users. That behavior impacts valued outcomes, such as work product quality and user productivity.

The need for a taxonomy of constraints was explained in the preceding section. A taxonomy of common user behaviors is also needed. Constraints are a stimulus to users as they operate their tools; user behavior when users encounter constraints is a response to that stimulus. In order to understand the impact of constraints, it is necessary to describe and measure behavioral responses.

A taxonomy of user behaviors in response to constraints has been developed. It includes the following descriptors:

- *Avoidance*. The user modifies his task approach pre-emptively because he knows that doing otherwise would trigger a constraint.
- *Compliance*. The user modifies his task approach to suit the limitations imposed by a constraint.
- *Subversion*. The user modifies his task approach to take advantage of known weaknesses in the tool, overriding the spirit but not the mechanism by which the constraint is implemented. This strategy also is known as 'workaround'.
- *Path-seeking*. The user modifies his task approach to find the least constraining path.
- *Deferral*. The user declines to modify his task approach, with the knowledge that subsequent system or human review may reverse, modify, or accept his decision to override the constraint.
- *Negation*. The user declines to modify his task approach, unconditionally overriding the constraint.

In categorizing any given behavior using this taxonomy, it is key whether the constraint is accepted, whether the attempted task approach is modified, and whether the user's decision is subject to later review (and possible reversal).

4. MEASURING THE IMPACT OF CONSTRAINTS

Taxonomies of constraint and user behavior can be applied empirically to assess the impact of constraints upon design process. The method has been standardized over many years of human factors research, aimed at improving the usability of computerized systems.

The method requires use of a human factors laboratory, in order to control for the potentially confounding variables in a typical workplace. The use of a lab reduces the ability to generalize findings to the workplace, but the precision of procedure and subsequent clarity of analysis more than compensate. Subsequent

in situ measurement can be useful, however, in fine tuning results to take into account contextual, socio-technical factors.

First, users are surveyed to assess individual differences relevant to computer use, such as experience in the task domain and experience with computerized design tools. Surveys also establish users' attitudes about and perceptions of constraint as it is encountered in the creation of work products.

Next, users are observed in the lab as they perform carefully specified scenarios with a given tool. These scenarios involve the design of artifacts typical of those created in the workplace. The observation includes automated monitoring of all keystrokes, mouse-clicks and system states, plus the recording of monitor displays. It also involves audio- and videotaping of user utterances and behavior.

Finally, users are debriefed to help determine reasons for specific behaviors noted during the observation.

During data analysis, transcripts from audio recordings are subjected to content analysis. Time on task and error rate data are used to identify portions of video recordings of interest, which are examined to categorize behaviors. Survey data and audio recordings are used to construct user mental models. Finally, metrics specific to the task domain are used to measure work product quality and user productivity. User decisions are mapped into a semantic network, to better understand design process and the impact of specific constraints.

5. OUTCOMES

Findings about the impact of constraints upon user behavior can be used to calibrate the means that computerized tools employ to guide the design process. An improved understanding of design decision-making can increase the ability of such tools to improve user productivity while protecting work product quality. Behavioral data in the context of constraint may even be useful in engineering adaptive tools that accommodate users' decision-making styles, experience levels, and expectations. The improvement of user satisfaction with their tools also is a secondary, but not insignificant, potential outcome.

Cross-cultural Comparison of Computer Anxiety: Concept, Measures and Related Variables

B. Han

Institute of Psychology, Chinese Academy of Sciences, Beijing 100101, China

1. INTRODUCTION: CA AND RELATED CONCEPTS

Computer anxiety (CA) was studied > 20 years ago. Whether it is called "CA," "technostress," "technophobia" or "computerphobia," it all refers to an aversion to computers and computer technology. Estimates indicate that as many as one of three adults suffers from the condition, and that this figure will not vanish with an increasing familiarity with computers (Lalomia and Sidowski 1993). Bradley and Russell (1997) identified three distinctive types of CA: damage anxiety, task anxiety and social anxiety. Extreme manifestations of CA accompanied by physiological reactions can be classified as computerphobia, which is overtly or covertly manifested in behaviors of rejection and avoidance, ranging from a simple unwillingness to work with computers to the act of vandalism (Dorinina 1995).

CA substantially reduced the effectiveness of mastering and using computers. Failure to get computer literacy (CL) may become a "critical filter" for those who will, therefore, not have access to many careers. As the most important predictor of computer performance (CP; Rosen and Weil 1995), CA reminds educators of its presence and impact. Studies on CA can also provide instruction to the marketing of technology production from the consumers' perspective, because "ownership of a technological device does not necessarily guarantee its use." Grouping of the consumers can be very helpful to technology producer.

Studies on CA in the 1980s were well reviewed by Rosen and Maguire (1990), Lalomia and Sidowski (1993) and Maurer (1994) from different perspectives, but there is no review on the research conducted in the 1990s, especially cross-cultural ones. This chapter will emphasize the measures developed and validated in different cultural settings; other related studies will also be reviewed briefly.

2. MEASURES: FACTOR STRUCTURE, VALIDITY AND VERIFICATION

Dozens of constructed measures have been developed, but only some have been validated with different subject groups, and the factor structure varied between measures (see Lalomia and Sidowski 1993 for a review of 12 scales developed in 1980s). Rosen and Maguire (1990) included 79 empirical studies (with 66 different measures) in their meta-analysis. Only five measures have been used by more than one researcher. Of these, only three have reported data concerning their factor structure. Only two studies have compared the factor structure of CA between groups. Cross-cultural validation of developed measure is still very rare to date. Given that the concept of computer technology is changing, some new items (e.g. Internet, information highway or national information infrastructure) should be included in a scale for assessing subjects' living in today's environment. Therefore, factors extracted from measures developed 10 years ago may not be valid at the present time. In addition, the changing trend may be different between countries.

