treatments, and emergencies. The report may be presented to the local organizing committee and to the sports organizations back home. This approach will help explain the need for the medical services used and assist in preparations for future international athletic events.

## TRIANGULAR FIBROCARILAGE COMPLEX

The *triangular fibrocartilage complex* (TFCC) is a structure found in the wrist. The TFCC serves as the primary stabilizer of the distal wrist joint, as well as provides for cushioning from certain activities. It works in a similar fashion to the menisci found in the knee and is often called the “wrist meniscus.” It can be injured either acutely during trauma or from repetitive overuse. There is some evidence that, over time, the TFCCs of all patients will begin to break down (usually beginning in the fourth decade of life) to a certain degree.

The TFCC is made up of several different structures. The primary components are the dorsal and palmar volar ligaments. These ligaments run from the radius to the ulna and provide for the structure of the TFCC. There is also a soft tissue disk that lies between these ligaments and provides extra support. Finally, a portion of the tendon sheath of the extensor carpi ulnaris (ECU) makes up a portion of the TFCC.

The TFCC can be injured either traumatically or through repetitive activity. Patients can suffer TFCC tears related to falls on their wrists and arms or from direct trauma to the ulnar side of the wrist. In particular, any trauma that results in the hand being forced downward against the ulna may result in a TFCC injury. TFCC injury from repetitive trauma and overuse is often seen in patients who perform activities that result in repetitive ulnar deviation of the wrist (e.g., lifting heavy weights, working with equipment such as hammers or drills). In addition, sports that result in repetitive compression of the wrist may result in TFCC tears; these sports include racquet sports, gymnastics, and diving. In addition, distal radius and ulnar fractures are often associated with TFCC tears.

The differential diagnosis of a TFCC tear includes, but is not limited to, fractures of the radius and/or ulna, tendinosis and tenosynovitis of the flexor or extensor tendons, displacement/snapping of the ECU tendon, injuries to other ligamentous or cartilaginous structures of the wrist (distal radioulnar joint [DRUJ], scapholunate, etc.), and arthroses of the wrist joint.

Diagnosis of a TFCC tear can be performed both clinically and radiographically. Typically, the

patient will experience discomfort of varying degrees with palpation of the structure. Patients with small tears may experience little to no pain or limitations, while patients with larger and/or chronic tears may have constant debilitating pain both at rest and with use. The location of the tear will be important as well. Typically, the more peripheral a tear, the more likely it is to cause the patient discomfort; central tears of the TFCC can often be asymptomatic.

The outermost structure of the TFCC is easily palpated along the lateral wrist between the ulna and the lateral carpal bones (pisiform and hamate). Palpation of the structure can be accentuated with radial deviation of the hand. There may also be associated swelling around the structure, as well as “clicking” of the wrist, which may be heard or felt by the patient. Patients may also experience decreased grip strength and pain with resisted wrist dorsiflexion. The Apley Grind is the most commonly used diagnostic test. This test is usually performed with the physician gripping the hand of the patient and applying downward pressure, causing the hand to deviate toward the ulna. The hand can then have a twisting force applied to it, causing the TFCC to be compressed and exacerbating the pain.

Radiographic studies can also be of benefit in diagnosing TFCC injuries. Although the TFCC is a cartilaginous structure, X-rays can sometimes be helpful, for several reasons. With both trauma to the wrist and chronic pain, plain radiographs are often ordered to evaluate for bony injury. Evidence of an ulnar fracture of any form could alert the clinician to the possibility of a TFCC injury. More important, the shape of the ulna can help in making the diagnosis. In general, the lengths of the ulna and radius in the wrist are the same. However, in some patients, the ulna may be either longer or shorter than the radius; this is defined as positive or negative ulnar variance, respectively. Both positive and negative ulnar variance can be associated with a higher rate of TFCC injury.

To truly evaluate the TFCC, magnetic resonance imaging (MRI) is often required. This test allows visualization of the soft tissue of the wrist. This will often reveal swelling along the cartilage and sometimes a tear in the cartilage. The test can be made more accurate by the injection of contrast medium into the wrist. This procedure is called an *MR arthrogram*, and it can allow for

better visualization of a TFCC tear, as the contrast material may actually track through the tear into other areas of the wrist where it was not injected. Computed tomographic (CT) arthrography may also be done, although it is typically not as accurate as MR arthrograms. Finally, the TFCC tear may be directly visualized through an arthroscopic procedure.

Treatment of TFCC tears can be both conservative and surgical. In general, nonoperative therapies are attempted first. Modalities such as protection from further injury, rest, and ice application are often helpful. Bracing is often used for mild and/or acute injuries as mild trauma to the TFCC may heal on its own. Bracing can be used with activities that cause pain and discomfort for the patient. At times, a cast can be used for a period of 2 to 4 weeks as well. This allows for immobilization as well as protection. This can be particularly helpful in cases of chronic TFCC injuries. Another option for treatment can be corticosteroid injection in or around the TFCC. This can be done for both diagnostic and therapeutic reasons. Also, both physical therapy and physiotherapy may be helpful. Finally, in cases that are resistant to conservative therapy, surgery can be an option. This surgery is usually accomplished arthroscopically and can be done for either acute or chronic tears. This intervention may result in either repair of the tear or excision of the fragments. Patients suffering from severe tears may be more likely to require surgical intervention. Also, if there are concomitant injuries to other structures of the wrist that require surgical intervention, then patients may undergo surgical correction of their TFCC injury at the same time.

## TRIANGULAR FIBROCARILAGE INJURIES

---

The *triangular fibrocartilage complex* (TFCC) is a complex ligament-cartilage complex that sits between the distal ulna and the ulnar carpus. It serves as the main stabilizer of the distal radioulnar joint (DRUJ) and plays an important role in load bearing across the ulnar wrist. Tears of the TFCC are an important cause of both acute and chronic ulnar-sided wrist pain. This entry reviews the anatomy of the TFCC and discusses the classification, evaluation, and treatment of TFCC tears.

### Anatomy/Function

The TFCC was first described by A. K. Palmer and F. W. Werner in 1981 and consists of an articular disk, a meniscus homologue, ulnocarpal ligament, dorsal and volar radioulnar ligament, and the extensor carpi ulnaris (ECU) sheath. It originates from the ulnar fossa of the distal radius and inserts into the base of the ulnar styloid. It is 2 millimeters (mm) thick on the radial side and 5 mm thick on the ulnar side. Distally, it inserts onto the lunate via the ulnolunate ligament (UL) and the triquetrum via the ulnotriquetral ligament (UT). The UL and UT ligaments are located volarly and are referred to as the disk carpal ligaments.

Blood supply is via the dorsal and palmar radiocarpal branches of the ulnar artery and the dorsal and palmar branches of the anterior interosseous artery. These vessels penetrate 10% to 40% of the periphery, leaving the central disk and radial portion avascular. As in the knee meniscus, peripheral tears are amenable to repair, whereas the central avascular portion does not heal.

As stated earlier, the primary function of the TFCC is as a stabilizer of the DRUJ. The volar portion of the TFCC prevents dorsal displacement of the ulna, and the dorsal portion prevents volar displacement of the ulna. Stability is achieved

through selective tightening of the dorsal and volar TFCC during pronation and supination. The TFCC also increases the gliding surface for the radius and acts as a buttress to the proximal carpal row.

Another major function is to cushion axial loading through the ulnocarpal axis. The majority (80%) of axial load is carried by the radius; however, this can vary based on ulnar variance. Ulnar variance is a measure of the relative length of the ulna in relation to the radius. Studies have shown that a positive ulnar variance of 2.5 mm can increase load transmission by the TFCC to 42% while a negative ulnar variance of 2.5 mm can decrease load transmission to 4%. The increased load across the TFCC that occurs with positive ulnar variance accounts for its increased association with TFCC tears.

### Examination/Evaluation

The most common symptom of a TFCC tear is ulnar-sided wrist pain with grinding or clicking during wrist range of motion. The mechanism of injury may be an acute fall onto an outstretched hand; a rotational injury with forced ulnar deviation, such as batting a baseball; or axial loading, such as in gymnastics. Chronic injuries result from overuse with repetitive rotation and loading of the ulnar wrist, also common in gymnasts. Isolated pain with pronation and supination may indicate injury to the articular disk, while constant pain with limited range of motion is associated with more peripheral tear.

Examination should include inspection for gross deformity, soft tissue swelling, erythema, and ecchymosis. Active and passive range of motion should include flexion, extension, pronation, supination, and radial and ulnar deviation. Patients are usually tender distal to the ulnar styloid in the soft depression just proximal to the pisiform. A painful click may be reproduced with repetitive pronation and supination of a clenched and ulnarly deviated wrist. Pain and/or clicking with the TFCC compression test may indicate a TFCC tear. This test involves wrist extension, ulnar deviation, and axial compression. DRUJ instability may be present, as evidenced by a positive "piano key sign," in which there is increased displacement of the distal ulna as the radius is held stable and the examiner forces or "shucks" the ulna in the volar and dorsal direction.

The ulna appears more prominent and ballotable, resembling a piano key.

Plain radiographs are a useful initial imaging modality for TFCC injuries because they may reveal a distal radius or ulnar styloid fracture and also allow for assessment of ulnar variance. The recommended views are zero-rotation PA (postero-anterior) and lateral. Triple-injection arthrography used to be the study of choice but has been shown to have poor correlation with arthroscopic findings and has fallen out of favor over the past 5 to 10 years. The utility of magnetic resonance imaging (MRI) is debatable, with sensitivity ranging from 17% to 100% in conflicting studies. A dedicated wrist coil can improve accuracy, but MRI is still not ideal for localizing tears. The gold standard is wrist arthroscopy, which can be used diagnostically and therapeutically.

### Differential Diagnosis

Examination should also be centered on excluding other common causes of ulnar-sided wrist pain. Dorsal pain may be caused by tendinitis or subluxation of the ECU. Patients with ECU tendinitis will have pain with resisted wrist extension and ulnar deviation. Subluxation may be present with a palpable, painful snap when a flexed, ulnarly deviated wrist is supinated. Lunotriquetral (LT) instability should be evaluated for with ballottement and shuck tests of the LT joint. Volar pain may be caused by flexor carpi ulnaris (FCU) tendinitis or a fracture of the hook of the hamate or pisiform. FCU tendinitis will present with pain with resisted wrist flexion and ulnar deviation. Hook of the hamate fractures present with hypothenar pain and are often caused by direct trauma to the hypothenar region from grasping an object, such as the butt of a golf club.

### Classification of TFCC Tears

In 1989, A. K. Palmer devised a classification system for TFCC tears, distinguishing acute tears from chronic tears and helping guide treatment strategies. Class I tears are acute, traumatic tears. They are further divided based on the location of the tear. Type IA tears are of the central, avascular portion of the articular disk. Type IB tears occur at the base of the ulnar styloid with or without a distal

ulnar fracture. Type IC tears are of the ulnolunate or ulnotriquetral ligament at the carpal attachment. Type ID tears are radial sided with or without a sigmoid notch fracture.

Type II tears are chronic and degenerative in nature, describing a spectrum of damage by repetitive loading and positive ulnar variance called ulnocarpal abutment syndrome. Types IIA and IIB tears do not have frank perforation but thinning of the disk without and with chondromalacia of the lunate or ulna, respectively. Type IIC tears are frank perforations of the central disk with chondromalacia. Type IID tears are frank perforations of the disk with chondromalacia and a tear of the LT ligament. Type IIE tears describe end-stage disease with perforation, chondromalacia, LT tear, and ulnocarpal arthritis.

### Treatment

The initial treatment for both acute and symptomatic chronic tears is a period of immobilization in a long arm cast for 4 to 6 weeks followed by physical therapy. A localized cortisone injection may provide some symptomatic relief as well. Acute, peripheral tears (Types IB and IC) that are not associated with positive ulnar variance do very well with nonoperative treatment. In contrast, acute avascular tears (Types IA and ID) and both acute and chronic tears associated with ulnar impaction do not heal well without surgical debridement and ulnar-shortening procedures. The emphasis should be on correcting positive ulnar variance as many studies have shown poor outcomes for simple TFCC debridement without ulnar shortening. Types IIA and IIB lesions may only require ulnar shortening without arthroscopic debridement as they do not have frank tears. Type IIC tears may be treated with a "wafer" procedure, in which a 2- to 4-mm section on the distal ulna is removed while keeping the styloid, TFCC, and ligaments attached. Type IID tears with LT instability require ulnar shortening along with LT ligament repair or possible LT fusion or pinning. Type IIE lesions require a salvage procedure.

The TFCC is a complex structure that stabilizes the DRUJ and supports axial load across the ulnar wrist. TFCC tears represent an important cause of ulnar-sided wrist pain. Injuries are often caused by acute falls on an outstretched hand or chronic

overloading of the ulnar wrist. The most common symptom is pain with clicking during wrist motion, and examination will often reveal pain with a TFCC compression test. TFCC tears are associated with positive ulnar variance, which can be seen on plain radiographs. Tears are classified as acute and degenerative, and treatment for both types is a period of immobilization followed by therapy. Arthroscopy is indicated for unstable lesions and those refractory to nonoperative treatment. Ulnar shortening should be performed for those with ulnar impaction syndrome.

## TRIATHLONS, INJURIES IN

---

In the late 1970s, several endurance junkies started a contest to see who was tougher by swimming, biking, and running across the Hawaiian landscape. Over the decades that followed, the sport of triathlon has undergone a stunning rise in popularity. The individual medley of endurance sports (swim, bike, run) is now a well-accepted sport in the Olympics at the 1.5/40/10-kilometer distance and enjoys a wide and growing participation base across the world. Distances range from short, "sprint" races lasting less than 1 hour to longer-distance, "ironman" races that can take competitors up to 8 to 16 hours to complete. Some even extend this to ultradistances competed over several days. Races typically use road bicycles for the bike portion, but off-road races using mountain bicycles have been gaining in popularity as well. The medical and musculoskeletal issues that arise in the longitudinal care of triathletes are, for the most part, those that arise with training for each individual discipline. For those medical or other support personnel involved in race

day coverage, however, a variety of other acute medical concerns may arise and need to be considered when planning for the medical coverage of such events.

### Swimming

While competitive swimming involves training and racing using the four traditional strokes (butterfly stroke, backstroke, breaststroke, and freestyle) in an enclosed pool with clear, chlorinated water, a triathlon swim occurs in open water with variable conditions and with a multitude of other athletes. Mass start races are characterized by “pack” swimming, and this can occasionally lead to issues such as blunt trauma to the face/eyes and finger sprains from contact with other swimmers. Both hypothermia and hyperthermia have been seen during and after open-water swims. Triathletes will typically use wetsuits to combat the cooler water temperatures, and this will allow most athletes to tolerate long swims in temperatures as low as 10 °C (50 °F). Despite this, hypothermia can ensue both during the swim and after the swimmers exit the water, due to a phenomenon known as “after-drop.” An athlete’s core temperature can continue to drop after leaving the cold water as blood continues to perfuse the cooler extremities. This has led to injuries as athletes attempt to transition to the bike with impaired coordination and judgment as a result of hypothermia.

On the other end, the use of wetsuits in water greater than 25 °C (78 °F) can lead to elevations in core temperature and symptomatic hyperthermia (heat exhaustion, syncope, or heat stroke), and for this reason, wetsuit use is restricted above this temperature. Increases in core temperature and heat stress can be additive (from day to day and from event to event) and may progress during a race. Further elevations in core temperature accumulated during the bike and run segments could predispose an athlete to more symptomatic heat illness or exercise-associated collapse later. Heat exhaustion may present with confusion, weakness, cramping, or hypotension and may lead athletes to drop out of the race and present to the medical tent on their own. Heat stroke represents a progression of heat illness with system failure at the metabolic and organ levels. This is usually seen in the later stages of the run segment, with the

athlete’s collapse or severe deterioration in the medical tent.

To those athletes accustomed to training in clear water with orderly passing, the chaos of group swims and the unpredictable water conditions (cold temperature, waves, currents) can lead to anxiety and panic attacks. This problem can be exacerbated when warmer water conditions preclude wetsuit use. Many of the weaker swimmers depend on the additional flotation provided by wetsuit use, and a last-minute prohibition of its use can cause significant anxiety. Severe panic attacks in open water raise concerns about near-drowning events or severe exacerbation of asthma in the triathletes, and these should be accounted for when planning race management. Other, less common medical concerns during open-water swims include bacterial infections from poor water quality (*Escherichia coli*, *Leptospirosis*), sudden death from cardiac embolism or fatal arrhythmias, and marine animal stings or attacks (e.g., jellyfish, coral, sharks).

Triathletes, however, still need to put in a significant amount of distance in the pool during training (albeit less than their competitive swimmer counterparts due to the bike and run training) and thus experience the same range of overuse injuries as swimmers do. The shoulder is, by far, the most commonly injured or painful area in swimmers. Shoulder stability is maintained by both the joint capsule and the rotator cuff and can be lost when either of the structures becomes weakened. The rotator cuff is a group of four muscles deep inside the shoulder that helps provide stability by holding the humeral head inside its socket. It also helps initiate the overhead motion of the arm up to shoulder level. To achieve full overhead motion, the scapula must also retract and tilt the shoulder socket upward. The muscles that accomplish this are the rhomboids, trapezius, and cervical paraspinals.

The tendons of the rotator cuff are prone to overuse and inflammation with the repetitive overhead motion of the swim stroke. When this happens, the tired or inflamed muscle-tendon unit becomes weaker. As this progresses, the cuff muscles no longer constrain the shoulder effectively, and the head of the humerus may elevate with arm motion, causing a painful impingement against the undersurface of the acromioclavicular (AC) joint. Load may also shift to the joint capsule and ligaments, as well as

the labrum (the cartilage rim around the shoulder joint). Such an imbalance can lead to painful multidirectional instability or labral tears. The scapular muscles must increase their share of moving the shoulder when the cuff is weak, and this can eventually cause overuse and lead to neck and upper back pain. The importance of a strong rotator cuff as a shoulder stabilizer becomes even greater in those with a high level of flexibility (congenital or otherwise) as these athletes cannot depend on the stabilizing effect of the shoulder capsule and ligaments.

Swimmers also experience injuries to various other structures. The repetitive lumbar spine extension and rotation forces during a swim stroke can lead to stress injuries to the posterior elements of the vertebra itself and, ultimately, to spondylosis or spondylolisthesis. Injuries to the knee, such as patellofemoral pain or chondromalacia, can also be seen. These are usually seen with greater use of breaststroke or eggbeater kick, but can also be seen in those athletes concurrently training for bicycling, such as triathletes.

### Cycling

Cycling injuries range from acute trauma to chronic overuse injuries. Triathletes, like cyclists, put in a lot of miles on the bike during the training process, and the old adage that “it is not *if* you will crash but *when*” holds true for triathletes. The most common crash-related injury is “road rash,” which is a traumatic abrasion or contusion caused by the body scraping against the pavement. Appropriately treated with good wound care, it heals and rarely causes a significant loss of training time. Fractures of the wrist (distal radius, scaphoid), clavicle and AC joint, and elbow (radial head) are relatively common, and fractures of the pelvis have also been reported. The speed of a crash can increase the severity of a fracture; however, it is the mechanism of impact with the ground that determines whether a fracture will occur. Off-road triathlons have the added risk of collision with a fixed obstacle or even penetrating trauma from tree roots. Head injuries such as concussion also can result when a rider strikes the ground, even if he or she is wearing a helmet. Helmets are mandatory during competition and should be used during training as well.

Nontraumatic injuries, however, dominate in terms of frequency of cycling injuries. Chronic neck pain is a frequent complaint and can result from the prolonged neck extension required for straight-ahead vision with normal positioning on standard handlebars. This can be exacerbated by the increased torso flexion/flat-back positioning required with aerodynamic time-trial bars. The pain can be due to muscle spasm and/or trigger points in the levator scapulae, trapezius, or cervical paraspinal muscles, as well as from cervical facet arthrosis or degenerative cervical disk disease. To some degree, this can be minimized with more upright positioning on the bike.

The use of the hands and wrist to support the upper body on the handlebars can lead to both ulnar nerve impingement in the Guyon canal laterally in the wrist as well as median nerve irritation in the carpal tunnel. Consistent use of padded cycling gloves helps reduce trauma to the ulnar nerve. Frequent hand position changes and avoidance of extremes of flexion or extension help combat median nerve irritation. Groin injuries are also quite common in cyclists. Chronic irritation of the perineal skin due to friction can lead to skin breakdown and subsequent abscess formation. This can be minimized with proper bike positioning, padded cycling shorts, and chamois cream to soften the pad. Compression of the pudendal nerve can also cause transient numbness in the genital area. Such compression is more common in triathletes who tend to ride on the nose of the bike saddle.

Knee problems are also quite common in cyclists and triathletes. The pedal stroke can put tremendous load on the patellofemoral articulation, and proper pedaling mechanics and bike positioning are imperative to avoid overloading the joint. Even with good form, an overly rapid progression of high-power/low-cadence pedaling too early in the season can overwhelm the quadriceps muscle's ability to maintain normal patellar tracking. Inflammation of the patellar joint surface (patellofemoral pain) or softening/erosion of patellar cartilage (patellar chondromalacia) can occur. Once established, patellofemoral pain can take months to resolve. Chronic quadriceps muscle tightness can add to the problem by increasing baseline compressive stress on the joint. Similar cartilage erosions can occur on the femoral side of the joint as well. Chronic stress and overuse can also cause a painful

intrasubstance degenerative change (tendinosis) within the patellar or quadriceps tendon. The same degenerative changes and inflammation that occur in the tendons of the knee also can occur in the Achilles tendon of the ankle with overuse. The iliotibial (IT) band attachment on the outside of the knee is also frequently injured with repetitive knee bending and friction at its attachment site.

### Running

Run training can cause similar problems with knee pain. Patellar and/or femoral chondromalacia, IT band syndrome, and patellar/quadriceps tendinosis are all common overuse injuries in runners with normal mechanics. Those with poor mechanics that result in knee valgus (knock-knees), however, can experience increased patellar maltracking and pain. Such mechanical issues include abnormal foot pronation and weak core and/or gluteal muscles. Rapid increases in mileage, a large amount of downhill running, and uneven running surfaces all can increase the likelihood of developing patellofemoral pain as well. Since triathletes tend to have stronger abdominal, gluteal, and quadriceps muscles from biking and swimming, they tend to have more issues with overuse patellofemoral pain, IT band syndrome, or plantar fasciitis in the foot. To some degree, the cross-training required in triathlon helps strengthen the muscles that protect triathletes from the abnormal mechanics seen in solo sport competitors.

A relatively common and insidious concern for triathletes, or for any other endurance athlete for that matter, is overtraining syndrome. At its worst, this can present as severe, chronic stress with pituitary suppression (decreased hormone levels, increased cortisol). The athlete feels tired, can't recover from training sessions, has elevated morning heart rates, can't reach maximum heart rate during exercise, and has symptoms of depression. There is a continuum of impairment in terms of clinical symptoms from minimal, with minor deficits in performance and mild depressive symptoms, to more significant, with mild immunosuppression (increased infections, etc.) and possible cardiac arrhythmias. Unless the symptoms are very severe, laboratory values are all within normal limits and the diagnosis is clinical. A more acute cardiac version has been seen in long-distance triathletes,

who, following a race, have shown transient (6–8 weeks) depressions in cardiac function that fully reverse with rest. Chronic issues with muscle strains of the calf, quadriceps, or hamstring can also relate to insufficient recovery time or overtraining. The likelihood of suffering a more severe tear of a muscle or tendon with training or competition is increased when muscle or connective tissue is compromised and unable to withstand previously tolerated stresses.

A more concerning overuse injury, largely secondary to running, relates to stress fractures. Bone is a dynamic organ, and when impact stress overloads a bone's ability to adapt, a mechanical failure of the structure can occur. This may initially present as an inflammation of the periosteum (the membrane covering the bone). When this happens along the back edge of the tibia, where the soleus and posterior tibial muscles attach, it is called "shin splints." Left unchecked, this accumulation of mechanical stress above that which can be repaired may progress to bone marrow edema and eventually to cortical fracturing. This can occur in the tibia, fibula, metatarsal bones of the foot, tarsal bones of the ankle, pubic rami and symphysis of the pelvis, and femur. As part of the process of adaptation to training, bones become denser and better able to handle the mechanical stress. Thus at a certain level, quality rest/recovery can become just as important as quality training.

### Conclusion

In general, triathletes experience the same overuse and traumatic injuries that their single-sport compatriots do. They simply have a larger exposure by training in all three disciplines. There are a few unique aspects associated with the open-water swimming and transitions, but the similarities outweigh the differences.

## TRIGGER FINGER

---

*Trigger finger* is the most common atraumatic, painful complaint of the hand and the fourth leading reason a person is referred to a hand surgeon. Its incidence is 28 cases per 100,000 people per year, with a lifetime risk of 2.6%. Having diabetes increases this risk to 10%. Trigger finger initially starts as discomfort in the palm that worsens with movement of the digits and progresses to “locking” of the involved digit in flexion. Adults are affected more than children. Women are affected two to six times more than men. The dominant hand is the most commonly affected, and the digits that trigger in descending order of frequency are the thumb followed by the ring, middle, pinky, and index fingers. Peak age of incidence is 55 to 60 years, with a smaller peak under 8 years of age. The usual treatment involves a cortisone injection, which is curative up to 90% for all except individuals with diabetes mellitus and rheumatoid arthritis.

### Anatomy

The flexor tendons connect the digits to the forearm muscles and are responsible for bending the digits. A membranous tendon sheath covers the outside of the tendon and is attached to the bones of the hand, starting at the metacarpal head (palm bone) and extending to the distal phalanx (last

finger bone). Different areas of the tendon sheath are thickened and function as pulleys to direct the tendon in its path and to prevent bowstringing. Trigger finger occurs when there is a mismatch in size of the flexor tendon, most commonly caused by a nodule, and the pulley. The most common area for the tendon to get stuck at is the first annular (A1) pulley, located over the joint of the metacarpal (palm bone) and proximal phalanx (initial finger bone). Occasionally, triggering can occur at other pulley sites.

### Causes

Trigger finger is often idiopathic. It does occur more commonly in people with metabolic problems such as diabetes mellitus and hypothyroidism and different rheumatologic conditions, including rheumatoid arthritis, psoriatic arthritis, amyloidosis, sarcoidosis, and pigmented villonodular synovitis. Interestingly, trigger finger is associated with duration of diabetes and not with sugar control in individuals with diabetes requiring insulin injection. Because repetitive finger movements due to one's occupation or sport can cause high tension across the A1 pulley, it is proposed to cause the development of fibrocartilaginous metaplasia of the pulley and tendon cells, thus creating the mismatch in size. Trigger finger commonly coexists with carpal tunnel syndrome, de Quervain tenosynovitis, and Dupuytren contracture. Sometimes, locking of the digit can occur if ligaments catch on the bony prominence of the metacarpal (palm bone) head, if there is swelling of the tendon at different locations, or if loose bodies are present in the metacarpal phalangeal joint. Rarely, a finger injury involving a laceration of the flexor tendon may present as a trigger finger from the cut portion of the tendon catching at the A1 pulley.

### Symptoms

Initially, pain is only felt in the palm at the metacarpal phalangeal joint. The pain can also radiate along the palm or along the digit. Locking of the digit occurs during active flexion-extension activities, often reported to worsen on rising in the morning. The athlete may complain initially of painless clicking of the digit with flexion that progresses to painful catching. Long-standing cases of

trigger finger may present as a stiff digit, which the person is unable to bend.

### Diagnosis

Trigger finger is diagnosed clinically from a history of locking of the digit and observation of triggering in the physician's office. Sometimes, a nodule on the flexor tendon is felt at the metacarpal phalangeal joint. Snapping or crepitus may be felt along the flexor tendon at the A1 pulley while the finger is passively flexed and extended. Laboratory evaluation is only required if there is suspicion that the nodule is secondary to medical conditions such as diabetes mellitus, rheumatoid arthritis, hypothyroidism, or gout. Occasionally, a radiograph of the hand is performed to look for loose bodies in the metacarpal phalangeal joint and arthritic changes in the metacarpal head or accessory bones of the hand.

### Treatment

If the triggering of a digit occurred with a specific activity, then avoidance of that activity will lead to resolution of the symptoms. Otherwise, the first-line treatment recommended involves an injection of steroid medication near the bump on the tendon. Oral or topical anti-inflammatory medications can be tried initially but are often unsuccessful. Splinting the involved digit with 15° of flexion at the metacarpal phalangeal joint can be tried, but this has a lower success rate in those with more severe disease, triggering of longer than 6 months' duration, and multiple trigger digits. Splinting needs to be done continuously for 6 weeks and has a success rate of up to 50%. Injection into the tendon sheath has a success rate of 90%, and if a second injection is required, it is half as beneficial as the first one. Steroid injection has a higher success rate in those with a palpable nodule, if the duration of symptoms is less than 6 months, and if the digit triggering is the thumb. Complications of steroid injection include dermal or subcutaneous fat atrophy, skin depigmentation, infection, and, very rarely, tendon rupture. If trigger finger persists despite the injection, surgical release can be curative and involves cutting the A1 pulley. This procedure is done under local anesthesia in the operating room as either an open or a

percutaneous procedure. With the open technique, an incision is made over the A1 pulley site, and the pulley is divided under direct visualization. For the percutaneous technique, a 18-gauge needle is used to divide the pulley without direct visualization. Potential complications of either procedure include digital nerve injury, bowstringing of the tendon (especially if the A2 pulley is divided), infection, hematoma, and persistent pain. Other reasons for surgery to be considered include a digit that is stuck in flexion and cannot be reduced and trigger thumb in an infant. Occasionally, a reduction flexor tenoplasty is performed, which involves cutting out the bulbous swelling of the tendon so that the tendon is smooth and glides without hindrance through the pulley.

## TROCHANTERIC BURSITIS

---

*Trochanteric bursitis* is inflammation of the bursa that lies on the outside (lateral) aspect of the hip, known as the greater trochanter of the femur bone. Bursitis can result from both overuse (chronic) and trauma (acute). It is common in all types of athletic and nonathletic populations.

### Anatomy

Bursae are small fluid-filled sacs that are usually found around joints or bony prominences. Their purpose is to create lubrication between two

uneven surfaces and provide frictionless movement. In this case, the bursa lies between the femur's greater trochanter, which is the hard bony prominence on the outside of the hip, and a strong tendon known as the iliotibial (IT) band. The IT band runs from the top of the hip, down the side of the leg, to the knee. Its main function is to abduct the leg as if to kick one's leg out to the side. However, when moving the hip forward and backward, as when walking, running, swimming, and biking, the IT band tends to rub over the greater trochanter and may irritate the bursa. When the bursa becomes inflamed, it swells and becomes compressed between the bone and the tendon, thus creating pain.

### Causes

Trochanteric bursitis is most often caused by overuse or direct trauma. Direct trauma such as a fall that causes the patient to land on the lateral hip region or a direct blow to the outer hip is more common in women and in the middle-aged or elderly population. However, direct trauma is frequently seen in contact and collision sports as well. These falls or blows will cause bleeding (hematoma) into the bursa, which then results in swelling. Usually, these hematomas are rapidly absorbed by the body, but not infrequently, they may result in scarring, adhesions, and calcifications, leading to a more chronic type of bursitis.

More commonly, chronic repetitive trauma is involved, which can occur from merely running or walking. Conditions that predispose patients to this type of trochanteric bursitis include postural abnormalities, which can be caused by scoliosis, degenerative spinal conditions, a wide pelvis (female runners), hip and knee arthritic conditions, leg length differences, flat feet, high-arched feet, overpronation of the feet, or even oversupination of the feet at heel strike. Improperly fitting shoes, worn-out shoes, running on uneven or hard (cement) surfaces, and sudden increases or changes in training are other causes of trochanteric bursitis. Another cause occurs in cycling when the seat is too high and the cyclist has to rock from side to side when pedaling, which results in repetitive sliding of the IT band over the bursa. At times, the bursitis develops spontaneously without any apparent cause.

### Symptoms

Patients affected by trochanteric bursitis will complain of a deep ache or burning pain over the greater trochanter on the outside of the hip. It will usually be worse with activity and may be worse both after rising in the morning or after prolonged sitting. It may get better after the first few steps only to recur later after walking for a ½ hour or more. The pain may radiate down the side of the leg toward the knee or ankle or into the buttock. The pain is usually worse at night while trying to lie on the affected side.

### Diagnosis

The diagnosis of trochanteric bursitis is usually clinical. A typical history can be confirmed on physical examination. There will be maximal point tenderness to palpation directly over the greater trochanter. Point tenderness just superior to the trochanter is usually more indicative of gluteus medius tendinitis, while point tenderness just posterior to the trochanter is more indicative of piriformis tendinitis. Pain will also be present during gait when the hip goes from flexion to extension. Pain may occur with passive hip adduction, abduction, or external rotation but not with internal rotation. Pain may also be present with active hip abduction. Rarely, a limp will be present.

An X-ray can be obtained to ensure that there are no bone spurs, calcifications, or arthritis that could be contributing to the problem. Occasionally, a magnetic resonance imaging (MRI) scan or a bone scan may be done if the diagnosis is unclear or if the problem does not resolve with treatment. These tests will help rule out tumor, occult fracture, or necrosis of the bone.

### Treatment

The goals for treatment include reducing pain and inflammation, as well as preserving mobility and preventing recurrence. Treatment recommendations may initially include a combination of rest, heat and/or cold application, stretching and strengthening exercises, activity and shoe modification, pain medication such as acetaminophen or ibuprofen, and osteopathic manipulation along with correction of any anatomical or biomechanical asymmetry (orthotics/heel lifts). Cross-training incorporating

low-impact activity such as biking, swimming, or using elliptical machines can minimize the pain and allow for continued exercise. Typically, resolution of symptoms occurs within 2 to 6 weeks of treatment. For persistent symptoms, more advanced treatments may be required, such as physical therapy, cortisone injections, or surgery.

While only a limited number of controlled studies have proven the usefulness of physical therapy for this condition, a specific and goal-directed program can often reduce symptoms. Physical therapy can be incorporated to teach the patient a home exercise program, emphasizing stretching specific tendons, including the IT band and tensor fascia lata, as well as stretching the external hip rotators, quadriceps, hamstrings, adductors, and hip flexors. Strengthening exercises should focus on the lower abdominals and the gluteal muscles. Other modalities used in physical therapy can also be employed, such as *phonophoresis*, which uses sound waves to allow for deep penetration of topical medications, and *iontophoresis*, which uses an electrical current to allow corticosteroids to penetrate the skin and minimize the inflammation to the bursa. Ultrasound therapy and soft tissue massage may also be helpful.

Cortisone injections are an important option within the comprehensive treatment plan. Randomized, controlled clinical trials have shown that corticosteroid and lidocaine injection for trochanteric bursitis is an effective therapy with a prolonged benefit. Trochanteric bursa injections are often performed without radiographic guidance, and a local anesthetic can first be used as a diagnostic injection. The needle is advanced to the greater trochanter (with contact on the bone being made to confirm depth and appropriate placement) and is then withdrawn slightly so that it is located within the bursa. The local anesthetic can then be injected directly into the bursa. If appropriate relief is achieved, this would be considered confirmation of trochanteric bursitis as the cause of the pain. This injection of local anesthetic can then be followed by the administration of steroids. An injection of 12 to 24 milligrams (mg) of betamethasone or 40 to 80 mg of methylprednisolone is commonly used. This injection may be repeated at 4 to 6 weeks if pain relief has been less than 50%. In most cases, in which the diagnosis of trochanteric bursitis seems straightforward from the clinical evaluation, a diagnostic injection with

local anesthetic is not necessary prior to the corticosteroid injection. Patients should be made aware of the risks of injection prior to the procedure.

Surgery is rarely indicated and is often reserved for severe cases that are recalcitrant to months of the conservative treatments discussed above. There are several surgical techniques that have been used in the past. One such technique involves excision of the bursa via incisions in the IT band over the greater trochanter. Another procedure is a trochanteric reduction osteotomy, which removes a portion of the trochanter. Arthroscopic bursectomy is the third option and allows for excision of the bursa using a scope. Finally, release and lengthening of the IT band is another surgical alternative. Surgical intervention carries the increased risk of anesthesia along with the direct surgical risks and should be considered only after appropriate non-operative interventions have been exhausted.

## TRUNK INJURIES

---

Injury to the trunk during sports is common and generally includes muscle and bone injury, but it can also include more serious injury to the internal organs. Examples of muscle injuries include strains of large muscle groups, such as the rectus abdominus and perivertebrals. Bones such as the lumbar vertebrae can sustain chronic injury, as in spondylolysis, or acute injury, as with transverse process fracture in blunt trauma. However, the predominance of musculoskeletal injuries may lead the practitioner to overlook a more serious injury. Below are some important and sometimes life-threatening injuries to be considered in the athlete with injuries to the trunk.

### Pneumothorax

A pneumothorax may occur spontaneously during a sporting event or acutely after blunt or penetrating trauma in sports activity. It occurs when air is introduced between the lung and the pleura, the membrane that surrounds the lungs. Depending on the mechanism with which the contact between these two surfaces was compromised, air can accumulate and compress the lung, resulting in chest pain and shortness of breath. This can lead to respiratory failure. If enough air accumulates, the pressure from this trapped air can compress the heart and limit its ability to fill and then pump blood, leading to cardiovascular collapse and death.

Spontaneous pneumothorax is caused by a ruptured bleb at the surface of the lung and leads to escape of air from the lung into the space between the lung and the pleura. It is most common in tall, thin males but can occur in any age-group or gender. It can occur at rest and also during vigorous exercise and can be mistaken for a musculoskeletal chest pain. The athlete generally will complain of moderate to severe pleuritic sharp pain on the left or the right, associated with varying degrees of

shortness of breath. Generally, a spontaneous pneumothorax is small and stable, but it can progress to the life-threatening complications described above. The patient needs to be transported to a medical facility where imaging can be done and a thoracostomy performed to relieve the pressure. In the event that immediate transport is unavailable and the patient is experiencing cardiovascular collapse, an emergent decompression needle thoracostomy can be performed by qualified medical professionals.

Traumatic pneumothorax can be caused by blunt or penetrating forces. The force required to cause a pneumothorax from blunt trauma is generally significant and has associated injury, such as rib fractures. Rib fractures require only pain medication as treatment, but all suspected rib fractures require a plain radiograph to rule out the diagnosis of pneumothorax. For penetrating trauma, such as skate-induced chest wall laceration in ice hockey, a plain radiograph should be ordered to rule out the diagnosis of pneumothorax even when suspicion is low for it. Any lacerations or punctures to the chest wall should not be explored, as this can cause a pneumothorax in some cases. Complications and treatment are the same as described above.

### Cardiac Contusion

High-speed blunt trauma to the chest can result in injury to the heart, the most dramatic effect of which is sudden death, or commotio cordis. Cardiac contusion in sports is rare but occurs when forces are transmitted from the ballistic (as in baseball) or opposing player (as in American football) to the chest of the athlete. The myocardium is bruised, which causes pain and can affect cardiac output and in rare cases can lead to failure. The diagnosis should be considered in any athlete who complains of chest pain after a high-speed impact. Evidence of significant injury, as with sternal fracture/injury or multiple anterior rib fractures, should increase suspicion of cardiac injury. Emergency evaluation includes a chest radiograph, electrocardiogram, and cardiac enzymes. If there is a high suspicion of cardiac contusion, an echocardiogram may be taken and/or the patient may be kept under observation.

### Solid Abdominal Organ Lacerations and Contusions

Blunt trauma to the abdomen can occur in all contact sports, including football, men and women's hockey and soccer, and countless others from professional-level activities to recreational sports such as bodyboarding. Forces transmitted from an object, such as a helmet or a knee, to the abdomen can be absorbed by the liver, spleen, or kidney. In the event that these forces are sufficient to cause bleeding, these organs may become bruised and occasionally lacerate. Lacerations can cause bleeding within the organ and impair the functioning of the organ itself. This is often seen with a kidney laceration, which results in decreased long-term renal function. Occasionally, the bleeding is not contained within the solid organ, and blood accumulates in the abdomen. If the bleeding is brisk or the injury is not identified in time, this bleeding can result in severe blood loss and occasionally in death. If surgery is indicated, attempts should be made to stop the bleeding and preserve organ function. As both are not always possible, occasionally the damaged solid organ will need to be removed.

Solid organ injury should be considered under the right clinical circumstances. In cases where solid organ injury occurs, the history will include a mechanism that fits clinically. Examples of mechanisms of blunt solid organ injury include the impact of a football helmet on the abdomen or back, a high-speed hockey puck to the stomach, or a bodyboard lodged between the abdomen and the beach sand. The athlete will complain of abdominal or flank pain with or without nausea or light-headedness. The abdomen or flank is usually tender, and in cases of significant bleeding, the pulse rate may be high and blood pressure low. Any patient with possible solid organ injury should be transported immediately to a local emergency room.

### Hollow Abdominal Organ Injury

Hollow organ injury, specifically large and small bowel trauma, is unusual after blunt trauma in athletics. Historically, the athlete will have a mechanism in which a forceful blunt trauma is sustained to the anterior abdomen. Mechanisms that can cause hollow organ injury include a fall from a bicycle with

impact from the handlebars, a surfboard wedged between the sand and the surfer's abdomen, or a knock from a football helmet to the abdomen. In mild cases, the athlete may complain of minimal pain associated with nausea, as in the case of a minor small bowel contusion. In case of a ruptured viscus, the athlete will have severe pain and vomiting. On physical exam, the mild small bowel contusions may be normal save for some tenderness to deep palpation. This is in contrast to the patient with a ruptured viscus, who will have severe tenderness to light palpation, rebound tenderness, as well as other evidence of an acute abdomen. The vital signs may be unstable, with a low blood pressure and fast heart rate. An initial, upright chest X-ray is the fastest and most specific way of determining if there is air in the abdomen, which would indicate a perforated viscus. Computed tomography is the most sensitive study to find evidence of a ruptured viscus, and it will also show evidence of hollow viscus contusion and injury to the solid organs. A hollow viscus perforation is a surgical emergency, whereas a contusion can be monitored clinically.

---

## TURF TOE

---

The term *turf toe* has become a commonly accepted name referring to a sprain involving the

hallux (great toe) metatarsophalangeal (MTP) joint of the foot. The name was first coined in 1976 after it was found that the frequency of injuries to the MTP joint was much greater during competition on artificial playing surfaces. The injury is fairly common; it is seen most often in football, but it also occurs in other sports such as wrestling, basketball, and dance, among others. Because this particular joint plays a key role in running, sprinting, and cutting, an injury can result in significant functional disability. It is thought to be underreported and not always appreciated as the significant injury that it may be or can become if it is not appropriately managed.

### Anatomy

The anatomy of the forefoot is intricate and quite complicated. The MTP joint of the hallux involves a metatarsal (long bone) with a rounded, cartilage-covered surface at the end, which joins with the concave base of the phalanx (toe bone). Stability of the MTP joint comes from medial (inside) and lateral (outside) collateral and metatarsosesamoid ligaments in addition to a strong plantar plate. There are also several different muscle tendons that run along either side and underneath the joint, attaching onto the phalanx. These structures together make up the intricate capsuloligamentous complex of the first MTP joint.

Motion in the joint consists primarily of plantarflexion (downward) and dorsiflexion (upward). Passive range of motion varies widely from 3° to 43° of plantarflexion and from 40° to 100° of dorsiflexion.

### Causes

The two primary causes of turf toe are the advent of artificial playing surfaces and the coinciding introduction of flexible-soled turf shoes. Artificial playing surfaces were introduced in the 1960s, and with that came a dramatic increase in the number of turf toe injuries. This is due to the increased friction caused by the artificial surface and shoe interface. When artificial turf was introduced, players were typically wearing a grass cleat with a metal plate in the sole, which attached to the cleats and added stability to the forefoot. After playing on the artificial surface, players complained of traction

problems, which led to the introduction of a flexible turf shoe. Both caused the incidence of turf toe injuries to increase dramatically.

As artificial turf ages, it stiffens. This has also been thought to contribute to the increasing incidence of turf toe injuries, although studies have not validated this hypothesis. Since natural playing surfaces are once again becoming the standard, it is expected that turf toe injuries will also decrease.

### Mechanism of Injury

The most common mechanism of injury is hyperextension of the great toe. This often occurs with tackling in American football, where the forefoot is fixed on the playing surface with the heel raised in a dorsiflexed position. A force from the tackler is thus directed down the lower leg into the foot, causing an exaggerated dorsiflexion and subsequent hyperextension of the great toe. This hyperextension can lead to varying degrees of injury to the plantar plate, capsule, and collateral ligaments or the cartilage surface of the bone.

Although most turf toe injuries occur with hyperextension, other mechanisms have been described as well. Hyperflexion, or "sand toe" (termed so because of its high propensity in sand volleyball players), injury is sometimes considered a variation of turf toe, although it often has a different clinical course and, thus, may need to be considered separately.

Varus (bending inside) and valgus (bending outside) are two other described mechanisms. Valgus is most commonly seen in a football lineman who is pushing off from a stance. Varus is rarely seen but can occur when an outward force is applied to a fixed forefoot.

### Diagnosis

The diagnosis is made by first eliciting how the injury occurred and, if available, watching a video replay of the incident. Patients may present with a single acute or multiple episodes of trauma. Classically, the MTP joint will exhibit tenderness, swelling, and pain with movement. At this point, if a turf toe diagnosis is suspected, X-rays with several different views should be obtained to assess for a capsular avulsion, sesamoid fracture or

migration, impaction injury, or separation of a bipartite sesamoid. A magnetic resonance imaging (MRI) scan is usually ordered if there are abnormalities on X-ray. MRI is the best tool to assess soft tissue and cartilage damage, as well as further evaluate for bony abnormalities. This will aid in grading the injury, as well as formulating a treatment plan and making an overall prognosis.

Most injuries are graded on a scale of I to III, with III being the most severe. Grade I is a stretch injury to the capsuloligamentous complex, with minimal symptoms associated with it. Grade II is a partial tear to the capsuloligamentous complex, with pain with weight bearing, bruising, and restricted range of motion. Grade III is a complete tear of the capsuloligamentous complex, with an associated disruption of the plantar plate from the metatarsal neck, impaction of the phalanx into the metatarsal head, and sometimes movement of the sesamoids. There is severe pain, swelling, bruising, and motion restriction, along with inability to bear weight.

### Treatment

The initial treatment of an acute turf toe injury should include the RICE protocol of rest, ice, compression, and elevation. Athletes with Grade I injuries often can return to play immediately, although often toe taping and/or using a stiff insole may be necessary or desired for protection. Grade II injuries will often require up to 2 weeks of rest. Patients with Grade III injuries should

remain non-weight bearing for several days and have prolonged rest, usually for 4 to 6 weeks. The athlete should slowly progress from walking to running to cutting and, finally, sport-specific activities. Painfree range of motion of 50° to 60° of upward flexion has also been proposed as a criterion for returning to play. Operative treatment is reserved for the most severe turf toe injuries, including large capsular avulsions with an unstable joint and diastasis of a bipartite sesamoid, or after conservative therapy has failed.

## ULNAR NEUROPATHY

---

*Ulnar neuropathy* is inflammation or compression of the ulnar nerve, resulting in paresthesia (numbness, tingling, and pain) in the outer (ulnar) side of the arm and in the hand near the little finger. The ulnar nerve provides motor control to the muscles in the forearm and hand. It also provides the sensations of touch, temperature, and texture to the volar surface, or undersurface, of the forearm, the palm, and specifically the fourth and fifth digits of the hand circumferentially. Ulnar neuropathy that originates at the elbow is most common, although it can also be caused by injury to the nerve as it passes through the wrist.

Approximately 40% of Americans experience some form of ulnar neuropathy at least once during their lifetime. While the ulnar nerve is structurally identically in men and women, men tend to develop ulnar neuropathy more than do women. The reason may be that men generally have less fat overlying the elbow to protect the exposed nerve, or it may be due to differences in work- or sports-related stresses. The onset of ulnar neuropathy is often insidious. As a result, many of those who are affected are middle-aged or older adults. Demographic risk factors include a family history of diabetes, alcoholism, and HIV (human immunodeficiency virus) infection. Direct compression from pressure on the elbow can trigger ulnar neuropathy; therefore, people who have desk jobs and spend extended periods of time working on computers are at risk of developing the disorder. Ulnar

neuropathy is variously known as *bicyclist's neuropathy*, *cubital tunnel syndrome*, *Guyon canal syndrome*, and *tardy ulnar palsy*. Its occurrence is most notable in cyclists from prolonged compression on the nerve while gripping the bicycle handlebars; yet it is often seen in sports such as tennis, baseball, softball, and golf, where a significant amount of time is spent gripping sports equipment.

### Anatomy

The anterior primary rami of the eighth cervical and first thoracic (C8 and T1) vertebrae contribute to form the medial cord of the brachial plexus. The medial cord leaves the axilla as the ulnar and median nerves. Though the ulnar nerve starts from the cervical nerve roots, its target motor and sensory innervations are located in the medial forearm and hand. The ulnar nerve travels along the posteromedial aspect of the arm, pierces the intermuscular septum, and courses beneath the medial head of the triceps. It enters the elbow at the ulnar groove between the medial epicondyle and olecranon. Then the nerve passes through the cubital tunnel into the forearm deep into the flexor carpi ulnaris. At the wrist, the ulnar nerve enters the hand distal to the ulnar styloid through the Guyon canal. The ulnar nerve is most susceptible to injury at these two tunnel sites. The muscles innervated by the ulnar nerve are the flexor carpi ulnaris, the flexor digitorum profundus, the palmaris brevis, the interossei muscles, the medial two lumbricals, the flexor

**Figure 1** Course of Ulnar Nerve, Showing Sensory Innervation in the Forearm and Hand

pollicis brevis, the adductor pollicis, and the hypothenar muscle group. The ulnar nerve provides sensory innervation to the medial palmar and dorsal aspects of the forearm (including the elbow) and hand and supplies sensation to the small finger and medial one half of the ring finger (Figure 1).

### History and Physical Exam

Ulnar nerve injuries can present initially as paresthesias anywhere along its sensory distribution. A typical complaint would be a feeling of “pins and needles” over the ring and small finger or medial forearm. Symptoms can include pain, weakness, and fine motor deficits. On examination, there may be clawing of the ring and small fingers or wasting of the intrinsic hand muscles.

Injuries at any point along the ulnar nerve can have distal manifestations in the hand and fingers. This makes it difficult to pinpoint the exact site where the ulnar nerve is injured. One exception is

lesions that occur at the Guyon canal. The dorsal cutaneous sensory branch of the ulnar nerve leaves the main ulnar nerve prior to the Guyon canal. Therefore, lesions at or distal to the Guyon canal would not present with dorsal sensory deficits. Identifying the correct location where ulnar nerve function is compromised affects rehabilitation and treatment recommendations. Other conditions in the differential diagnosis for ulnar neuropathy should be worked up if suspected, including C8-T1 radiculopathy, brachial plexopathy, thoracic outlet syndrome, peripheral polyneuropathy, and overuse syndromes.

There are certain provocative tests that may trigger ulnar nerve symptoms and help localize the lesion. These tests include the following:

- *Elbow flexion test:* Similar to the Phalen test for the median nerve and carpal tunnel syndrome, this maneuver can elicit symptoms due to cubital tunnel syndrome. The elbow is placed in full flexion with wrist extension for 3 minutes. A positive test is when numbness, tingling, and/or pain occur over the ulnar distribution.
- *Froment sign:* The patient is asked to hold a piece of paper between the thumb and the index finger. Patients with ulnar nerve injury will have difficulty holding onto the piece of paper and will compensate with the flexor pollicis longus muscle by flexing at the thumb’s interphalangeal joint.
- *Tinel sign:* Percussion over the ulnar groove, medial epicondyle, cubital tunnel, or Guyon canal may reproduce symptoms. This is a very nonspecific test with variable results.
- *Wartenberg sign:* The small finger is in an abducted position at rest due to muscle weakness and asymmetric pull from unaffected muscles.

### Imaging and Testing

Radiographs of the upper extremity are often obtained, but in the absence of associated musculoskeletal trauma, they rarely demonstrate abnormalities that aid in the diagnosis or treatment of ulnar neuropathy. The most frequent findings demonstrate degenerative changes, fractures, or bone spurs that can contribute to nerve impingement. Conversely, electrodiagnostic tests, such as nerve conduction studies and electromyography

(EMG), are extremely helpful to accurately localize the lesion and determine the severity of injury. Occasionally, there are multiple sites of injury to the ulnar nerve that can be distinguished on electrodiagnostic testing.

### Specific Ulnar Nerve Injuries

Some specific ulnar nerve injuries are listed below.

- *Ligament of Struthers.* As the ulnar nerve passes through the intermuscular septum in the upper arm, it passes under a tough fascia layer called the arcade or ligament of Struthers. Here, the ulnar nerve can become entrapped. Conservative management tends to yield poor results; therefore, a surgical release of the ligament is often necessary.

- *Ulnar Groove.* The ulnar groove is a common site for ulnar nerve injury. Here, the nerve is at risk of being injured by direct trauma (fractures), traction injury such as valgus stress at the elbow from throwing (valgus overload syndrome), and recurrent subluxation of the nerve in and out of the groove. Compressive injury can occur at this site from leaning on the elbows or from the application of a tight cast, splint, or brace. Elbow flexion often reproduces or exacerbates the painful symptoms. Treatment options begin with conservative pain management and occupational therapy to maintain elbow range of motion and forearm strength. Biomechanical evaluation and loose protective padding or splinting around the elbow can help reduce the symptoms. Surgery (ulnar nerve release or ulnar nerve transposition) may be indicated if conservative treatment fails.

- *Cubital Tunnel Syndrome.* The ulnar nerve enters the forearm through the cubital tunnel under the medial epicondyle and olecranon. The borders of the cubital tunnel are the two heads of the flexor carpi ulnaris, the medial collateral ligament of the elbow, and the pronator aponeurosis. Ulnar nerve entrapment can occur anywhere along this tunnel. Injuries are typically due to repetitive motion. Treatment tends to be conservative and similar to the treatment, described above, for ulnar groove injuries. A surgical cubital tunnel release is reserved for those who fail conservative management.

- *Guyon Canal Compression.* The Guyon canal is formed by the pisiform bone, the hook of the hamate, the flexor carpi ulnaris, and the carpal ligament. The dorsal cutaneous sensory branch of the ulnar nerve leaves the main ulnar nerve proximal to the Guyon canal. Therefore, compressive lesions at or distal to the Guyon canal would not present with dorsal sensory paresthesias. Bicycle riding (*handlebar palsy*), push-ups, ganglion cysts, or lipomas can all cause ulnar nerve compression at the Guyon canal. Treatment includes activity modification (wrist padding or holding the handlebar from the side position instead of the top), stretching exercises, and nonsteroidal anti-inflammatory drugs (NSAIDs). Surgical interventions can be considered if symptoms fail to improve.

- *Hypothenar Hammer Syndrome.* Hypothenar hammer syndrome is caused by repetitive impact on the hand causing ulnar nerve injury at the Guyon canal. In addition to nerve injury, there can also be distal ischemia with arterial thickening, thrombosis, and possible aneurysm formation. In addition to the symptoms above, other complaints may include cold intolerance and pain over the palm of the hand. Treatment adjuncts to the above include vasolytic agents or vascular repair.

### Conclusion

Ulnar nerve injuries are common. While the presenting symptoms are similar in most cases, it is essential to identify the exact anatomic location of compression or injury in order to properly treat this condition. Athletes who present with signs and symptoms of ulnar neuritis or ulnar neuropathy are often difficult to treat due to the frequent repetitive nature of the trauma induced from gripping sport-specific equipment. Modifications in grip technique as well as padding and other adjustments may help significantly alleviate the symptoms of this condition. When the etiology of the ulnar neuropathy is unclear, electrodiagnostic testing is helpful and should be performed. Referral to a sports or orthopedic specialist is indicated for refractory and frequently reoccurring cases.

## ULTIMATE FRISBEE, INJURIES IN

---

Ultimate Frisbee (also known as *Ultimate*, in reference to a disc brand sometimes used in the sport) is a noncontact sport that is played in 42 countries by hundreds of thousands of men, women, and youth. In 2007, it was estimated that 824,000 people in the United States reported playing Ultimate at least 25 times a year. The Ultimate Player's Association (UPA) is the national governing body of the sport in the United States, while the World Flying Disc Federation (WFDF) provides international governance for the sport. Ultimate is played formally at the club, college, master's, and youth levels. In 2001, Ultimate debuted as a medal sport at the World Games in Japan.

### Overview of the Sport

It is generally agreed that the sport was developed in 1968 on the east coast of the United States, and the first official rules for the game were codified in 1970. Despite having spread worldwide, the sport has had very little media coverage and is unfamiliar to many people. A brief overview follows.

The game is typically played by two teams of seven individuals on a regulation field that is 70 yards (yd; 64 meters [m]) by 40 yd (36.6 m) with end zones 25 yd (22.86 m) deep, approximating

the dimensions of an American football field. Though any surface, indoors or outdoors, may be used, generally an Ultimate game is played outdoors on a grass field (variants of the traditional game include indoor and beach Ultimate). A plastic disc (the "Frisbee") whose regulation weight is 175 grams is used. Individuals try to advance the disc down the field, and scoring is achieved each time the offense completes a pass into the defense's end zone. Substitutions are allowed after scores or during injury time outs. A game is won when a specified number of points are accumulated (typically an odd number from 13 to 21), with two clear points on the opponents score, or after 80 minutes of play.

Physical contact between players, including picks and screens, is minimized in the game. The offense may advance the disc in any direction by completing a pass to a teammate. Players may not run with the disc after catching it. If a pass is not caught by a teammate, the defense immediately takes over possession and becomes the offense. Change of possession can also occur by the defense intercepting a pass or when an individual holds the disc for longer than 10 seconds. Ultimate is thus a transition game like basketball.

Several unique rules of Ultimate bear special mention. The game is self-refereed; that is, players are responsible for resolving any disputes at all levels of the game. Calls are typically made within the flow of play. There are clear rules for resolution of disputes, so self-refereeing does not lead to extended discussion or uncertainty about how to continue. The game, therefore, is interrupted much less frequently than many other team sports.

True to its origins in the countercultural 1960s, Ultimate is a sport that aims to be inclusive (teams are often of mixed gender) and in some important respects de-emphasizes competition. The sport places a high value on sportsmanship and fair play, codifying this in the rules as an overriding ethic known as the "Spirit of the Game." Ultimate players are often serious, motivated, and competitive athletes who nevertheless place a premium on the basic joy of play. According to Ultimate Players Association's *Official Rules of Ultimate* (11th edition), "such actions as taunting opposing players, dangerous aggression, belligerent intimidation, intentional infractions, or other 'win-at-all costs'

behavior are contrary to the Spirit of the Game and must be avoided by all players” (sec. I. Introduction: B. Spirit of the Game, p. 2). Though this has not been studied, it may be expected then that there might be fewer injuries incurred consequent to fighting among players.

It can be difficult to find other sports with which to compare Ultimate. The sport combines the nonstop movement and athletic endurance of soccer with the aerial passing skills of football. Some commentators have even compared the game with rugby: Though widely dissimilar in their approach to contact, both games involve plenty of running and frequent, deliberate diving to the turf. Some rules of the game, such as self-refereeing and the codified sportsmanship ethic, are almost unique. Overall, Ultimate is a team sport fulfilling the expected requirements of a team sport such as soccer—for example, skill, fitness, sportsmanship, and organization.

### Injuries

Like other sports defined as “noncontact,” there is ample opportunity for Ultimate players to be involved in collisions, either with each other or with the ground. The nature of the game involves frequent cutting and sprinting, which can inevitably lead to muscle strains, ankle sprains, and knee injuries.

It is a common practice in Ultimate to dive full-length, propelling one’s body horizontal to the ground, to catch a low disc. This maneuver is a signature moment in an Ultimate game, and is known as “laying out” or “going ho” (as in “going horizontal”). Laying out is a skill, like sliding in baseball, that can be taught properly: As the disc is caught, the whole body rolls in a twisting motion as it hits the ground, dissipating forces over a broad area from the ulnar aspect of the forearm to the torso and buttocks. Predictable consequences, including shoulder, arm, and rib injuries or severe friction injuries to the skin, can result if the layout is not executed correctly.

To perform at high levels, the player must be fit. As a transition game with little stoppage time, Ultimate places unresearched but predictable demands on the body. While on the field, players are almost continuously moving and are frequently sprinting. In terms of strenuousness, Ultimate would

likely then have similar physiological demands to soccer, another high-dynamic/low-static sport. It would be expected that players attempting Ultimate without the requisite levels of endurance, strength, speed, and flexibility would put themselves at higher risk of injury.

Unfortunately, there has been little research done on the injury patterns seen in Ultimate. A review of the relatively sparse literature found two surveys of injuries seen in the sport; the references can be found in the Further Readings at the end of this entry.

The first survey, published in 1991, assessed injuries that occurred in tournaments played in Europe from 1986 to 1990. The survey reported the following:

- Of all injuries, 66.6% affected the lower limbs; the most common injury involved a strain of the thigh muscle.
- Skin injuries, including friction burns, occurred at a higher rate than seen in other similar sports.
- “Minor” knee ailments such as patellar bursitis were more common than “major” injuries such as anterior cruciate ligament (ACL) tears.
- The pattern of knee injuries in general was quite different from that of many other sports and was found to be predominantly overuse injuries.

This study noted that three factors appeared to have the greatest influence on the sport’s injury pattern: (1) the preparticipation fitness level of the player, (2) the organization of a tournament and squad size (more games and smaller squads allowing fewer substitutions, resulting in more frequent injury), and (3) the state of the field (hard, packed, and stony fields causing more skin and soft tissue injuries).

The study went on to recommend injury prevention practices, including clothing such as bike shorts and soft protectors on the elbows and knees to minimize the skin exposed to trauma. Though this has not been studied, such protective measures would be expected to minimize the number of lacerations, abrasions, and incidents of bursitis seen in the sport.

The second study, published in 2006, was based on a self-reported survey administered to athletes at an American tournament sponsored by the UPA in 2002. The survey asked players to

report retrospectively injuries sustained in their careers; the study reported the following:

- Of the players surveyed, 71% had sought medical care.
- Eighty-eight percent had missed an Ultimate game or practice due to injury.
- Injuries included muscle strains (76%) and ankle (65%), knee (53%), shoulder (37%), head (30%), and rib (21%) injuries.
- A third of shoulder injuries occurred from a “layout” maneuver.
- A third of head injuries resulted in concussion.

The authors concluded, “The results of this survey demonstrate that Ultimate Frisbee injuries are common, that players are plagued with recurrent injuries, and that medical care is often sought.”

Both studies noted that hand injuries were surprisingly infrequent. Given the fact that players must catch a typically fast-moving, hard plastic disc or as defenders be expected to block a throw at the point of release, hand injuries might be expected to be more common; however, in the British study, the rate of injury to the hand was only 5.7%, and in the American study, the rate was 8%.

Ultimate, like many other sports, can put participants at risk from environmental hazards, such as heat illnesses and lightning strikes. Other entries in this encyclopedia can be consulted to review the management of these conditions.

An unusual tradition in tournament Ultimate bears a final note: One of the regular prizes given out at some tournaments is for the “worst injury.” Like “extreme sports” such as snowboarding or surfing or like a conventional and rugged sport such as rugby, there is a cultural emphasis in Ultimate on injuries as almost a badge of honor. Injuries preventing participation are not valued as they keep the participant from playing; but a laceration or severe abrasion that does not prevent play can be storied. Some have speculated that in such sports, injury rates may be higher as participants seek this unique “reward,” playing intensely or beyond the limits of their endurance. It would be interesting to do more research on this phenomenon.

Overall, much more study specific to sports medicine is needed in this relatively new and growing sport. Increased injury surveillance can better elucidate injury patterns, and subsequent preventive measures might be put in place. Research into preparticipation conditioning levels might inform injury prevention practices. Investigations into environmental hazards or protective clothing might likewise reduce injury rates. Unique aspects of the sport—the “Worst Injury of the Tournament” award and “The Spirit of the Game”—could be studied and their effect on injury patterns and athletic health elucidated.

## ULTRASOUND

---

Ultrasound technology has been used widely in the medical field for visualization and diagnosis of many conditions, including pregnancy, abdominal problems, and blood clots. More recently, the use of ultrasound in diagnosing and treating conditions

in sports medicine has become more prevalent. Ultrasound imaging provides excellent visualization of tendons, ligaments, muscles, nerves, certain joints, and bones. It is exceptionally helpful in diagnosing tendon damage, ligament tears, and muscle strains. Sports medicine physicians frequently use ultrasound to make a particular diagnosis and guide their treatment recommendations.

### Ultrasound Principles

An ultrasound machine uses a transducer that is connected to the monitor and computer of the machine (see photo, top of right column). The transducer is the device actually applied to the skin, using coupling gel, when images are being obtained. Electrical energy is transformed into sound waves by crystals in the transducer. This is called the piezoelectric effect and is fundamental to all ultrasound technology. Ultrasound is unique because it uses these sound waves to produce an image instead of using radiation, which is used for producing images for X-rays or computed tomography (CT). Ultrasound waves penetrate the skin and reflect back to the transducer after hitting certain tissues under the skin. This reflection of sound waves is converted into the images seen on the screen when performing a diagnostic ultrasound exam. Tissue that reflects the sound waves strongly appears bright white and is considered *hyperechoic*. (see image, bottom of right column). Tissue that poorly reflects sound waves appears dark and is considered *anechoic*. Tissue that falls somewhere in the middle of this spectrum is considered *hypoechoic*. Transducer frequency is an important concept for diagnostic ultrasound and is measured in megahertz (MHz). The higher the frequency of the transducer, the higher the resolution of the images obtained. However, higher-frequency transducers do not penetrate very deep, which limits the depth at which images can be obtained. Lower-frequency transducers penetrate deeper but do not provide as good image resolution as higher-frequency transducers.

### Tendon Pathology

Athletes frequently encounter the pain of tendinitis when training and competing in their

Ultrasound technique

chosen sport. Tendinitis that does not heal well can become chronic, developing into tendinopathy. Tendinopathy occurs after the inflammatory response by the body has stopped but the tendon has not fully healed. Ultrasound demonstrates very well the changes associated with tendinopathy, such as partial tears, thickening, and cyst formation. Tendons normally appear as hyper-echoic structures with fiber-like architecture and are imaged well with ultrasound due to their close proximity to the skin surface. A normal tendon will appear as smooth parallel lines of fibers without interruption or thickening, as demonstrated in the image of the Achilles tendon.

Normal Achilles tendon viewed with ultrasound. (Note that the image is necessarily of low resolution.)

Source: Photo courtesy of Joel M. Kary, M.D.

Tendinopathy, commonly found in patellar, quadriceps, and Achilles tendons, will appear thickened with areas of hypoechogenicity. Abnormal blood vessel formation sometimes occurs with tendinopathy, and this can be picked up using power Doppler settings. Power Doppler provides visualization of small blood vessels with slow flow rates, which is typical of abnormal blood vessels in tendinopathy. Ultrasound is superior to magnetic resonance imaging (MRI) when imaging tendons because it can provide high-resolution images of the individual fibers of the tendon. Tendon ruptures and tears also occur commonly in athletes. Once again, ultrasound images will clearly visualize the disruption of the tendon fibers and any blood filling the tear. In addition, the tendon can be viewed in motion while obtaining ultrasound images, providing a dynamic nature to the examination. This can be helpful in determining the size of the tendon tear and how many fibers are still intact. Rotator cuff tendon tears of the shoulder are common and are easily visualized using ultrasound.

### Ligament Pathology

Ligaments appear as hyperechoic, tightly arranged, fibrillar structures providing a soft tissue connection between bones. Ligament sprains and tears occur in many sports, especially in those involving sprinting, sudden changes of direction, and jumping. Ultrasound provides excellent imaging of the superficial ligaments found in the elbow, ankle, and knee. Complete rupture of a ligament will appear as an interruption to the ligament fibers, usually with local fluid collection from the tear. Ultrasound provides an advantage, in comparison with other imaging modalities, when evaluating ligament tears. Because ultrasound allows for dynamic motion during evaluation, the ligament can be put under stress, and the amount of joint opening can be assessed. This is very helpful in determining the grade of a ligament tear and in prescribing appropriate treatment. Common ligament tears that can be diagnosed by ultrasound include the medial and lateral collateral ligaments of the knee, the ligaments of the ankle, and the ulnar collateral ligament of the elbow.

### Muscle Pathology

Muscle tissue can be damaged during sports by a direct blow or sudden movements causing a tear. Muscle strains are exceedingly common in athletic participation and are readily visualized with ultrasound. Under visualization with ultrasound, muscle tissue appears as hypoechoic bundles separated by hyperechoic planes of tissue. Described another way, when viewed in long axis, muscle appears like veins in a leaf, and when viewed in cross section, it appears like a “starry night” pattern. A direct blow to a muscle can lead to accumulation of blood within the muscle tissue, known as a *hematoma*. This is seen as an anechoic or dark fluid collection within the muscle fibers and can be measured using ultrasound. Muscle tears are seen as discontinuity of the muscle fibers and can be accentuated by pressure from the transducer when doing an ultrasound examination.

### Advantages of Ultrasound

The use of magnetic resonance imaging (MRI) or computed tomography (CT) in evaluating sports injuries can be quite expensive. In comparison, ultrasound is a less expensive imaging alternative providing superior images of many common sports injuries. Claustrophobia can be ruled out with patients undergoing ultrasound examination, which is done with the athlete seated or lying down on a comfortable exam table. Ultrasound examination can actually be performed as an extension of the physical exam, providing additional valuable information to the clinician. The body part being examined can be viewed in motion with ultrasound, observing the soft tissue and bony anatomy in “real time.” This is particularly helpful in making the diagnosis of athletic injuries, the symptoms of which only occur when the tendon or muscle is in motion, such as a dislocating ankle tendon or a shoulder rotator cuff tendon getting compressed during the throwing motion. Another advantage of ultrasound is the ability to quickly perform comparisons of the injured body part with the uninjured side. As the technology has improved, ultrasound units have become more portable while still maintaining superior image quality. This portability is convenient in sports medicine as the unit can be used readily in the athletic training room or

on the sideline. Ultrasound can be used to guide injections. The needle can be visualized during the entire injection, thereby ensuring accurate placement of the injection and avoiding damage to any nearby blood vessels or nerves.

### Limitations of Ultrasound

The accurate use of ultrasound is operator dependent, and it requires extensive training and practice to become proficient. Errors can be made by not recognizing the difference between normal and abnormal anatomy. Athletes with a large body habitus provide a unique challenge as ultrasound waves have trouble penetrating deep enough to provide adequate images for diagnosis. Due to the inability of ultrasound waves to penetrate through bone, the visualization of deep joint structures and bone is best done using other imaging techniques such as X-ray, MRI, or CT.

---

## URTICARIA AND PRURITUS

---

*Urticaria*, or “hives,” represents a dermatologic allergic reaction, of which there are specific types. They are typically pruritic, white, or red nonpitting plaques.

Urticaria is caused by dilation of blood vessels and edema within the epidermis. Classic hives are

typically 10 to 15 millimeters (mm) in diameter, will blanch with pressure, and typically result from an allergic trigger. For athletes, classic urticaria may result from exposure to medications such as aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs), which may lead to mast cell degranulation. However, urticaria more commonly associated with exercise and sports are often smaller—2 to 4 mm typically. It is also known as *cholinergic urticaria*.

Cholinergic urticaria is part of a subgroup of urticaria known as *physical urticarias*, which are caused by physical stimulation. Physical urticarias represent 17% of all urticarias, and are most often seen in young adults. They include dermatographism, immediate-pressure and delayed-pressure urticaria, localized or generalized heat-induced urticaria, exercise-induced anaphylaxis, solar urticaria, X-ray-induced urticaria, and argon-laser induced urticaria. A person may have several types of physical urticarias, such as cholinergic urticaria along with solar urticaria. About 80% of all urticaria are idiopathic. About 10% to 20% of the population will suffer from urticaria at some point in their lifetime. If urticaria lasts for 6 weeks or more, it is defined as *chronic*. Chronic urticaria is most often idiopathic.

Cholinergic urticaria occurs when vasodilation of capillaries in the superficial dermis leads to increased transudate. It typically occurs when an antigen is bound by immunoglobulin (IgE) to release histamine from mast cells or basophils. As histamine levels increase, the level of pruritis also increases. Other factors, such as prostaglandins, leukotrienes, platelet-activating factor, and bradykinin and the complement system are also involved.

Cholinergic urticaria occur with any increase in core body temperature, which can occur with exercise. Aerobic activities and exercising in a hot environment are more likely to elicit urticaria. It is characterized by 2 to 4 mm wheals surrounded by large flares. It often starts within 2 to 3 minutes of exercise initiation, and starts on the thorax and neck and then spreads to the rest of the body. Tingling, itching, or a burning sensation on the skin may occur before the hives develop. The hives may coalesce, in which case they will resemble angioedema.

Wheezing and dyspnea may also develop in cholinergic urticaria. It may be difficult to identify

cholinergic urticaria if the hives do coalesce. Those who are prone to cholinergic urticaria often also develop the same urticarial reaction with anxiety, a hot shower, sweating, or with any other elevation in body temperature. It is important to take a good history to determine if there are other triggers, such as with hot baths and showers, or with emotional stress and anxiety, or with ingestion of hot or spicy foods, to distinguish cholinergic urticaria from EIA (Exercise-induced anaphylaxis). Cholinergic urticaria is classically reproducible with exercise, stress, or hot showers, while EIA is not. There may be other signs of cholinergic stimulation, such as lacrimation, salivation, and diarrhea.

*Cold urticaria* is another type of urticaria that can be seen in athletes. It primarily occurs in cold-weather sports or in swimming. Wheals can be large or small, but they are generally confined to the area exposed to the cold. Diagnosis can be made with observation of hives on skin after 5 minutes of cold application and subsequent skin rewarming. The treatment consists of avoiding cold exposure and wearing protective warm equipment, as well as antihistamines.

The gold standard for diagnosis of cholinergic urticaria is passive warming, either in a warm bath or a sauna. An increase in the core body temperature of 0.7 °C to 1 °C is needed. In case there is a possibility that exercise-induced anaphylaxis is the true diagnosis, testing should be done under controlled conditions, with epinephrine, resuscitative equipment, and medical personnel at hand, and a IV set should be in place. Another test that is diagnostic is the methacholine test, where an intradermal injection of 0.01 milligram (mg) methacholine produces localized hives. However, the sensitivity is only about 30%. The passive heat challenge is the best test.

Treatment of cholinergic urticaria consists of avoidance of triggers primarily, such as bathing in hot water, and strenuous exercise in hot weather. Hydroxyzine, an H1 histamine antagonist, is an

anticholinergic that has been shown to be most effective at reducing urticarial hives. Hydroxyzine, which is typically dosed at 100 to 200 mg over a 24-hour period, is most effective. In cases refractory to hydroxyzine, danazol anabolic steroid could be effective, but this treatment should be avoided at all costs, considering the side effects. Cyproheptadine may be used as adjunctive treatment if there is associated cold urticaria. Treatment of pulmonary symptoms with cromolyn sodium can be effective. For long-term treatment, an exercise program with gradual increases in duration and intensity may be effective in producing tolerance. Avoidance of obvious triggers, such as NSAIDs or aspirin before exercise is essential. Exercising with an EpiPen if there is any concern for EIA is important. However, care must be taken in athletes competing at NCAA (National Collegiate Athletic Association), Olympic, or professional levels to avoid certain medications that may be banned or restricted, such as anabolic steroids, albuterol, or decongestants.

## VEGETARIANISM AND EXERCISE

---

Vegetarian diets are common among athletes. A balanced vegetarian diet, meaning one guided by thoughtful and informed food choices, certainly may meet the needs of athletes and even be the foundation for some healthful lifelong habits. For young athletes, however, because growth is still occurring, the priority is to provide enough calories and nutrients for optimal growth and development while still supporting higher activity needs. This entry discusses the vegetarian diet as it relates to sports nutrition.

Individuals choose vegetarianism for a wide variety of reasons. Some of these include health benefits such as the prevention of certain chronic diseases, cultural beliefs, family practices, peer influences, and animal rights or environmental issues. Some athletes insist that a vegetarian diet may improve their performance. Others adopt a vegetarian diet to meet the increased carbohydrate demands of training or to assist in weight control. Of concern are those athletes who describe their dietary intake as “vegetarian” to hide restrictive dietary intake or to mask disordered eating behaviors.

### Types of Vegetarian Diets

Many foods meet the criteria for a vegetarian diet. The term *vegetarian* is used to describe diets based exclusively on plant foods to those containing some animal foods. Table 1 outlines various vegetarian diets.

### Vegetarian Diets and Performance

While there is no evidence that being a vegetarian gives any direct athletic advantage, healthy vegetarian athletes can perform as well as nonvegetarian athletes. A plant-based or vegetarian diet may be ideal for performance as it is generally high in complex carbohydrates. Only the caloric needs change, as plant-based diets are low in fats. Added fat, especially in the form of monounsaturated fats (olive oil, avocados, nuts, and peanuts), as well as essential fatty acids (fish and flax seed oils), may help provide additional calories to a vegetarian diet.

Vegetarianism does not greatly affect the fundamentals of optimal sports and performance nutrition. However, seeking advice from a dietitian may be beneficial in crafting an ideal performance nutrition plan.

### Protein and Vegetarian Diets

Amino acids are the building blocks of protein. If a food contains the right combination of essential amino acids, it is called a *complete protein*. All animal-derived proteins and soy are complete. The remaining plant sources of protein contain many, but not all, of the essential amino acids and thus are considered *incomplete proteins*.

Previously, it had been suggested that vegetarians combine different plant foods at individual meals to ensure that all essential amino acids were provided at the same time. However, the American Dietetic Association has since stated that combining plant sources of protein meal by meal to meet

**Table I** Vegetarian Diets

| <i>Type of Vegetarian Diet</i> | <i>Diet Description</i>                                                                                                                                                                         |

the body's requirement for essential amino acids is unnecessary. Thus, as long as a variety of plant proteins are eaten throughout the day, adequate amino acids will be obtained.

A favorable eating regimen for vegetarian athletes is to ensure that protein-rich foods are included at each meal. Many athletes have limited time for meal preparation, particularly at lunch. Convenient and portable protein alternatives include ready-prepared beans (hummus, baked beans, and bean salad), nut and seed spreads (peanut butter and tahini), and ready-made luncheon meals made from soy or wheat gluten.

Along with including adequate protein, it is also crucial to obtain adequate calories so that protein is not used as an energy source. Athletes often have the misconception that the protein they consume is the only nutrient that is responsible for building more muscle. Actually, it is consuming enough calories that preserve protein for muscle repair and growth. Excess protein does not provide any advantage, and special protein supplements are generally not necessary. In summary, an athlete needs adequate protein, calories, and, most important, enough calories to spare, or make available, protein for growth and repair of tissues.

### Meeting Vitamin and Mineral Needs

Athletes who are vegetarians have to include vegetarian alternatives in their diet that supplement certain vitamins and minerals that are commonly found in animal-based foods, such as vitamin D, riboflavin, vitamin B<sub>12</sub>, iron, calcium, and zinc.

Vitamin D is important for bone health. Athletes need to ensure that they get adequate vitamin D from sun exposure and/or through fortified foods or supplements. Cow's milk, certain soy milks, and many breakfast cereals are fortified with vitamin D.

Riboflavin is low in vegetarian diets that do not include dairy products. It is an essential vitamin for the production of energy and thus important for athletes. Plant sources of riboflavin include fortified whole grains, soybeans, dark green leafy vegetables, avocados, nuts, and sea vegetables.

Vitamin B<sub>12</sub> is needed for the production of normal red blood cells. Its deficiency may result in pernicious anemia and associated dementia. B<sub>12</sub> is only found in animal products. The semivegetarian will obtain adequate B<sub>12</sub> if fish and dairy products are consumed. The vegan will need to obtain B<sub>12</sub>

through a supplement, nutritional yeast, fortified grains, or soymilk.

Calcium is essential for all athletes for optimal bone health. Vegetarians who do not include dairy products in their diet need to include calcium sources from plants or supplements. Athletes with low dietary calcium intake may have increased risk of bone fractures and stress fractures. Plant-based sources of calcium include kale, bok choy, turnip greens, and Chinese cabbage.

All athletes, especially female athletes, are at risk for iron deficiency. Iron plays a critical function in transporting oxygen throughout the body. There is also loss of iron due to heavy training. The absorption of iron from animal-derived foods is much higher than from plant sources. However, vitamin C significantly improves iron absorption from nonanimal sources. A diet rich in fruits and vegetables provides adequate vitamin C. Cooking in cast iron pots may also increase the iron content of certain foods. Iron-fortified breakfast cereals, spinach, beans, molasses, whole-grain products, textured vegetable protein, and some dried fruits (dried apricots, prunes, and raisins) are also good sources of iron.

In summary, with proper planning, athletes can choose a vegetarian diet that meets nutrient needs for athletic performance as well as for optimal health.

## VOLKMAN CONTRACTURE

Volkman contracture, also known as *Volkman ischemic contracture*, is a permanent flexion contracture of the hand at the wrist, resulting in a clawlike deformity of the hand and fingers. It may affect a single finger or the flexor muscles of the entire forearm. It may result from injury to brachial artery and is usually associated with supracondylar fracture of humerus, sometimes consequent to a high-impact fall as in skateboarding or other sports. It can also result from an intense twist of the upper arm, falling on an outstretched hand, or severe contraction of muscles. Baseball pitchers and other athletes who participate in throwing sports such as javelin and discus are vulnerable to this condition.

### Classification

*Ischemia* is defined as cell death due to lack of blood supply. The intensity of injury depends on the type of cell and its energy requirements.

Ischemic injuries are classified in various ways. One is according to the severity of involvement:

*Grade I:* Ischemia

*Grade II:* Ischemic contracture

*Grade III:* Ischemic contracture associated with nerve involvement

They may also be classified according to the structures involved:

*Type I:* Contracture involving forearm muscles with intrinsic muscles intact

*Type II:* Contracture involving forearm muscles associated with paralysis of intrinsic muscles

*Type III:* Contracture involving forearm muscles as well as intrinsic muscles

*Type IV:* Mixed type

Tsuge's classification comprises three types, according to the extent and the muscle groups involved.

*Mild:* It is characterized by flexion contracture of two or three fingers with minimal loss of sensation.

*Moderate:* The thumb gets stuck in the palm, and all fingers are flexed; the wrist may be flexed with associated loss of sensation.

*Severe:* All muscles in the forearm, including both the flexors and extensors of the wrist and fingers, are involved.

### Anatomy

The brachial artery branches into the radial and ulnar arteries. The radial artery is superficially positioned, whereas the ulnar artery is deeply placed, passing deep into the pronator teres muscles. The ulnar artery gives rise to the common interosseous artery, which immediately divides into the anterior and posterior interosseous branches. The anterior interosseous artery provides blood supply to the flexors of the forearm and hand.

### Causes

Ischemic contracture may be caused by the following:

- Fracture
- Compartmental syndrome
- Tight bandages
- Arterial embolus
- Arterial insufficiency
- Improper use of a tourniquet
- Improper use of a plaster cast

Volkmann contracture occurs when there is insufficient blood supply (ischemia) to the forearm and is the end result of an untreated or relatively inadequately decompressed compartment syndrome in which ischemic necrosis of muscles has developed. The key factor in all cases of ischemic contracture is reduction in compartment size or increase in the content of a closed, uncompromising osteofascial compartment, which is enough to cause occlusion of small vessels.