Intercorrelations of scales purporting to measure CA have shown that CA is a very robust concept, and its various operational definitions (measures) exhibit a high degree of convergent validity (Gardner et al. 1993) and concurrent validity (Harrison and Rainer 1992). However, some scales measure many dimensions; others assess one more than the other. Studies on the predictive validity of CA on computer usage (CU) or CP are inconsistent (Szajna 1994), despite the demonstrated convergent validity of the CA construct. One possible reason of the conflict is the different factor structure between measures; another is the difference between subjects groups (e.g. culture, education and CL). The effect of CA on academic achievement in a computer course can also probably be overcome by other factors (e.g. motivation of students, good instruction, etc.; Maurer 1994).

3. RELATED VARIABLES

It is well documented that CA correlated negatively with CU and CP, but the effects of related variables were mixed. Although females have less positive attitudes, prior computer experience (CE) and access to computer than males (Maurer 1994), gender in general was not a predictor of CA (Anderson 1996). Older adults have more positive attitudes and less CA than young adults, and the factor structure was similar for younger and older adults (Dyck et al. 1998).

Education major students had significantly higher CA than computer and business major students (Maurer 1994). Rosen and Weil (1996) found that the CA in clinical psychologists, elementary school and secondary school teachers is higher than it in university students. Cognitive style is an important determinant of CA, with intuitive and thinking individuals exhibiting lower anxiety then their sensing and feeling counterparts (Shermis and Lombard 1998).

CE is the most prominent predictor of technophobia among many others (Anderson 1996). Qualitative (Todman and Monaghan 1994) and quantitative (Charness et al. 1992) differences between CE will lead to different levels of CA. The character of the initial stage of the person's interaction with the computer is a key factor in the etiology of CA (Dorinina 1995). Quality of prior CE is beyond simple exposure to computers in the forming of CA (see Chorpita and Barlow 1998 for a review). Hemby (1998) found that gender, keyboarding skill, age, socio-economic status and self-directedness are adequate predictors of CA in business communication students.

Tseng et al. (1998) found that self-rating of mood measured by the three methods (pen-based personal digital assistants, conventional computer and paper assessment) co-varied divergently with measures of CA and private self-consciousness. The attitude toward computers (ATC) is related but different with CA. ATC measures were developed based on a three-component (behavioral, affective, cognitive) model of attitudes (Charlton and Birkett 1995), or were concerned solely with the affective domain (Evans et al. 1995). There is only a small overlap between computerphobia and other anxiety measures (e.g. mathematical,

state, trait, test), but they are a separated construct (Shermis and Lombard 1998), and these relationships rarely account for > 10% of the variance in predicting computerphobia (Rosen and Maguire 1990).

4. CROSS-CULTURAL DIFFERENCE

Most of the studies on CA are based on subjects from Western countries; only several studies have assessed CA or ATC across countries (see Rosen and Weil 1995, Weil and Rosen 1995 for a short review), and four studies compared Chinese subjects with their Western counterparts directly. Do the conclusion and treatment in these studies stay valid in other cultural settings? Is there any difference for the occurrence and effect of CA on performance? Given that there exist differences in educational systems and technological policies between countries, one can predict some cross-cultural difference. Despite the popularity of CA and technology improvement everywhere, cross-cultural study on CA was rare and the findings were mixed.

Allwood and Wang (1990) showed some differences between college students majoring in Psychology and Computer Science in their conceptions of computers, with the Chinese students showing a more optimistic view of the future impact of technology than Swedish students. Collis and Williams (1987) found that the Chinese students (8th and 12th grade) were more positive in their ATC than their Canadian counterparts.

Marcoulides (1989, 1991) and Marcoulides and Wang (1990) proved the factor invariability of their Computer Attitude Scale (CAS). They found that the Chinese and American college students have similar degree of CA and structural component, named "general CA" and "computer equipment anxiety."

Rosen, Sears and Weil (1992) developed measures for diagnosing the technophobic, Computer Anxiety Rating Scale (CARS), Computer Thought Survey (CTS) and General Attitudes toward Computers Scale (GATCS). Each subscale has 20 items. The three factors — interactive computer learning anxiety, consumer technology anxiety, observational computer learning anxiety — for their CARS seemed not valid for subjects from other cultural settings.

Han *et al.* (1999) administered Rosen, Sears and Weil's (1992) CARS to 126 Chinese college students majored in English (grade 2) and found five factors interpretable as interactive computer learning anxiety, consumer technology anxiety, observational computer learning anxiety, general CA and computer equipment anxiety. The mean score of Chinese students is 54.27 (SD 14.41). It is higher than the American students' score of 41.46 (14.25). The difference of factor structure and mean score between Chinese and American college students showed the cultural effect on CA.

Comparison between 10 countries (Australia, Czechoslovakia, Germany, Hungary, Israel, Italy, Japan, Spain, Yugoslavia) showed that each possessed an unique culture-dependent model of CA (Rosen and Weil 1995). People in those countries (e.g. Singapore and Israel) where governments value technology very high, and where the computer was introduced by confident, well-trained teachers, were very comfortable with computers and technology. Of Japanese university students, 60% was tested as technophobic, no matter the popularity of advanced technical products in their environment. The lack of an early infusion of technology could be the possible reason since the Japanese government decided not to integrate computers at the primary level.