The blockade immediately results in ischemia of the nerve and muscle. If the pressure is not relieved in time, it may result in damage to muscle contracture and nerves.

Decrease in the compartment size can be attributed to the following causes:

- Constrictive casts and dressings
- Persistent localized external pressure

- Injuries due to heat
- Burn Escher
- Plastic surgery of facial defects

This can also be attributed to an increase in compartment content resulting from hemorrhage, bleeding diathesis, or anticoagulation.

### Diagnosis

The hallmark symptom of Volkmann contracture is pain that does not improve with rest or non-sedative analgesics. It will continue to get worse as time passes, and if the pressure is allowed to persist, there will be decreased sensation and weakness.

Besides pain, symptoms include pallor, pulselessness, paresthesias (numbness), and paralysis. Aggravation of pain on passive stretch is the most reliable finding on physical examination. Other symptoms include decreased sensation, weakness, and induration of the forearm. Pulselessness and paralysis are late symptoms. The forearm may show swelling and is also shiny. There is a typical flexion contracture of the wrist along with clawing of the fingers.

An absolute diagnosis is made based on direct measurement of the compartment pressure. It is done by inserting a needle into the compartment that is attached to a pressure meter. When the pressure is above 45 millimeters of mercury (mmHg) or when it is within 30 mmHg of the diastolic pressure, a diagnosis of compartment syndrome is made. This is the general test to diagnose compartment syndrome.

### Treatment

Early recognition and timely treatment of imminent Volkmann ischemia decrease the presentation and severity of late contracture and hand dysfunction. Ideal treatment requires a thorough examination of the extent of damage of the ischemia, followed by conservative therapy or operation.

Management presents considerable challenges. The success in achieving a potentially functional and aesthetically satisfactory result is greatest in the acute phase. A physician should be immediately consulted in case of an injury to the elbow or forearm and if swelling is also present.

### *Nonsurgical Treatment*

If there is a forearm or elbow fracture, a proper initial splinting of the hand in functional position should be performed; the area must be kept still, and the arm should be raised above the level of the heart. This helps in preventing further injury and excessive swelling. When the extent of injury is determined, conservative treatment techniques such as rest and ice should be started to help decrease the swelling. Pain relief and anti-inflammatory medicines may be prescribed. Casts and surgery also may be indicated, depending on the injury. Bed rest or use of a protective device (a knee brace or wrist guard) is usually advised. Physiotherapy may also be of help in rehabilitation. Early mobilization, range-of-motion exercises, followed by stretching and strengthening exercises are part of rehabilitation.

### *Surgery*

The best treatment is early surgical intervention to release the pressure in the forearm in order to prevent permanent injury to muscles and nerves. Reconstructive surgery to lengthen and sometimes transfer muscles may restore some hand function.

Muscle sliding is considered the most effective method. It results in the best preservation of resting length of muscle.

Other methods include the following:

- Tendon lengthening
- Neurolysis
- Scar excision
- Tendon lengthening
- Tendon transpositions
- Nerve grafting

#### **Stage 1 Contracture**

Muscle-sliding operation usually results in complete recovery. It consists of median nerve neurolysis and removal of necrotic debris. For isolated muscle injuries, tendon lengthening is recommended.

#### **Stage 2 Contracture**

Transposition of flexor tendons has an equal effect to muscle-sliding operation. It is an imperative procedure that helps in the prevention as well

as control of imbalance deformity, its indication depending on the personal as well as professional profiles of the individual patient. A tendon transfer procedure alleviates the suffering from functional impairment and provides a far better alternative to permanent external splints. This is usually a secondary procedure for replacing function, which is done after evaluation of the functional motor loss.

#### **Stage 3 Contracture**

The primary treatment option is muscle-sliding operation. Some secondary procedures such as tendon transpositions and nerve grafts are often necessary.

#### **Stage 4 Ischemic Contracture**

Muscle-sliding operations may help in improving deficiency in extension; however, wrist arthrodesis is of great help. The aim of arthrodesis is to achieve a relatively painfree wrist by eliminating movement. In this procedure, the bones are fixed. This procedure is more beneficial for young, active patients or middle-aged patients but not for elderly patients. Extensor tendon transpositions may be of benefit.

### **Long-Term Prognosis**

Prognosis is variable and depends on the severity of the disease and the stage at which intervention is made. If the pressure is released earlier by surgery, before the onset of any permanent damage, then the prognosis is excellent. High compartment pressure for a longer period of time can result in permanent nerve damage. Cubitus varus and loss of radial pulse are the other complications reported.

## VOLLEYBALL, INJURIES IN

---

Volleyball is the sport with the highest rate of jumping during practice and competition. Jumping seems to be the riskiest activity in volleyball because the majority of injuries are associated with jumping and landing. Defense is associated with a small number of injuries, while serving, passing, and setting are associated with even fewer injuries.

Epidemiologic studies of volleyball injuries have identified some of the risks of injury in the sport. The highest rate of injury in volleyball is associated with blocking, followed by spiking. These are also the two sport-specific activities that require a jump with every repetition.

Injury rates during competition have been evaluated. An injury is defined as "any condition causing the athlete to present to the medical staff

during a tournament." In high-level play, a rate of injury between 1 per 25 hours and 1 per 50 hours is common. Injuries in American intercollegiate play have also been studied. "Any condition that resulted in missing a practice or match" is how an American intercollegiate group defines injury. Each practice or match was counted as one exposure. The rate of injury was about 4 per 1,000 athlete exposures in women's intercollegiate training and competition. This ranked volleyball second to softball for the lowest injury rate among 15 intercollegiate sports. Playing on a softer surface, such as sand, also seems to decrease the risk of injury.

### Ankle Sprains

In volleyball, 15% to 60% of recorded injuries are ankle sprains. Ankle injuries are almost always associated with landing from blocking or spiking in the front court. The most common mechanism of injury occurs when the blocking player lands on an opposing spiker's foot that has come underneath the net and across the center line in the "conflict zone." The rules of volleyball allow a player's foot to cross this line beneath the net as long as some portion of the foot remains in contact with it. It often results in an inversion injury, where the ankle rolls outward. The ligaments on the outside, or lateral side, of the ankle are injured.

An ankle brace or orthosis is often recommended while actively rehabilitating, as it decreases the reinjury risk. Stirrup-style braces, particularly pneumatic-type orthoses such as the Aircast® brand, have been shown to decrease injury risk fourfold. The risk of reinjury is greatest during the first year after an initial injury, so it is recommended that braces be worn for a year after an ankle sprain. Braces have not been shown to decrease risk of injury in ankles that have not been previously sprained.

It may be possible to prevent a significant number of ankle sprains with a fairly simple prophylactic program. First, advise all players not to allow any part of their foot to touch the center line during practice. Second, identify "problem attackers." These are players who jump forward (doing a broad jump) when spiking the ball. These players should be coached to take longer last-approach steps and jump straight upward instead of out. A twofold decrease in ankle sprains may be anticipated. It should be easy to convince players that

this is a good idea, because this technique actually results in a higher vertical jump.

### Patellar Tendinitis (Tendinosis)

Patellar tendinosis (*jumper's knee*) is by far the most frequent overuse injury in volleyball. It is probably so common because of the high frequency of jumping inherent in the sport. Patellar tendinosis has been found to be more common in players who play more than four times weekly and are 20 to 25 years old. Players who have been in the sport for 2 to 5 years are also more likely to have symptoms. Plyometric training has *not* been associated with patellar tendinitis in these elite players. Most players with this condition have pain at the bottom part of the kneecap.

It may be possible to identify players who are at increased risk for patellar tendinosis. Those who can generate the greatest amount of power during jumping have been found to be at greater risk. These are also the players with the highest vertical jumps. Perhaps, they may not need as much jump training as their teammates. Deeper knee flexion at takeoff for jumping may also place players at greater risk. Coaching attention to proper jumping technique might help these players avoid injury.

Patellar tendinosis can usually be managed conservatively with ice, short-term anti-inflammatory medication, and alterations in training activity. Closed-chain eccentric strengthening of the quadriceps muscle can result in stronger fibers in the patellar tendon. An example of this sort of exercise would be leg presses where the athlete "works the negative." These exercises should be used to rehabilitate this condition.

### Shoulder Tendinitis (Tendinosis)

The most common shoulder injuries in volleyball players are rotator cuff and biceps tendinosis as a result of overuse. They account for 8% to 20% of injuries in volleyball. Repetitively striking the ball overhead places a cumulative stress on the shoulder. Striking the ball at the highest point in the arm swing may place the shoulder at particular risk in this sport. These forces predispose the shoulder tendons to impingement with spiking and overhead serving. The tendons get impinged between

the head of the humerus, or arm bone, and the acromion process, which sits above the shoulder.

A player who has shoulder pain and/or weakness should be evaluated by a physician, athletic trainer, or physical therapist. Sometimes, the entire shoulder girdle (including the shoulder blade) moves in an abnormal pattern. A rehabilitation program will often be prescribed. Abnormal shoulder blade movement should be addressed first. This usually involves shoulder retraction exercises. Then, rotator cuff exercises will help stabilize the ball in the socket.

### Suprascapular Nerve Injury: A Volleyball-Specific Injury?

An unusual condition that may be present in up to one third of elite volleyball players is suprascapular nerve compression. Several factors may be involved with this problem, but the nerve is usually compressed by the bone of the shoulder blade near where it innervates the infraspinatus muscle. This is the muscle that externally rotates the shoulder. So players typically have isolated weakness of external rotation when a trainer evaluates their shoulder strength. Interestingly, the majority of the players with this condition do *not* have shoulder pain.

Players with this condition who have no pain probably do not require further evaluation or treatment. Findings of isolated external rotation weakness and infraspinatus atrophy should be noted on preparticipation physical exam for future reference, in case the player develops symptoms. In those with significant symptoms, such as shoulder pain, magnetic resonance imaging (MRI) may be helpful if surgery is being considered, because up to two thirds of affected individuals may have an abnormality called a ganglion cyst compressing the nerve.

### Other Injuries

Volleyball players often suffer relatively minor hand or back injuries. These injuries are common yet rarely result in time missed from the sport. Sprain of the outside ligament of the thumb (metacarpal-phalangeal radial collateral ligament) is the most frequent hand injury seen in volleyball players. It often occurs with blocking and may require splinting or taping.

Low back injuries account for up to 14% of volleyball injuries. In teenage athletes, back pain should be evaluated by a physician, because back pain is unusual in this age-group and almost always occurs secondary to a condition that may respond to treatment. One such condition is spondylolysis, which is essentially a stress fracture of the low back. Athletes who have pain when they bend backward with their lower back (lumbar extension) should be evaluated by a sports medicine physician. This may occur in hitters, when they must repeatedly reach back behind their heads to contact the ball.

Severe knee injuries requiring surgery on the anterior cruciate ligament (ACL) are also rare, but these injuries seem to be more common in female players. A good way to evaluate female athletes who may be at risk for this injury is to observe players as they land after jumping off of a box. Those whose knees come together (into valgus) and touch

on landing—"kissing knees"—should be considered for a program of exercises to prevent ACL injury.

## WARTS (VERRUCAE)

---

Warts, or *verrucae*, are common skin findings that are often considered benign. However, in the athletic population they have the potential to cause significant pain and, thereby, impair performance. Although warts are found in every age-group, children and young adults are the most commonly affected, and athletes are at particular risk.

Human papillomavirus (HPV) is a virus that infects the skin and mucous membranes. There are more than 150 different types of HPV that cause warts in various areas of the body. Recently, several types of HPV have received additional attention because of their association with cervical cancer. The HPV vaccine is aimed at minimizing the spread of subtypes 16 and 18. The vast majority of HPV infect the skin and cause cutaneous warts. These types of HPV have virtually no potential to cause cancer.

Transmission of HPV occurs when the virus comes into contact with areas of damaged, even minimally damaged, skin. Transmission can be skin to skin or skin to fomite, such as shower room floors. Participation in sports can cause trauma to the skin, particularly to the feet and hands. In addition, the shared use of shower facilities and weight training equipment introduces multiple potential sources of exposure to HPV.

It is difficult to know exactly when an HPV infection occurs, because there is a lag time between exposure to the virus and the appearance of the resultant warts. The viruses commonly have

an incubation period of between 1 and 6 months. Once individuals are infected, they risk passing this infection to other areas of their own skin through activities that cause minor skin trauma, such as shaving or scratching. Most subtypes of HPV cause specific types of warts that have predilections for certain areas of the body.

### Symptoms

Two types of warts that frequently affect athletes are common warts and plantar warts. Common warts make up approximately 70% of cutaneous warts. They can be found anywhere on the body, but these most frequently affect the backs of hands and fingers. In children, these warts often appear on the face and neck. These warts are often described as “irregularly surfaced domed lesions.”

One study looked at the acquisition of new common hand warts in runners and members of the crew team at a university. Rowers experienced hand trauma through weight training and rowing. Runners, on the other hand, experienced hand trauma from weight lifting alone. The study noted a significant increase in new common hand warts in crew team members compared with track team members. The authors postulated that trauma to wet, macerated hands made crew team members more susceptible to HPV and the resultant common warts.

Plantar warts are found on the sole of the foot and often cluster in the areas that bear significant pressure. The ball of the foot and the heel are the two most commonly affected sites. Because of their

location, plantar warts can become callused and appear to grow into the foot. These warts are often found in small groups and can produce significant pain during weight bearing. Athletes with plantar warts may feel the sensation of having a pebble in their shoe while running or walking. Several factors predispose athletes to plantar warts, including communal showers, excessive perspiration, and repetitive microtrauma to the foot.

It is important to note that plantar warts can cause symptoms similar to stress fractures; therefore, plantar warts must not be overlooked when investigating plantar foot pain. A case report describes a 24-year-old female tennis player who was forced to stop play in the middle of a tennis match. She had tenderness over the ball of her foot, and it was suspected that she had a stress fracture. Following 2 weeks of rest, she returned to competition, and again the pain returned. Notably, she had calluses over the painful area of her foot. These calluses were pared down, exposing multiple dark spots (the "seeds" commonly found in plantar warts). Her plantar warts were treated, and she subsequently returned to play.

This situation illustrates how debilitating plantar warts can be for an athlete and the need to include plantar warts in the differential diagnosis for foot pain. Part of the difficulty in diagnosing plantar warts is that they are often covered with a callus. Once the callus is removed, plantar warts have a characteristic appearance: multiple black speckles, which are actually small blood vessels. These small blood vessels are the hallmark of plantar warts and differentiate them from other skin findings.

### Treatment

There are several options available for the treatment of both common and plantar warts. Treatment can be broken down into three categories: (1) observation, (2) mechanical destruction, and (3) stimulation of the patient's immune system. Given the fact that cutaneous warts are caused by viruses, the immune system can potentially eradicate the viruses and the resulting warts. Warts affect patients with intact and impaired immune systems alike. However, individuals with impaired immune systems may never be able to mount an immune response significant enough to fight HPV.

Most warts in a healthy patient will resolve spontaneously (without intervention) over months or years. One study demonstrated the spontaneous resolution of two thirds of warts over 2 years. However, this process may take longer and be less successful than interventional measures. The longer the warts remain, the greater the potential for spread to different areas of the skin and to other people. Furthermore, the spread of warts may result in larger or more numerous warts, which may be more difficult to eventually remove.

Although most warts will resolve without intervention, the option of observation is much less desirable for athletes whose performance is impaired due to warts. These individuals may be more appropriate candidates for mechanical destruction. Mechanical destruction can be accomplished through a variety of measures. The most common types of mechanical destruction include topical acids, freezing, and curetting. However, it is important to note that destructive measures, particularly curetting, have the potential to leave a scar. Such scars, especially in the case of plantar warts, can be painful and can potentially inhibit the athlete's ability to run or even bear weight on the affected foot. Therefore, athletes must be cautious with more aggressive means of wart destruction.

Topical acids are effective, safe if properly used, and available over the counter. Salicylic acid is a common preparation often used as a first-line interventional treatment for both common and plantar warts. However, instructions for application can be complex and, thus, decrease patient compliance with treatment. To maximize the efficacy of salicylic acid, a regimen that includes daily soaking, debridement with an emery board, topical application of the acid, and occlusion with duct tape should be followed. This stepwise treatment should be repeated every 24 hours. Several studies have demonstrated that topical acids are more effective and faster at eliminating warts than simple observation (no intervention).

Freezing, or cryotherapy, involves the use of liquid nitrogen or nitrous oxide to destroy warts. The wart is frozen using a cryogun until the entire wart and up to 2 millimeters (mm) of the surrounding tissue turn white. A second freeze after thawing makes this method more effective. Following the freeze, the affected area will blister and then gradually slough and heal over the next

few weeks. The freeze destroys the wart but also stimulates the immune system that aids in the destruction of any remaining HPV. Although much less complex than topical therapy, this method has the potential to cause blistering and pain, particularly in the case of plantar warts. While in training, athletes must decide whether the functional impairment from their warts is severe enough to warrant the potential complications of freezing.

Occlusion with duct tape alone has been used by many practitioners and has been the subject of several studies. Although the exact mechanism of treatment with duct tape is not known, several theories have been proposed, including suffocation of warts, immune response stimulation, and mechanical debridement. In 2002, a study compared the efficacy of cryotherapy with that of duct tape occlusion. The results showed that duct tape occlusive therapy was significantly superior to cryotherapy in resolving common warts. However, two other studies have questioned the efficacy of duct tape occlusion as a successful therapeutic intervention. These studies demonstrated no significant differences in the resolution of warts when compared with placebo treatments such as corn pads or moleskin coverings. Though they showed a nonsignificant initial resolution of the wart, return of the wart was equally demonstrated. Questions still remain as to whether differences in the type of duct tape, silver versus transparent, could account for the divergent outcomes of these studies.

There are also various methods that have been used to stimulate the immune system to facilitate the destruction of HPV and the resulting warts. These methods are directed at enhancing the immune response both locally and systemically. Injection of *Candida* into the base of a wart is one way to generate a local immune response. The body's natural response to the fungus will supply the injected region with host cells that target the *Candida* as well as the viruses causing the wart. Similarly, topical agents such as imiquimod cream and diphenylcyclopropanone generate a local inflammatory response that enhances virus destruction. Interestingly, the H2 antagonist cimetidine (a medicine frequently used for the treatment of heartburn) has been used in an attempt to stimulate human immune cells to facilitate the regression of warts. Although early uncontrolled studies supported the efficacy of high-dose cimetidine,

more rigorous double-blind controlled trials have contradicted these findings.

### Conclusion

Warts are a common skin finding that have the potential to cause pain and impair performance in athletes. Although there are several methods for treating warts, preventive measures can help athletes avoid an HPV infection. Athletes who use communal showers should wear sandals and avoid direct contact with shower floors. Athletes may consider the use of drying agents to avoid moisture, which, by leading to maceration of the skin, increases the likelihood of infection with HPV. If athletes do develop warts, they should take into account the potential for side effects when selecting a treatment modality.

## WEIGHT GAIN FOR SPORTS

---

Many sports require an athlete to lose or maintain weight to optimize performance. Conversely, some sports and sports positions require weight gain for a greater competitive advantage. In some cases, the extra pounds can mean the difference between

winning and losing. This entry describes how athletes may safely gain weight to achieve a competitive advantage.

Gaining weight is important for those who are underweight or who require greater strength. Gaining weight may also increase energy and endurance. Endurance is a person's ability to cope with intense and frequent exercise, such as distance running, swimming, or biking over long time periods or distances. Weight gain may also help an athlete to build muscle and increase strength. This strength may offer some athletes a protective advantage in sports such as football or hockey. The optimal time for gaining weight is during the off-season or at the beginning of the season.

Gaining weight may not be easy. In fact, often it is harder than losing weight, as athletes may use energy faster than they consume it. The question for the athlete is how to gain weight while still maintaining a healthful diet. In short, weight gain requires excess calorie intake. Each pound of weight gain requires 3,500 additional calories (cal; 1 cal = 4.2 joules). This is achievable by incorporating an extra 500 cal/day into the diet. If an athlete consumes an additional 500 cal/day for 1 week, then 1 pound (lb; 1 lb = 0.45 kilograms) of weight gain should be the outcome. Ideally, this should be combined with a resistance training program. The goal is not just to increase weight but also to increase lean muscle mass.

A combination of protein, carbohydrate, and fat is optimal for weight gain. The percentages of each of these macronutrients are approximately as follows: carbohydrate at 50% to 65%, protein at 15% to 20%, and fat at 25% to 30%. If these percentages are viewed as grams per day, the following is recommended: carbohydrate at 5 to 10 grams per kilogram per day ( $\text{g kg}^{-1} \text{day}^{-1}$ ), protein at 1.0 to 1.7  $\text{g kg}^{-1} \text{day}^{-1}$ , and fat at approximately 1  $\text{g kg}^{-1} \text{day}^{-1}$ .

Maintaining a healthful diet of whole grains, fruits and vegetables, lean protein, and heart-healthy fats will help optimize performance. Weight gain, just like weight loss, takes time. The overall goal is to gain about 0.5 to 1 lb/week. Athletes trying to gain weight should consume three meals and two or three snacks each day. Skipping meals such as breakfast may make it more difficult to obtain the necessary calories needed to gain weight.

## Weight Gain Methods

Many athletes think that additional calories should be obtained only from protein. Studies show that consuming excess protein (defined as more than 1.8  $\text{g kg}^{-1} \text{day}^{-1}$ ) may increase the oxidation of excess amino acids. Furthermore, excess protein may be converted to fat. Thus, a diet with too much protein has no advantage for muscle gain, when compared with a lower protein intake that is coupled with resistance training.

The speed at which weight gain occurs may depend on the athlete's genetic makeup, the calories consumed in excess of metabolic and training needs, the number of rest and recovery days per week, and the training program itself. Weight gain is achieved by ensuring that each meal and snack are made up of healthful, higher-calorie foods. Beverages are one easy way to increase calories. For example, instead of water, the athlete may add juice, milk, milk shakes, and instant breakfast drinks to meals or snacks. It is also important to snack regularly and carry healthful snacks each day to encourage snacking. Such snacks may include dried fruit, yogurt, cheese and crackers, nuts and peanuts, bran or fruit muffins, and multigrain bagels with cream cheese or nut butters.

Athletes may think that the need for extra calories gives them the right to eat whatever they want, but this may be detrimental to both performance and overall health. Substitutes may be found for many food items. For example, instead of using butter, canola or olive oil may be substituted. Mayonnaise may be replaced with avocado spread. Natural peanut butter may be spread on bagels, crackers, or bread instead of butter or cream cheese. Eating healthful foods in abundance is how an athlete gains weight safely and effectively. There is no need to add calories with fast food or junk food when calories are easily added by making favorable choices at meal and snack times.

Many athletes wonder whether protein supplements are helpful when trying to bulk up. These supplements are often marketed as ways to gain extra muscle quickly. However, the main reason why protein supplements help an athlete gain muscle is that they contain extra calories. Also, contrary to what some people believe, most athletes need only a small amount of extra protein to gain weight and muscle mass. The protein in the supplements is often too high. Caloric and protein

needs may be met by eating a variety of healthy foods each day. If extra calories are needed, readily available weight gain drinks such as Ensure or Boost contain the extra calories and are marketed specifically for weight gain.

There are also unhealthful ways of gaining weight. A few of these are human growth hormone (HGH), anabolic steroids, and insulin. HGH use may increase the risk of diabetes, hypertension, joint pain, and possibly colon cancer. Anabolic steroids have been linked to many health problems, including breast growth and shrinking of testicles in men, voice deepening and growth of body hair in women, heart problems, liver disease, and aggressive behavior. Insulin is sometimes used in bodybuilding to increase the bulk of muscles. Insulin is a natural hormone secreted by the pancreas in response to high sugar levels. Its main use is to regulate sugar levels in the body. However, if one is not diabetic, taking insulin unnecessarily may cause the pancreas to stop producing insulin naturally, which might lead to diabetes.

### Weight Gain Tips

Weight gain requires that an athlete eat consistently and not skip meals or snacks. Portions should be larger than normal, and calorically dense foods should be encouraged. Higher-calorie meals may also result from reading food labels to determine which foods have more calories than an equally palatable counterpart. For example, cranberry apple juice has more calories than does orange juice (170 vs. 110 cal/8 fluid ounces [oz; 1 oz = 29.57 milliliters]), granola has more calories than do Cheerios (700 vs. 100 cal/cup), and corn has more calories than do green beans (140 vs. 40 cal/cup).

In terms of individual food groups, the following guidelines may be helpful. Choose heavy breads such as honey bran, rye, and pumpernickel instead of lighter breads such as white bread. Choose cereals such as granola, instead of rice puffs or corn flakes. The caloric value of cereals may also be increased by adding nuts, raisins, and other dried fruits. When choosing fruits, bananas, pineapple, mangos, raisins, dates, and other dried fruits have more calories per serving than do watery fruits, such as watermelon, grapefruit, apples, and peaches. Starchy or sugary vegetables, such as corn, carrots, and peas, have more calories per serving than do less starchy vegetables, such as green beans, broccoli,

and summer squash. Lentils, lima beans, chili beans, and other beans are also high in calories. These foods are good choices, because they also provide both carbohydrates and protein. In terms of other protein foods such as meat, fish, and poultry, certain types and cuts are higher in calories. Dark meat of poultry, fatty fish such as salmon and trout, and some cuts of lean red meat are high in calories, including round or sirloin steak, ground round, fresh or boiled ham, or center-cut loin chops.

## WEIGHT LIFTING, INJURIES IN

---

Weight lifting is performed by itself as a competitive sport and by athletes in other sports as part of training programs to increase muscle strength, endurance, and power. The high amount of resistance and repetitive movements in weight lifting can cause both acute and chronic injuries to muscle, tendon, and bone. The body parts most commonly injured by weight lifting include the shoulders, knees, and lumbar spine. Although serious injuries can occur, most weight lifting injuries are relatively minor.

General guidelines should be followed to decrease the risk of injury from weight lifting. As in any other sport, athletes should perform a proper warm-up before weight lifting. This can

Personal trainer demonstrates proper technique for squat exercise with barbells.

Source: David H. Lewis/iStockphoto.

include stretching, cardiovascular exercises, or performing several repetitions of lifting light weights with controlled movements.

Proper technique is also critical to minimize the risk of injury. A spotter should be used when appropriate. Young athletes should always be under direct supervision when lifting weights.

To avoid injuries from overtraining, adequate time should be given for muscle recovery. Performance-enhancing substances should be avoided. Specific injuries and prevention techniques are discussed in the sections that follow.

### Shoulder Injuries

The inherent instability of the glenohumeral joint combined with the high amount of weight used during exercises involving movements of the glenohumeral joint place soft tissues around the joint at risk of injury. Strains of the rotator cuff and deltoid muscles are common. Weight lifting exercises, such as front and lateral deltoid raises, and military presses that involve resisted overhead movements can place the athlete at risk for subacromial impingement.

In addition to the glenohumeral joint, the acromioclavicular joint is also stressed with repetitive overhead movements, dips, and bench press. Osteolysis of the distal clavicle joint is a relatively common condition in weight lifters.

Anterior shoulder structures, including the glenohumeral ligaments, are stressed during weight

lifting exercises where the arm moves beyond the body in the coronal plane. This movement occurs when performing a bench press, behind-the-head latissimus pull-down, pec deck machine, and dumbbell chest fly through a full range of motion. A back squat is an example of a lower extremity exercise that can also stress the shoulder joint as it places the shoulder in excessive horizontal abduction and extension. Athletes with glenohumeral joint laxity are predisposed to injury with these exercises.

A rupture of the pectoralis major muscle is an example of a traumatic upper extremity injury that can occur while weight lifting. Although it is not a common injury, the injury classically occurs while performing a bench press. Rupture of the pectoralis major insertion requires surgical repair.

### Shoulder Injury Prevention

Minor modifications to traditional weight lifting exercises can decrease the stresses on the shoulder joint that lead to the injuries discussed earlier. During the latissimus pull-down, the bar should always be lowered in front of, not behind, the head. A narrow grip during the latissimus pull-down and bench press will decrease stress on the anterior shoulder structures and acromioclavicular joint. Decreasing the range of motion with a bench press, cable fly, pec deck machine, and dumbbell chest fly so the arm stays anterior to the coronal plane of the body will also decrease stress on the anterior shoulder structures. When performing overhead movements, externally rotating the humerus will rotate the greater tuberosity and minimize the risk of subacromial impingement.

Maintaining proper muscle balance will also help decrease the risk of shoulder injury. Specifically, strengthening of the rotator cuff and scapulothoracic muscles is needed to avoid muscular imbalance, as most common weight lifting exercises strengthen the deltoid and anterior chest muscles.

### Knee Injuries

Anterior knee pain is a common complaint of weight lifters. Anterior knee pain can be caused by strain or injury to any of several structures, including the patellar tendon and patellofemoral joint. Patellofemoral joint stresses are high during deep knee flexion in weight bearing, such as squatting, leg press, and lunges, especially when the exercise is performed beyond 90° of knee flexion. Knee extensions strengthen the quadriceps in a

non-weight-bearing position. With this motion, the patellofemoral joint stresses increase as the knee extends beyond approximately 45°.

The menisci in the knee are also susceptible to injury during weight lifting. Acute and degenerative meniscal injuries can occur due to high loads on the tibiofemoral joint with the knee in a flexed position, such as during squats and lunges.

### Knee Injury Prevention

Avoiding deep squats and lunges (limiting knee flexion to less than 90°) will minimize stress on the patellofemoral joint and meniscus. Non-weight-bearing knee extension exercises should be performed from 90° to 45° of knee flexion to minimize patellofemoral joint stress.

### Lumbar Spine Injuries

Exercises that place excessive forces on the lumbar spine include squats and deadlifts. The most common injuries to the lumbar spine during weight lifting are muscle strains and stress injury or fracture to the pars intraarticularis (spondylolysis). Spondylolysis results from repeated hyperextension of the spine.

Athletes should maintain a neutral spine position whenever possible with all types of weight lifting exercises. Co-contraction of the multifidus with the deeper abdominal muscles (transverse abdominis, internal and external obliques) will stabilize the lumbar spine and avoid excessive forces from hyperflexion and hyperextension movements during weight lifting exercises. Excessive hyperextension during exercises such as military press, bench press, and squats should be avoided.

### Special Considerations

#### *Competitive Weight Lifting*

Competitive weight lifting consists of power lifting and Olympic weight lifting. Competitive power lifts include deadlifts, squats, and bench press. Olympic weight lifts consist of the clean and jerk and the snatch. Athletes in these two competitive weight lifting sports want to reach as high a one-repetition maximum as possible and often lift weights three to five times their body weight. This requires the athlete to generate extremely large muscle forces and high joint torques.

Injuries to the lumbar spine and knees are the most common in Olympic weight lifting, whereas injuries to the lumbar spine and shoulder are the most common in power lifting. When performing a squat, power lifters position the bar lower on their back and lean their trunk more forward, resulting in less ankle dorsiflexion and a more posterior hip position, ultimately leading to less knee extension torque and less risk of knee injury. In contrast, when weight lifters perform the snatch, they are in a position of deep knee flexion, which increases stress on the knee joint. Although the low bar squat position used by power lifters results in less stress to the knee joint, it does increase stress on the anterior shoulder structures.

#### *Youth and Weight Lifting*

Weight lifting can be safe and beneficial for pre-adolescents and adolescents. An appropriately designed program will improve muscle strength and have general health benefits. It will not have any adverse effects on growth or lead to any medical risk in an otherwise healthy child. The increases in muscular strength seen in preadolescents are likely due to neural gains (changes in motor unit activation and recruitment) rather than due to muscle hypertrophy.

Free weights, elastic bands, exercise machines, and body weight are all various modes of resistance that can be used. Body weight resistance exercise is beneficial to emphasize proper technique and incorporate core strength. If exercise machines are used, they must be sized appropriately.

A weight training program for youth should emphasize proper technique, which requires appropriate supervision. A low to moderate resistance level should be used, with a higher number of repetitions (2–3 sets, 8–15 repetitions). The program can be performed two to three times per week.

---

## WEIGHT LOSS FOR SPORTS

---

Weight loss is a reduction of the total body weight. This reduction is due to a mean loss of fluid, body fat, or adipose tissue and/or lean mass—namely, bone mineral deposits, muscle, tendon, and other connective tissue. Weight loss can be unintentional or intentional. Unintentional weight loss refers to the involuntary loss of weight secondary to genetics, some medical conditions, activities, or medications that decrease body mass. Intentional weight loss refers to the voluntary loss of total body mass in an effort to improve fitness, health, and/or appearance. Intentional weight loss in sports refers to the intentional loss of total body mass in an effort to improve fitness or athletic performance and/or to meet a sport-specific weight requirement. Weight loss occurs when an individual is in a state of negative energy balance. When the human body is spending more energy in work and heat than it is gaining from food or other nutritional supplements, it will use the stored reserves of fat or muscle. Although weight loss may involve loss of fat, muscle, or fluid, weight loss for the purposes of maintaining health should aim to lose fat while conserving muscle and fluid.

## Weight Loss Techniques

The most often recommended weight loss techniques are adjustments to eating patterns and increased physical activity. Other methods of losing weight include the use of drugs and supplements that decrease appetite, block fat absorption, increase metabolism, or reduce stomach volume. Finally, surgery may be used in case of morbid obesity.

### Dieting

One of the aspects of energy balance that affects body weight is energy intake. An examination of the weight loss literature shows that changes in energy intake play a significant role in reducing body weight. The currently available scientific evidence appears to indicate that the macronutrient content of the diet will affect body weight only when there is also a reduction in the total energy intake.

Athletes usually require a greater caloric intake than nonathletes. The actual energy intake (number of calories) depends on the athlete's body composition, weight, height, age, stage of growth, and level of fitness as well as the intensity, frequency, and duration of exercise activity. Athletes need to eat enough to cover the energy costs of daily living, growth, building and repairing muscle tissue, and participating in sports. Athletes need to be informed that weight is not an accurate indicator of body fat or lean muscle mass and that body composition measurements can be more helpful.

When athletes regularly restrict energy intake to less than 1,500 kilocalories per day (kcal/day; 1 kcal = 4,184 joules) for women and less than 1,800 kcal/day for men, they are at increased risk of poor nutritional intake. This level of energy intake is too low to meet the nutritional needs of the body and fuel the body for exercise, especially if physical activity is high.

Commercial programs recommend various combinations of macronutrient compositions for weight loss, including high-fat, high-protein, and high- and low-carbohydrate diets. Despite the popularity of many of these dietary approaches, the optimal macronutrient composition of the diet for weight loss has not been determined. Despite the different potential mechanisms for how changes in protein intake may affect weight loss, evidence from clinical trials supporting optimal protein and

carbohydrate intake for long-term weight loss and weight maintenance is lacking.

### *Exercise*

Scientific evidence suggests that the combination of dietary modification and exercise is the most effective behavioral approach for weight loss, and the maintenance of exercise may be one of the best predictors of long-term weight maintenance. Despite the importance of exercise, there is little evidence that suggests that exercise alone produces magnitudes of weight loss that are similar to what can be achieved with dietary modification. Also, when examining the effect of exercise on body weight, it has been suggested that there may be “responders” and “nonresponders” to the same exercise intervention. In general, daily guidelines for exercise are 60 to 90 minutes to prevent weight gain and over 90 minutes to maintain weight loss.

### *Behavior Modification for Weight Loss*

Behavior modification for weight loss means lifestyle changes to develop a long-term healthy eating plan and exercise program. There is evidence that including behavioral principles within a weight loss program improves long-term outcomes. Maintaining contact with participants long term improves long-term weight loss outcome, and this is considered an important component of behavioral weight loss programs. Another important component of behavioral weight loss programs is self-monitoring of eating and exercise behaviors. There is consistent evidence that individuals who self-monitor these behaviors are more successful at weight loss than those individuals who are inconsistent with self-monitoring. The use of portion control diets may also improve weight loss outcomes by minimizing choice and providing specific guidance to adults that precipitates weight loss.

### *Pharmacological Treatment*

All current guidelines consider pharmacotherapy to be an adjunct to lifestyle modification interventions and limit its use to patients with obesity or overweight patients with additional comorbidities (e.g., hypertension, dyslipidemia, or Type 2 diabetes).

Despite the interest in the potential use of pharmacotherapy for the management of body weight, there are few drugs approved for this use, and their safety and effectiveness have not been established for use beyond 2 years. Most available weight loss medications approved by the FDA are appetite-suppressant medications. These include sibutramine, phentermine, phendimetrazine, and diethylpropion. Appetite-suppressant medications promote weight loss by decreasing appetite or increasing the feeling of being full. These medications make the patients feel less hungry by increasing one or more brain chemicals that affect mood and appetite. Phentermine and sibutramine are the most commonly prescribed appetite suppressants in the United States. *Amphetamines are a type of appetite suppressant. However, amphetamines are not recommended for use in the treatment of obesity due to their strong potential for abuse and dependence.*

Another category of medication used for weight loss is orlistat. This medication reduces the body's ability to absorb dietary fat by about one third. It does this by blocking the enzyme lipase, which is responsible for breaking down dietary fat. When fat is not broken down, the body cannot absorb it, so it is eliminated, and fewer calories are taken in.

All weight loss agents should be used only under the direct supervision of a physician.

### **Pathologic Strategies and Health Concerns**

Pathologic weight loss strategies include any weight loss behaviors or actions that are potentially harmful to the athlete. These strategies include restrained eating, chronic dieting, bingeing and purging, skipping meals, fasting, excessive exercise, dehydration, and laxative, diuretic, and emetic abuse.

### *Nutritional Deficiencies*

To lose weight, athletes frequently restrict food intake by skipping meals, eliminating food groups, fasting, or eating only one to three foods a day. Severe energy restriction is especially a problem for female athletes, and this pattern can lead to the female athlete triad (amenorrhea, eating disorder, and osteoporosis). Female athletes typically need less energy than male athletes due to their smaller body size. In addition, even female athletes who are not dieting frequently have energy

and nutrient intakes that are below the recommended levels.

### *Disordered Eating*

For some athletes, chronic dieting to maintain a low body weight can be the first step toward developing a clinical eating disorder such as anorexia nervosa or bulimia nervosa. Persistent dietary restriction can lead to binge and purge eating. Bingeing includes consuming large quantities of food at one time, followed by purging through practices such as self-induced vomiting; the use of emetics, laxatives, or diuretics; and excessive exercise. Bingeing and purging are extremely dangerous practices that can lead to clinical eating disorders, tooth decay, poor performance, dehydration, and even death due to fluid and electrolyte imbalances.

### *Dehydration and Laxative Abuse*

Dehydration is a practice commonly used for rapid weight loss in athletes needing to “make weight.” One way of doing this is by exercising intensely in hot environments while wearing vapor-impermeable suits. Also, some athletes combine this activity with fluid restriction and the use of diuretics, emetics, and laxatives. This practice is extremely dangerous and has resulted in several documented deaths.

## WINDSURFING, INJURIES IN

---

Windsurfing is a challenging and exhilarating aquatic sport that has gained worldwide appeal fairly quickly, including its introduction as an Olympic sport in 1984. There is something for everyone in this sport, whether you are a recreational amateur, Olympic competitor, or Professional Windsurfing Association champion. Exercise, excitement, thrill, and challenge are among the stimuli to participate, while trauma, injury, and overexposure to the elements represent the downside. Knowledge of the sport, proper equipment, and windsurfing skills help ensure that the positive aspects of windsurfing are enjoyed and the risks are avoided.

Windsurfing is an ingenious combination of Hawaiian-style wave surfing and the more accessible sport of wind sailing. The marriage of a one-person sailboard and a one-person sail by means of a universal (polyaxial) joint brought the intuitive burst to reality. Wave surfers are no longer limited to the few locations worldwide where the “perfect wave” might appear and impart massive kinetic power to propel a surfboard. Rather, one can now harness the more ubiquitous power of the wind to propel a sailor through the water and waves. The inception of the windsurfer was a “Eureka moment.”

### Basic Equipment

The sport of windsurfing requires a sailboard commonly referred to as a windsurfer and a rig consisting of sail, mast, and boom. The rig is attached to the sailboard by means of a universal joint that allows the rig to be tilted, pivoted, or flipped into various positions. The sailboard provides the flotation on which the sailor stands, sails, steers, and maneuvers through the water and waves. The rig supports the sail, which captures the wind power and allows the sailor to transfer it to the sailboard. Adjustments in the positions of the rig and sail provide the means by which to steer the board and finely balance the amount of wind power transferred to the board. A fin provides lateral resistance and lift to the board. Sail power and fin allow the windsurfer to hydroplane, making it the fastest sailing vessel on the water, capable of attaining speeds of over 50 miles (mi; 1 mi = 1.60 kilometers) per hour.

The booms may be aided by hand, or a harness may be worn to allow the sailor to hook into the straps attached to the booms. This permits the sailor to balance sail power against body weight, removing the burden from the arms and freeing the sailor to make fine adjustments to sail position. Foot straps are affixed to most sailboards, allowing the sailor to anchor his or her feet to the board and more efficiently transfer wind power to the board. Foot straps not only prevent the windsurfer from being thrown (catapulted) from the board but also provide a potential mechanism for injury to the lower extremities because they lock the feet in place and can thereby cause twisting injuries to the ankles and knees. Ancillary equipment includes gloves, booties, harness, wet suit, life jacket, and helmet.

The length and volume of windsurfers vary according to the ability of the sailor, the type of sailing intended, and the conditions of wind and water. Novice sailors and low wind conditions require larger boards for greater flotation and moderate-sized sails, which allow greater control. Slalom and freestyle sailing are accomplished on smaller boards, which are faster and more maneuverable but more difficult to sail. High wind days and wave sailing require that the smallest boards and sails be used. Sailors must carefully assess the wind velocity, water conditions, and local topography and their own sailing abilities prior to selecting the equipment used on any given day. Too small a

board or rig on a low wind day may leave the sailor stalled or sunk (underpowered). Too large a board or rig on a high wind day may put the sailor in an uncontrollable situation, either blown off course or thrown about at the mercy of the wind and waves (overpowered).

### What Can Go Wrong?

For the most part, windsurfing is a safe and enjoyable endeavor. Even an unsuccessful day of windsurfing is typically a “good day at the beach” with sun, water, waves, companionship, and recreation. Potential problems with equipment, weather conditions, or sailing ability may lead to injury. Medical studies estimate that the rate of injury to windsurfers is approximately 1.5 per year, with the majority of injuries being minor. These would include strains, sprains, contusions, or bruises, which rarely require medical attention. An ill-equipped novice sailor may develop hand blisters if improper gloves are worn or scrapes and scratches if no protective booties are worn. While

Windsurfer in Dingle Peninsula, County Kerry, in Ireland. Most of the injuries common to windsurfing are minor and include strains, sprains, contusions, or bruises.

Source: Ingmar Wesemann/iStockphoto.

learning to manipulate the sailboard and rig into correct positions, there is an intuitive inclination to force one's equipment into position rather than use simple physics and wind power to do the work. These undue efforts produce backaches, muscle strains, joint sprains, and contusions, which constitute the garden-variety problems that heal quickly. Beginners can avoid many of these struggles and injuries by taking lessons from certified instructors, consulting instruction manuals, or viewing the many excellent instructional videos that are available. *Windsurfing Magazine* and windsurf.com are good sources of information.

There are potentially serious, and frankly dangerous, situations that may lead to severe physical harm. Extreme overexposure to environmental elements can occur if a sailor is incapable of upwind sailing and consequently is blown downwind and away from the intended destination. Sailors have been stranded out at sea or even lost entirely. Equipment failure and major alterations in wind velocity or direction can produce similar results, blowing a sailor drastically off course. Prolonged exposure to the elements may lead to severe sunburn, dehydration, exhaustion, hypothermia, or drowning. These potential dangers underscore the importance of knowing your local conditions, the prevailing winds, the weather forecast, and equipment maintenance. Solo sailing is a hazard, and it is a windsurfing maxim to be with a "buddy sailor" and to know the whereabouts of rescue boats or vehicles. "Never leave your board" is another important maxim since it serves as your flotation device and may be kicked or paddled for long distances. Ancillary equipment such as a Coast Guard-approved life jacket, a wet suit, gloves, sunglasses, and booties help protect from exposure. Waterproof radios are expensive but may be crucial to the solo sailor who has ventured off course or become stranded. It is imperative to stay with your board, avoid solo sailing, and know the universal "sign of distress" to alert others to your plight. This involves sitting on your sailboard and raising both hands straight overhead and crisscrossing them back and forth.

### Physical Injuries

Much of windsurfing's appeal is its overall safety. Being blown off course typically results in much

paddling and walking rather than dramatic rescues. Similarly, most falls, collisions, or mishaps lead to splashy and refreshing immersions into the water, followed by uphauling or water starting to get back on course.

As a sailor progresses in his or her abilities, there is typically the urge to seek more challenge and greater speed and perform stylized turns, and wave jumping. Freestyle sailing involves phenomenal loops, rolls, and other aerial acrobatics. Higher speeds, crowded races, and advanced aerial maneuvers create the circumstances that may cause severe high-energy injuries. These injuries most frequently involve the lower extremities, affecting the knee, ankle, and foot. The lower extremity is placed at higher risk because of the foot straps that lock the foot onto the board. While the foot strap gives the sailor greater control over the board, the converse is unfortunately also true. Just as a ski bound to the foot of a skier can impart greater leverage and injury to the leg of a skier, the foot strap can impart greater leverage of the board and rig to the lower extremity of the sailor. If uncontrolled leverage due to a fall, aborted turn, or poor landing from a jump is transmitted to the vulnerable lower extremity, ligamentous tears may occur to the foot, ankle, or knee. Further leverage will cause complete rupture of ligaments or fracture of bone. Lower extremity injuries reported among windsurfers include midfoot sprains and complete disruption of the tarsal bones of the foot, known as Lisfranc fractures. The collateral ligaments of the ankle or knee may be disrupted, or the anterior cruciate ligament of the knee may be torn. Knee injuries of this severity are commonly associated with a "popping" sensation rapidly followed by pain, swelling, and difficulty bearing weight. Immediate emergency treatment involves *rest*, *ice*, *elastic compression*, and *elevation* (RICE) followed by medical evaluation. Most sprains are partial tears and respond to rest, use of splints, and temporary use of a cane or crutches. Fractures, dislocations, or complete ligamentous disruption typically requires surgical treatment.

While most serious windsurfing injuries involve the lower extremity, other body parts are also at risk. The most common serious upper extremity injury is dislocation of the shoulder during high-velocity falls, catapults, or collision with other sailors. Chest wall contusions or rib fractures may

result from collision with one's booms. Head, neck, and spinal injuries also have been reported and are typically associated with high-energy aerial acrobatics, collision with other sailors, or direct contact with the sea bottom. These catastrophic injuries may lead to concussions, skull fractures, vertebral fractures, spinal cord injuries, or death. Prevention, caution, and head protection are the keys to avoiding these catastrophic injuries. Windsurfers must follow sailing's "rules of the road," which determine who has the right of way on the water when conditions are crowded. Riders must know both their abilities and their limitations. Winds too strong, waves too high, and waters too crowded must signal caution. While helmets are not everyday requirements, they are an absolute must for high winds, crowded racing conditions, and freestyle sailing. Whenever in doubt, it is always prudent to decide on the side of caution.

Last, whether you are on home territory or on an exotic windsurfing vacation, it is important to do a little preparatory work researching your destination. Fortunately, most windsurfing destinations provide resources describing the local conditions, such as prevailing winds, water depths, rock or coral formations, and temperature extremes. Local flora and fauna may also provide potential hazards, such as sea urchins, needle fish, jellyfish, sharks, or marine bacteria, which may cause infection of scrapes or puncture wounds.

## WOMEN'S HEALTH, EFFECTS OF EXERCISE ON

---

Cardiovascular disease (CVD) remains the leading cause of morbidity and premature mortality in

women in the United States and most industrialized countries and, more recently, contributes to the significant disease burden in the developing nations. The prevalence of obesity and inactivity among Americans continues to rise. Exercise, for the physiologic reasons discussed below, has a beneficial effect in both preventing CVD among women and treating it once it occurs. Inactivity is also associated with multiple other cardiovascular risk factors, including obesity, diabetes, and hypertension. Furthermore, beyond its widely touted promotion of cardiovascular health among women, exercise has been shown to have multiple beneficial effects on other aspects of women's health. Among women, exercise has been shown to decrease the risk of colon and breast cancer, decrease the risk of osteoporosis, and boost cognitive and psychological well-being. In considering the myriad beneficial effects of exercise among women, it should be noted that these are independent of diet and weight loss.

### Cardiovascular Adaptation to Exercise Training

Typical cardiovascular adaptations to regular aerobic physical training include lowered blood pressure and heart rate, mild increases in the dimensions of the heart cavity, augmentation of the amount of blood pumped by the heart, as well as increases in heart muscle mass. In addition to the structural changes that occur with training, changes in heart physiology also occur. These include an enhanced pumping and relaxation function of the right and left ventricles, the heart chambers that pump blood to the lungs and the aorta, as well as an increase in the amount of oxygen consumed by the body, known as the  $\dot{V}O_2\text{max}$ .  $\dot{V}O_2\text{max}$  is widely considered to be the gold standard metric for cardiovascular fitness.

While the majority of cardiovascular adaptations to training are similar between men and women, unique cardiovascular adaptations to exercise in women have been described. While both men and women exhibit increases in their heart chamber sizes and muscle mass, the body surface-adjusted increases in mass are not as substantial in women as in men. In addition, females exhibit lower  $\dot{V}O_2\text{max}$  compared with males, likely due to lower myocardial mass.

Additional physiologic differences between men and women may contribute to the improvement in  $\dot{V}O_2$ max observed with regular physical exercise. While the mechanism of increased  $\dot{V}O_2$ max in men appears largely due to increases in the volume of blood pumped by the heart, in women, the improvement appears to be related to the increased extraction of oxygen from muscle at the cellular level.

### The Role of Exercise in the Reduction of Cardiovascular Risk Factors

Regular physical exercise is of great value in reducing established cardiovascular risk factors, including obesity, diabetes mellitus, and hypertension. In addition, there are a multitude of beneficial cardiovascular effects of regular physical exercise that result in physiologic, psychological, as well as biochemical improvements, all of which lead to a reduction in overall cardiovascular risk. These changes include reduction in the likelihood of obesity, improved blood pressure control in hypertensive individuals, reduction in serum cholesterol, decreased insulin resistance and other markers of inflammation, improved function and less stiffening of the large and small blood vessels, and reduction in the risk of pathologic blood clots. In contrast, physical inactivity and poor physical fitness are associated with a potentially harmful blood-clotting profile in middle-aged women with coronary heart disease.

Many women with multiple risk factors for heart disease are able to manage their risk factors through diet and exercise alone. For those women who require medical therapy to treat high cholesterol and high blood pressure, regular aerobic exercise provides an additional benefit.

### Exercise in the Patient With Established CVD

CVD includes disease of the arteries of the heart, such as coronary artery disease (CAD), high blood pressure (hypertension; HTN), peripheral arterial disease (PAD), cerebrovascular disease, rhythm disturbances, diseases of the heart valves, and disorders of the small blood vessel not associated with actual blockages (small vessel disease). This entity of small vessel disease appears to be more common in women than men.

Exercise training is a significant component of rehabilitation of individuals who survive a heart

attack (myocardial infarction; MI). Gradual, supervised regular physical exercise in survivors of MI not only introduces a healthy lifestyle habit to a potentially sedentary group but also enhances recovery from MI. Many of the benefits of exercise in this group include those described earlier but also include the psychological benefits afforded by regular physical activity. This is of particular value in this group due to the high prevalence of depression in survivors of MI and individuals who have undergone coronary artery bypass grafting. Female survivors of heart attack are much less likely than their male counterparts to participate in cardiac rehabilitation and currently miss out on the multiple beneficial aspects of this highly valuable but optional component of cardiovascular care.

The potential benefit of regular exercise in patients with PAD has also been demonstrated. A study examining the benefit of regular exercise in 118 patients with PAD demonstrated lower likelihood that the individuals who exercised would experience or die from a cardiovascular complication over the 5 years of follow-up.

Exercise can also lead to benefits among women with heart failure. Heart failure occurs when the heart can either not pump or not relax efficiently enough to deliver adequate blood supply to the body. Unfortunately, heart failure has reached epidemic proportions in the United States. Heart failure associated with abnormal heart relaxation (diastolic dysfunction) is common in women, particularly women over the age of 65. There is preliminary evidence available to suggest that regular physical activity not only treats the diastolic dysfunction but also treats the conditions that may be responsible for its presence in the first place, including obesity, high blood pressure, and diabetes. A recent large study examined regular aerobic exercise in men and women with reduced pumping function of the heart. This study found that regular aerobic physical activity leads to reductions in hospitalizations for heart failure and was not dangerous in this group of patients.

### Exercise and Other Aspects of Women's Health

In addition to its beneficial effects on cardiovascular health, exercise has been shown to confer myriad other health benefits among women.

Exercise increases bone mineral density and, thus, prevents osteoporosis. Increased leisure-time activity, such as walking, has been shown to reduce the risk of hip fracture among postmenopausal women. It is worth noting that the beneficial effects of exercise may stem more from muscle strength, resistance, and balance training than from the intensity of the exercise itself. Furthermore, caution should be used in blanket recommendations to elderly women to exercise, as vigorous exercise among elderly patients may predispose them to the risk of falls and, thus, increase the risk of fracture.

In the realm of exercise and cancer, women who engage in regular physical activity have been shown to have a decreased risk of both colon and breast cancer. For women diagnosed with breast cancer, exercise has been shown to improve survival. As far as cancer risk is concerned, it is not entirely clear how much exercise confers risk reduction or at what stage of life. For breast cancer, it is postulated that exercise achieves this effect in women via reduction in adipose tissue and, thus, decreased overall estrogen production.

Finally, exercise has been shown to have numerous beneficial effects for women in terms of psychological well-being and cognitive function. Exercise has been shown to have utility in the treatment of major depressive disorder, with a dose-response effect, meaning that a certain level of exercise was necessary to achieve this response. Among women with premenstrual syndrome, exercise also seems to have a beneficial effect on both physiologic and psychological symptoms. Also for women with postpartum depression, a regular exercise program (three times per week) seems to mitigate depressive symptoms. Finally, among elderly women, a recent trial showed that a 6-month exercise intervention was associated with a modest improvement in cognitive function.

### How Much and When?

Questions invariably arise when discussing the effects of exercise on women's health, namely, how much is exercise is enough and at what stage in life. These questions are difficult to assess because, as discussed earlier, exercise is associated with multiple different health benefits for women and each one may be associated with a different amount of exercise, at various stages of life. Thus,

these questions continue to be investigated. For now, basic recommendations by the Centers for Disease Control and Prevention as well as the American College of Sports Medicine exist, suggesting at least 30 minutes of moderate-intensity physical activity on most days of the week. Indeed, a recent study following both men and women between the ages 50 and 71 years over time found that adherence to these guidelines, namely, engaging in moderately intense physical activity greater than 3 hours/week, led to a risk reduction of 27% in death from any cause among women in this age-group. This reduced risk was independent of other cardiovascular risk factors and body mass index.

Though these recommendations for a minimal amount of exercise exist, this does not mean that more exercise is not additionally beneficial. Again, the type of exercise, its intensity, and the age of greatest benefit depend on what outcome is being assessed. A recent prospective analysis among elderly women suggests that women who had previously had a sedentary lifestyle and began exercising after 65 years of age had reduced mortality.

Specifically, those women who increased their physical activity levels to a calorie expenditure equivalent to 1 mile (1.60 kilometers) per day of walking from their initial routine, to a follow-up 6 years later, had a reduction in cardiovascular mortality, cancer, and all-cause mortality. This benefit was not seen among women who began exercising after 75 years of age. Women who were consistently active, both before and after the 6-year intervention, had a similar risk reduction to those who only began exercising when the study began. Interestingly, recent physical activity levels were a better predictor of longevity than past. Another study, looking at 40,000 women, showed not only that there is a direct association between physical activity and decreased mortality but that the greatest benefit was seen among women who go from a sedentary lifestyle to one involving moderate physical activity.

### Conclusions and Future Directions

In sum, exercise confers multiple health benefits for women. In the realm of cardiovascular health, exercise both prevents disease and improves outcomes among women with existing CVD. Exercise also has a role in mitigating cardiovascular risk factors, including hypertension, diabetes, and obesity.

Outside cardiovascular health, exercise has been shown to reduce the risk of osteoporosis, cancer, depression, and cognitive decline. Active investigation continues into optimal exercise regimens for women to achieve these health benefits, though research to date suggests that a clear health benefit occurs for most women who begin exercising, even if they have been inactive in the past.

## WORLD ANTI-DOPING AGENCY

---

The World Anti-Doping Agency (WADA) is a private Swiss law foundation, founded in 1999, responsible for ensuring fair competition in sports around the world. Its mission is to promote, coordinate, and monitor the fight against doping in all its forms. The WADA Code provides the basic framework for the agency's work, that is, "to protect the athlete's fundamental right to participate in doping-free sport and thus promote health, fairness, and equality for athletes worldwide." The objectives of the agency are to preserve the integrity and value of sports and youth, actively promote the "level playing field" philosophy, and act independently, professionally, and without bias or influence.

WADA is composed and funded equally by the Olympic movement and governments of the world. It is situated in Lausanne, Switzerland, and has its headquarters in Montreal, Canada. In 1999, the International Olympic Committee (IOC) held the first World Doping Conference in Sport in Switzerland. It was attended by the sports movement and representatives of several governments in

an effort to establish an organized and cohesive plan to control a growing, complex problem in the world of competitive sports. There were several important results of this conference, including the establishment of the World Anti-Doping Code (the Code), the International Convention Against Doping in Sport (the Convention), and the Copenhagen Declaration on Anti-Doping in Sport (the Declaration).

Because many governments cannot be legally bound by a nongovernmental document such as the WADA Code, the International Convention was drafted under the auspices of UNESCO (United Nations Educational, Scientific and Cultural Organization), the body responsible for education, science, and culture. The Convention was unanimously adopted at the 33rd UNESCO General Conference in 2005. Separately, the Copenhagen Declaration was finalized at the World Conference on Doping in Sport in 2005. This declaration is the political document that signals a government's intention to formally recognize and implement the Code. As of 2007, 192 countries have signed the Declaration, and 80 UNESCO member states have become part of the Convention. In addition, more than 570 sports organizations have adopted the Code.

WADA is made up of a Foundation Board, an Executive Committee, and several other committees. The Foundation Board and Executive Committee comprise equally members of the Olympic Movement and governments. Government representation is allocated according to the five Olympic regions: Africa, Asia, the Americas, Europe, and Oceania (Australia and New Zealand). The Foundation Board has 38 members and is the agency's supreme decision-making body. The board delegates the management and running of the agency, including the performance of activities and the administration of assets, to the Executive Committee. Other committees such as the Athletic Committee or the Health, Medical and Research Committee act as advisors and provide guidance for WADA programs.

WADA received \$18.3 million from the Olympic Movement to fund its first 2 years. Since 2002, funding was sourced equally from the Olympic Movement and the governments of the world. The governments agreed to a regional formula, and within each region, governments agree internally to each of their individual shares.

WADA prioritizes its work to focus on seven areas emanating from the Code.

1. *Code adoption, implementation, and compliance:* The agency ensures that sports and government agencies accept the principles of the Code. It assists in organizing a systematic testing process and ensures adjudication of results.
2. *Science and medicine:* WADA promotes global research to stay current on doping substances and methods. In addition, it maintains the annual List of Prohibited Substances and Methods, accredits antidoping labs worldwide, and monitors "therapeutic use exemptions."
3. *Antidoping coordination:* The Anti-Doping Development Management System (ADAMS) is the web-based database management system in place to assist stakeholders in coordination and compliance.
4. *Antidoping development:* The agency facilitates coordination of activities in regions where there are limited antidoping activities, so that resources can be pooled.
5. *Education:* WADA coordinates effective strategies and education to assist stakeholders in their education programs.
6. *Athlete outreach:* Antidoping experts take every opportunity, including one-on-one interaction at sporting events, to answer questions and educate athletes and stakeholders about the dangers and consequences of doping.
7. *Out-of-competition testing:* The agency contracts with stakeholders to help fulfill their responsibility for "no-notice out-of-competition" testing.

The Prohibited Substances and Methods list, as well as many other resources for athletes and stakeholders, is available on the WADA website and is updated annually ([www.WADA-ama.org](http://www.WADA-ama.org)). The general categories of banned substances include androgenic anabolic steroids and other anabolic agents, hormones (e.g., growth hormone, erythropoietin, and insulin), hormone antagonists and modulators, beta-2 agonists, diuretics, and masking agents. Gene doping is specifically prohibited as well, although at this time, there is no reliable

testing for this. Blood doping and other methods to enhance oxygen transfer are prohibited.

There is a process, of course, to ensure that an athlete who needs a substance that could be considered a doping agent for medical reasons, such as insulin or albuterol, can use it in a medically responsible way to treat an illness or condition. A Therapeutic Use Exemption (TUE) application is submitted to the athlete's local sports federation for review by a panel of independent physicians, called a Therapeutic Use Exemption Committee (TUEC). Preapproval, with possible monitoring of medication levels, is determined by the local federation. WADA does not accept TUE applications, but it has the power to overturn an exemption that has been granted or overturn a denial if it is determined that international standards were not followed.

There are three basic criteria to determine if an athlete will be granted a TUE: (1) the athlete would experience significant health problems without taking the prohibited substance or method; (2) the therapeutic use of the substance would not produce significant enhancement of performance; and (3) there is no reasonable therapeutic alternative to the use of the otherwise prohibited substance or method.

The problem of doping is an extremely complex one, often with enormous financial, political, and cultural implications. WADA has created an intricate system with checks and balances, as well as international representation to work for and protect athletes and sporting events, large and small, around the world.

*Michael O'Brien*

## WRESTLING, INJURIES IN

---

Wrestling is a sport in which the clinician faces many unique challenges. A strong knowledge of infectious skin diseases and issues related to weight control is imperative for anyone concerned with

this sport. Many common sports medicine injuries will be encountered in wrestling. One common injury definitively seen in wrestling is concussion.

### Concussion

Concussion is defined as any impact to the head or to the trunk, chest, or neck that radiates force to the head. It is often believed that concussion needs to have loss of consciousness or amnesia associated with it, but this is not the case. Although common, these symptoms do not necessarily need to be present. Concussion is characterized by a spectrum of symptoms, including but not limited to headache, dizziness, nausea, vomiting, confusion, cognitive difficulties, and balance disturbances. These symptoms occur quickly after impact, are neurological in nature, and generally abate spontaneously over time. For an athlete experiencing symptoms, a complete physical examination, including a thorough neurological and mental status examination, should be performed. Diagnostically, a computed tomography (CT) scan or magnetic resonance imaging (MRI) scan is ordered by physicians to rule out further pathology, such as bleeding within the brain. Concussion is treated symptomatically. Only when an athlete is symptom-free, is not taking any medicines for symptom control, and has normal mentation can he or she be placed on a return-to-sport protocol. A symptomatic wrestler is never allowed to return to his sport.

### Auricular Hematoma (Cauliflower Ear)

An auricular hematoma occurs from trauma to the cartilaginous portion of the ear. In this area, blood collects between the skin and cartilage. If not treated in a timely manner, the deformity to the ear can become permanent. Treatment is via aspiration of the blood before it clots and application of a pressure dressing or other device to avoid further bleeding and accumulation of blood.

### Epistaxis (Nosebleed)

A nosebleed occurs most often when there is breaking of the small vessels at the front of the nose due to trauma. Quite often, wrestlers are prone to recurrent nosebleeds because of continued trauma to the nose. It is important to try to stop the bleeding as quickly as possible. This is done by tilting the head

forward and pinching the nostrils until the blood stops. A cotton plug or dental gauze placed in the nose can continue to hold pressure so that a wrestler can finish the match. If the bleeding becomes recurrent, then cauterization of the nasal vessels can often lead to permanent relief of the symptoms.

### Sprains and Strains

A sprain refers to an injury to a ligament where it is stretched or, in the worst case, completely torn. A strain refers to an injury to a tendon or muscle where it is “pulled” or partially torn. Sprains and strains can happen to any joint in the body and are common in wrestling due to the consistent contact between the wrestlers and the contact of the athletes with the mat surface. They are characterized by pain, swelling, redness, loss of motion, and loss of strength at a joint. During competition, sprains and strains can be treated by the PRICES protocol, which refers to *protection* of the joint, *rest*, *ice*, *compression*, *elevation*, and *support* of the joint. Once a more severe injury is ruled out by either physical examination by a physician or further radiological studies, physical therapy, taping/bracing, and anti-inflammatory medications are used to try to treat these conditions. Unfortunately, many complete sprains, such as those of the anterior cruciate ligament, or tendon/muscle tears, such as that of the patella tendon, require surgical intervention to reestablish proper functioning of the affected joint.

### Fractures

A fracture is a medical condition in which there is a break in the bone. It can happen to any bone in the body. In wrestlers, the bones that are frequently fractured are the nasal bones, the bones of the fingers or toes, and those of the wrist and ankle, though other bones may also undergo fracture. Fractures are identified by pain, swelling, bruising, and redness at a fracture site. Physicians are suspicious of a fracture if there is pain directly on a bone or if they can feel a break, or step-off, in the outer covering of the bone, or cortex, when they follow the smooth contour of a bone. There is also a loss of motion or strength if a joint is involved. In general, suspected fractures are splinted or braced at the site of competition, ice is applied, and the athlete is sent for confirmation of the fracture. X-rays, MRI, CT, or bone scan can confirm fracture in a wrestler. Fractures are treated

by splinting or casting to allow bone alignment for healing. For those fractures whose alignment cannot be maintained by splinting or casting, surgery is necessary to insert hardware to keep the bone ends together in order to allow the fracture to heal.

### Cervical Strain (Neck Strain) and Lumbar Strain (Back Strain)

This injury occurs when there is a strain or injury to the muscles of the neck/back, usually during a takedown or bridging. It is characterized by pain and sometimes spasm of the muscles that line the spinal column. As long as there is no injury to the spinal cord or column, this injury usually heals without much difficulty. Treatment is icing and anti-inflammatory medications to the neck/back as well as physical therapy to the neck/back muscles to stretch and strengthen them.

### Dislocated Shoulder

This injury occurs when the humeral head, or top of the arm bone, becomes separated from the glenoid, or shoulder bone. There is often pain deep within the shoulder and possibly numbness down the arm on the same side. One can often see the top of the humerus, either in front or behind the glenoid. When this occurs, it is important to be sure that the athlete has normal neurovascular status and absence of obvious fracture before even considering reducing or putting the shoulder back in place. If there is no qualified person available, the arm should be splinted and the athlete sent to the hospital for reduction. An X-ray at the hospital can then aid in determining the position of the humerus, rule out fracture, and assist in the reduction. Once reduced, the shoulder is checked for further pathology with an MR arthrogram. If there is no further pathology, physical therapy should bring the shoulder back to normal function. If there is further pathology, often surgery is performed to repair the damaged soft tissue structures and prevent another episode of dislocation.

### Acromioclavicular (AC) Separation (Separated Shoulder)

This occurs when a wrestler lands directly on his or her shoulder, usually during a takedown. This results in a sprain of the ligament between the

acromium, or shoulder bone, and the clavicle, or collarbone. This is often demonstrated by the clavicle being elevated above the acromium. An X-ray can confirm this. This injury often responds well to physical therapy and usually does not require surgical intervention.

### **Brachial Plexopathy (Burner or Stinger)**

This injury occurs when the neck is forcibly side bent as the shoulder on the same side of the body is depressed, causing a stretch of the brachial plexus, the site where the nerves that innervate the upper extremity on the affected side exit out the neck and through the shoulder area. This can happen when a wrestler is forcibly taken to the mat. The wrestler usually complains of burning pain from the base of the neck through the entirety of the affected extremity. The condition usually lasts seconds with an initial episode but takes longer to resolve after each successive episode. The pain usually resolves on its own in several seconds to several minutes depending on the number of past episodes a wrestler has endured. There is generally no work-up done by the physician unless the condition becomes chronic. In this case, X-rays are ordered to look for bony structural issues that may be causing the injury. These may be followed by MRI or CT scan to further evaluate both bony and soft tissue structures to determine if there is an anatomical reason for the injury and to determine whether the wrestler should be removed from the sport because of the danger of neurological damage from repetitive injury due to his or her anatomy. Initial stingers are usually returned to play once the symptoms have resolved. Those who have repetitive episodes will need further examination to make sure that anatomy is not contributing to the injury and usually undergo a cervical stretching and strengthening program to prevent further injury.

### **Ulnar Collateral Ligament Sprain of the Elbow**

The elbow is essentially a hinge joint made from the coming together of the radius and ulna (the two smaller forearm bones and the larger humerus, or upper arm bone). Wrestlers typically suffer injury to the ulnar collateral ligament of the elbow, which is the ligament connecting the ulna and

humerus, when posting after a takedown or during an arm chop when the wrestler is beginning on the bottom position. Both these maneuvers can lead to stress on this ligament and a possible stretch, sprain, or tearing of the ligament. The physician can check the integrity of the ligament by putting force on it. If moves and “gaps” are more than on the opposite side, there is concern for a sprain or tear. An X-ray can determine if this is due to fracture. MRI can show the extent of damage to the ligament. A complete tear would require surgical repair in a wrestler. A sprain would require possibly bracing to let the ligament begin to heal, followed by physical therapy to regain normal elbow function.

### **Ulnar Collateral Ligament Tear of the Thumb (Gamekeeper’s Thumb)**

This injury occurs when the thumb is abducted or forced away from the rest of the hand. This movement may sprain or tear the ulnar collateral ligament that connects the proximal phalanx of the thumb to the first metacarpal. Wrestlers with this injury cannot oppose the thumb. An X-ray can rule out fracture at the joint. MRI can show damage to this ligament. Treatment involves casting or splinting of the thumb for sprains and surgery for complete tears.

### **Back Pain**

Back pain in wrestling is usually due to a muscle strain or “pulled muscle” during competition. Some forms of back pain in wrestling are not due to muscle strain. One such cause is herniation of a vertebral disk. Disk herniation occurs when the soft jelly-like part of the disk escapes through a tear in the annulus fibrosis, which is the tougher covering of the disk. When radicular symptoms, pain or numbness occurring in either lower extremity or both, are present, the pain may be due to a herniated disk causing stenosis or pressure on the nerve that innervates that particular lower extremity. A less common cause of back pain sometimes found in wrestling is a spondylolysis, or stress fracture of the pars portion of the vertebra. This can occur due to the consistent flexion and extension of the back while wrestling. Physical examination, X-rays, MRI/CT scans, and bone scans can often

elucidate which of these conditions is causing the back pain. Muscle strains, herniated disks (with and without stenosis), and annular tears are usually treated conservatively with rest, icing, physical therapy, and anti-inflammatory medications. Epidural injections, injection of cortisone at the area of disk herniation, or surgery, may be needed if pain cannot be treated conservatively. Return to sports is usually guided by pain tolerance in the wrestler unless neurological symptoms occur. Spondylolysis treatment is more controversial. Many physicians recommend physical therapy and return to sports when painfree. Others recommend bracing followed by physical therapy and then return to sports. There is no consensus on treatment for this condition.

### **Trunk Pain**

Pain in the area of the trunk is common in wrestling. This is often caused by movements in which one wrestler grasps the other wrestler, trying to expose his or her back. Pain in the rib area can be due to rib fracture or due to a strain of the small muscles between the ribs, the intercostals. It can also be due to strain of any of the abdominal muscles. Symptoms of rib fracture or muscle strains in the trunk can include pain at the site of injury, pain with movement, or difficulty breathing. With pain, an immediate physical examination should be performed, including listening to the lungs, to be sure that a fractured rib has not pierced a lung, creating a pneumothorax. X-rays are diagnostic of rib fractures. Treatment for rib fractures as well as strains includes rest, icing, medications for relief and pain, and physical therapy. Return to wrestling after a rib fracture is allowed when the fracture has healed, to avoid pneumothorax. Pain is the guide for wrestlers with simple strains.

### **Groin Strain (Groin Pull)**

A strain of the muscles of the groin can occur in an area where the external rotators or flexors of the hip are located. This injury is characterized by movement in these planes. These injuries are usually self-limiting but can take several weeks to heal. Treatment is usually with rest, icing, anti-inflammatory medicines, and rehabilitation.

### **Knee Meniscal Tear**

The meniscus is the shock absorber found between the femur, or upper leg bone, and tibia, or lower leg bone. There is one on the inside of the knee, or medial, and one on the outside, or lateral. Meniscal tearing occurs during a plant-and-twist injury, such as getting a foot caught in the mat when the wrestler is attempting to escape his or her opponent. Wrestlers often report feeling or hearing a “pop” or “tear.” This is often accompanied by swelling within the knee and pain at the knee joint line. Often, it is difficult to walk on the affected leg. Physicians can test the affected meniscus for tearing by performing the McMurray test. In this test, the physician attempts to catch a piece of the damaged meniscus between the femur and tibia by manipulating the knee. X-rays cannot reveal a meniscal tear. An MRI test usually can detect meniscal tears. Meniscal tears are treated usually by surgery to either repair the damaged meniscus, if good blood supply is present, or remove the damaged part of the meniscus in a procedure called a partial meniscectomy. Surgery is usually followed by physical therapy. Meniscal tearing that does not produce symptoms can also be treated by physical therapy with or without cortisone injection.

### **Patella Dislocation/Subluxation**

The patella is also called the kneecap. It sits in the groove of the femur, or top leg bone, and aids in extension of the knee. It is stabilized at the top of the bone by the quadriceps tendon and on the bottom by the patellar tendon. With certain moves, the patella can reach the edge of the groove and almost slide over it, referred to as a subluxation. If the kneecap does in fact pass over the groove, it is referred to as a dislocation. The kneecap often moves laterally, or to the outside of the leg, with this movement. Patients often complain of hearing a “pop,” have immediate pain and swelling at the knee, and may visualize the kneecap on the outside of the femoral groove. Often, the kneecap will go back into place as the wrestler moves secondary to the pain he or she has from the displacement of the kneecap. If it does not go back into place on its own, the kneecap is often stabilized with an immobilizer or a brace. The physician usually performs an Apprehension Test, where he or she places

outside stress on the kneecap to see if the symptoms of kneecap subluxation/dislocation can be mimicked. X-rays are often taken to ensure that there is no fracture, and the physician will manipulate the kneecap back into place. This may be followed by an MRI test to be sure that there is no subtle fracture that was missed by the X-ray or that there is no tearing of important soft tissue structures holding the kneecap in place. Surgery may be necessary to repair these tissues. Physical therapy is then done to maximize function and strength, either after surgery or in the absence of soft tissue damage after a patella dislocation.

### Prepatellar Bursitis

The patella has a fluid-filled sac, called a bursa, between it and the underlying soft tissue. This bursa is necessary to allow the soft tissue structures above the patella to pass over the bone without causing injury. In competition, wrestlers often land directly on their knees, causing a compressing force on the bursa as it is trapped between the bone and the mat surface. This can lead to an inflammation of the bursa or bursitis. The hallmark of a prepatellar bursitis is swelling just above the patella. The swelling feels like a fluid-filled sack and renders the knee painful when one tries to kneel on the affected knee. There are usually no tests used to diagnose this problem as its appearance itself is diagnostic. Often, the bursal fluid will recede on its own. If the fluid does not recede on its own, it can be aspirated by a physician. Once recovered, the wrestler can return to competition. If the bursa becomes infected, the condition is called a septic bursitis. Antibiotics are usually given to the athlete to treat the infection, and aspiration is delayed until the infection has cleared.

### Ankle Sprain

An ankle sprain is caused when the foot either turns out (or everts) or turns in (or inverts) during activity as the body weight passes over it. The athlete at the time of the sprain sometimes hears a “pop” followed by immediate pain and swelling in the affected area of the ankle. Walking, or ambulation, is often difficult, and crutches must sometimes be used. Once an ankle sprain occurs, the ankle is usually immobilized and iced immediately.

The physician usually checks range of motion and strength to assess damage to the joint. Certain tests, such as the Anterior Drawer Test or Tilt Test, check the integrity of the ligaments after a sprain. X-rays are often ordered to rule out associated fractures. Weight-bearing X-rays may be performed to be sure that the bones of the ankle have retained their alignment or have held together the functioning unit of the ankle, called the *mortise*. MRI may be necessary to look at the soft tissue damage more intently or determine if there has been damage to the ligaments or soft tissue between the tibia and fibula that may necessitate early surgical intervention. Simple ankle sprains are generally treated with protection, rest, ice, compression, elevation, and support. Physical therapy is usually necessary to restore movement and function.

### First Metatarsal Sprain (Turf Toe)

This condition refers to a sprain of the collateral ligaments—or ligaments that connect the two sides of a joint—that connect the first metatarsal, or last foot bone, to the proximal phalanx, or first toe bone. The condition gets its name commonly from football, where the first toe can be sprained when it gets caught in the artificial turf during play. The principle is the same in this case, as the toe gets caught in the mat and sprains the joint. The athlete commonly complains of loss of motion and/or strength, pain, swelling, and possibly redness at the site. After the physician checks motion and strength, X-rays may be obtained to be sure that there is no underlying fracture at the joint. If there is no fracture, treatment consists of applying ice to the joint, therapeutic taping, physical therapy, and sometimes shoe modification to make the sole of the wrestling shoe stiffer in order to keep the toe straight. Pain is usually the limiting factor for the athlete’s return to play.

## WRIST DISLOCATION

---

The wrist joint serves as a link between the hands and the upper body, and a great deal of force is transmitted through this joint. The specific arrangement of bones and the presence of ligaments provide flexibility to the joint. Although this flexibility helps in the movement of our hands and fingers, it also allows for dislocation.

*Wrist dislocation* means that the wrist bones have been knocked out of position or a bone has come out of place in the wrist joint. It is sometimes also referred to as carpal dislocation. Such an injury is common among athletes. It is usually experienced in sports with increased force vectors (height and speed), for example, adult inline skaters and football players. Other cases include falls from a height, as seen, for example, in gymnasts.

The most common cause of injury is high energy, but low-energy trauma has also been described as the cause of carpal dislocation in some reports.

Wrist dislocation is a serious injury and requires immediate emergency care. In a study by Larsen and Lauritsen, as many as 2.5% of all cases presented in various emergency departments of the United States are wrist injuries. Ten percent of all carpal injuries are subluxations and dislocations, perilunate dislocation being the most common type.

The initial evaluation and treatment of wrist injuries can be performed by emergency physicians and/or family practitioners. Early recognition of a

dislocation and determination of proper treatment can prevent complications, including prolonged pain, discomfort, and surgery, and time lost from sports participation.

### Anatomy

The wrist comprises 10 bones: 8 of these are the carpal bones, and the remaining 2 are (lower ends of) the forearm bones (see Figure 1).

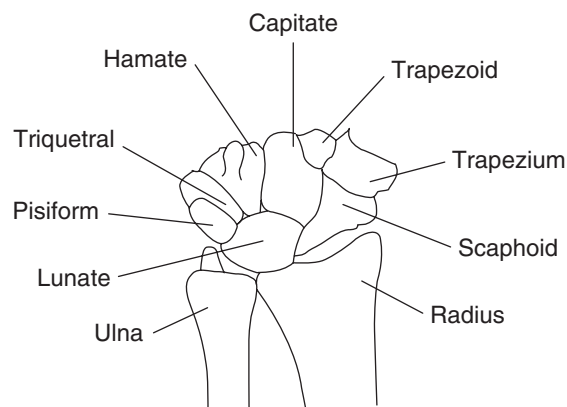

The carpal bones are arranged in two rows and include the scaphoid, lunate, triquetrum, and pisiform in one row and the trapezium, trapezoid, capitate, and hamate in the other. The forearm bones are the radius and the ulna.

A complex set of ligaments holds the carpal bones together and assists in movement. These ligaments are named according to the bones they hold together. Dorsal ligaments are weaker than other ligaments; making this side of the joint more vulnerable to dislocations.

### Types of Wrist Dislocation

Wrist dislocations can be divided into two types:

*Perilunate dislocations:* The lunate remains aligned with the radius, but the capitate dislocates. It is more common than lunate dislocation as the radial-lunate ligaments are stronger than the lunate-capitate ligaments. Seventy-five percent of the cases are associated with scaphoid fractures (known as trans-scaphoid perilunate dislocation).

**Figure 1** Bones of the Wrist Joint

*Lunate dislocations:* In these, the lunate bone dislocates, and the other carpal bones remain in alignment. This type of dislocation is less common than perilunate dislocation.

### Causes

Wrist dislocation can occur as a result of either of two causes:

1. *Repetitive activity:* Repeated stress on the carpal ligaments renders them more prone to injury, especially in athletes. In some cases, the overuse may be so great that the wrist bones slip.
2. *Trauma:* Sudden extreme pulling or stretching of the ligaments or a severe blow to the bones, commonly due to falling on an outstretched arm, can result in dislocation. This type of dislocation most commonly involves displacement of the lunate bone, but other bones of the wrist can also be involved.

### Stages of Dislocation

Mayfield and coworkers have classified wrist dislocation into four stages:

*Stage I:* Scapho-lunate dislocation due to a tear in the ligaments holding these bones together

*Stage II:* Lunate-capitate subluxation that results from injury to the capito-lunate joint

*Stage III:* Lunate-triquetral dislocation resulting from injury to the ligament

*Stage IV:* Lunate dislocation resulting from injury to the dorsal radio-lunate ligament (the ligament that holds the lunate against the radius)

### Clinical Evaluation

The evaluation of a wrist dislocation begins with a history and physical exam.

#### History

The typical history is one of a person who attempts to brace for a fall. The force of the body landing on the palm results in a dislocation. Sometimes athletes can dislocate their wrist on

falling on an outstretched hand when they have mistimed a landing, as in gymnastics. Wrist dislocation is also seen in football, where defenders try to stop oncoming forces with resistance. Often the resistance is great enough to lead to a wrist dislocation.

#### Physical Examination

On physical examination, the following signs and symptoms are observed in a case of wrist dislocation:

- Extreme pain at the time of the injury that worsens with movement
- Loss of wrist and hand mobility or decrease in the range of motion
- Deformity or contortion of the wrist
- Tenderness around the wrist and hand area
- Swelling of the wrist
- Hand weakness (unilateral)
- Decrease in grip strength
- Numbness and paralysis of the hand in case of severe injury (due to pressure, pinching, or cutting of blood vessels or nerves)

Sometimes neither the patient nor the physician is able to appreciate the severity of the trauma, and the dislocation may present itself after a delay. Therefore, during the evaluation of a patient with wrist injury, dislocation should always be suspected.

#### Diagnostic Tests

Sometimes tests are required to make the diagnosis of a wrist dislocation. Tests that can be done include the following:

*X-rays of the wrist:* Radiographs of both hands are taken for comparison, and bone alignment is checked along various planes/axes.

*Bone scan:* A radioactive tracer is injected into the blood and gets attached to all the bones of the body. A computer scan generates a picture of the skeleton by reading the radiation levels. Any abnormalities are easily observed.

*Magnetic resonance image (MRI) of wrist:* An MRI scan provides good resolution of soft tissue as well as bone.

*Wrist arthroscopy:* This is a surgical procedure used to diagnose and treat problems inside a joint. Small incisions are made around a joint, and a pencil-sized instrument called an arthroscope is inserted. The arthroscope contains a miniature lens and camera, which project the three-dimensional images of the joint onto a screen.

*Arthrography:* It is useful in detecting tears of the ligaments.

## Treatment

### *Nonsurgical Approach*

All types of injuries need to be assessed by a physician. If there is no evidence of fracture and the injury is not very severe, the wrist bones may align themselves properly and heal with time. There may be a need for repositioning the bones to reduce the dislocation. If there is an associated wrist fracture, surgery is performed to restore the joint to its normal position.

### *Surgical Approach*

Surgical reconstruction or replacement of the joint is required in acute or recurring dislocations. It is performed under anesthesia. The surgeon opens the hand and wrist area and aligns the bones properly. In case of major damage, other devices such as surgical screws may also be used.

### *Associated Measures*

Along with treatment, the following measures should be incorporated to enhance successful healing:

- Elevation of the wrist
- Rest and immobilization, perhaps with a sling for 2 to 8 weeks
- Ice, which helps in reducing acute pain and swelling
- Compression of the wrist (cold compresses may be used)
- Elastic (ACE) wrap
- Cast or splint for a wrist dislocation
- Physical therapy for a wrist dislocation, including exercises designed to build up the muscles of the hand and wrist, helpful in

restoring full functional strength and motion in the hand and wrist

- Occupational therapy for a wrist fracture

### *Symptomatic Treatment*

The following medications may be included in this treatment:

*Nonsteroidal anti-inflammatory drugs (NSAIDs):* These lower the elevated body temperature and relieve pain without impairing consciousness and have anti-inflammatory effects.

*Narcotic pain medication:* These are strong pain relievers and cause loss of feeling.

## Prevention

Use of gloves, wrist guards, or tapes, if the sport permits, can provide some protection to the wrist. Implementation of proper technique and maintenance of good strength and good flexibility can prevent wrist injuries. In case of an injured wrist, the patient should return to play only after achieving full recovery.

## Return to Sports

The dislocated joint and the injured ligaments require a minimum of 6 weeks for complete healing. On returning to work, the patient may support the wrist with a tape or a brace initially if he or she is required to perform lifts or bear weight on the involved wrist.

Sometimes, undergoing special exercise programs, physical therapy, or occupational therapy to restore full strength may be necessary. A physician should be consulted in all cases before resuming routine physical activities.

## WRIST FRACTURE

---

In sports, the wrist is one of the most vulnerable parts of the body. Wrist fractures are among the most common sports-related injuries. Surveys have shown that women, beginners, and younger athletes are more prone to wrist injuries, and it is recommended that they wear wrist guards that help protect the wrist from injury.

Wrist fracture is the most common fracture in patients under 65 years of age and accounts for about one sixth of all fractures seen in hospital emergency departments. It is defined as a break in one or more of the bones in the wrist, but when clinicians are describing wrist fracture, they are usually referring to a fracture of the distal end of the radius (one of the two bones in the forearm, the other being the ulna). The other bones of the wrist joint may also be broken, but the term *wrist fracture* usually implies a fracture of the end of the long bone of the forearm.

Fractures of the wrist most commonly occur as the result of a person extending his or her hand to break a fall, due to which a large amount of force is applied to the wrist, causing the fracture (usually seen in sports where a fall on a hard surface is likely, such as skating, basketball, and hockey); or they may be due to a large force being directly applied to the wrist (e.g., a direct blow during contact sports or a blow from a stick, as in hockey or

lacrosse). Injuries related to sports, car accidents, and falls from a height are important contributing causes of wrist fracture. In older individuals, osteoporosis may play a significant role by making the bones brittle and more susceptible to fractures, even with minor trauma.

### Anatomy

The wrist is made up of two long bones in the forearm (ulna and radius) and eight short bones (carpal bones). The radius is located on the thumb side of the forearm, while the ulna is located on the side of the little finger. The carpal bones are situated in two rows (four in each) at the wrist joint and have synovial joints between them, but movement at these joints is restricted. The ulna and radius are joined at the proximal radio-ulnar joint near the elbow and the distal radio-ulnar joint at the wrist.

The wrist joint is a complex synovial joint between the distal end of the radius and the end of the ulna with the proximal row of carpal bones (the distal row of carpal bones make the carpo-metacarpal joints with the metacarpal bones of the hand). The joint between the radius and ulna is fixed due to the articular disk covering the end of the ulna. The surfaces of carpal bones form a convex contour that articulates with the concave surface of this articular disk and radius. At each joint, the end of the bones is covered by a cartilage, which allows for smooth movements. The bones are held together by ligaments. The joint cavities are filled with synovial fluid, which reduces friction. This arrangement allows for movement at the wrist around two axes, side to side, and the bending and straightening of the wrist. Rotation of the wrist is brought about by combinations of these movements.

In addition, there are a number of nerves and blood vessels traversing this region that may be damaged due to injury to the wrist.

### Classification of Wrist Fractures

Generally, the different patterns of fracture of the wrist are the Colles fracture, the Smith fracture, the Barton fracture, and the Chauffer fractures. The classification of fractures is based on the

pattern of injury involved, the behavior and outcome of that pattern, and the need to distinguish between conditions requiring different treatment strategies. Furthermore, the fracture may be extra-articular or intraarticular (extending into the joint cavity or not), it may be a closed injury or a compound fracture, and comminution (the amount of crumbling at the fracture site) may be extensive or minimal.

In assessing the stability and determining treatment, many features of the fracture must be considered, such as radial shortening, radial angulation, comminution, articular incongruity, accompanying soft tissue injuries, and associated ulnar fractures.

In addition, other bones of the wrist may also be broken in wrist fractures, the most common being the scaphoid (carpal bone articulating with the radius) (Figure 1a) and the “hook” of the hamate (Figure 1b).

### Symptoms and Evaluation

Wrist injuries inflicted in vehicle accidents or sports or in any other way can result in wrist fractures. The first symptom experienced by the person is pain that occurs immediately after the injury and does not subside. The intensity of pain varies with different kinds of fractures and from person to person. Other symptoms may be swelling and tenderness around the wrist, bruising around the wrist, limited range of motion of the thumb and wrist, and visible deformity of the wrist. These symptoms can also be due to other conditions, so it should not be assumed that there is a fracture. A doctor should be consulted.

Diagnosis can be made by observing the deformity of the distal radius, but it should be confirmed by an X-ray. Computed tomography (CT) scans and magnetic resonance imaging (MRI) can also be helpful in confirming the diagnosis if fractures are not seen on X-ray immediately after the injury.

### Treatment

The treatment differs widely depending on the nature and severity of the injury. The treatment plan consists of the following:

**Figure 1** Wrist Fractures

*Note:* (a) Fracture of the scaphoid and (b) fracture of the hook of the hamate.

- It involves approximating the pieces of the fractured bone together, which may require anesthesia and also may require surgery.
- The pieces of bone should be kept in position while the bone heals and the ends join.

After the reduction of the fracture, different modalities may be employed to hold the bone in place (stabilization):

- A cast may be used with or without surgery.
- Internal fixation may be done with a metal plate and screws.

- Percutaneous pin fixation may be done.
- External fixation may be done.
- A combination of these modalities may also be used.

The typical treatment is immobilization with a plaster of paris cast for 5 to 6 weeks to allow union of the bones. The use of other modalities depends on the nature and extent of the injury, and appropriate treatment for each case is determined by the surgeon. For athletes requiring the use of their wrist, such as in tennis, motocross, or cycling, recovering from a fracture without stiffness is important. This is done by performing surgery only when necessary to realign the bones and treating postsurgery without a cast to allow early motion of the wrist and fingers. Due to the functional importance of the hand, the period of immobilization is kept to a minimum to avoid dysfunction of the hand and wrist. The more motion these patients have, the easier it is to resume their sport.

### Follow-Up and Recovery

It is common practice to repeat X-rays at about 1 week during the follow-up period. Follow-up is also needed to determine when the cast may be removed, when the fracture has healed and the rehabilitation is complete. Removal of the cast is followed by rehabilitation for 1 month or more, a short period of which may involve the use of a wrist brace for comfort.

Return to sports should be decided by the patient's physician. Braces should be used to stabilize the wrist during sports or even normal activities. In most cases, athletes can return soon after the immobilization with some protection for the wrist or after adequate postoperative healing, as recommended by the doctor. When the pain subsides, the athlete should work on strengthening the wrist and improving its function, as directed by the doctor. This is usually achieved by performing stretching exercises such as

- wrist range of motion,
- wrist stretch,
- wrist extension stretch,
- wrist flexion stretch, and
- forearm pronation and supination.

These are followed by strengthening exercises such as

- wrist flexion,
- wrist extension, and
- grip strengthening.

It is important during fracture healing that the flexibility of the fingers and hand be maintained. The patient may start hand and wrist exercises as soon as the wrist is stable, to recover the flexibility, strength, and function of the wrist. It is recommended to stay off sports for 6 weeks at least, but the time for recovery varies according to the severity of injury, on any associated injury, and on factors related to the individual. Full recovery may take 6 to 12 weeks, when the patient may resume normal activities, but it is not unusual for maximal recovery from a wrist fracture to take several months. Some patients may, however, have residual stiffness or pain, and even arthritis may develop. On occasion, reconstructive surgery or additional treatment may be required.

### Prevention

Certain risk factors increase the chance of developing wrist fractures:

- Advancing age
- Postmenopause
- Poor nutrition
- Osteoporosis
- Decreased muscle mass
- Contact sports such as soccer or rugby
- Skating, bike sports, skateboarding
- Vehicle accidents

Risk of injury may be avoided by following these simple guidelines:

- Putting oneself at risk for trauma should be avoided.
- The diet should include adequate calcium and vitamin D.
- Proper safety equipment should be used in sports training and contests.
- Fair play and a healthy competitive spirit should be practiced.

- Rules must be enforced to minimize risk of injury to players.
- The athletes should be provided proper coaching and training by qualified specialists.

Prompt medical attention should be easily available to the athlete at all times, especially in cases of emergency.

## WRIST INJURIES

---

The wrist is frequently injured in sports. Sprains are the most common wrist injury, accounting for 20% to 50% of injuries, followed by contusions (15%–30%) and fractures (5%–35%). Distal radius fractures are the most common fracture seen in emergency departments; scaphoid fractures are the most common carpal fracture. Acute injuries of the wrist occur in sports such as football, hockey, and snowboarding, most often from falls. Falls resulting in wrist injuries can also be seen in recreational activities such as rollerblading and biking. Overuse wrist injuries occur in sports such as golf, gymnastics, and racquet sports. It is important to recognize wrist injuries and ensure appropriate treatment to avoid impairments that may affect

not only sports participation but also activities of daily living.

Wrist injuries are more common in children and adolescents than in adults participating in sports. Wrist and hand injuries account for between 3% and 20% of all athletic injuries in the younger population. Possible reasons to explain this increased frequency of wrist injuries in young athletes include increased sports participation by younger athletes; the increased popularity of “extreme” sports; the use of age- or size-inappropriate equipment; increased risk of injury of the immature musculoskeletal system in children, particularly with excessive frequency or intensity of certain sport-specific activities; and poor sport-specific techniques, poor supervision, and inadequate coaching.

### Anatomy

The joints of the wrist include the radiocarpal joints and the distal radioulnar joint. The radius articulates mainly with the scaphoid. The ulna articulates primarily with the lunate. Movement at the radiocarpal joints includes flexion-extension and radioulnar deviation. Movement at the distal radioulnar joint includes pronation-supination.

The carpal bones in the wrist consist of a proximal row, including the lunate, triquetrum, and pisiform, and a distal row, including the trapezium, trapezoid, capitate, and hamate. The proximal and distal rows of carpals are bridged by the scaphoid bone. The ossification centers of the carpal bones appear on X-rays in a predictable pattern. The capitate appears first at less than 1 year of age, followed by the hamate, triquetrum, lunate, scaphoid, trapezium, trapezoid, and pisiform. All ossification centers are apparent on X-rays by 10 years of age. The distal radial epiphysis appears by 1 year of age, whereas the distal ulnar epiphysis becomes visible by 6 to 7 years of age. These physes close by 16 to 18 years of age, when skeletal growth has been completed. Knowledge of the appearance of these ossification centers and epiphyses can help avoid confusion between normal structures and possible fractures and bony injuries in children and adolescents.

Wrist stability is imparted by several extrinsic and intrinsic ligaments. The carpal bones are stabilized by the intercarpal ligaments and allow for transmission of forces across the wrist. There are many extrinsic tendons that traverse the wrist,

including the wrist flexors (flexor carpi radialis, palmaris longus, flexor carpi ulnaris) and wrist extensors (brachioradialis, extensor carpi radialis longus, extensor carpi radialis brevis, extensor carpi ulnaris).

## Evaluation of Injuries

### *Details of Injury*

The mechanism of injury, including the position of the wrist, the direction and magnitude of the involved force, and subsequent symptoms of weakness, pain, or instability, can help determine the cause of wrist pain. Acute injuries are usually the result of a *fall on an outstretched hand* (FOOSH). Striking a solid object with a piece of equipment, such as a bat, golf club, or tennis racquet striking the ground, can result in a fracture of the hook of the hamate. Rotational stress to the distal radioulnar joint, as well as forced ulnar deviation and rotation, may result in a tear to the triangular fibrocartilage complex (TFCC). More severe wrist injuries may prevent an athlete from returning to activity immediately following injury.

The exact location of pain helps narrow the differential diagnosis. Wrist injuries may result in mechanical symptoms such as clicking, snapping, or swelling. Previous injuries to the upper extremities may predispose an athlete to wrist injuries. Other important details such as hand dominance, type of sport, position played, level of performance, and occupation may affect management of the injury.

### *Physical Findings*

Wrist injuries may cause obvious deformity, swelling, or bruising of the wrist. The athlete may hold the wrist in various positions to avoid pain. The range of motion of the injured wrist may be decreased flexion-extension, supination-pronation (hand down/hand up), and radial-ulnar deviation. Normal range is 20° of radial deviation and 60° of ulnar deviation. Comparing the range of motion of the injured wrist with that of the uninjured side can emphasize any decreased movement of the injured wrist. Decreases in wrist movement can also be seen when the hands are placed in the “prayer position” and “reverse prayer position.” The prayer position evaluates wrist extension. The patient apposes the palms with the elbows flexed and the wrists

extended. Normal range of motion is 70° of wrist extension. The reverse prayer position evaluates wrist flexion. The patient apposes the dorsal aspects of the hands with the elbows and wrists flexed. Normal range of motion is 80° of wrist flexion.

Bony injuries of the wrist may result in tenderness to palpation or deformity. Bony prominences that may be tender to palpation include the distal forearm, the radial snuffbox, the base of the metacarpals, the lunate, the head of the ulna, the radioulnar joint, the pisiform, and the hook of the hamate.

Special tests of the wrist that may point to a specific injury include the Watson test and TFCC integrity. The Watson test evaluates scapholunate stability. The examiner places a thumb on the scaphoid tuberosity with the patient’s wrist in ulnar deviation. The wrist is then deviated radially while the examiner applies pressure on the scaphoid. A positive test for scapholunate dissociation occurs if the patient feels pain dorsally over the scapholunate ligament or the examiner feels the scaphoid move dorsally. Assessment of TFCC integrity involves placing the athlete’s wrist in dorsiflexion and ulnar deviation and then rotating the wrist. A positive test for a tear of the TFCC occurs when overpressure causes pain and occasional clicking at the ulnar aspect of the wrist.

Wrist injuries may result in nerve damage or injury to the blood vessels in the wrist as well.

### *Investigations*

In the setting of a traumatic wrist injury, routine X-rays can show possible fractures. X-rays should include posterior-anterior (PA), lateral, and PA with radial and ulnar deviation views. If a ligament injury is suspected, a PA view with a clenched fist can indicate possible injury. The normal PA view should demonstrate a smooth line joining the proximal ends of the proximal row of carpal bones and the “C” shape of the midcarpal joint (the Gilula arcs). On the normal lateral view of the wrist, the proximal pole of the lunate fits into the concavity of the distal radius, and the convex head of the capitate fits into the distal concavity of the lunate. These bones should be aligned with each other and the base of the third metacarpal.

Specialized X-ray views can be ordered for specific suspected injuries. If a scaphoid fracture is of concern, scaphoid views should be obtained. A

carpal tunnel view with the wrist dorsiflexed allows the hook of the hamate and ridge of the trapezium to be inspected.

Other modalities that are helpful to diagnose wrist pain, such as ganglions or occult fractures, include ultrasound, radionuclide bone scan, computed tomography (CT) scan, and magnetic resonance imaging (MRI). Ultrasonography is helpful to assess soft tissue abnormalities such as tendon injury, ganglions, synovial cysts, or thickening. Bone scans are helpful to rule out subtle fractures. CT scans can also evaluate fractures that may not be apparent on plain films. MRI can evaluate soft tissue injuries, such as a tear of the scapholunate ligament, more effectively than CT. Arthroscopy is an increasingly used procedure for diagnosis and therapy. It is an excellent tool for detecting scapholunate tears and is the investigation of choice for patients with ulnar-sided wrist pain that persists following an acute injury (see Table 1).

### Prevention of Injury

Many wrist injuries in sport can be prevented. The use of protective wrist guards has been shown to reduce wrist fractures in sports such as snowboarding and inline skating. Studies have shown that the

incidence of wrist fractures was reduced by half in participants who wore wrist guards while snowboarding. Similar studies on inline skating found that athletes who did not wear wrist guards were more than 10 times more likely to injure their wrist than those who did wear wrist guards.

In younger athletes, it is important to use age- and size-appropriate equipment to reduce injury. For instance, studies on youth soccer have shown that distal radius fractures are more common in younger children using an adult-sized ball than in those who use a junior-size ball.

### Return to Sports

Return-to-play recommendations vary somewhat according to the specific injury, the treatment modality, and the sport-specific demands of the individual athlete. In general, full unprotected return to play is not allowed until the athlete has regained full active and passive range of motion and almost full strength of the affected wrist. Bony or ligamentous injuries usually require 3 to 6 weeks to heal. Athletes should not participate in sports unless the injury is appropriately immobilized in a cast or splint. Wrist injuries do have the potential for delayed or failed healing despite appropriate initial

**Table 1** Types of Wrist Injuries

| <i>Acute</i>                                  | <i>Chronic</i>                                                 |
|-----------------------------------------------|----------------------------------------------------------------|
| Distal radius fracture                        | Ganglion cyst                                                  |
| Scaphoid fracture                             | Intersection syndrome                                          |
| Wrist ligament sprain/tear                    | Kienböck disease                                               |
| Hook of hamate fracture                       | de Quervain tenosynovitis                                      |
| Triangular fibrocartilage complex (TFCC) tear | Dorsal pole of lunate and distal radius impingement (gymnasts) |
| Distal radioulnar joint instability           | Tendinopathy (flexor carpi ulnaris, extensor carpi ulnaris)    |
| Scapholunate dissociation                     | Posterior interosseous nerve entrapment                        |
| Carpal bone dislocation                       | Inflammatory arthropathy                                       |
| Carpal tunnel syndrome                        | Degenerative joint disease                                     |
|                                               | Nonunion of scaphoid fracture                                  |

treatment, requiring subsequent surgical intervention. Therefore, early referral to an orthopedic or hand surgeon is recommended for follow-up. Another consideration in determining when an athlete is ready to return to sports is the safety of the injured athlete as well as the other participants. If an athlete is considering returning to sports wearing a protective device, permission should be obtained from trainers, coaches, and officials.

## WRIST SPRAIN

---

A *sprain* is an injury to a ligament. Ligaments are a type of tissue that connects bones to bones and provides stability to joints. One may think of ligaments as analogous to ropes. *Sprain* comes from the French word *espraindre*, which means “to wring.” A wrist sprain is an injury to the ligaments of the wrist. Often, sprains occur from falls or sports-related injuries that involve forcibly

bending the wrist backward (hyperextension) or excessive pressure through the long axis of the joint (axial loading), with subsequent damage to the ligaments of the wrist joint.

### Anatomy

The wrist comprises many different types of structures, including eight small bones (called carpal bones), multiple ligaments, cartilage—a firm covering of the bones (e.g., the tip of your nose), and specific junctions with the bones of the hand (metacarpals) and forearm (radius, ulna). The joint where the radius and ulna are connected near the hand is called the distal radial ulnar joint (DRUJ). This joint is particularly susceptible to injury during falls.

Several structures in the wrist deserve particular mention, including the triangular fibrocartilage complex (TFCC). The TFCC is a special type of tissue (a mix between fibrous tissue and cartilage) that absorbs stress during axial loading of the wrist and limits lateral movement of the carpal bones. Throwing a “jab” or “punch” in boxing, for example, would be axially loading the wrist joint. This special cartilage (TFCC) also stabilizes the DRUJ.

There are two types of ligaments in the wrist—extrinsic, which connect the radius and ulna to the carpal bones, and intrinsic, which connect the carpal bones to each other.

Extrinsic ligaments have two components, *volar*—the palmar or underside of the wrist and hand, and *dorsal*—the backside (knuckle side) of the wrist and hand.

The volar radiocarpal ligaments are stronger and thicker than the dorsal and so provide the majority of motion stability in the wrist. The most important ligament of this group is the radioscaphocapitate, which attaches the radius (forearm bone) to the scaphoid and capitate (carpal bones). Intrinsic ligaments are also called interosseous ligaments. They originate on the carpal bones and are within the capsule of the wrist.

The most common ligament indicated in wrist sprains is the scapholunate, which is an intrinsic ligament between the scaphoid and lunate bones. It comprises dorsal collagen bundles that provide a structure that lends to its superior stability. Another important interosseous ligament is the lunotriquetral, connecting the lunate and triquetrum carpal bones.

### Classification of Injuries

Sprains are classified based on severity, ranging from mild to moderate to severe injury. Typically, Grade I sprains represent the least amount of injury—a stretching of the ligament fibers—and result in minimal or no loss of function at that joint. Grade II sprains usually equate to a partial tearing of the ligament. This may be observed by increased swelling and pain of the joint along with moderate dysfunction. The most serious of wrist sprains would be a complete tear of the ligament, a Grade III sprain. This results in an unstable joint and requires immobilization (splinting) and often referral to a specialist.

### Injury Setting and Symptoms

Wrist sprains occur in many settings and due to a variety of reasons, including direct injury, chronic repetitive trauma and loading activities, or falls and sports-related injuries. Sprains are more common in adults than in children due to the different anatomy of the developing bones in children. In younger populations, similar injuries more often produce fractures of the immature bone rather than damage to the ligaments. Commonly, skiing, skating, snowboarding, and inline skating are sports associated with wrist sprains, but they can occur in any contact or noncontact sports under certain conditions. At times, specific wrist injuries are classified as *falls on an outstretched hand* (FOOSH), such as fractures of the scaphoid bone or disruption of the scapholunate ligament.

Patients with wrist sprains may report feeling a tear or hearing a pop during the event. Areas of the wrist or hand may swell, demonstrate bruising, or be painful to touch. Patients have difficulty and pain with movement of the wrist. Wrist and hand anatomy is intricate, and diagnosing an injury may present a difficult task, so an evaluation should include a detailed history, a careful physical exam, and often radiographs. The exam should consist of general inspection, a neurovascular evaluation, palpation of bony prominences and ligaments, and assessment of joint range of motion and stability.

### Treatment

Sprains usually heal completely within 4 to 6 weeks. Conservative treatment involves splinting in a neutral position with either a brace or a compressive elastic wrap, rest from painful activity, application of ice

packs, and taking nonsteroidal anti-inflammatory drugs (NSAIDs) to reduce swelling and for pain relief. After a period of immobilization and before returning to full activity, patients should exercise to improve wrist range of motion and strength. This may include work with a resistance band or weights for wrist extension, flexion, and ulnar and radial deviation (ulnar deviation: side movement in the direction of the little finger; radial deviation: side movement in the direction of the thumb).

Grade III sprains or complete tears of ligaments may require surgical correction and repair. These injuries represent unstable joints, and the wrist must be immobilized at the discovery of injury to prevent additional or more serious injury.

While most wrist sprains heal with conservative therapy and without other intervention, some important conditions must not be missed due to varying treatments and risk of adverse events. These include injury to the TFCC, carpal bone dislocation (displacement), DRUJ, or any fracture of the carpal bones or forearm bones (radius or ulna).

## WRIST TENDINOPATHY

---

Overuse wrist tendon injury, or *tendinopathy*, occurs regularly in athletes participating in sports with repetitive wrist and hand movement. Unlike more proximal tendinopathies (e.g., rotator cuff), which are typically degenerative and noninflammatory, symptoms from wrist tendinopathy frequently involve inflammation of the outer tendon sheath, known as paratenonitis. The most

common wrist tendinopathies in athletes involve the dorsal/extensor aspect of the wrist, such as de Quervain disease, intersection syndrome, and extensor carpi ulnaris (ECU) paratenonitis.

Risk factors for athletic wrist tendinopathy include muscle weakness or imbalance, overuse from training load, improper technique or equipment, and inadequate rest. The accurate diagnosis of wrist tendinopathy requires skilled history taking and physical examination, and advanced imaging is infrequently necessary. Treatment of inflammatory tendinopathy of the wrist includes rest, noninvasive anti-inflammatory modalities (e.g., ice, anti-inflammatory medications), risk factor modification, and occasional local corticosteroid injection. With an accurate diagnosis and a treatment plan customized for the athlete, the sport, and the severity of the condition, most athletes with wrist tendinopathy return to their sport quickly and very rarely have long-term limitation.

### Anatomy

Tendons consist of longitudinally oriented, closely grouped collagen bundles with an outer covering called the paratenon. In areas such as the wrist, where tendons bend at acute angles over bone, the paratenon is thicker and lined with synovium and is called a tendon sheath. The synovium of the tendon sheath both provides mechanical resistance to shearing forces and produces synovial fluid, lubricating the tendon to decrease frictional injury.

Wrist tendons are divided into extensor tendons, which run over the dorsal aspect of the wrist, and flexor tendons, which run over the volar/palmar aspect of the wrist. The side of the wrist closest to the radius (and thumb) is referred to as the radial aspect of the wrist, and that closest to the ulna (and fifth finger) is referred to as the ulnar aspect of the wrist. The relative anatomic course of each of these wrist and finger tendons is represented in Figure 1 (extensors) and Figure 2 (flexors). The dorsal/extensor wrist is divided into six compartments, numbered from the radial to ulnar aspects, the first two of which are frequently involved in athletic wrist tendinopathies. The first dorsal compartment consists of the abductor pollicis longus (APL) and extensor pollicis brevis (EPB) tendons. The second dorsal compartment includes both extensor carpi radialis brevis (ECRB) and extensor carpi radialis longus (ECRL) tendons.

### Pathology

*Tendinopathy* is a broad term that includes tendinitis, tendinosis, and paratenonitis. *Tendinitis*

Tendons of the dorsal aspect of the wrist: (a) abductor pollicis longus, (b) extensor pollicis brevis, (c) extensor carpi radialis longus, (d) extensor carpi radialis brevis, (e) extensor pollicis longus, (f) extensor digitorum, (g) extensor indicis, (h) extensor digiti minimi, and (i) extensor carpi ulnaris

refers to inflammation of the tendon substance and rarely occurs without the presence of underlying degenerative tendon change, or *tendinosis*. *Paratenonitis*, or alternatively *tenosynovitis*, involves inflammation of the paratenon/tendon sheath, can occur alone or in combination with tendinosis, and constitutes the majority of wrist tendinopathy. However, elite and older athletes also often have some component of underlying tendinosis contributing to their symptoms.

De Quervain disease and intersection syndrome are the two most common athletic wrist tendinopathies. De Quervain disease is a paratenonitis of the tendons in the first dorsal compartment. Intersection syndrome, while not a classic paratenonitis, represents inflammation of the crossover area where the musculotendinous junctions of the first dorsal compartment meet with the tendons of the second dorsal wrist compartments. Less common wrist tendinopathies in sports include the separate syndromes of ECU and FCU (flexor carpi ulnaris) paratenonitis along with the infrequent flexor carpi radialis (FCR) paratenonitis and carpal tunnel syndrome from paratenonitis of the digital flexor tendons.

### Causes

Wrist tendinopathy in athletes results from chronic microtrauma due to tendon overuse. While athlete ageing and tendon underuse can contribute to degenerative tendon changes, most wrist tendinopathies are caused by a combination of numerous factors, the most important being excessive repetition of wrist and hand motion. Such motion is required in many sports, including racquet sports (tennis, squash), golf, baseball, volleyball, gymnastics, rowing, and rock climbing. Other factors contributing to wrist tendinopathy include muscle imbalance or weakness, improper technique (e.g., excessive wrist radial deviation on the tennis forehand), improper equipment (e.g., size of the bat or racquet handle), and inadequate recovery time.

Causative sports for specific wrist tendinopathies are those that involve motions isolating the involved tendons. For example, de Quervain disease affects two tendons exerting their action on the thumb and is common in sports that require strong or repetitive thumb motion, such as racquet (tennis) and other hand grip sports (rowing and golf). Intersection syndrome involves tendons that

act on both the thumb and the radial aspect of the wrist, is caused by repetitive wrist extension in radial deviation, and is encountered in many of the previously mentioned sports, along with weight lifting and downhill skiing. ECU paratenonitis and tendinosis occur from excessive wrist extension in ulnar deviation and are seen especially in racquet sports, golf, and rowing. FCU paratenonitis is also common among golf and racquet sport athletes.

## Clinical Evaluation

### History

Suspicion for wrist tendinopathy in an athlete generally stems from pain over the involved tendon(s). Pain from paratenonitis is typically constant and proportional to activity level and can be seen in athletes of all ages. Patients with paratenonitis usually report a recent increase in the duration or intensity of their sports activity and often note accompanying swelling, stiffness, and wrist "squeaking." Alternatively, athletes with tendinosis will complain of more intermittent pain and will usually have a remote history of overuse. Patients with tendinosis will also typically complain of pain that starts during the warm-up phase, decreases during activity, and increases during the cooldown and recovery phases. Finally, patients with tendinosis will describe a course of pain that begins as sharp and intense and becomes more dull and achy over time. Because paratenonitis can be seen in combination with tendinosis, symptoms from both processes can co-occur.

Accompanying symptoms such as paresthesia, weakness, radiation of pain, blunt trauma, fever, and overlying skin changes should be ruled out in the athlete with tendon pain. The presence of these symptoms should prompt consideration of more extensive differential diagnosis and work-up. Of note, rheumatologic conditions such as rheumatoid arthritis affect the synovium, causing both arthritis and paratenonitis, and should be suspected in an athlete with recurrent or diffuse paratenonitis.

### Physical Examination

A thorough examination of the affected forearm, wrist, and hand along with comparison with the nonaffected side is necessary in evaluating athletes with suspected wrist tendinopathy. They will

have pain to tendon palpation, especially under tension with manual muscle testing. As with most inflammatory conditions, patients with wrist paratenonitis will have associated palpable swelling and increased temperature over the affected area of the tendon. Patients with wrist paratenonitis can also have crepitus and occasional catching with passive movement of the involved joint, as in passively flexing and extending the wrist in ulnar deviation to evaluate ECU paratenonitis. Finally, the athlete will often have pain with the tendon in full stretch, such as the Finkelstein maneuver, in which the patient is asked to make a clenched fist about the adducted thumb and the examiner subsequently places the patient's wrist in ulnar deviation. Pain over the radial styloid (distal radius) with this maneuver is highly specific for de Quervain disease.

### Imaging

Clinical assessment with history and physical examination is usually sufficient for accurate diagnosis and classification of wrist tendinopathy. Plain radiographs in tendinopathy are routinely negative, and advanced imaging is rarely required. However, in cases recalcitrant to initial therapy or where more significant tendon disruption is suspected, magnetic resonance imaging (MRI) and ultrasound can serve as helpful adjuncts. On the MRI scan, paratenonitis demonstrates increased (fluid) signal in the tendon sheath on T2 and STIR (short inversion time inversion recovery) sequences, whereas tendinosis shows less uniform increased intratendinous signal on the same sequences. Ultrasound examination of paratenonitis demonstrates anechoic signal (representing fluid) in the surrounding tendon sheath, and in tendinosis, it shows hypoechoic intratendinous regions.

### Treatment

The mainstay of wrist tendinopathy treatment is conservative therapy relying on relative rest, ice, analgesics (e.g., oral or topical nonsteroidal medications), physical therapy, and short courses of wrist bracing or splinting, to include thumb spica immobilization in cases of de Quervain disease. In paratenonitis, use of topical (e.g., iontophoresis) or systemic corticosteroid treatment can be beneficial,

and local injections of topical anesthetic and corticosteroid into the tendon sheath by skilled hands are often effective in confirming the diagnosis and treating the condition. In cases with underlying tendinosis, anti-inflammatory treatments do not treat the underlying degenerative pathology and cannot prevent recurrence. The most widely accepted treatment modality for tendinosis is eccentric muscle strengthening of the affected muscle-tendon unit. In all tendinopathies, adjustment of the underlying modifiable risk factors, such as errors in technique, training schedule, or equipment, must always be addressed for adequate treatment and prevention of recurrence. In rare cases where the athlete's wrist tendinopathy does not respond to conservative treatment, surgical release of the tendon sheath or debridement of the degenerative tendon may be indicated.

### Conclusion

Wrist tendinopathy from tendon overuse commonly affects athletes participating in tennis, golf, and other sports requiring repetitive wrist and hand motion. Inflammation of the tendon sheath surrounding the tendon, or paratenonitis, is the most common underlying pathology in these cases and often responds to conservative therapy with relative rest, analgesics, and anti-inflammatory modalities without long-term sequelae.

## YOUNG ATHLETE

---

Youth participation in sports has increased dramatically in recent years. Children are becoming involved at younger and younger ages and are training with increasing intensity. Understanding their unique needs with respect to injury patterns, changing body habits, and psychological development is key to dealing with the child athlete. A sensible approach to training that takes into consideration skill level and motivation, as well as physical and emotional development, will help prevent injuries and promote enjoyment of the sport. For the child who becomes involved in competition, acquisition of skills and fitness must be balanced with avoidance of overtraining. It is important to have some knowledge of the types of injuries our young athletes sustain and an understanding of the prevention and rehabilitation of these injuries. Finally, the most influential people in the child athlete's life, coaches and parents, need to help the child keep winning in perspective.

### Uniqueness of the Child Athlete

Growth and development are the most important features that distinguish young athletes from adults. The changing mechanical properties of growing bones and tissues give rise to maturation-related injuries. Bone growth occurs first, followed by a secondary lengthening of muscle-tendon units and ligaments. Many experts feel that during a growth spurt, there is a relative decrease in flexibility

before the soft tissues catch up with bone growth. This decrease in flexibility places the child at risk for injuries such as Osgood-Schlatter apophysitis or patellofemoral pain. The imbalances in muscle strength and flexibility that occur during these periods of growth are risk factors for both sudden (acute) injuries and overuse injuries. Growing bones themselves are weakened because bone matrix formation and mineralization do not occur at the same rate. As a result, children's bones are less dense than those of adults.

The types of bony injuries sustained by children are quite different from adult injuries. For example, a similar mechanism of injury may produce a displaced or comminuted fracture in an adult bone, but it may only cause bending (plastic deformation) of the softer bone of the child athlete. The inherently weak growth plate (physis) is involved in 30% of all fractures of the long bones of children. During different stages of development, the relative strength of the physes changes, with the time of the greatest vulnerability to injury being the onset of the adolescent growth spurt. At such times, if stressed, the musculoskeletal system will break down at the growth plates before the adjacent ligaments tear. In prepubescence and again in late pubescence after growth has slowed, the physes may actually be stronger than the adjacent ligaments; therefore, true sprains are more likely to occur than injuries to the physes.

The main concern with growth plate injuries is the potential for altered growth. This also depends on the child's stage of development. For example, repetitive microtrauma to the wrists in gymnasts

during early puberty may result in a temporary decrease in growth of the growth plate at the lower portion of the forearm (the distal radial physis). Normal growth is restored once the trauma stops. The same injury to a midpubertal gymnast may result in permanent loss of growth.

Other areas of growth tissue occur at the tendon insertions of large muscle groups. These sites are known as apophyses and are subject to injuries unique to the growing athlete. A common site of apophyseal injury is the insertion of the patellar tendon into the top of the shin (tibial tubercle). Repetitive stress at this site can cause either apophysitis or avulsion fracture. Apophyseal injuries will be discussed later in this entry. It is important to remember that the tissues of the young athlete are in transition, which has a great bearing on the types of injuries sustained.

The child athlete differs from the adult in other ways as well. The response of the cardiovascular system and the body's control of temperature (thermoregulation) to exercise in children is different from that in adults. Thermoregulation will be discussed in greater detail later. Regarding cardiovascular differences, children generally use more oxygen for a given activity and rely on anaerobic metabolism less than adults do during exercise. They tend to have higher heart rates and pump less blood from the heart with each beat (lower cardiac stroke volume) as well. This can affect how well the child tolerates physical activity. In addition, reaction time decreases as the child matures.

With increasing strength and endurance, particularly in the latter half of childhood, speed of movements and general skills increase. Thus, the innate tools that the child athlete has at his or her disposal vary with physical maturation. This should be kept in mind when setting goals for the child in sports.

### **Thermoregulation: Exercise in the Heat**

Approximately 80% of energy released during exercise is in the form of heat. If the mechanisms for heat loss are not functioning properly, the athlete may experience a 1 °C increase in body temperature per 5 minutes of activity. If this is allowed to continue, it would be potentially fatal within 20 minutes. Mild dehydration, as little as 1.2%, may make it even more difficult to control body temperature.

Once water deficits are greater than 3%, there is a significant risk of heat illness. Heat-related illnesses include a spectrum of conditions ranging from heat cramps, which are painful, sustained muscle contractions, to life-threatening heat stroke.

### *Uniqueness of Children*

The thermoregulatory mechanisms in children are slightly different from those in adults. Compared with adults, children produce more heat per kilogram (kg) while walking and running. They begin to sweat at a higher core temperature and sweat less per square meter. They have a lower cardiac output at a given metabolic level and less blood flow to the skin for removal of heat by convection. Their larger body surface area per kilogram results in increased heat exchange between the environment and the skin, causing greater heat stress. Their thermoregulatory impairment from dehydration is also greater.

Children are slower than adults to acclimatize to heat. Acclimatization involves physiologic changes that increase tolerance to exercise in the heat. This adaptation is influenced by age, duration of exposure to heat, rate of body heat production, severity of environmental stress, and the preexisting level of conditioning of the athlete. These differences in thermoregulation place the child athlete at increased risk of heat illness, especially in extreme heat.

### *Prevention of Heat Illness*

Prevention of heat illness addresses environmental conditions, hydration, clothing, conditioning, and acclimatization. Activity should be modified in the face of high ambient temperature or humidity. For temperatures less than 19 °C (67 °F), the players most susceptible to heat stress should be under close observation. Unlimited supplies of drinking water should be available on the field, and athletes should be encouraged to take fluids when ambient temperatures are between 19 and 25 °C (67 and 77 °F). Water breaks should be scheduled every 20 to 25 minutes. For temperatures above 25 °C (77 °F), practice sessions should be reduced and, if possible, scheduled for early morning or late afternoon. Susceptible players,

such as those with a history of heat illness, should be withheld from participation. At any temperature, if relative humidity is greater than 95%, activity should be modified as per the requirements for temperatures  $>25^{\circ}\text{C}$ .

Athletes may lose 2% to 3% body weight before thirst develops, at which point performance is already impaired. To ensure adequate hydration, adolescent athletes should be encouraged to drink 235 milliliters (ml; 8 ounces [oz]) of water 10 to 15 minutes prior to workout and 235 to 350 ml (8–12 oz) at 20- to 30-minute intervals throughout the practice. Younger, smaller athletes will need slightly less than this amount (approximately 150 ml of cold tap water every 30 minutes for a 40-kg child). After workout, drinking to quench thirst will replenish only one third to one half of fluid losses; therefore, athletes should weigh themselves before and after workout (without clothes) and should drink 1 liter/kg lost (2 cups/pound). Plain water is adequate for most activities of young athletes.

Appropriate clothing for training in the heat is lightweight, single layer, and absorbent. As much skin as possible should be exposed to air, and sweat-saturated articles of clothing should be changed. If helmets are worn, they should be removed between drills, because a significant proportion of heat loss occurs via the head. Sauna suits for weight reduction should never be permitted.

Athletes should start the season as physically fit as possible. A preseason conditioning program will give the child a good baseline fitness level, which will not only decrease the risk of heat illness but also help prevent other problems such as overuse injuries. An attempt should be made to acclimatize the athlete before beginning a strenuous program or before travel to a warm climate.

### Common Injuries Associated With the Child Athlete

Several injuries occur more frequently, or in some cases uniquely, in the skeletally immature athlete. These injuries can be divided into either acute or overuse types. Acute bone injuries encountered exclusively in the child athlete include *growth plate* (physeal) *injuries* and *apophyseal avulsion fractures*, which occur when large tendons pull off (avulse) fragments of bone and growth cartilage at the sites where tendons and bones join. Other fractures seen

in children (torus, greenstick, plastic deformation) occur because of a lesser degree of mineralization and thinner cortices than in adult bones. There are also several overuse injuries that are seen primarily in young athletes. The most common of these are discussed in this section.

### Acute Injuries

#### Growth Plate Injuries

At certain times during development, growth plates are weaker than the surrounding soft tissues; therefore, when a joint is placed under abnormal stress, such as a sudden, forceful inversion of the ankle, the result is a fracture through the growth plate. This is accompanied by swelling and tenderness on the outer aspect of the ankle. There may be some tenderness over the ligaments, but if there is bony tenderness over the lateral ankle, it is likely to be a growth plate injury. This relative weakness of the physes is maximum at the onset of the growth spurt. Immediate management includes ice, elevation, and compression. Immobilization and crutches may be necessary for pain control. Early institution of physical therapy will restore function and help prevent reinjury. It is possible for young athletes to sprain ligaments rather than injure physes, particularly adolescents nearing physical maturity and prepubescent athletes.

#### Avulsion Fractures

Children with open physes also have apophyses at the insertion of large tendons into bone. Like growth plates, these cartilage structures are subject to injury, particularly during rapid growth. The most common acute injury to the apophysis is an *avulsion fracture*. Avulsion fractures are typically seen in 14- to 17-year-old males. These occur frequently around the pelvis, into which several large muscles insert. These athletes will complain of severe pain at the affected site and inability to continue activities. Pain will worsen with contraction of the muscle responsible for the avulsion injury. Athletes should apply ice and use crutches during the acute phase. Relative rest with early institution of physical therapy will hasten the recovery. Full range of motion and normal strength should be regained prior to return to sports participation.

### Overuse Injuries

Overuse injuries result from repetitive micro-trauma to bones and soft tissue. Growth is a risk factor for overuse injury in the young athlete. Growth cartilage is inherently weak when compared with the adjacent bone and is unable to withstand excessive repetitive stress. Many experts feel that flexibility decreases with growth, as muscles and tendons are stretched by the growing bones. Muscle tightness is a well-known risk factor for overuse injury among athletes of all ages. Training error is another recognized risk factor for overuse injury. Examples of training errors include sudden increases in training intensity or duration. These errors are encountered frequently in the context of summer sport camps, where children may increase their participation in a given physical activity from a few hours per week to a few hours or more each day.

#### Little League Elbow

*Little League elbow* refers to a number of different conditions that cause pain about the elbow. The forces generated during throwing result in valgus stress to the elbow, with compression on the outer aspect and tension on the inner aspect of the joint. Specific diagnoses can include medial epicondyle apophysitis, overgrowth of the radial head, osteochondritis dissecans of the radial head, and premature closure of the radial growth plate at the elbow. If there is swelling and decreased range of motion in the joint, there may be a problem with the cartilage and bone of the joint or there may be a loose body in the elbow. The child should be referred to a physician for evaluation, and further pitching should be avoided until an assessment has been done. Management includes avoidance of aggravating activities and initiation of physical therapy for range of motion followed by strength exercises. Once pain has resolved, range of motion is full, and careful evaluation of the throwing technique to correct errors that may have contributed to the injury is done, *gradual* return to play is possible. If the number of throws per week is limited to not more than 300, it may help prevent some of these injuries.

#### Osgood-Schlatter Apophysitis

Osgood-Schlatter apophysitis is a painful response to repetitive stress at the patellar tendon/tibial

tubercle junction. Injury of the apophysis results in pain with jumping and running and tenderness to touch. Swelling may be seen over the tibial tubercle on the upper portion of the lower leg. This condition is most often observed in young athletes who have patellar maltracking or who have recently undergone a growth spurt. In the latter situation, muscles about the knee become very tight, placing added stress on the extensor mechanism. A similar stress injury (Sinding-Larsen-Johansson syndrome) occurs at the lower pole of the patella. The presentation of Sinding-Larsen-Johansson syndrome is similar to that of Osgood-Schlatter, except that the point of maximal tenderness is the lower portion of the patella. Reassurance is the first part of treatment for Osgood-Schlatter apophysitis. Athletes and their parents need to know that this condition will resolve when growth is complete. In the meantime, attempts must be made to decrease pain and secondary inflammation and to prevent recurrence. The child should be advised to stop any jumping or running activities until the pain and swelling have subsided. Application of ice three or four times per day while the symptoms are severe may be enough to reduce the pain. Nonsteroidal anti-inflammatory drugs, or NSAIDs, are of limited use other than as analgesics, unless there is significant secondary soft tissue swelling present. A home exercise program must begin immediately to work on hamstring and quadriceps stretching. When the pain has decreased, strengthening of these muscles can begin. The athlete is permitted to return to full activity only when jumping and running are pain free. A strap brace may be placed over the patellar tendon to reduce the pull of the quadriceps on the tibial tubercle. A knee pad to protect the tibial tubercle from direct trauma may reduce incidence of flare-ups. This condition can recur and occasionally can lead to avulsion fractures of the tibial tubercle.

#### Osteochondritis Dissecans

Osteochondritis dissecans (OCD) is an injury that affects a localized area of cartilage on the joint surface (articular cartilage) of bone, along with a small portion of underlying (subchondral) bone. Although the exact cause of this condition is not entirely clear, there appears to be some localized insufficiency of the blood supply to the bone, likely

exacerbated by repetitive trauma or compressive forces. As the bone loses its blood supply, the overlying articular cartilage and subchondral bone may become unstable. In more severe cases, the bone and cartilage fragment becomes a loose body in the joint. OCD in the knee usually occurs on the inner aspect of the lower end of the thighbone (femur). This condition is also seen in the outer aspect of the elbow in Little League elbow and in the ankle (talus). A child with OCD of the knee may present with intermittent joint swelling, pain, and limited range of motion. Management depends on the severity of the OCD and the maturity of the child. In a growing child with intact cartilage overlying the bony defect, full range of motion, and no locking, nonsurgical treatment may be adequate. The child is restricted from impact activities such as jumping and running, and early physical therapy is initiated to maintain or regain range of motion. Other treatments may include limitation on weight bearing or use of bracing. Resistive weight training should be withheld for 6 to 12 weeks until bone healing occurs. It may be as long as 6 to 12 months before the athlete can resume full activities. Arthroscopic surgery may be necessary in the presence of mechanical symptoms such as locking, if magnetic resonance imaging (MRI) suggests an unstable fragment, or if more conservative treatment does not result in healing after 3 to 6 months.

#### Sever Apophysitis

Sever apophysitis is an injury to the calcaneal apophysis that results in tenderness at the insertion site of the Achilles tendon in the heel. Children will usually present with posterior heel pain after activity. The condition occurs in both feet in two thirds of cases and typically occurs between 7 and 14 years of age. On examination, the most tender point is the back of the heel at the Achilles tendon insertion. There may be pain with passive stretching of the calf muscles or with active plantarflexion of the ankle (downward). Squeezing the heel (squeeze test) is usually painful. To unload the painful heel, weight bearing and gait may be altered. This may result in pain and tenderness of the Achilles tendon or under the arch of the foot, clinically suggestive of Achilles tendinosis or plantar fasciitis. Treatment includes heel cups to

decrease stress on the apophysis, cessation of all painful activities, and institution of physical therapy. The therapy is aimed at reducing secondary inflammation through application of ice, as well as increasing the flexibility and strength of the calf muscles. When the pain has subsided, the athlete can increase physical activity as long as the pain does not recur.

#### Spondylolysis

Spondylolysis is a stress fracture of the pars interarticularis, which is one of the posterior elements of the spine. This injury is most commonly encountered in sports that require repetitive extension of the spine, such as gymnastics, figure skating, and ballet. Football and hockey players may also develop this injury from the repetitive stress of sled training or body checking, respectively. The athlete will complain of low back pain with extension movements of the spine. The athlete may note tightness of the hamstrings on the affected side. On examination, there is often some degree of muscle spasm alongside the defect in the lower back. Provocative tests such as extension of the spine (arching backward) will reproduce the symptoms. There will be a relative tightness of the hamstrings on the affected side. When dealing with gymnasts and dancers, it is important to remember that they are usually extremely flexible; therefore, left and right asymmetry should be noted.

Plain X-rays may show the fracture, but a special bone scan, SPECT (single-photon emission computed tomography), will be able to definitively diagnose the lesion. Treatment involves cessation of the offending activities. A rigid, custom polypropylene brace is often used to limit extension. The brace is worn for 23 hours a day, with 1 hour out for physical therapy and showering. Once the athlete is painfree in the brace, return to modified activity is allowed. Duration of bracing is generally 6 months to allow for bony healing. Many athletes are able to return to their sport while wearing the brace.

#### “It Is Not Whether You Win or Lose . . . ”

It has been shown that children have a much greater likelihood of dropping out of sports where the greatest emphasis is on winning. It is easy for the child athlete to begin to equate winning with

success and losing with failure. Fear of failure places an enormous amount of stress on the child athlete. If a child feels that his or her "success" depends on a win, then every competitive situation becomes even more stressful and every loss adversely affects self-worth. Winning is an important goal in competitive sports, but it needs to be kept in a healthy perspective. While striving to win, the sense of success should come from putting out maximal effort. Young athletes should feel that even though they make mistakes or lose games, as long as they are trying their best, their parents and coaches will approve. This will greatly enhance the child's enjoyment of the sport, making continued participation much more likely.

### Prevention Techniques

When discussing prevention in sports, one must differentiate between physical and psychological injury. The physical injuries discussed in this entry include overuse and acute trauma, as well as heat illness. Prevention of overuse injuries involves addressing risk factors before they become problematic. Preparticipation physical examinations can identify muscle imbalances and other physical factors that may predispose the athlete to injury. Preseason conditioning can reduce the risk of injury to muscles and tendons. Athletes should be educated regarding specific preventative techniques such as stretching muscles when warm and aggressively working on flexibility during growth spurts. To allow tissues to adapt to increasing work loads, training should not increase more than 10% per week. Prevention of acute injuries involves ensuring adequacy of equipment (e.g., football helmets) and striving to ensure that young athletes are matched up based on size and maturation rather than age. Rules that are meant to minimize serious trauma (e.g., no spear tackling in football) should be adhered to. Prevention of heat illness was covered earlier in this entry.

Prevention of psychological injuries is an important part of dealing with young athletes. Psychological stress occurs when athletes perceive that the demands placed on them exceed their skills. If failure is perceived as catastrophic, the stress on the athlete increases significantly. If personal value becomes dependent on success, this also adds to stress. As a result, if stress levels

become too high for the athlete to cope with, he or she may withdraw from sports. If training continues, the child may develop physical symptoms such as headache or abdominal pain as a direct result of the stress or as a mechanism to avoid participation. Such situations can be avoided by addressing the causes of stress. De-emphasizing winning can significantly reduce stress. Coaches play a key role in reducing stress among athletes by enhancing enjoyment of the sport. They can provide immediate reinforcement for good plays and good efforts. Correcting errors should be done in a positive way by explaining how correct techniques will be beneficial. Coaches should not emphasize the errors that the young athlete has made. Mistakes should never be met with disapproval or yelling.

Parent-induced stress can be difficult to address. This occurs in situations where the child becomes an extension of the parents, who want their little athlete to either follow in their footsteps ("star" athlete parents) or succeed where they have fallen short. The following guidelines for parents may be helpful in these situations.

1. Parents should remain seated in the spectator area during the contest.
2. Parents should not yell instructions or criticism to their children.
3. Parents should make no derogatory comments to players, parents of the opposing team, officials, or league administrators.
4. Parents should not interfere with their children's coach. They must be willing to relinquish the responsibility for their child to the coach for the duration of the contest.

### Conclusion

Because of the many benefits, both physical and mental, of sports participation children need to be encouraged to become involved. Ideally, the sport should choose the child, which means that the suitability of the child for a particular sport is considered before he or she begins. For example, a child with pes cavus (high-arched feet) may be better suited to swimming than running; however, in most cases, the child is already involved in his or her sport when problems arise. It is the role of the coach, parent, and physician to monitor the effects

of the activity on the child. Intervention before problems arise can be accomplished by addressing risk factors early. When injuries occur, adequate rehabilitation will help prevent recurrence. The concept of “winning at all costs” should not be ingrained in the child athlete; rather, enjoyment of the sport should be the primary goal. It is important to remember that the elite young gymnast is not only an athlete but a child as well.

## YOUTH FITNESS

---

Fitness is a state of well-being that allows the body to function efficiently and effectively during school, work, leisure, and sports activities. In general, there are two main categories of fitness. *Health-related fitness* is said to include cardio-respiratory endurance, muscular strength, muscular endurance, flexibility, and body composition, whereas *skill-related fitness* components include agility, coordination, reaction time, balance, speed, and power. Both are associated with numerous physiological and psychological benefits during childhood and adolescence. In addition, positive behaviors that are acquired during the school-age years are likely to be carried over into adulthood. Thus, youth who enjoy fitness activities and learn how to live a physically active life are more likely to become active, healthy adults.

### Current Health and Fitness Status

Although youth tend to be more active than adults, nowadays fewer children and adolescents walk or ride their bicycles to school, and sedentary pursuits such as television viewing and “surfing” the Internet have decreased youngsters’ need to move. A majority of children do not participate in any organized physical activity during nonschool hours, and physical education and recess periods are unfortunately viewed as expendable in some school districts. It is becoming more apparent that the lack of daily physical activity along with the greater accessibility to energy-dense foods is contributing to the increasing prevalence of obesity among school-age youth.

These trends have significant implications for the present and future health of children and

adolescents, given the increased prevalence of cardiovascular disease risk factors and obesity-related comorbidities such as Type 2 diabetes, heart disease, and cancer. If current trends continue, the health-related consequences of physical inactivity and childhood obesity will likely pose an unprecedented burden on youth, their families, and our health care system. As a result, the promotion of safe, effective, and enjoyable fitness activities for children and adolescents with different needs, goals, and abilities has become a major public health issue.

### General Youth Fitness Guidelines

Children and adolescents should be encouraged to be physically active as part of play, recreation, sports, and school activities. Researchers and health care providers recommend that school-age youth participate daily in 60 minutes or more of moderate to vigorous physical activity that is developmentally appropriate, that is enjoyable, and that involves a variety of activities. This recommendation provides a reasonable standard that even sedentary boys and girls can achieve with a modest commitment to physical activity and support from their parents and schools. Youth can increase the amount of time they have for physical activity by reducing sedentary leisure pursuits such as television viewing, computer use, telephone conversations, and video games. Sedentary youth should gradually increase the amount of physical activity by about 10% per week until they reach the 60-minute goal.

Since youth will rarely perform prolonged periods of physical activity without rest or recovery, youth should be encouraged to accumulate their physical activity requirement throughout the day rather than perform a continuous bout of physical activity at a predetermined intensity. While continuous moderate-to-vigorous physical activity is not physiologically harmful, it is not the most appropriate method of exercise for youth, who tend to enjoy nonsustained activities or games. Watching children on a playground supports the premise that youth tend to have short bursts of physical activity followed by brief rest periods to recover and recharge. Participation in age-appropriate fitness activities is more likely to become a lifelong habit if youth experience success, gain confidence in their

physical abilities, establish a base of general fitness, and become aware of the health benefits of physical activity.

### Health- and Skill-Related Fitness Activities

Unlike most adult fitness programs that isolate fitness components, youth fitness programs should provide participants with the opportunity to improve both health- and skill-related components of fitness. While the components of health-related fitness relate specifically to health enhancement and disease prevention, skill-related components are necessary to perform daily activities as well as recreational pursuits and sports skills.

### Health-Related Fitness Activities

While most youth can accumulate 60 minutes of daily physical activity, health-related activities including aerobic games, strength training, and flexibility exercises must be punctuated with brief rest periods. Stop-and-go games or circuit training activities that alternate higher-effort and lower-effort segments have proven to be effective. While the standard means of assessing aerobic exercise intensity in adults is heart rate monitoring, this type of assessment is problematic for healthy children, who have great difficulty finding and counting their pulse rate during exercise. Moreover, there is little need for healthy children to monitor their heart rate response because adult target heart rate formulas are inappropriate for youth under 16 years of age. Generally, simple observations may be sufficient for determining physical exertion during youth fitness activities.

Despite traditional concerns associated with youth strength training, research clearly demonstrates that strength training can be a safe, effective, and worthwhile activity for children and adolescents provided that age-appropriate training guidelines are followed. Although there is no scientific evidence to suggest that the risks and concerns associated with youth strength training are greater than those of other sports and recreational activities in which children and adolescents regularly participate, youth strength training programs must be competently supervised, properly instructed, and appropriately designed. In general, if a child is ready for participation in some type of

sport activity (generally at age 7 or 8), then he or she may be ready to strength train. Different types of equipment, including free weights (e.g., barbells and dumbbells), child-size weight machines, elastic bands, medicine balls, and body weight exercises, have proven to be safe and effective for children and adolescents.

While flexibility is a well-recognized component of health-related fitness, long-held beliefs regarding the traditional practice of warm-up static stretching have been questioned. Research findings suggest that static stretching immediately before exercise has no significant effect on injury prevention and can have a negative influence on strength and power performance in children and adolescents. Children and adolescents should perform low- to moderate-intensity dynamic activities (e.g., walk, jog, hop, skip, and jump) during the warm-up period and static stretching exercises during the cooldown period. Because gains in flexibility are specific to the flexibility exercises performed at each joint, youth should perform a variety of static stretches for the upper body, lower body, and mid-section. The cooldown may actually be the ideal time to perform static stretching exercises because the muscles are already warmed up and participants need to recover from the exercise session with less intense activities.

### *Skill-Related Fitness Activities*

Most youth programs focus primarily on enhancing the health-related components of fitness and underemphasize the importance of developing skill-related fitness abilities that are characteristic of how children move and play. Games, activities, and exercises that involve skipping, hopping, twisting, kicking, and throwing can help youngsters develop the necessary prerequisite movement skills prior to facing the demands of more demanding fitness programs and sports training sessions. With competent instruction and quality practice time, children and adolescents can learn the skills needed for successful and enjoyable participation in recreational activities and organized sports.

### **Leadership and Instruction**

The challenges associated with promoting youth fitness should be met with enthusiastic leadership,

creative programming, and effective age-specific teaching strategies. A major objective of youth fitness programming is for physical activity to become a habitual part of children's lives and, if possible, persist into adulthood. With this objective in mind, parents, teachers, and youth coaches must strive to increase participants' self-confidence in their physical abilities. To achieve this objective, clear instructions should be provided so that participants can experience success and develop a sense of mastery of a specific skill. Thus, the focus of youth fitness programs should be on positive experiences instead of stressful competition in which most children fail.

Professionals should understand the uniqueness of childhood and adolescence and should genuinely appreciate the fact that youth are active in different ways and for different reasons compared with adults. Professionals who choose to work with children and adolescents need to relate to youth in a positive manner and understand how they think. Participation in a youth fitness program is a personal choice. Thus, it is unlikely that children will continue in a program if they do not understand the games or are unable to perform the exercises. Along with the primary objective of engaging youth in fun physical activities, professionals who work with children and adolescents are also responsible for class management, quality instruction, transition periods, and skill development. Needless to say, the development of successful youth fitness programs requires preparation, coordination, and understanding of the physical and psychosocial uniqueness of childhood and adolescence.

# Glossary

---

- acclimation** The process of adjusting physiologically or psychologically to different environmental conditions, such as altitude or temperature
- acetabular labrum** A ring of fibrous cartilage that runs along the socket of the hip joint
- acetabulum** The socket of the hipbone in which the head of the femur rests, forming a ball-and-socket joint
- achondroplasia** The most common form of dwarfism, a genetic disorder that affects the development and maturation of bone from cartilage
- acromioclavicular (AC) joint** The joint located at the top of the shoulder between the acromion and the clavicle
- actinic conjunctivitis** An eye disease characterized by inflammation of the conjunctiva due to prolonged exposure to ultraviolet light
- acute fracture** Break of bone or cartilage in which the fracture line is sharp and the surrounding bone appears normal
- acute injury** An injury that occurs with a rapid onset after a single event
- adhesion** Fibrous band of scar tissue that forms between tissues not normally bound together, often resulting from injury
- agonist** A contracting muscle that is resisted by an antagonist muscle
- air embolism** Any obstruction of the circulatory system caused by the entry of air bubbles into the bloodstream, often through ruptured alveoli
- all-around development** The emphasis on the development of the three primary attributes of athleticism, flexibility, and musculoskeletal and cardiovascular capacities
- allograft** The surgical transplant of tissues or organs between different individuals of the same species
- ALPSA (anterior labral periosteal sleeve avulsion)** A lesion at the distal end of the shoulder associated with shoulder dislocation
- alternative medicine** Healing practices that fall outside the realm of conventional medical practice, such as homeopathy, acupuncture, naturopathy, or herbalism
- alveoli** Tiny air sacs within the lungs that facilitate the exchange of carbon dioxide and oxygen; the terminal points of the airways within the lungs
- amenorrhea** The absence or abnormal cessation of a menstrual period in a premenopausal female when menstruation should be present
- anabolic-androgenic steroid** A synthetic drug that is used to stimulate muscle and bone growth by mimicking the male hormone testosterone

- anaerobic threshold** The point during exercise when the body begins to work the muscles without the use of oxygen; the limit at which aerobic exercise can be maintained
- aneurysm** An abnormal blood-filled swelling of an artery or vein from weakness of the blood vessel wall
- ankle inversion test** A range-of-motion test performed on the ankle; positive tests reveal a potential tear of the calcaneofibular ligament of the ankle
- annular ligament** A strong band of fiber that surrounds the wrist or ankle joint
- anomalous coronary arteries** Congenital variation in the origin, pathway, termination, number, or structure of the coronary arteries; most anomalies are clinically silent and do not affect quality of life
- anorexia athletica** A condition in which people engage in excessive exercise to lose weight, typically associated with anorexia nervosa
- anorexia nervosa** A condition in which people intentionally starve themselves for fear of gaining weight, usually characterized by extremely low body weight and body image distortion
- antagonist** The counterpart of the contracting, or agonist, muscle responsible for the lengthening or stretching of the agonist
- anterior apprehension test** A clinical test for assessing the instability of a shoulder, in which apprehension with abduction and external rotation of the joint suggests anterior instability
- anterior drawer test** A measure of the stability and integrity of the anterior cruciate ligament of the knee
- aortic stenosis** A cardiovascular disease characterized by the abnormal narrowing of the aortic valve between the left ventricle and the aorta
- Apley grind test** A commonly applied diagnostic test in which the physician grips the hand of the patient and applies downward pressure, causing the hand to deviate toward the ulna
- Apley scratch test** A clinical test used to assess the range of motion of the shoulders by asking the patient to scratch his or her back
- Apley test** A clinical test used to assess knee or shoulder injuries
- apophysis** A natural swelling or outgrowth, or protuberance, on any part of a bone
- apophysitis** An inflammation of an apophysis
- apprehension test** A clinical test used to assess the location and severity of injuries, which is performed by manipulating a patient's joints and gauging his or her pain response
- arachnoid mater** The weblike protective covering of the brain and spinal cord; the middle of the three layers of meninges
- arrhythmogenic right ventricular dysplasia** A genetic disorder of the heart that is characterized by abnormal, arrhythmic ventricular contractions
- arteriovenous malformation** A congenital disorder characterized by an abnormal connection of veins and arteries, often resulting in internal bleeding and headaches
- arthrofibrosis** A condition most often associated with the knee, characterized by the growth of scar tissue resulting in limited joint mobility
- arthroscopic portal** Small incision through which arthroscopic surgery is performed
- arthroscopy** A minimally invasive surgery that allows the physician to examine the interior of a joint and diagnose and treat common knee, shoulder, and other joint problems

- articular (hyaline) cartilage** A tough, fibrous connective tissue that forms on the surface of bones within joints and aids in joint mobility
- aseptic necrosis** A condition in which the lack of blood supply to the bone may cause bone tissue death
- ataxia** The lack of motor coordination or the inability to coordinate skeletal muscle contractions
- athlete's heart syndrome** A medical condition in which the heart enlarges in response to the physiologic stresses of strenuous physical training; typically benign but difficult to distinguish from more serious cardiovascular illnesses
- athlete's nodules** A general term for relatively hard, discrete, roughly spherical, abnormal cutaneous masses occurring in individuals who engage in sports
- athletic pseudonephritis** The occurrence of protein and white and red blood cells in the urine in response to strenuous physical activity, often mimicking the problems associated with kidney disease but clearing up completely after 3 days of rest
- atlantoaxial instability** Increased flexibility of the ligaments between the atlas and the axis, the two bones at the top of the spinal column, with neurologic symptoms occurring when the spinal cord is affected
- atlas (vertebra)** The uppermost cervical vertebra of the spine
- atopy** An allergic reaction that becomes apparent almost immediately in response to a stimulus; genetically determined hypersensitivity to an allergen
- ATP (adenosine triphosphate)** A complex chemical compound derived from adenosine that is formed by the energy released from food and is used to perform cellular metabolic functions; energy molecule of a cell
- auditory exostosis** Benign bony growth located in the external auditory canal; frequently present in athletes who engage in water sports
- autograft** Tissue that is taken from one site and grafted onto another in the body of the same individual
- avascular necrosis** Death of the cells in a bone or joint due to depletion of blood supply
- avulsion** A painful separation of a muscle from its attachment to a bone
- avulsion fracture** Bone fracture that occurs when a tendon pulls off a piece of bone from a larger bone mass, usually as a result of a violent or forceful muscle contraction
- axial compression test** A test performed by pressing on the top of the patient's head with his or her neck in a neutral position; test is positive if the pain is aggravated
- axial pain (syndrome)** Pain referring to the central part of the body; back pain distinguished from the limbs
- axis** The second uppermost cervical vertebra, which provides a pivot for turning the head
- axon** A long extension of a neuron responsible for conducting a signal away from the cell body
- balance** The capacity to remain in a controlled position without falling or losing coordination
- Bankart lesion** A tear of the anterior glenoid labrum that is caused by violent movement of the arm
- Basilar skull fracture** Fracture that occurs at the base of the skull or the portion underneath the brain

- belly press test** A clinical test used to assess the function of one of the four muscles of the rotator cuff located within the shoulder, the subscapularis; performed with the patient in a standing position with his or her hand on the stomach, pushing as hard as possible
- Bennett fracture** A bone fracture of the first metacarpal between the thumb and wrist
- bipartite** Consists of two parts or divisions
- Blount disease** A growth disorder of the tibia in which the lower leg angles inward; characterized by a bow-shaped lower leg
- bony Bankart lesion** A fracture of the front lower portion of the glenoid; *see* Bankart lesion
- bony edema** A swelling of a bone that occurs following an injury
- boutonniere deformity** A deformity of the finger in which the joint nearest to the knuckle is bent inward due to misalignment of the tendons
- bowlegs** Legs that bend outward instead of angling inward; the opposite of knock-knees
- boxer's fracture** A fracture in the fourth or fifth metacarpal, which comprises the knuckles
- brachial plexus** An arrangement of nerves that conducts signals from the spine to the shoulder and allows for movement of the arm
- bronchitis** A respiratory disorder characterized by inflammation of the mucus membranes lining the bronchial tubes
- bronchoconstriction** Constriction of the bronchioles (airways in the lungs) due to the tightening of surrounding smooth muscle; can cause coughing, wheezing, and shortness of breath
- bulge** Swelling or outward protrusion
- bulimia nervosa** An eating disorder characterized by episodes of binge eating followed by behaviors designed to prevent weight gain, such as purging, fasting, or excessive exercise
- bursa** (*pl.*, bursae) A small, fluid-filled sac that provides a cushion between bones and tendons and/or muscles around a joint. Aids in reducing friction between bones and allows free movement
- bursitis** Painful inflammation of a bursa caused by pressure, repetitive stress from overuse, or infection
- cam impingement** An abnormal shape of the proximal femoral epiphysis that causes the femoral head to fit awkwardly within the socket, resulting in mild to severe pain
- capsulorrhaphy arthropathy** A disease afflicting the shoulder characterized by deterioration of the joint surface due to previous repairs of recurrent dislocations
- cardiovascular drift** A phenomenon that describes an increase in heart rate with prolonged exercise (greater than 10 minutes) despite the exercise continuing at the same intensity
- catharsis** In psychiatry, the process of release of repressed memories, ideas, or emotional tension
- cauda equina syndrome** A serious neurological condition characterized by a dull pain and numbness in the buttocks, genitals, and/or thigh with uncontrolled bladder and bowel function due to compression of the spinal nerves
- central nervous system** The part of the nervous system consisting of the brain and spinal cord; responsible for integrating environmental signals
- cerebral edema** An excess accumulation of fluid in the intracellular and extracellular spaces of the brain; a serious condition requiring emergency treatment

- cerebrospinal fluid** The fluid surrounding the brain and spinal cord that protects the spinal cord and provides nutrients
- cervical spine** The part of the vertebral column comprising the first seven vertebrae inferior to the skull
- chair sign** A clinical test to check for elbow stability and integrity, in which the patient is seated with elbows flexed at 90°, with forearms supinated and arms abducted, and then tries to rise from the chair pushing down only with the arms
- chiropractic** An alternative or complementary medical system that focuses on maintaining correct alignment of the musculoskeletal system; spinal manipulation is the most common treatment method, and many people visit chiropractors for treatment of low back pain
- chondrolysis** Disappearance of the cartilage on the joint surface of the femur (articular cartilage) as a result of disintegration or dissolution
- chondromalacia** A degeneration or softening of the articular cartilage
- chondromalacia patella** A softening of the cartilage on the articular surface of the patella that causes pain, particularly during flexion
- chondroplasty** The smoothing of torn cartilage on the joint surface
- chronic exertional compartment syndrome** An exercise-induced neuromuscular condition that causes swelling and pain in the arms and legs
- closed fracture** A fracture that does not pierce the skin
- coarctation of the aorta** A congenital disorder characterized by narrowing of the aorta, thereby decreasing blood flow to the body
- coccyx** The end of the spinal column; the base of the spine where the vertebrae are fused
- co-contraction** A type of contraction when both agonist and antagonist muscles fire at the same time
- Colles fracture** A fracture to the distal end of the radius bone located in the forearm
- comminuted fracture** A fracture involving extensive fragmentation of bone
- commotio cordis** Sudden heart failure due to a severe blow to the chest; most common in extreme contact sports
- compartment** A group of related muscles found in the same area of the body
- compartment syndrome** An acute medical issue characterized by the overuse of the same muscle or muscle group and decreased blood flow in a confined anatomical space
- complementary medicine** A diverse set of systems of holistic medicine based on philosophies other than those used in conventional Western medicine; often called *preventive medicine*
- compound fracture** The former term for a broken bone that has gone through the skin; now called *open fracture*
- concentric movement** The part of the movement where the agonist muscle contracts, for example, the lifting motion of an exercise
- concussion** An injury to the brain caused by a violent blow or rapid shaking; a mild concussion may involve no loss of consciousness; severe concussion may cause prolonged unconsciousness. An athlete who has had a concussion should return to play only with a physician's approval

- conditioning** Development of physical fitness through adaptation of the body and its various systems to a program of exercise
- conduction** The act of transmitting heat, sound, or nervous impulses from one area of the body to another
- condyle** A rounded epiphysis of a bone usually encased in the articular cartilage
- contralateral** Of or relating to the opposite side
- contusion** A blunt force injury that does not break the skin but causes underlying tissue damage, with bleeding under the skin (bruising)
- convection** The transfer of heat via gas or liquid
- coordination** The ability to conduct more than one set of muscle movements in unison
- coracoid** The bony prominence of the scapula
- costochondritis** An inflammation at the point where the ribs fuse with the sternum
- crepitus** A grinding noise or sensation within a joint or the lungs
- cruciate** Cross-shaped
- crutch palsy** Compressive injury to the nerve complex (the brachial plexus) located in the underarm
- cyanosis** A medical condition characterized by a bluish discoloration of the skin or mucous membranes; a symptom that indicates a dangerously low level of oxygen in the discolored area
- de Quervain disease** *See* de Quervain tenosynovitis
- de Quervain tenosynovitis** A painful inflammation of the tunnel that surrounds the two tendons that control the movement of the thumb
- debridement** Surgical removal of dead, damaged, or infected tissue and foreign matter from a wound or burn
- deep vein thrombophlebitis** The formation of a blood clot within a vein, typically located in the leg; causes the extremity to become swollen, painful, red, and/or warm
- dehydration** An excessive deficiency of body water
- dens** A superior projection of the vertebral body that goes up into the anterior ring of the atlas
- depressed skull fracture** A skull fracture in which fragmented bones press into brain tissue and cause neurological trauma
- dermatophyte** A parasitic fungus that infects the skin
- dermis** The deep vascular layer of the skin located beneath the epidermis
- diabetes mellitus** A condition characterized by hyperglycemia, resulting from the inability to appropriately control blood sugar and regulate insulin levels
- diaphragm** A muscular partition between the thoracic and abdominal cavities that regulates breathing
- diaphragmatic breathing** The act of breathing deep within the lungs by focusing on lowering the diaphragm rather than expanding the chest
- diaphysis** The main shaft of a long bone
- diastatic skull fracture** Fracture that occurs along the growth plates or sutures of the skull
- disability** A physical or mental impairment that prevents a person from performing one or more major life activities

- disk herniation** A condition of the vertebral column in which a tear in the outer, fibrous ring (nucleus pulposus) of an intervertebral disk allows the soft, central portion (anulus fibrosus) to bulge out, commonly known as a *slipped disk*
- disk-osteophyte complex** A medical condition where the soft tissue of the intervertebral disk extrudes beyond its normal parameters
- displaced** Pertaining to the removal from the normal position, location, or place
- distraction test** An orthopedic test performed on the knee; positive tests indicate a ligamentous injury of the knee
- diuretic** Any substance that increases the amount of urine production by the kidneys and reduces the amount of water in the blood, thereby decreasing the blood volume
- dorsal** Pertaining to the back surface of a body part, such as the backside (knuckle side) of the wrist and hand
- dorsiflexion** Backward flexion or bending toward the dorsal side; flexing the ankle and pointing the toes upward
- drawer test** An orthopedic test that is used to detect torn cruciate ligaments in the knee
- dura** *See* dura mater
- dura mater** The outermost layer of the meninges, the membranes surrounding the brain and spinal cord
- dysesthesia** A condition characterized by an unpleasant, abnormal sensation such as burning, caused by lesions of the nervous system
- eccentric contraction** A condition that occurs when the force generated by the muscle cannot overcome the resistance placed on the muscle; also, a lengthening contraction of the muscle
- eccentric movement** A movement in which the agonist muscle elongates
- ecchymosis** The escape of blood within subcutaneous tissue that results in discoloration or bruising
- echocardiogram** A sonar imaging scan used to study the structure and motions of the heart
- edema** A swelling of tissue due to the accumulation of excess fluid
- effusion** The discharge or outpouring of a fluid into a body cavity
- electrocardiogram** A medical record that is used to measure the electrical rhythms of the heart
- endogenous** Produced, occurring, or caused by factors within the body of an object or organism
- endotenon** A thin retinacular structure investing each tendon fiber
- endurance** The ability to withstand stress and hardship or sustain an activity over time; a measure of stamina
- epicondyle** A protrusion of a bone above the condyle that provides the surface area to which ligaments and tendons can attach
- epidermis** The outermost layer of the skin surface of vertebrates, which is on top of the dermis
- epidural space** The space between the dura mater and the lining of the spinal canal
- epiphysis** The rounded end of a long bone
- epitenon** A component that surrounds the tendon and contains the vascular, lymphatic, and nerve supply and is in turn surrounded superficially by the paratenon
- erythema** An abnormal red discoloration of the skin due to the dilation of cutaneous blood vessels

- euhydration** A normal state of body water content
- evaporative heat loss** The loss of body heat due to the evaporation of sweat from the body
- excision** Surgical removal of a portion or all of an organ or other structure
- exercise-associated hyponatremia** Dangerously low levels of sodium within the blood due to excessive exercise
- exercise-induced hematuria** The presence of blood within the urine due to excessive exercise
- exogenous** Produced, occurring, or caused by factors outside the body of an object or organism
- extra-axial hemorrhage** Blood loss within the intracranial space; increases pressure, causing headaches
- extreme-risk injury** Injury needing immediate medical attention
- extrusion** A bulge or protuberance, pushing out
- facet joints** Small joints located between adjacent vertebrae
- fascia** A continuous sheet of connective tissue that separates and bonds together muscles and other organs
- fasciotomy** A surgical procedure in which fascia is removed from the body to relieve tension and pressure
- female athlete triad** A medical condition seen in some female athletes, characterized by disordered eating, amenorrhea, and osteoporosis
- FEV<sub>1</sub> (forced expiratory volume in 1 second)** The volume of air an athlete can expel in the first second of a forced expiration; the most important parameter examined in determining airway obstruction
- first-degree strain** A minor strain characterized by only a few muscle fiber tears
- flail chest** A severe medical condition characterized by fragmentation of the ribs due to stress
- flexibility** The ability of a muscle or extremity to relax and yield to stretch forces
- focal fibrocartilage dysplasia** An uncommon, normally harmless bone lesion that causes deformity of the long bones in youth
- fontanelle** The gaps located between the bones of the cranium in an infant or fetus
- foramen (*pl.*, foramina)** Any opening or orifice within the body
- Freiberg disease** An osteochondrosis affecting the metatarsals (long bones of the foot)
- Freiberg sign** The reproduction of pain caused by passive internal rotation of the hip with the leg in an extended position
- fulcrum test** By placing the left hand under the glenohumeral joint to act as a fulcrum, the apprehension test becomes a fulcrum test
- functional limitation** Any health problem that prevents an individual from completing a task
- ganglion cyst** A small, abnormal, fluid-filled sac (usually less than 2 centimeters) that develops near a joint capsule or tendon sheath
- gastrocnemius soleus (calf muscle) strain** A strain or tear, with the sensation of a pop being felt, due to the simultaneous stretching and active contraction of the muscle
- genu valgum** A medical condition characterized by an inward curvature of the legs so that the knees touch when a person is standing straight; commonly known as *knock-knees*

- genu varum** A medical condition characterized by an outward curvature of the legs; commonly called *bowlegs*
- GLAD lesion (glenolabral articular disruption)** Lesion characterized by a labral tear associated with an injury to the glenoid articular cartilage
- glenohumeral joint** The shoulder joint that functions as a ball-and-socket joint; composed of the glenoid socket and the humeral head
- glenohumeral ligaments** Three bands of connective tissue that strengthen the glenohumeral joint
- glenoid** Any shallow depression of a bone resembling a pit or socket
- glenoid labrum** A rim of articular cartilage that surrounds the margin of the glenoid cavity in the shoulder blade
- glial cell** Nonneuronal cell that provides nutrients and removes waste from other neural cells
- glycogenolysis** The process by which glycogen is broken down in the liver into individual molecules of glucose
- gout** A form of arthritis caused by a buildup of uric acid in the joints
- gradual progressive throwing** A shoulder rehabilitation technique in which throwing motions help stabilize the shoulder
- gray matter** A large component of the central nervous system comprising glial cells, neuronal cell bodies, dendrites, axons, and capillaries
- grind test** A clinical test used to determine the integrity and problems associated with the meniscus of the knee
- Hawkins-Kennedy test** A test that attempts to cause external compression of the rotator cuff and consequently re-create the patient's pain
- hemarthrosis** Bleeding into joint spaces
- hematocrit** The volume percentage of red blood cells in a blood sample
- hematoma** Swelling formed by excess accumulation of blood
- hematopoiesis** The production of blood cells
- hemorrhage** A copious discharge of blood from the blood vessels
- hemothorax** Accumulation of blood located within the pleural cavity, or the area surrounding the lungs
- hepatitis** Inflammation of the liver caused by certain viruses or other factors such as alcohol abuse or medications
- hepatomegaly** Abnormal enlargement of the liver
- heterotopic bone formation/ossification** The formation of bone in abnormal locations, such as in soft tissue or muscle
- Hill-Sachs lesion** A depression in the head of the humeral epiphysis due to a forceful impact against the glenoid rim
- hip dysplasia** An abnormal formation and deterioration of the hip socket that is characterized by excessive pain and arthritis
- hip impingement** A condition that is characterized by excessive friction within the ball-and-socket hip joint

- hip quadrant test** A clinical test that indicates arthritis, avascular necrosis, and/or an osteochondral defect within the hip
- Homans sign** A sign of deep vein thrombosis; is positive when pain is located within the calf muscles
- hop test** A clinical test used to measure the horizontal and vertical power of the legs by performing three consecutive jumps
- hydrogenation** A form of chemical reduction, a chemical reaction between molecular hydrogen (H<sub>2</sub>) and another compound or element, usually in the presence of a catalyst; commonly employed to reduce or saturate organic compounds
- hyperpronation** The extreme inward rotation of the foot during gait
- hyperalgesia** An increased response to pain caused by damage to the peripheral nerves
- hyperesthesia** A state of abnormal increase in sensitivity to sensory stimuli
- hyperlipidemia** An excess quantity of lipids in the blood
- hypertrophic cardiomyopathy** A condition where the heart muscle becomes abnormally enlarged, limiting the amount of blood that can enter the heart and thereby reducing pumping ability
- hyphema** A collection of blood in the anterior chamber of the eye often caused by trauma; causes blurry vision, pain, and tearing
- hypodermis** The lowermost subcutaneous level of the three skin layers
- hypohydration** *See* dehydration
- hypothalamus** The part of the brain responsible for the control of endocrine glands and the autonomic nervous system
- hypoxia** Decreased availability of oxygen to body tissues
- iatrogenic** Describing inadvertent harmful consequences or complications resulting from medical treatment
- idiopathic** A disease of an unknown origin
- iliotibial band** A band of fascia that spans from the iliac crest of the pelvis region to the knee joint; can become inflamed due to excessive running
- impingement** Striking or excessive pressure on a tissue, often from encroachment by adjacent structures
- infective endocarditis** An inflammation of the membrane that lines the cavities of the heart and forms part of the heart valves, generally caused by an infection
- influenza** An acute, highly contagious viral disease; also referred to as the *flu*
- inguinal hernia** A protrusion of the intestines through the inguinal canal where the flesh of the abdomen meets the thigh
- injury, catastrophic** An extremely serious injury that may result in disability and loss of bodily functions, with full recovery doubtful
- injury, nonfatal** A broad range of types of injury from acute to catastrophic with no life-threatening issues
- injury, serious** An injury in which mortality is probable
- integrative medicine** A combination of alternative and conventional medicine to provide a more comprehensive healing plan for the patient

- intersection syndrome** Inflammation of the crossover area where the musculotendinous junctions of the first dorsal compartment meet with the tendons of the second dorsal wrist compartments
- interval training** An exercise strategy in which an athlete raises his or her exercise intensity above the anaerobic threshold for a short period of time and then dips back below the threshold and keeps exercising
- intervertebral disk** A fibrocartilaginous disk that provides cushion and support between two adjacent vertebrae
- intervertebral foramen** An opening between vertebrae that transmits nerves from the spine throughout the body
- intraarticular dilation** An expansion within the joint
- intra-axial hemorrhage** A hemorrhage that takes place within the central part of the body
- iontophoresis** Therapy that uses small electric currents to deliver medicine into tissues of the body
- ipsilateral** Positioned on or affecting the same side
- irrigation** Cleansing injured tissue by rinsing with sterile saline, with or without antibiotics in the solution
- ischemic necrosis** A condition in which the lack of blood supply to the bone may cause bone tissue death
- isometric contraction** A contraction that generates muscle force but in which no joint movement occurs, such as holding a squat for 10 seconds
- isotonic contraction** A contraction that occurs when the muscle contracts and joint movement occurs
- jerk test** A clinical test used to determine the integrity of the knee joint (possible torn meniscus), also called Hughston's jerk test, to distinguish from the simple knee-jerk test of neurological reflex by tapping the patellar tendon.
- Jobe's empty can test** A clinical test used to determine the integrity of the supraspinatus tendon
- joint aspiration** The removal of fluid from within a joint
- joint effusion** The escape of intraarticular fluid
- joint integrity** A measure of the stability and durability of a joint
- joint of Luschka** Small synovial joints between adjacent lower-cervical vertebral bodies—a frequent site of arthritis formation
- Jones fracture** A fracture of the fifth metatarsal of the foot
- knock-knees** A condition in which the legs curve inward at the knees; *see* genu valgum
- kyphosis** An abnormal backward curve in the spinal column
- labrum** A thickened portion of connective tissue that surrounds the sockets of the shoulder and hip joints
- Lachman test** A test that is used for examining the integrity of the anterior cruciate ligament of the knee
- lactate threshold** The point at which lactic acid buildup in the muscles begins to impair performance
- lamina** (*pl.*, laminae) A broad plate which extends from the pedicle to the median line of the vertebra, two laminae fusing to complete the roof of the vertebral arch

- laminectomy** Surgical removal of any part of the lamina
- lateral epicondylitis** A painful inflammation of the tendon that wraps around the elbow; also called *tennis elbow*
- lateral pivot-shift test** A clinical test used to evaluate the anterolateral structures of the knee
- lift-off test** A clinical test used to check the stability of the shoulder
- ligaments** Fibrous connective tissues responsible for connecting bones, cartilage, and other structures
- linear fracture** A fracture that runs parallel to the axis of the bone
- load and shift test** An orthopedic test used to check for the stability and integrity of the shoulder
- loose body** A free-floating piece of bone or cartilage that has broken away and is moving around a joint
- lordosis** An inward forward curve of the lower spine
- lucid interval** A temporary improvement in a patient's condition following a traumatic brain injury, after which the patient's condition deteriorates
- Ludloff sign** A test checking the ability to flex the thigh while sitting down; is positive if patients fail to perform the test, and negative if performed effectively
- lumbar** The portion of the spinal column between the thorax and the pelvis, commonly called the lower back
- luteal phase** The second half of the menstrual cycle lasting from ovulation to menstruation
- malleolar bursitis** Swelling and pain over the ankle bone caused by irritation of the bursa, a fluid-filled sac that aids in reducing friction between moving bones
- McMurray test** A test used to determine whether a meniscal tear is present in the knee by bending the lower leg, straightening it out, and rotating it; is positive if pain is found around the area of the meniscus
- medial and lateral patellar glide test** A test used to determine the stability of the lateral retinaculum in the knee and the medial aspect of the knee
- medial epicondylitis** An overuse injury, commonly known as *golfer's elbow*, that causes pain in the inside of the elbow
- medial tibial stress syndrome** An overuse injury, commonly known as *shin splints*, causing irritation in the shinbone, which is located in the front of the lower leg
- mediastinum** The central cavity surrounded by the lungs, containing the heart, proximal aorta, and vena cava and lined by a protective tissue, the pericardium
- meninges** Protective coverings of the brain and spinal cord, consisting of three layers from outermost to innermost—namely, the dura mater, arachnoid, and pia mater
- meniscal cartilage** The cushioning tissue of the knee between the femur and the tibia
- meniscus** A structure consisting of both the lateral and the medial cartilage of the knee, acting as a pad between the joints of the femur and the tibia and providing a smooth surface for the joints to glide on
- menorrhagia** Excessive menstruation that lasts for more than 7 days
- metabolic ketoacidosis** A condition that usually affects patients with diabetes when the body has very low levels of insulin and starts to break down body fat, leading to the formation of a high concentration of ketone bodies, and thus causing the blood to become too acidic

- metaphysics** The study of reality in relation to such questions that may not be answered scientifically; also, the study of subjects relating to mind and matter
- metatarsalgia** An overuse injury that causes pain in the middle region of the forefoot
- microfracture** A surgical technique in which tiny holes are made in the exposed bone in an area of the joint where the full thickness of the cartilage has been completely damaged
- microtrauma** The term given to microscopic injuries such as microtears in muscles, tendons, and tissues
- milk test** An orthopedic measure to test elbow instability
- Monteggia fracture** A break in the ulna bone of the forearm, along with dislocation of the radial head
- Morton neuroma** Irritation, pain, and swelling of the nerve located between the third and fourth toes of the foot
- moving valgus stress test** A test used to determine whether the medial collateral ligament (MCL) of the elbow is torn
- MR (magnetic resonance) arthrogram** A test used to examine the joints in the body, such as the knee or shoulder, in which a contrast-enhancing dye is injected to facilitate viewing by magnetic resonance imaging
- muscle hypertrophy** The increased cross-sectional size of the muscle fibers
- muscle strength** The ability of the muscle to create force against physical objects
- muscular endurance** The ability of a muscle to perform and maintain repeated muscle contractions over long periods of time
- myocarditis** An inflammation of the heart muscle (myocardium)
- myocardium** Cardiac muscles that make up the bulk of the heart wall
- myofascial release** The adding of pressure with the thumb over the muscle spasm to decrease the contraction
- myositis ossificans** The formation of bone within muscle tissue; occurs after the tissues surrounding the muscles are damaged in a traumatic injury
- Neer test** A test that attempts to cause external compression of the rotator cuff and consequently recreate the patient's pain
- nerve impingement** (or "pinching" of the nerve) Refers to pain in or impaired function of a nerve that is under pressure
- nerve root** A part of a collection of nerve fibers that branch off from the spinal cord. Dorsal roots are composed of sensory fibers that bring information into the spinal cord. Ventral roots are composed of motor neurons that carry commands from the spinal cord to the muscles and internal organs
- nerve tracts** A collection of nerve fibers located in the central nervous system (CNS)
- neurons** Nerve cells; the conducting cells of the nervous system that receive and transmit information through chemical and electrical signals
- Noble compression test** A test used to check for iliotibial band syndrome
- nondisplaced** A type of fracture in which the bone maintains its normal alignment after breaking

- nonpurging-type bulimia nervosa** An eating disorder involving excessive eating along with attempts to compensate afterward through diet pills, fasting, or excessive exercise
- nonunion** A fractured bone that failed to heal properly
- nuchal ridge** A thick crest located on the back of the neck and base of the skull (occipital bone)
- nucleus pulposus** A gelatinous substance found in the center of intervertebral disks of the spinal column; aids in shock absorption
- Ober test** A test used to evaluate the shortening of the iliotibial tract muscle
- O'Brien test** A test used to evaluate acromioclavicular joint injury in the shoulder
- OCD** *See* osteochondritis dissecans
- occipitocervical injuries** An injury of the cervical spine in which the cranium dislocates from the neck, a severe injury that can be fatal if not treated immediately
- odontoid process** A toothlike structure found in the second vertebra of the neck
- open fracture** A fracture in which the bone penetrates through the skin, also called a compound fracture
- orthorexia nervosa** An eating disorder characterized by an excessive concern with eating healthy foods (not officially recognized as a medical diagnosis)
- orthosis** A support device used to brace or correct the function of specific limbs—for example, arch supports that are used to correct foot function
- os acromiale** Pain in the shoulder due to the failed fusion of the bone at the front of the shoulder roof known as the acromion
- os odontoideum** A separation of the top of the dens from the C2 vertebral body
- ossicle** The smallest bones in the body, of which three are located in the middle ear
- osteoarthritis** A form of arthritis; a degenerative disease that affects joints and also leads to the gradual breakdown of cartilage and the formation of “bone spurs” on joints
- osteoblasts** Cells in the body that are responsible for bone formation
- osteochondral injury** An injury that affects the articular cartilage and the bone underneath
- osteochondritis** Inflammation of bone and cartilage
- osteochondritis dissecans (OCD)** An injury in which fragments of cartilage and bone are separated from the end of the bone and are loose in the joint space
- osteochondrosis** The necrosis or breakdown of growth centers in the pediatric or skeletally immature patient followed by regeneration or healing
- osteoclast** A body cell that not only breaks down bone tissue but also absorbs it back into the body
- osteolysis** The active resorption of bone matrix by osteoclasts as part of an ongoing disease process
- osteonecrosis** A condition in which the lack of blood supply to the bone may cause bone tissue death
- osteopenia** A condition in which the level of bone mineral density is below normal levels, but not as severe as in osteoporosis
- osteophyte** An abnormal growth of bone in damaged joint areas, more commonly known as a *bone spur*; commonly seen in osteoarthritis due to the nature of degenerative joints

- osteoporosis** A disease that causes bones to lose density, strength, and tissue over a period of time, leaving bones fragile and more susceptible to injuries such as fractures
- osteotomy** A surgical procedure that involves cutting the bone to promote proper alignment and healing in the affected joint area; can be used for arthritis treatment and to fix bones that may have grown incorrectly
- otalgia** Ear pain, of which there are two types: (1) pain originating from the outside of the ear, or *referred otalgia*, and (2) pain that originates from within the ear, or *primary otalgia*
- otorrhea** A discharge of fluid from the ear canal
- Ottawa ankle rules** A set of guidelines established to help physicians determine whether X-rays are needed to diagnose possible fractures in the foot or ankle
- Ottawa knee rules** A set of guidelines established to help physicians determine whether X-rays are needed to diagnose knee injuries
- outer annulus** The outermost layer of fibrocartilage in an intervertebral disk, tears or ruptures of which may permit extrusion of the nucleus pulposus into the surrounding tissue
- overreaching** A condition in which an athlete trains excessively, causing stress, fatigue, and sometimes poor athletic performance
- Pace sign** A test used to determine whether a patient has piriformis syndrome, a compression of the sciatic nerve by the piriformis muscle of the thigh
- paraplegia** Partial or complete paralysis of the lower extremities caused by a spinal cord defect or traumatic injury
- paratenon** The external covering of the entire tendon
- paratenonitis** Inflammation of the paratenon, the outermost layer of the tendon
- paresthesias** The occurrence of abnormal nerve sensations such as tingling, burning, itching, and “pins and needles,” sometimes caused by nerve damage
- parietal pleura** A specialized skinlike surface that lines the thoracic cavity
- patellar tendinosis** Inflammation or long-term damage to the tendon that connects the bottom of the kneecap to the top of the shinbone
- patellar tendon** The attachment of the quadriceps muscle to the tibia
- patellar tilt test** A test used to assess the tightness of the lateral side of the knee and also pain around the kneecap (patella)
- Pavlik harness** A soft brace used for babies less than 6 months old with thighbone fractures
- periodization** The process of splitting up time into blocks; in sports medicine, the splitting up of a training regimen into phases
- periosteum** A membrane/tissue covering all bones
- peripheral nervous system** Composed of the nerves outside the brain and spinal cord, which also connect the central nervous system to the sensory organs, limbs, and muscles
- pertussis** A contagious bacterial disease that causes violent coughing, commonly known as whooping cough
- pes planus** A condition in which the arch of the foot collapses and touches the ground, commonly called *flat feet*

- petechiae** Round red spots that are visible on the skin due to bleeding under the skin
- phalanges** (*sing.*, phalanx) The bones of the fingers and toes
- pharmacokinetics** The study of what happens to a drug after it is taken into the body, that is, how it is metabolized
- phonophoresis** A technique using ultrasound to help the body absorb therapeutic drugs through the skin
- physiatrist** A physician who specializes in physical and rehabilitation medicine
- physis** The growth plates at the ends of long bones
- pia mater** The innermost layer of the meninges, the membranes surrounding the brain and spinal cord
- pincer impingement** A form of hip abnormality in which the front edge of the hip socket sticks out too far
- piriformis sign** A test used to determine whether the pain originating in the gluteus maximus causing referred pain down the leg is due to piriformis syndrome
- pivot-shift test** A test used to determine the stability of the anterior cruciate ligament (ACL) in the knee
- plantar fascia** A series of connective tissues that start from the heel and support the arch in the foot
- plantarflexion** Bending of the foot in a downward direction
- pleura** A membrane that surrounds the lungs and also covers the diaphragm and lines the inner chest wall, forming a potential space for lung expansion
- pleural cavity** The body cavity that surrounds the lungs
- plica syndrome** An inflammation of the plica (*see* plicae) found in the knee
- plicae** Bands of synovial tissue located in the lining of a joint
- plication** A surgical procedure used to tighten tissues by folding them into tucks and suturing them
- pneumomediastinum** A pathological condition consequent to trauma to the chest in which air leaks from the injured lungs into the middle of the chest (mediastinum)
- pneumonia** An inflammation of the lungs caused by infection
- pneumothorax** A serious condition that occurs following the collapse of a lung, in which air collects in the pleural space surrounding the lungs and makes breathing difficult
- popliteal** Refers to the structures in the back of the knee, such as veins, nerves, arteries, and so on
- positive J sign** A test that shows the patella tracking laterally as the knee changes from flexion to extension
- posterior drawer test** A test to evaluate the posterior cruciate ligament (PCL) in the knee, especially for tears and ruptures
- posterior Lachman test** A test used to diagnose a torn anterior cruciate ligament (ACL)
- posterior sag test** A test used to determine instability in the posterior cruciate ligament
- posture** The position in which the body is held upright against gravity while standing or sitting down
- power** A force that is exerted over a period of time

- progressive muscle relaxation** A set of skills whereby the athlete is trained to control the tension of his or her muscles by alternatively consciously flexing them, holding the tension, and then slowly releasing them
- progressive overload** The increased stress placed on the body during exercise
- prolotherapy** A form of therapy that involves injection of a substance into the body to strengthen weakened tissues and also alleviate pain
- proprioception** The ability to sense the position and movement of muscles
- protrusion** An extension beyond the usual limits
- pseudocyst** An abnormal sac that resembles a true a cyst but lacks membranous lining
- pterygium** An abnormal growth that begins on the white of the eye and invades the cornea, the clear tissue covering the iris and the pupil, which may result from overexposure to sunlight and can be surgically removed. May also refer to a winglike triangular membrane abnormally occurring in the neck, eyes, knees, elbows, ankles, or digits
- pubendal nerve compression syndrome** Pain in the pelvic area due to compression activities such as cycling
- pubendal nerve entrapment syndrome** Chronic pain in the pelvic area due to stretching, inflammation, or compression of the pubendal nerve
- pulmonary contusion** Bruising of the lungs that causes pain and difficulty in breathing
- pulmonary edema** Excess fluid buildup in the lungs; can be caused by circulatory problems such as congestive heart failure
- pulse oximetry** A method in which the oxygen saturation of the hemoglobin is monitored
- purging-type bulimia nervosa** A type of disorder in which the bulimia patient uses vomiting, laxatives, diuretics, or enemas to rid the body of consumed calories
- purpura** Bleeding under the skin characterized by purple or red discoloration spots
- push-up sign** A test for posterolateral instability in the elbow
- pyrogen** A substance that causes a rise in body temperature and subsequent fever; released by certain bacterial infections
- quadriceps tendon** The tendon above the patella (kneecap)
- radiation heat loss** The loss of heat from the body, most significant between sunset and sunrise, due to infrared emission
- radicular pain** Muscle weakness, tingling, numbing, and pain due to the compression of a spinal nerve root
- radicular symptom** Pain manifested in the legs or arms due to a compressed spinal nerve root
- radiculopathy** The inflammation of spinal nerve roots
- reduction** The technique of returning a fractured bone to its proper alignment
- release test** A test in which a force that decreases the patient's pain is removed, causing the pain to return
- relocation test** A test used to determine whether anterior instability is present within the shoulder
- Renee creak test** A test used to diagnose pain and tightness in the iliotibial band; is positive if pain is present when standing on the affected leg with knee flexion at 30°

- retromalleolar groove** A concavity located in the fibula, which when abnormally shaped can lead to tearing of the peroneus brevis (PB) tendon
- reversibility** Reduction or complete loss of fitness as the result of not training
- rheumatoid arthritis** An autoimmune disorder that causes chronic inflammation in the joints and can also affect other organs in the body
- rhinitis** An inflammation of the mucous membrane inside the nose, commonly known as a stuffy nose, that is associated with the common cold and allergies
- rhinorrhea** Fluid nasal discharge; “runny nose.” Following head injury, may indicate leakage of cerebrospinal fluid, a serious condition requiring prompt medical attention
- ribs, false** Five ribs, located inferiorly to the true ribs, called “false” because not directly connected to the sternum
- ribs, floating** The lowest two sets of ribs attached to the vertebrae in the lower back
- ribs, true** The uppermost seven pairs of ribs, attached to the sternum
- rickets** A disorder that leads to the weakening and softening of bones in children; caused by lack of vitamin D and, in some cases, lack of adequate calcium intake
- righting reflexes** A neuromuscular response that enables the body to regain its normal position when it has been displaced
- rotator cuff** A structure composed of four muscles that stabilize the shoulder joint and allow shoulder movement, namely the supraspinatus, infraspinatus, teres minor, and subscapularis
- sacrum** The triangular bone located in the base of the spine, composed of five fused sacral vertebrae forming the rear of the pelvis
- sarcopenia** The degenerative loss of muscle mass and strength due to aging
- second-degree strain** An injury in which the muscle is overstretched, causing inflammation and pain; involves most of the muscle fibers tearing and difficulty performing certain movements
- second impact syndrome** A condition involving a second concussion before the first has properly healed; a serious, often fatal injury in which the brain rapidly swells up, causing an increase in the intracranial pressure
- secretory phase** The second half of the menstrual cycle
- septal hematoma** Bleeding within the nasal septum
- sequestration** An abnormal separation of a part from a whole, such as a portion of a bone by a pathological process or a portion of the circulating blood into the surrounding soft tissue from a broken blood vessel
- Sever disease** Pain in the heel due to the inflammation of the growth plate (calcaneus) located in the back of the foot
- shear injury** An axonal injury to the brain due to accelerated rotational forces
- shoulder capsule** A structure that provides extra stability to the shoulder joint
- SLAP lesion (superior labrum anterior-posterior)** An injury to the glenoid labrum, located in the shoulder
- slipped disk** A condition of the vertebral column in which a tear in the outer, fibrous ring (nucleus pulposus) of an intervertebral disk allows the soft, central portion (annulus fibrosus) to bulge out.  
*See* disk herniation

**slump test** A physical examination to evaluate the sciatic nerve in cases of pain in the spinal and lower extremities

**Smith fracture** An injury to the distal radius (forearm bone)

**spasm** An involuntary contraction of a muscle

**specificity** A measure of a test's ability to rule out a disease

**Speed test** A test to evaluate whether pain is present in the bicipital groove of the shoulder

**spica** A body casting to treat fractures

**spinal stenosis** A narrowing of the space enclosed by the spinal column, causing pressure on the spinal cord

**spirometry** A test used to measure the breathing capacity of the lungs

**spondylolisthesis** Forward displacement of a vertebra over a lower segment due to a congenital defect or fracture in the pars interarticularis

**spondylolysis** The breaking down of a vertebra, usually leading to small stress fractures from an overuse injury

**spondylolytic** A term used to describe a patient with a degenerative disorder of the pars interarticularis, a structure found in the vertebrae

**spondylosis** A degenerative disorder that affects the intervertebral disks in the spine, often referred to as spinal osteoarthritis

**sports concussion** A head injury caused by either mild or severe impact during sports activity that causes the brain to shake violently within the cranium

**sports hernia** A condition that occurs when muscles and tendon in the lower abdomen become weakened, usually causing chronic groin pain in athletes; not a true hernia

**Spurling test** A test for pain in the neck originating from the spinal nerve roots

**Stener lesion** A condition that occurs when the ulnar collateral ligament (UCL) tears and the surrounding tissue of the overlying thumb tendon gets lodged between the torn UCL fibers

**stenosis** A condition in which the blood vessels and tubular organs become narrowed and constricted

**strain** The stretching or partial tearing of the muscle, resulting in inflammation and pain

**strength** The ability of a muscle to generate and resist physical force

**stress fracture** A small crack in a bone, usually caused by overuse

**stress fracture test** A bone scan used to evaluate the injured area on the bone

**stretch reflex** A muscle contraction in response to stretching within the muscle; also known as a myotatic reflex

**stroke volume** The amount of blood that is pumped out of a ventricle in the heart during a contraction

**structural tolerance** The ability to withstand weeks or months of high-volume training without the incidence of injury, illness, or fatigue that may lead to overtraining

**Stryker notch view** An X-ray view used to evaluate for Hills-Sachs lesion after a dislocation

**subacromial impingement** Pain in the shoulder caused by friction between the rotator cuff and acromion

- subarachnoid space** The meningeal space located between the arachnoid and the pia mater
- subchondral bone** A bone layer that underlies the articular cartilage
- subcutaneous emphysema** A pathological condition that occurs when air is trapped beneath the tissues in the skin of the chest, neck, and face
- subdural space** The space between the dura mater, the outermost meningeal layer, and the underlying arachnoid mater, caused by an injury or a pathologic process such as a subdural hematoma
- subluxation** A condition that occurs when the patella, commonly called the kneecap, becomes partially dislodged from its normal position
- subtalar neutral position** The normal position of the foot when one walks
- sulcus sign** A test to evaluate the presence of inferior instability within the glenohumeral joint
- superior retinaculum** The ligament binding the extensor tendons closest to the ankle joint
- surfer's ear** A condition that occurs when the ear canal becomes blocked due to abnormal bone growths, called exostoses, caused by prolonged exposure to cold water and wind
- surfer's myelopathy** A nontraumatic spinal cord injury in which blood flow to the spine is interrupted when the back is hyperextended, sometimes causing partial or complete paraplegia
- swan-neck deformity** A hand deformity in which the distal joint of the finger is pointed inward and the proximal joint outward
- synchondrosis** A cartilaginous joint that joins bone to bone, such as the sternocostal joints where the first ribs join the sternum
- syncope** A temporary loss of consciousness, commonly known as fainting
- synostosis** A condition in which two separate bones fuse together as one
- synovial cyst** A cyst that is filled with synovial or joint fluid to produce its characteristic bulge
- synovial fluid** The lubricant that serves to reduce friction of the articular cartilage within the joint capsule
- synovial tendon sheath** A membrane consisting of an outer fibrotic sheath and an inner synovial sheath, which may be found in areas subject to increased mechanical stress where efficient lubrication is required
- synovitis** An inflammation of the synovium, the tissue that lines the joints
- synovium** A soft tissue that lines the joints and produces synovial fluid
- syringomyelia** A disorder characterized by the formation of a cyst in the spinal cord
- tachycardia** A heart rate faster than normal
- tarsal coalition** A condition in which two bones in the back of the foot (tarsal bones) are fused
- tendinitis** The inflammation of the tendon; rarely occurs without the presence of underlying degenerative tendon change
- tendinopathy** Tendon injuries such as tiny tears, pain, and inflammation
- tendinosis** A noninflammatory repetitive injury to the tendon resulting in microtears that do not heal properly

- tendon** A band of fibrous connective tissues that connect a muscle to a bone
- tenodesis stabilization** Procedures that are indicated for patients with lateral ankle instability with failed anatomic repair; consists of a suture of the end of a tendon to a bone
- tenosynovitis** An inflammation of a tendon and its sheath
- tenotomy** A surgical procedure that involves cutting or releasing a tendon
- tension pneumothorax** A condition that forms a one-way valve, allowing air to enter the pleural space but not to escape; the buildup of air within the pleural space producing pressure on the lungs, thus making breathing difficult
- tetraplegia** A traumatic spinal injury that causes complete paralysis of all limbs
- therapeutic exercise** A therapy with goals such as improving musculoskeletal function, recovering from injuries, and providing relaxation
- thermoregulation** Control of body temperature
- third-degree strain** The most severe type of strain, which occurs when a muscle has been completely ruptured due to an injury
- Thomas test** A test used to evaluate whether a patient can extend the hips
- Thompson test** A test used to evaluate for an Achilles tendon rupture
- thoracic kyphosis** An abnormal forward curvature of the upper back region
- thoracic spine** The middle region of the spine, consisting of 12 vertebrae
- tibia vara** A growth disorder of the upper shinbone, causing a bowlegged appearance
- tinea capitis** A contagious infection of the scalp caused by a fungus, commonly called ringworm
- tinea corporis** A contagious fungal infection affecting the skin, commonly known as ringworm
- tinea cruris** A fungal infection affecting the groin area, commonly called jock itch
- tinea pedis** A fungal infection of the foot, commonly known as athlete's foot
- Tinel test** One of two tests used to diagnose the presence of carpal tunnel syndrome
- tophi** The buildup of uric acid in joints, bones, and cartilage
- torticollis** A pathological condition involving uncontrolled spasms of the neck muscles so that the neck remains in a twisted position with the head tilted and turned to one side
- toss** The act of disengaging a member of a cheerleading team from either a pyramid or a base arrangement
- traction apophysitis** An inflammation of an unfused apophysis caused by excessive pull of an attached tendon
- training load** The product of all three fundamental components of training: frequency, duration, and intensity
- trans fat** An unsaturated fat that is made into a solid by adding hydrogenated oils during manufacturing
- Trendelenburg test** A test to evaluate hip function, specifically of the gluteus medius muscle, in which the patient is asked to stand on one leg
- triangular fibrocartilage complex** A structure found in the wrist that is made up of several different structures, the primary components are being the dorsal and palmar volar ligaments

- trochanter** Two bony projections located near the end of the thighbone
- trochlear groove** The concave surface in the knee joint where the patella makes contact with the femur
- tuberosity** A protuberance on a bone, especially where a muscle or ligament is attached
- turf toe** Pain at the base of the great toe caused by jamming the foot
- uncinate process** Any hooklike process, such as that keeping a vertebra from sliding backward off the vertebra below it
- uric acid** A heterocyclic compound of carbon, nitrogen, oxygen, and hydrogen with the formula  $C_5H_4N_4O_3$ ; a chemical created when the body breaks down substances called purines
- valgus** Bowlegged position
- valgus stress test** A test to evaluate the medial collateral ligament (MCL) in the knee
- varus** Knock-kneed position
- varus stress test** A test to evaluate the lateral collateral ligament (LCL) in the knee
- vertebra** (*pl.*, vertebrae) Any of the separate segments comprising the vertebral column; there are normally 33 of them, differing in size and structure according to location
- vertebral foramen** The opening in the center of the vertebra through which the spinal cord passes
- vesicle** A small sac containing fluid
- visceral pleura** A membrane covering the lungs and lining the inner wall of the chest
- $\dot{V}O_2\text{max}$**  Refers to the peak oxygen uptake and the body's ability to use it during exercises that increase in intensity over time
- volar** Refers to the the palmar surface, or underside of the wrist and hand
- volar plate** A thick ligament found in the fingers preventing hyperextension injuries
- West Point view** A specially positioned X-ray view used to detect a Bankart lesion of the shoulder
- white matter** The portion of the brain containing myelinated nerve fibers; also part of the central nervous system
- “winging”** Lifting off of the medial border of the scapular shoulder
- xerosis** A condition in which the skin is abnormally dry
- Yergason test** A test that is conducted by having the patient flex the elbow and rotate the hand from a palm-down position to a palm-up position while the examiner resists the motion
- Zanca view** An X-ray view used to evaluate the acromioclavicular (AC) joint in the shoulder

# Appendix A

## Taping and Bracing Techniques

The step-by-step procedures in this appendix describe the basic taping and bracing techniques used today in sports medicine. The following table lists the various supplies typically used in these procedures.

**Table 1** Taping Supplies and Equipment

| <i>Type</i>              | <i>Properties</i>                                                                         | <i>Size</i>                                               | <i>Brands</i>                                    | <i>Uses</i>                                                                                             |
|--------------------------|-------------------------------------------------------------------------------------------|-----------------------------------------------------------|--------------------------------------------------|---------------------------------------------------------------------------------------------------------|
| Adhesive spray           | Typically aerosol spray that makes the skin more adhesive                                 | Cans come in various sizes of 4 to 12 oz                  | Tuff Skin                                        | First step before applying any tape or elastic wrap. Always ask about potential allergy before applying |
| Elastic wraps            | Made of cotton with elastic properties                                                    | Can vary in size from 2 to 6 in. and length of 5 to 11 yd | Ace Wrap                                         | Can be used for initial injury for compression or used for spicas and wraps to provide support          |
| Adhesive stretch tape    | Stretchy tape with adhesive properties to stick to skin or other products such as padding | Can vary from 1 to 4 in. and 2.5 to 5 yd                  | Powerfast<br>Lightplast                          | Can be used for compression or to secure padding                                                        |
| Nonadhesive stretch tape | Stretchy tape that sticks to itself                                                       | Can vary from 1 to 4 in. and 2.5 to 5 yd                  | Powerflex<br>Activ-Flex<br>Cohesive stretch tape | Can be used for compression or used as the basis of some tape jobs when prewrap is not needed           |
| Prewrap                  | Made of foam and provides an under layer before the tape is applied                       | 2¾ in. × 30 yd                                            | Mueller<br>Cramer                                | Placed under most taping procedures to decrease chafing and blisters                                    |
| White zinc tape          | Nonelastic tape with adhesive properties to stick to skin or other products               | Can vary from ½ to 4 in. and 2.5 to 5 yd                  | Coach<br>Zonas<br>Jaybird<br>Cramer              | Used as the primary tape in most procedures due to its nonelastic properties                            |

*Note:* 1 inch (in.) = 2.54 centimeters; 1 yard (yd) = 0.91 meters; 1 ounce (oz) = 28.35 grams.

This appendix includes discussions of 19 of the most common taping procedures, organized by body region:

- |                                         |                                                 |                                      |
|-----------------------------------------|-------------------------------------------------|--------------------------------------|
| 1. great toe taping                     | 8. medial collateral ligament taping            | 14. elbow hyperextension tape        |
| 2. arch taping                          | 9. patellar tendinitis strap                    | 15. ulnar collateral ligament taping |
| 3. closed basket weave                  | 10. thigh compression wrap                      | 16. lateral epicondylitis strap      |
| 4. Achilles taping                      | 11. hip spica for adductor strain               | 17. wrist hyperflexion taping        |
| 5. medial tibial stress syndrome taping | 12. rib compression wrap                        | 18. buddy taping                     |
| 6. McConnell taping                     | 13. shoulder spica for acromioclavicular taping | 19. thumb spica                      |
| 7. knee hyperextension taping           |                                                 |                                      |

### Great Toe Taping

Great toe taping is applied after injury to the first metatarsophalangeal (MTP) joint of the great toe after a hyperextension or hyperflexion injury and is associated commonly with “turf sports,” such as football, soccer, and field hockey. The goal of taping is to limit excessive and/or painful extension or flexion of the MTP joint.

#### Procedure

**Materials.** Adhesive spray, 1½-inch (in.; 1 in. = 2.54 centimeters [cm]) white tape, 1-in. white tape.

**Positioning and Preparation.** The patient is made to lie in the supine position with the knee in extension, foot in relaxed position, and great toe in neutral position. Apply adhesive spray to the foot and great toe where the tape will be applied.

#### Application

1. Apply an anchor around the midfoot with the 1½-in. white tape. Apply the second anchor with the 1-in. tape around the great toe distally.

1.

2.

2. Apply a fan strip with the 1-in. white tape from the second anchor on the distal great toe. Position the great toe into slight flexion within the painfree range. Secure the first fan strip to the initial anchor. Repeat two to three times with additional fan strips to secure the great toes in painfree position.

3. To secure the fan strips, place the 1½-in. white tape over the initial anchor and the 1-in. white tape over the second anchor.

*Final Assessment.* Check for circulation and ensure that the application has limited the painful motion and is functional for the athlete.

#### Additional Notes

4. To limit painful flexion, reverse the fan strips, applying ventrally while placing the great toe in slight extension.
5. To gain additional support for cases of multidirectional instability and/or pain, apply toe spica consisting of two 1-in. white tape strips crossing over the medial MTP joint of the great toe prior to the final anchors. Secure with anchors as described above.

\**Custom/Prefabricated Items.* Great toe extension may also be limited by prefabricated steel inserts or a precut plantar fascia strip.

\*

### Arch Taping

Arch taping is applied to those individuals who require additional support to their arch in an effort to prevent excessive pronation. With this goal, excessive motion may be limited during gait, and pain in the lower extremity structures irritated by this motion may resolve.

#### Procedure

*Materials.* Adhesive spray, 1½-in. white tape, 1-in. white tape.

*Positioning and Preparation.* The patient is made to lie in the supine position with the knee in extension and the foot in relaxed position. Lightly spray the arch with the adhesive spray, and let it dry.

#### Application

1. Gently apply a half-anchor of the 1½-in. white tape around the metatarsal heads, pulling from the lateral to the medial direction.
2. Apply the 1-in. white tape in an X pattern with three “Xs” running from the first metatarsal head around the heel and returning to the fifth

1.

2.

metatarsal head and three “Xs” running from the fifth metatarsal head around the heel and returning to the first metatarsal head. Overlap each “X” while filling in the arch space. Use a minimum of six “Xs” to fill in the entire arch space.

3. Apply the 1½-in. white tape half-anchors, pulling lateral to medial to cover the arch. Anchors should start proximal and continue distally. Be sure to cover all the loose ends.
4. Complete by securing with two full 1½-in. white tape anchors around the metatarsal heads.

*Final Assessment.* Check for circulation, and ensure that the application has limited the painful motion and is functional for the athlete.

*\*Custom/Prefabricated Items.* Supporting the arch can also be achieved by purchasing off-the-shelf orthotics or custom shoe inserts.

### Closed Basket Weave

The closed basket weave is used after an inversion ankle sprain and is one of the most commonly seen tape procedures in sports medicine. It can be used both as a prevention measure and to limit inversion after injury.

#### Procedure

**Materials.** Heel and lace pads, adhesive spray, 1½-in. white tape, prewrap.

**Positioning and Preparation.** The patient is made to lie in the supine position with the knee in extension and ankle in a dorsiflexed position. Lightly spray the ankle with the adhesive spray, and let it dry.

#### Application

1. Apply at least one heel and lace pad at the front of the ankle and the other at the back where the Achilles tendon inserts into the calcaneus. Secure the pads with the prewrap, and cover the area where the tape will be applied.
2. Apply one anchor of the 1½-in. white tape 6 in. above the malleoli, adhering the prewrap to the skin. The second anchor should be placed around the midfoot while avoiding direct compression of the base of the fifth metatarsal.
3. Apply a stirrup running from the medial to lateral direction, from the medial proximal anchor to the lateral side, extending just above the anchors on both sides; this should cover the posterior one third of the malleoli. Apply the first

horseshoe starting directly on the metatarsal anchor along the first metatarsal, traveling behind the heel, and ending along the fifth metatarsal. Apply horseshoes always from the medial to lateral direction unless your goal is to limit eversion, in which case the pull would be in the opposite direction.

4. Apply each additional stirrup in the same fashion while overlapping by half the width of the tape. The second stirrup should cover the middle one third of the malleoli, with the third stirrup covering the anterior one third. Apply horseshoe strips in the same manner, with each strip slightly shorter than the previous, leaving a staircase appearance. Apply the stirrups and the horseshoes in an alternating fashion.

5. Follow the third horseshoe up the leg until you have completely enclosed the ankle and have ended just past your initial anchor. These strips should continue to be applied by overlapping half the width of the tape. Apply additional arch support until the bottom is enclosed.

6. Start applying the tape on the lateral malleolus, and pull around the arch of the foot to begin a figure-eight pattern.

7. Continue the figure-eight pattern by completing a full turn around the ankle so that the roll of tape ends on the medial side, moving downward toward the medial malleolus.

8. From this position, direct the roll of tape to the outside of the heel, and apply a heel lock, ending with the roll of tape moving in a caudal position.

9. Continue by pulling the tape up and around the ankle with a complete turn.

10. Once around the ankle, continue along the lateral ankle, moving toward the medial side of the heel, and apply another heel lock.

10.

11. Once around the ankle, the tape may finish anywhere. Additional figure-eight and heel locks may be added depending on the severity of the injury or the size of the athlete.

11.

*Final Assessment.* Check for circulation, and ensure that the application has limited either the painful motion or the inversion and is functional for the athlete.

*\*Custom/Prefabricated Items.* A number of ankle braces can be purchased with the benefits of self-application and increased cost-effectiveness.

### Achilles Taping

Achilles taping is applied to those individuals who suffer from pain with plantarflexion and where additional support and help with this motion are required. The goal of this tape job is to assist in the motion of plantarflexion and alleviate pain and discomfort.

#### Procedure

**Materials.** Prewrap, adhesive spray, 1½-in. white tape, 3-in. heavy-duty tape.

**Positioning and Preparation.** The patient is made to lie in the prone position with the knee in extension and the foot in relaxed position, slightly plantarflexed. Lightly spray the foot and ankle with the adhesive spray.

#### Application

1. Apply the prewrap around the foot, ankle, and lower leg. Apply an anchor of the 1½-in. white tape around the metatarsal heads and the other anchor 6 in. above the malleoli. Starting dorsally on initial anchor, apply the 3-in. heavy-duty stretch tape running to the anchor on the lower leg while the foot maintains a relaxed position. The first strip should run in a straight fashion.

2. Apply two additional 3-in. heavy-duty stretch tape strips with each crossing over the painful site to form an X pattern.
3. Cover the anchors with the 1½-in. white tape, ensuring that there are no loose ends.

*Final Assessment.* Check for circulation, and ensure that the application has limited the painful motion and is functional for the athlete.

### Medial Tibial Stress Syndrome Taping

Medial tibial stress syndrome (MTSS) or shin splint taping is applied to those individuals who suffer from pain in their lower leg during activity. Also known as an *open spiral*, the goal of this taping is to compress the musculature of the anterior lower leg to alleviate pain.

#### Procedure

*Materials.* Adhesive spray, 1½-in. white tape.

*Positioning and Preparation.* The patient is made to lie in the supine position with the knee in extension and foot in relaxed position. Lightly spray the lower leg with the adhesive spray, and let it dry.

#### Application

1. Apply a strip of the 1½-in. white tape starting laterally, or opposite to the painful side and 2 in. below. Wrap the tape around lower leg while squeezing the Achilles tendon, and end the strip just past the starting point. Always pull the tape so that the painful area moves toward the tibia.
2. Continue to apply additional strips in the same fashion. Be sure to overlap

half of the previous strip. Each strip is applied tightly. Continue strips application until you are 2 in. above the painful site. Each individual strip should overlap and enclose the previous strip. Complete by applying a full anchor on both proximal and distal ends.

*Final Assessment.* Check for circulation, and ensure that the application causes limited pain and is functional for the patient.

*\*Custom/Prefabricated Items.* A number of commercial compression sleeves are available that re-create the same effect.

### McConnell Taping

McConnell taping is applied typically to treat patellofemoral stress syndrome (PFSS), which typically occurs with abnormal tracking of the patella. The goal of taping the patella is to restore proper tracking mechanics of the patella and to decrease or relieve painful knee biomechanics.

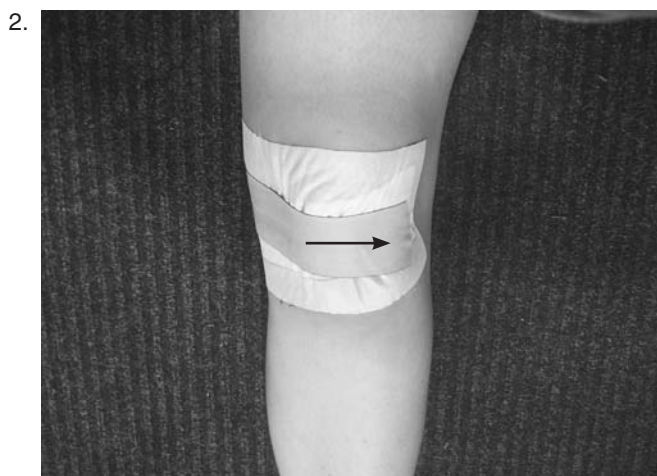

#### Procedure

*Materials.* Adhesive spray, 2-in. cover-all, 1½-in. leukotape, scissors.

*Positioning and Preparation.* Check the skin for wounds and irritation. Remove excessive hair with a razor. The patient should be made to lie in the supine position on a table with the knee fully extended; the quadriceps should be fully relaxed to allow patella mobility. Apply adhesive spray to the knee where the tape will be applied, and allow it to dry.

#### Application

1. Cut strips of coverall long enough to cover the patella and the medial knee. Then apply these strips as a base covering the patella and medial knee.

2. To limit lateral tracking, apply a strip of leukotape laterally on the patella, then pulling medially and placing the other end over the medial knee. Cut off the excess tape.
3. Apply two or three more strips as described above, covering the patella.

*Final Assessment.* Check the range of motion (ROM) of the knee and the comfort of the tape. Ensure that the application has limited the painful motion and is functional for the patient.

**Additional Notes**

4. To ensure that the tape will remain on and not fall off prematurely during activity, you may wrap it with nonadhesive stretch tape.
5. To limit tilting in other directions, pull the leukotape in the opposite direction of the motion that you are trying to limit.

*\*Custom/Prefabricated Items.* Abnormal patella tracking can also be altered by using a commercial brace with a patella buttress.

## Knee Hyperextension Taping

Knee hyperextension taping is applied when a knee hyperextension injury has occurred. The goal of this tape job is to limit painful knee extension.

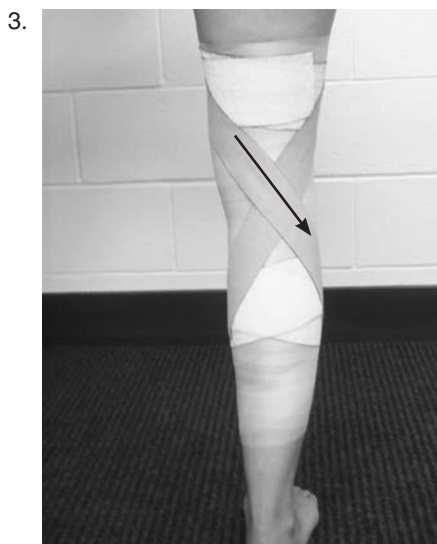

### Procedure

**Materials.** Adhesive spray, prewrap, 2-in. heavy-duty elastic tape, 3-in. adhesive elastic tape, scissors.

**Positioning and Preparation.** Check the skin for wounds and irritation. The patient should be standing with the affected knee flexed 25° to 35° or within a painfree ROM. The patient should have a good portion of his or her weight over the affected leg and with the quadriceps contracted so that the wrap is not too tight. Apply adhesive spray to the lower leg and thigh where the tape will be applied.

### Application

1. Apply the prewrap over the entire area that will be taped, starting at the midthigh and continuing distally to the midgastrocnemius. (*Note:* The longer the level of the tape job, the more effective it will be in preventing painful ROM.) Apply two anchors with the 3-in. adhesive elastic tape over the prewrap, one on the midthigh and the other on the midgastroc.
2. Apply strips of the 2-in. heavy-duty elastic tape in an X pattern behind the knee. The first strip should be applied laterally on the thigh anchor, crossing the posterior knee and ending at the medial anchor on the gastrocnemius. Cut off the excess heavy-duty elastic tape.
3. The second strip is applied medially on the thigh anchor, crossing the posterior knee and ending on the

lateral anchor on the gastroc. Cut off the excess heavy-duty elastic tape.

4. Apply two more strips as described above, creating an X pattern behind the knee.
5. Cover the distal anchors up to the tibial tuberosity with the 3-in. adhesive stretch tape. Cover the proximal anchors distally with the 3-in. adhesive stretch tape, ending 3 in. above the superior patella. *Note:* To ensure normal tracking of the patella, do not cover the patella with the tape.

*Final Assessment.* Check the ROM of the knee and the comfort of the tape. Ensure that the application has limited the painful motion of the knee and is functional for the athlete.

4.

5a.

5b.

\**Custom/Prefabricated Items.* Off-the-shelf braces with an ROM lock can limit the painful ROM—such as a knee immobilizer.

### Medial Collateral Ligament Taping

Collateral ligament taping is applied when either the medial collateral ligament (MCL) or the lateral collateral ligament (LCL) is sprained. The goal of this tape job is to protect the ligament from further injury.

#### Procedure

*Materials.* Adhesive spray, prewrap, 1½-in. white tape, 3-in. adhesive elastic tape.

*Positioning and Preparation.* Check the skin for wounds and irritation. The patient should be standing with the affected knee slightly flexed and within a painfree ROM. The patient should have a good portion of his or her weight over the affected leg and with the quads contracted so that the wrap is not too tight. Apply adhesive spray to the knee and thigh where the tape will be applied.

#### Application

1. Apply the prewrap over the entire area that will be taped; starting at the upper thigh and continuing down to the midgastrocnemius. Apply two anchors with the 3-in. adhesive elastic tape on the upper thigh and midgastroc.
2. Apply strips of the 1½-in. white tape in an X pattern over the MCL.

The first strip will be applied on the anterior thigh anchor, crossing the medial joint line and ending at the posterior anchor on the gastrocnemius.

3. The second strip will be applied on the posterior thigh anchor, crossing the medial joint line and ending on the anterior anchor on the gastroc.
4. Apply two or three more strips as described above, creating an X pattern over the medial joint line.
5. Cover the distal anchors up to the tibial tuberosity with the 3-in. adhesive stretch tape. Cover the proximal anchors distally with the 3-in. adhesive stretch tape ending 3 in. above the superior patella. *Note:* Do not cover the patella with the tape, to ensure normal tracking of the patella.

*\*Final Assessment.* Check the ROM of the knee and the comfort of the tape. Ensure that the application is functional for the patient and gives support to the MCL.

#### Additional Notes

To tape for an LCL sprain, follow the previous steps, with the X pattern applied over the LCL.

*\*Custom/Prefabricated Items.* Off-the-shelf braces with a medial stabilizer can be applied.

### Patellar Tendinitis Strap

A patellar tendinitis strap is applied for a patient suffering from patella tendinitis (jumper's knee) or Osgood-Schlatter disease. The goal of this tape job is to decrease pain by applying pressure to the tendon and decreasing the stress of the tendon on the tibial tuberosity, where it inserts.

#### Procedure

*Materials.* Prewrap, 1½-in. white tape.

*Positioning and Preparation.* Check the skin for wounds and irritation. The patient should be standing with the affected knee slightly flexed and within a painfree ROM.

#### Application

1. Apply the prewrap, encircling the knee over the patella six to eight times with equal tension.
2. Apply three strips of the 1½-in. white tape anteriorly in the center of the prewrap.

3. Roll the prewrap and tape from the proximal to distal direction to create a strap. Place the strap over the patellar tendon.

*Final Assessment.* Check the ROM of the knee and the comfort of the tape. Ensure that the application has adequate pressure on the patellar tendon and is functional for the patient.

*\*Custom/Prefabricated Items.* Jumper's knee straps can be purchased over the counter to re-create this tape job.

## Thigh Compression Wrap

A thigh compression wrap may be applied after an injury such as a contusion or muscle strain to either the hamstring or the quadriceps muscle group. The goal of this wrap is to compress the muscle group and the origin of pain while providing support.

### Procedure

**Materials.** Adhesive spray, 6-in. single elastic bandage, 1½-in. white tape. **Note:** Depending on the size of the patient, you may have to use a larger elastic wrap, 6 in. × 5 yards (yd), 6 in. × 11 yd, or 4 in. × 11 yd (1 in. = 2.54 cm; 1 yd = 0.91 meters [m]).

**Positioning and Preparation.** The patient should be standing with the involved knee flexed between 20° and 30° while keeping the majority of the patient's weight on the involved side. Apply spray on the area to be wrapped, and allow it to dry.

### Application

1. Begin distal to the site of pain, and apply the compression wrap around the area to be treated in a herringbone fashion with the "Xs" central over the site of pain.
2. Continue proximally overlapping the compression wrap by half the width of the wrap.
3. Secure the wrap with the 1½-in. white tape by placing an "X" over the painful area, and anchor at the top and bottom.

**Final Assessment.** Check for circulation, and ensure that the application has limited the painful motion and is functional for the athlete.

\**Custom/Prefabricated Items.* Commercial compression sleeves, both with and without additional padding, are available.

### *Hip Spica for Adductor Strain*

A hip spica may be used for a number of conditions, including support of the adductor and hip flexor groups in addition to securing padding after an injury to the hip bone, or “hip pointer.” The goal of this supportive wrap is to compress the muscle group and origin of pain while providing support and aiding in the natural motion of the muscle group.

#### *Procedure*

*Materials.* Adhesive spray, 4-in. double-elastic bandage, 1½-in. white tape. *Note:* Depending on the size of the patient, you may have to use a larger elastic wrap, such as 6 in. × 11 yd.

*Positioning and Preparation.* The patient should be standing with the involved leg placed in an internally rotated position. Ask the athlete to assume a slightly forward-lunge position that flexes the knee and causes the hip to adduct. Gently spray the thigh area that will be

wrapped, which acts as the anchor for this tape procedure. *Note:* For maximum support, have the athlete wear spandex or tight shorts so that the wrap can be as close to the body part as possible.

#### Application

1. Secure the wrap to the leg by anchoring the wrap around the thigh while pulling laterally to medially.
2. Continue wrapping up and around the trunk, crossing deep in the groin over the adductor muscle group.
3. Finish the wrap on the thigh, and secure with the 1½-in. white tape by tracing the pattern once around the thigh and trunk. Add more tape strips as needed.
4. To secure the wrap further, you can trace the pattern of the wrap with the 3-in. adhesive elastic tape.

#### Additional Notes

To provide supportive taping for the hip flexor, begin in a similar fashion to the hip adductor wrap but with the patient in a slightly forward-lunge position with a slight forward bend at the trunk. Pull the wrap from medial to lateral, and place an “X” over the site of pain or the hip flexor group.

*Custom/Prefabricated Items.* Commercial compression garments can be purchased that offer focal and general compression.

## Rib Compression Wrap

A rib compression wrap is used to relieve the pain of a rib fracture or intercostal strain, secure a protective pad over an injured site, or control swelling. The goal of the wrap is to provide support to the injured area and decrease pain.

### Procedure

**Materials.** Adhesive spray, 4-in. × 5-yd elastic wrap, 1½-in. white tape. **Note:** Depending on the size of the patient, you may have to use a larger elastic wrap, 6 in. × 5 yd, 6 in. × 11 yd, or 4 in. × 11 yd.

**Positioning and Preparation.** Check the skin for wounds and irritation. The patient should be standing with the arms abducted. Apply adhesive spray to the torso where the elastic bandage will be applied.

### Application

The procedure described below is for a rib fracture. The injured area is marked “+.”

1. Start the wrap superiorly to the injured site, encircling the torso and overlapping about 2 in. each time around.
2. Work your way caudally, covering the injured site and ending over the wrap superiorly to the injured area.
3. Apply two to three strips of the 1½-in. white tape at the end of the wrap to secure it.

4. To secure the wrap, you may encircle the wrap and tape with the 3-in. adhesive elastic tape.

*Final Assessment.* Check the ROM of the torso and the comfort of the athlete during respiration. Ensure that the application provides support to the injured site and is functional for the athlete.

*\*Custom/Prefabricated Items.* Rib belts can be purchased off the shelf to obtain similar results.

### *Shoulder Spica for Acromioclavicular Taping*

The acromioclavicular (AC) wrap may be applied after an injury to the AC joint from direct contact, such as tackling in football or forced horizontal adduction. The goal of this wrap is to provide protection and general compression to the AC joint and shoulder in general.

***Procedure***

*Materials.* Adhesive spray, compression wrap (various widths and lengths), 1½-in. white tape.

*Positioning and Preparation.* The patient should be placed in a standing or seated position with the involved arm at the side and the hand on the hip.

Spray the humerus with the adhesive spray, as this will act as the anchor for this tape procedure.

#### Application

1. Begin wrapping the midhumerus in a clockwise fashion (lateral to medial), and continue in a spiral fashion while overlapping by half the width of the wrap, moving distal to proximal for at least two times around the humerus.
2. Pull medially across the chest and under the opposite axilla, and continue around the torso. Apply the greatest amount of tension over the shoulder and the least amount of tension as you wrap around the torso. Encircle the humerus again.
3. Repeat the pattern at least twice or as needed depending on the size of the patient and the support needed. End the wrap on the arm. Secure the wrap with the 1½-in. tape by tracing the pattern on the humerus.

*Final Assessment.* Check for circulation, and ensure that the application has limited the painful motion and is functional for the athlete.

#### Additional Notes

In association with many AC joint injuries, an “AC pad” is often applied directly over the AC joint to provide padding to the injured joint below. Apply the AC pad if needed prior to securing the AC wrap.

*\*Custom/Prefabricated Items.* Other commercial items that are commonly used to support the shoulder either after injury or during actual play include the Sully Stabilizing Brace.

## *Elbow Hyperextension Tape*

Elbow hyperextension taping is very similar to the knee hyperextension taping technique. This is applied when an elbow hyperextension injury has occurred, with the goal of limiting painful extension.

### *Procedure*

**Materials.** Adhesive spray, prewrap, 2-in. heavy-duty adhesive elastic tape, 3-in. adhesive elastic tape, scissors.

**Positioning and Preparation.** Check the skin for wounds and irritation. The patient should have the affected elbow in slight flexion within a painfree range and supinated. Apply adhesive spray to the forearm and humerus where the tape will be applied.

### **Application**

1. Apply the prewrap over the entire area that will be taped; starting at the midhumerus and continuing distally to the midforearm. (*Note:* The longer the level of the tape job, the more effective it will be in preventing painful ROM.) Apply two anchors with the 3-in. adhesive elastic tape, one on the midhumerus and the other at the midforearm.
2. Apply a strip of the 2-in. heavy-duty adhesive elastic tape over the anterior elbow. The first strip will begin on the anterior anchor of the humerus and follow the midline of the humerus distally to the forearm, where it ends at the second anchor at the midforearm. Cut off the excess heavy-duty elastic tape.
3. The next two strips will create an X pattern over the anterior elbow. The second strip will be applied laterally on the distal humeral anchor, crossing the anterior elbow and ending at the medial anchor on the forearm (ulna). The third strip will be applied medially on the

distal humeral anchor, crossing the anterior elbow and ending at the lateral anchor on the forearm (radius). Cut off the excess heavy-duty elastic tape.

4. Cover the tape job with the 3-in. adhesive elastic tape. *Note:* Do not cover the olecranon process with the tape, to ensure ease of movement.

*Final Assessment.* Check the ROM of the elbow to make sure that it is within the painfree ROM and functional for the patient. Check the distal capillary refill and the comfort of the tape for the patient.

*\*Custom/Prefabricated Items.* Off-the-shelf braces with an ROM lock can limit the painful motion of the elbow.

4.

\*

### Ulnar Collateral Ligament Taping

This taping procedure is similar to the collateral ligament taping of the knee. Collateral ligament taping is applied when either the ulnar collateral ligament (UCL) or the radial collateral ligament (RCL) is sprained. The goal of this tape job is to protect the ligament from further injury.

#### *Procedure*

*Materials.* Adhesive spray, prewrap, 1½-in. white tape, 3-in. adhesive elastic tape.

*Positioning and Preparation.* Check the skin for wounds and irritation. The patient should be standing with the

1.

affected elbow slightly flexed within a painfree ROM and supinated. Apply adhesive spray to the forearm and humerus where the tape will be applied.

**Application**

1. Apply the prewrap over the entire area that will be taped, starting at the midhumerus and continuing distally to the midforearm. Apply two anchors with the 3-in. adhesive elastic tape over the prewrap, one on the midhumerus and the other on the midforearm.

2.

2. Apply strips of the 1½-in. white tape in an X pattern over the UCL. The first strip will be applied on the anterior humeral anchor, crossing the medial joint line and ending at the posterior anchor on the forearm.

3.

3. The second strip will be applied on the posterior humeral anchor, crossing the medial joint line and ending on the anterior anchor on the forearm.

4. Apply two or three more strips as described above, creating an X pattern over the UCL.

5. Cover the tape job with the 3-in. adhesive elastic tape. *Note:* Do not cover the olecranon process with the tape, to ensure ease of movement.

*Final Assessment.* Check the distal capillary refill and the comfort and function of the tape for the patient.

#### Additional Notes

To tape for an RCL sprain, follow the previous steps but with the X pattern applied over the RCL.

\**Custom/Prefabricated Items.* There are various off-the-shelf braces that can be purchased that will re-create the function of the tape procedure for the UCL.

### *Lateral Epicondylitis Strap*

A lateral epicondylitis strap is used for a patient suffering from lateral epicondylitis (tennis elbow). The goal of this tape job is to decrease pain by applying pressure to the common extensor bundle to decrease the stress of the extensor muscles on the bony attachment.

#### **Procedure**

**Materials.** Prewrap, 2-in. adhesive elastic tape, 1½-in. white tape.

**Positioning and Preparation.** Check the skin for wounds and irritation. The patient's arm should be in a relaxed supinated position.

#### **Application**

1. Apply the prewrap around the elbow two to three times distal to the lateral epicondyle, approximately ½ in.
2. Apply six strips of the 1½-in. white tape in the center of the prewrap distal to the lateral epicondyle.
3. Cover the prewrap and the 1½-in. white tape strips with the 2-in. adhesive elastic tape.

*Final Assessment.* Check the distal capillary refill and the comfort and function of the tape for the patient.

*\*Custom/Prefabricated Items.* Prefabricated lateral epicondylitis straps can be purchased over the counter.

### Wrist Hyperflexion Taping

Taping to the wrist is applied after an injury to any of the carpal bones or the wrist in general or to limit painful motion. The goal of this tape job is to provide stability and limit painful motions about the wrist to allow it to be used in athletic participation.

#### Procedure

*Materials.* Adhesive spray, 1½-in. white tape, prewrap.

*Positioning and Preparation.* Place the patient's wrist in a neutral position with the fingers abducted. Spray the area to be wrapped, and apply the prewrap as needed.

#### Application

1. Begin by applying two anchors on the midforearm and one around the hand just proximal to the metacarpophalangeal (MCP) joints. Be sure to keep the MP joints uncovered while slightly folding the tape before it crosses the thumb crease.
2. Apply parallel strips starting at the anchor on the hand and running to the anchor on the forearm. Complete

by applying at least two “Xs” in a similar fashion, crossing over the carpals. Apply parallel strips and “Xs” to the opposite side. If needed, add additional strips to the side in which you intend to limit the most motion (the dorsal side to prevent flexion and ventral side to prevent extension).

3. Close the entire forearm with the anchors.
4. Apply two figure-eight patterns starting on the dorsal side at the ulnar styloid process. Pull the tape between the thumb and the index finger, making sure that you place a small fold in the tape as it crosses through.

5. Continue to pull the tape across the palm to the dorsal side of the hand.
6. Continue to pull around the wrist, and end on dorsal side of the wrist. Repeat as necessary.

*Final Assessment.* Check for circulation and ensure that the application has limited the painful motion and is functional for the athlete.

*\*Custom/Prefabricated Items.* Various prefabricated splints are available, such as the wrist splint. The velcro allows effortless application by the patient.

## Buddy Taping

Buddy taping is the easiest and most common taping procedure for a patient to apply. It is typically used when an interphalangeal (IP) joint has been sprained. The goal of this tape job is to use one digit as a support for the injured digit to protect the sprained IP joint from further injury.

### Procedure

**Materials.** Adhesive spray, 1-in. white tape.

**Positioning and Preparation.** Check the skin for wounds and irritation. The patient's hand should be relaxed and placed in a painfree position. Apply adhesive spray to the digits where the tape will be applied.

### Application

The following taping procedure is for a sprained proximal IP of the fourth digit. For any other digits, simply repeat the steps as indicated.

### Additional Notes

This is typically a procedure for a sprain in the second to fifth digits; this procedure is not used for the first digit. For a sprained first digit, see the section Thumb Spica.

1. Place the third digit next to the fourth digit in a comfortable, painfree ROM.
2. Apply a strip of the 1-in. white tape to encircle the proximal phalanges of the third and the fourth digits.
3. Apply a second strip of the 1-in. white tape to encircle the middle

phalanges of the third and the fourth digits. \*

*Final Assessment.* Check the distal capillary refill of the third and fourth digits. Ensure that the tape is giving support to the fourth digit and is functional for the patient.

*\*Custom/Prefabricated Items.* Various prefabricated splints are available, such as the aluminum finger splints and the Stax plastic finger splints.

## Thumb Spica

The thumb spica is used when the MCP joint of the first digit has been sprained. The goal is to limit multidirectional instability and prevent painful motion.

### Procedure

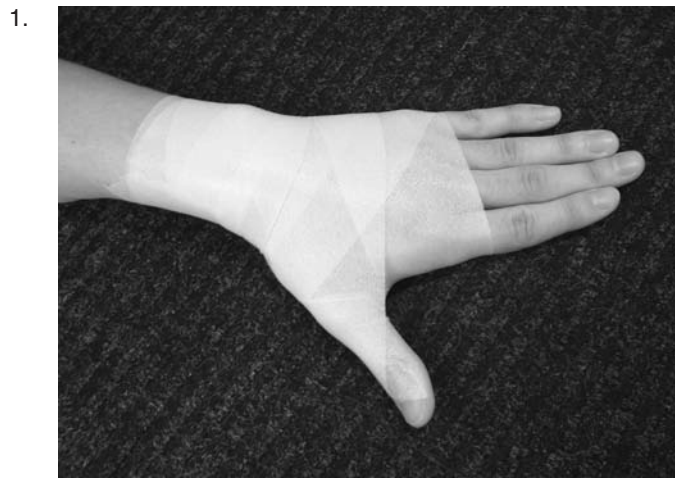

**Materials.** Adhesive spray, prewrap, 1-in. white tape, 1½-in. white tape.

**Positioning and Preparation.** Check the skin for wounds and irritation. The patient should be relaxed, with his or her thumb slightly abducted and extended into a painfree position. Apply the adhesive spray to the first digit and the distal wrist where the tape will be applied.

### Application

The following procedure is for a hyperflexion injury to the MCP of the first digit. To prevent hyperextension of the joint, follow the steps below, but place the X pattern on the volar aspect of the thumb.

1. Cover the thumb, the proximal hand, and the distal wrist with the prewrap.
2. Place two anchors with the 1½-in. white tape encircling the wrist.
3. Begin a strip of tape on the dorsal aspect of the anchors on the distal wrist. Continue this strip distally, crossing the lateral joint line of the MCP joint of the first digit.

4. Continue the tape around the joint, crossing over the posterior aspect of the MCP joint of the first digit and ending on the volar aspect of the anchor on the wrist. You should have created an X pattern on the dorsal aspect of the MCP joint of the first digit.
5. Apply one or two more strips as indicated above, moving more distally on the first digit. *Note:* Do not cross the IP joint of the first digit.
6. Cover the anchors on the wrist with the 1½-in. white tape.

*Final Assessment.* Check the distal capillary refill of the first digit. Ensure that the tape prevents painful hyperflexion and is functional for the patient.

#### Additional Notes

Use caution when removing the tape from the first digit, so as to prevent damage to the distal phalanx; removing the tape with scissors is recommended.

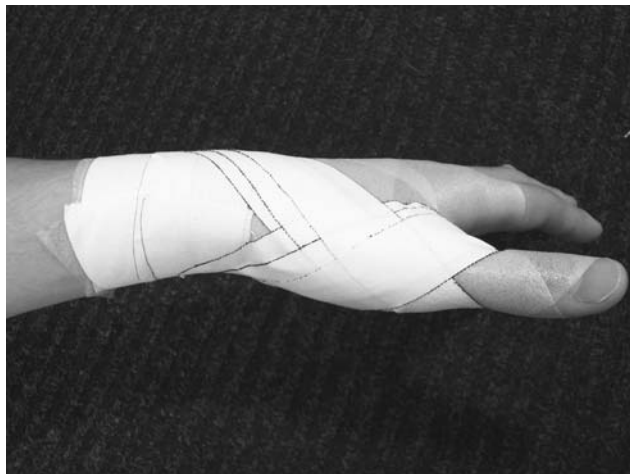

4a.

4b.

5.

\**Custom/Prefabricated Items.* Pre-fabricated thumb braces can be purchased to obtain similar results.

6.

\*

## Conclusion

Just as all medical procedures have evolved, so too has the advancement of both taping and bracing applications. Although taping after the initial injury is rare, taping and bracing for support and protection during athletic participation and activities of daily living is a well-established practice that continues to undergo refinement based on sound knowledge and the practical experience of trained practitioners.

## Organizations

### *Health, Fitness, and Safety*

#### **American Alliance for Health, Physical Education, Recreation and Dance (AAHPERD)**

**Website:** <http://www.aahperd.org>  
**Publications:** *Research Quarterly, Health Education; Journal of Physical Education, Recreation and Dance*

An alliance of associations providing support to professionals involved in physical education, recreation, fitness, sports and coaching, dance, and health education and promotion.

#### **American Association for Physical Activity and Recreation (AAPAR)**

**Website:** <http://www.aahperd.org/aapar>

An association linking professionals in education with community-based programs, promoting creative and active lifestyles through physical activity and recreation across the life span.

#### **American Council on Exercise (ACE)**

**Website:** <http://www.acefitness.org>

A nonprofit organization that protects against ineffective fitness products, while also providing ongoing public education, outreach, and research, and sets certification and continuing education standards for fitness professionals.

#### **American School Health Association (ASHA)**

**Website:** <http://www.ashaweb.org>

An association that organizes and advocates for effective school health policies that contribute to

optimal health and academic outcomes for all school-age children.

#### **American Sport Education Program (ASEP)**

**Website:** <http://www.asep.com>

An organization providing an educational program for coaches based on sports sciences such as sport physiology, sport psychology, and sport biomechanics.

#### **American Swimming Coaches Association**

**Website:**  
<http://www.swimmingcoach.org>  
**Publication:** *Journal of Swimming Research*

A swimming association dedicated to enhancing coaching and building a stronger swimming community.

#### **Canadian Fitness Professionals (CAN-FIT-PRO)**

**Website:** <http://www.canfitpro.com>

An organization providing education and certification for fitness professionals throughout Canada.

#### **Cooper Institute for Aerobics Research**

**Website:** <http://www.cooperaerobics.com>

A nonprofit, founded in 1970, that has established an international reputation for research and education in preventive medicine.

**Exercise Safety Association (ESA)**

**Website:** <http://www.exercisesafety.com>

A national organization for fitness professionals providing certification and membership as well as fitness instructor training.

**International Fitness Professionals Association (IFPA)**

**Website:** <http://www.ifpa-fitness.com>

An association affiliated with Doctors Fitness Centers (DFC) and the Fitness Institute of Technology (FIT), providing fitness professionals the education and certification necessary to treat more than 65 different diseases, disabilities, and dysfunctions.

**Joint Commission on Sports Medicine and Medical Science**

**Website:** <http://www.jcsportsmedicine.org>

A voluntary forum that meets annually to discuss current issues in the profession as well as those that concern the future of sports medicine.

**National Alliance for Youth Sports (NAYS)**

**Website:** <http://www.nays.org>

An organization whose aim is to make the sports experience safe, fun, and healthy for youth by ensuring that the adults involved have proper training and information.

**National Association for Health & Fitness (NAHF)**

**Website:** <http://www.physicalfitness.org>

A nonprofit organization that promotes physical fitness, sports, and healthy lifestyles by fostering and supporting governors' and state councils and coalitions that promote and encourage regular physical activity.

**National Association of Speed and Explosion (NASE)**

**Website:** <http://www.naseinc.com>

**Publication:** *Sportspeed*

An educational organization and certification agency that includes coaches, strength and

conditioning coaches, personal trainers, educators, and physicians focusing on the improvement of speed in short sprints to enhance athletic performance.

**National Athletic Trainers' Association, Inc. (NATA)**

**Website:** <http://www.nata.org>

**Publication:** *Athletic Training Journal*

A professional membership association for certified athletic trainers geared toward enhancing and advancing the athletic training profession.

**National Council of Youth Sports (NCYS)**

**Website:** <http://www.ncys.org>

An organization that represents more than 185 organizations (44,000,000 youth in organized sports) in the youth sports industry and promotes physical activity in youth via organized sports.

**National High School Coaches Association (NHSCA)**

**Website:** <http://www.nhsca.com>

**Publication:** *Coaches Quarterly Magazine*

A national nonprofit association that centers on the influence and professionalism of coaches and provides insurance coverage and educational programs for its participants.

**National Institute for Fitness and Sport (NIFS)**

**Website:** <http://www.nifs.org>

An Indiana-based nonprofit organization that conducts research for enhancing health and athletic performance and provides physical fitness programs and health and fitness education for individuals and corporations.

**National Operating Committee on Standards for Athletic Equipment (NOCSAE)**

**Website:** <http://www.nocsae.org>

**Publication:** *NOCSAE Manual*

A committee that develops performance standards for the protective equipment used in a variety of

sports and commissions scientific research on the mechanisms of athletic injuries.

### **National Strength and Conditioning Association (NSCA)**

**Website:** <http://www.nasca-lift.org>  
**Publications:** *National Strength and Conditioning Association Journal, Journal of Applied Sport Science Research*

An association that promotes and disseminates research on strength and conditioning to improve athletic performance and fitness.

### **National Youth Sports Safety Foundation (NYSSF)**

**Website:** <http://www.nyssf.org>

A national nonprofit organization working to minimize the number and severity of sports-sustained youth injuries.

### **President's Council on Physical Fitness and Sports (PCPFS)**

**Website:** <http://www.fitness.gov>  
**Publication:** *PCPFS Newsletter*

A volunteer committee working with the U.S. Department of Health and Human Services to engage, educate, and empower Americans of all ages to adopt a healthy lifestyle that includes regular physical activity and good nutrition.

### **Sport in Society, National University Consortium for Sport in Society**

**Website:** <http://www.sportinsociety.org>  
**Publication:** *Journal of Sport and Social Issues*

An organization based at Northeastern University that promotes the use of sports to help prevent interpersonal violence, improve the health of impoverished youth, and foster social diversity.

### **U.S. Consumer Product Safety Commission (USCPSC)**

**Website:** <http://www.cpsc.gov>

The U.S. federal agency charged with protecting consumers and families from products that may pose a hazard or threat.

## *Sports*

### **Amateur Athletic Union of the United States (AAU)**

**Website:** <http://www.aausports.org>  
**Publication:** *InfoAAU*

A national nonprofit, volunteer, multisport organization dedicated to the promotion and development of amateur sports and physical fitness programs.

### **American Junior Golf Association (AJGA)**

**Website:** <http://www.ajga.org>  
**Publication:** *AJGA Tour Talk Newsletter*

A nonprofit organization dedicated to the growth and development of competitive junior golfers striving to earn college golf scholarships.

### **Canada Games Council**

**Website:**  
<http://www.canadagames.ca>

The governing body for the Canada Games: a private, nonprofit organization that promotes ongoing partnerships with organizations at the municipal, provincial, and national levels and provides support in organizational planning, ceremonies, marketing, and sponsorship.

### **Canadian Association for the Advancement of Women and Sport and Physical Activity (CAAWS)**

**Website:** <http://www.caaws.ca/e>

An association supporting and promoting women in sport while providing leadership and education.

**Canadian Blind Sports Association (CBSA)**

**Website:** <http://www.canadianblindsports.ca>

The national governing body for goalball, advocating for the blind and visually impaired within the sports system.

**Canadian Centre for Ethics in Sports (CCES)**

**Website:** <http://www.cces.ca>

A nonprofit organization devoted to promoting ethical conduct in sport and responsible for the implementation and management of Canada's Anti-Doping Program.

**Canadian Colleges Athletic Association (CCAA)**

**Website:** <http://www.ccaa.ca>

The national governing body for college sports in Canada.

**Canadian Deaf Sports Association (ASSC-CDSA)**

**Website:** <http://www.assc-cdsa.com>

An organization that supports deaf athletes who meet the requirements for participating in international competitions, especially the Pan American Games for the Deaf, the Deaflympics, and the World Deaf Championships.

**Canadian Interuniversity Sport (CIS)**

**Website:** <http://www.cis-sic.ca>

The national governing body of university sports in Canada, comprising 52 member universities.

**Canadian Wheelchair Sports Association (CWSA)**

**Website:** <http://www.cwsa.ca/en/site>

A national sports organization, founded in 1967, representing wheelchair athletes.

**Coaches of Canada**

**Website:** <http://www.coachesofcanada.com>

The national organization that represents, promotes, and regulates the profession of athletic coaching in Canada.

**International Amateur Swimming Federation (IASF)**

**Website:** <http://www.fina.org>

The world governing body for swimming, diving, water polo, synchronized swimming, and open-water swimming, promoting the development of swimming worldwide.

**National Association for Girls and Women in Sports**

**Website:** <http://www.aahperd.org>

**Publication:** *The Women in Sport and Physical Activity Journal*

An association within the American Alliance for Health, Physical Education, Recreation and Dance that advocates for girls and women in sports.

**National Association for Sport and Physical Education (NASPE)**

**Website:** <http://www.aahperd.org/naspe>

**Publication:** *Journal of Physical Education and Recreation*

An association within the American Alliance for Health, Physical Education, Recreation and Dance dedicated to enhancing knowledge and increasing support for quality physical education programs.

**National Collegiate Athletic Association (NCAA)**

**Website:** <http://www.ncaa.org>

The national governing body for intercollegiate athletics in the United States.

**National Dance Association (NDA)**

**Website:** <http://www.aahperd.org/nda>

**Publication:** *Journal of Physical Education, Recreation, & Dance*

An association that strives to promote quality dance by providing leadership, disseminating research, and collaborating with external partnerships.

**National Federation of Interscholastic Coaches Association (NFICA)**

An association that aims to improve the athletic participation experience while establishing consistent standards and rules for competition.

**National Intramural-Recreational Sports Association (NIRSA)**

**Website:** <http://www.nirsa.org>  
**Publications:** *NIRSA Journal*, *NIRSA Newsletter*

A research and educational resource for collegiate recreational sports that promotes superior recreational programs, facilities, and services for diverse populations.

**Special Olympics**

**Website:** <http://www.specialolympics.org>

An international organization that holds a competition every 2 years as well as yearlong training for people who have intellectual disabilities.

**Special Olympics Canada**

**Website:** <http://www.specialolympics.ca>

A national nonprofit organization that provides sports training and competition opportunities for athletes with intellectual disabilities.

**United States Olympic Committee**

**Website:** <http://www.teamusa.org>

A committee responsible for training, entering, and underwriting the full expenses for the U.S. teams in the Olympic, Paralympic, Pan-American, and Parapan-American Games, as well as overseeing the process by which U.S. cities seek to be selected as a host to these games.

**United States Soccer**

**Website:** <http://www.ussoccer.com>

The governing body for soccer in the United States, promoting the development of soccer at all recreational and competitive levels.

**United States Sports Academy**

**Website:** <http://www.ussa.edu>

An independent, nonprofit, accredited sports university providing programs in instruction, research, and service to prepare those pursuing careers in the profession of sports.

**US Figure Skating (USFS)**

**Website:** <http://www.usfsa.org>

The national governing body for figure skating and a member of the International Skating Union (ISU) and the U.S. Olympic Committee (USOC), comprising member clubs, collegiate clubs, school-affiliated clubs, and individual members.

**USA Athletic Congress (USAAC)**

**Website:** <http://www.usaac.org>  
**Publication:** *American Athletics Annual*

An association that promotes good sportsmanship by recognizing athletes who have excelled within their respective sports, working in conjunction with international federations and national governing bodies to improve sports participation around the world.

**USA Gymnastics**

**Website:** <http://www.usa-gymnastics.org>

The national organization for gymnastics, encouraging participation and excellence and setting the rules and policies that govern gymnastics in the United States.

**USA Swimming**

**Website:** <http://www.usaswimming.org>

The national governing body for swimming in the United States.

**USA Volleyball**

**Website:** <http://www.usavolleyball.org>

The national governing body for volleyball in the United States.

**Women's Sports Foundations (WSF)**

**Website:**  
<http://www.womenssportsfoundations.org>  
**Publications:** *Women's Sports and Fitness*, *Headway*

A foundation that advocates for equal opportunity for women in sports, focusing on the psychological, physical, and social benefits of sports participation.

## Sports Medicine

### Academy for Sports Dentistry (ASD)

**Website:**

<http://www.academyforsportsdentistry.org>

**Publication:** *Sports Dentistry Newsletter*

A forum for medical professionals, coaches, and trainers to exchange ideas pertinent to sports dentistry, as well as for the collection and dissemination of research regarding the prevention and occurrence of dental injuries among athletes.

### American Academy of Orthopaedic Surgeons (AAOS)

**Website:** <http://www.aaos.org>

**Publications:** *AAOS Report, The Bulletin*

An association of musculoskeletal specialists that provides education and practice management services for orthopedic surgeons and allied health professionals, advocates for enhanced patient care, and disseminates orthopedic knowledge to the public.

### American Academy of Pediatrics (AAP) Committee on Sports Medicine & Fitness (COSMF)

**Website:** <http://www.aap.org/sections/sportsmedicine>

A division of the American Academy of Pediatrics, providing educational programs, policy statements, collaborative partnerships, media outreach, advocacy work, and research awards to promote safe physical activity and the highest level of treatment in pediatrics.

### American Academy of Physical Medicine and Rehabilitation (AAPMR)

#### Special Interest Group on Sports Medicine

**Website:** <http://www.aapmr.org>

**Publications:** *Archives of Physical Medicine and Rehabilitation, Journal of Physical Medicine*

An academy representing patients with, or at risk for, temporary or permanent disabilities and helping physicians acquire the continuing education, practice knowledge, leadership skills, and research findings needed to provide quality patient care.

### American Academy of Podiatric Sports Medicine (AAPSM)

**Website:** <http://www.aapasm.org>

An academy that helps further the understanding, prevention, and management of lower extremity injuries in sports through professional education, scientific research, public awareness, and membership support.

### American College of Sports Medicine (ACSM)

**Website:** <http://www.acsm.org>

**Publications:** *Medicine and Science in Sports and Exercise, Sports Medicine Bulletin, Exercise and Sport Sciences Reviews*

An association that promotes healthy lifestyles through the diagnosis, treatment, and prevention of sports-related injuries as well as the advancement of exercise science and the dissemination of research.

### American Medical Society for Sports Medicine (AMSSM)

**Website:** <http://www.amssm.org>

A forum for primary care sports medicine physicians to promote professional relationships and advance the discipline of sports medicine through education, research, advocacy, and quality patient care.

### American Optometric Association (AOA) Sports Vision Section (SVS)

**Website:** <http://www.aoa.org/x4787.xml>

**Publication:** *SVS News and Views*

An association that is specific to optometric sports vision, striving to advance care through

education, injury prevention, and enhancement of visual performance.

**American Orthopaedic Society for Sports Medicine (AOSSM)**

**Website:** <http://www.sportsmed.org>  
**Publication:** *American Journal of Sports Medicine*

A national organization of orthopedic surgeons committed to sports medicine education, research, communication, and fellowship.

**American Osteopathic Academy of Sports Medicine (AOASM)**

**Website:** <http://www.aoasm.org>  
**Publication:** *Clinical Journal of Sports Medicine*

An educational forum for primary care physicians and health care professionals to attend to the quality of health care, promoting fitness and exercise guidelines and providing a collegial environment to expand the knowledge of sports medicine.

**American Physical Therapy Association (APTA)**

**Website:** <http://www.apta.org>  
**Publication:** *Physical Therapy*

A national organization committed to the advancement of physical therapy practice and research, promoting the prevention, diagnosis, and treatment of movement dysfunctions and the improvement of the physical health and functional abilities of all members of the public.

**British Association of Sport and Exercise Medicine (BASEM)**

**Website:** <http://www.basem.co.uk>

The oldest sport and exercise medicine association in the United Kingdom (founded in 1953) and the official UK representative to both the European Federation of Sports Medicine Associations (EFSMA) and the International Federation of Sports Medicine (FIMS), dedicated

to the promotion of good health through physical activity and the provision of sports medicine expertise to optimize athletic performance at all levels.

**Canadian Academy of Sports Medicine (CASM-ACMS)**

**Website:** <http://www.casm-acms.org>

An organization of physicians dedicated to the practice of medicine as applied to all aspects of physical activity, including health promotion and disease prevention.

**Canadian Athletic Therapists Association (CATA)**

**Website:** <http://www.athletictherapy.org/en/index.aspx>

A nonprofit organization dedicated to promoting injury prevention, emergency services, and rehabilitative techniques for active individuals.

**Canadian Physiotherapy Association (CPA)**

**Website:** <http://www.thesehands.ca>

An association of physiotherapists, physiotherapy support workers, physiotherapy students, and affiliate members dedicated to advancing the field of physiotherapy and improving the health of all individuals.

**Canadian Society for Exercise Physiology (CSEP)**

**Website:** <http://www.csep.ca>  
**Publication:** *Canadian Journal of Applied Physiology*

An organization of professionals involved in the scientific study of exercise physiology, exercise biochemistry, fitness, and health.

**Gatorade Sports Science Institute (GSSI)**

**Website:** <http://www.gssiweb.com>

A research and educational facility that studies with scientists around the world the effects of

exercise, the environment, and nutrition on the human body.

**International Federation of Sports Medicine (FIMS)**

**Website:** <http://www.fims.org>

An international organization dedicated to the study of sports medicine as well as the dissemination of findings to help athletes maximize their potential.

**International Society of Arthroscopy, Knee Surgery, and Orthopedic Sports Medicine (ISAKOS)**

**Website:** <http://www.isakos.com>

An international society that provides a forum for surgeons to advance the exchange and dissemination of information on education, research, and patient care in arthroscopy, knee surgery, and orthopedic sports medicine.

**National Collegiate Athletic Association (NCAA) Committee on Competitive Safeguards and Medical Aspects of Sports**

**Website:** <http://www.ncaa.org>

**Publications:** *The Sports Medicine Handbook, Injury Surveillance Annual Report*

A committee whose mission is to provide expertise and leadership to the NCAA to help it promote a healthy and safe environment for student-athletes through research, education, collaboration, and policy development.

**Society for Adolescent Medicine (SAHM)**

**Website:**

<http://www.adolescenthealth.org>

**Publication:** *Journal of Adolescent Health Care*

A multidisciplinary organization of health professionals with the common goal of understanding the health needs and concerns of adolescents and enhancing public awareness through education, research, clinical services, and advocacy activities.

**Sport Physiotherapy Canada**

**Website:** <http://www.sportphysio.ca>

An organization, founded in 1972, dedicated to providing therapy, rehabilitation, and counseling to athletes before, during, and after injury.
